The Web Conference 2019
Conference Chairs' Welcome

It is our great pleasure to welcome you to *The Web Conference 2019*. The Web Conference is the premier venue focused on understanding the current state and the evolution of the Web through the lens of computer science, computational social science, economics, policy, and many other disciplines. The 2019 edition of the conference is a reflection point as we celebrate the 30th anniversary of the Web.

The technical program of this year's edition of the conference consists of three keynotes (Jeff Dean, Lawrence Lessig and Claire Wardle), one panel to celebrate the 30 years of the Web, 12 tracks for refereed research papers (including full papers and short papers), and a demonstrations track that are published in the main volume of the proceedings. The companion volume of the proceedings includes 23 workshops, most of the 22 tutorials, and the Ph.D. Consortium. We also have several other co-located events and special tracks: W4A, BIG, The Web of Health, The Open Web, Building an Ethical Web, and W3C.

We are thankful to all the people that helped us organizing the conference and that are listed in the next section. Without them, this would have never happened. Special thanks to all our sponsors, as they make the quality difference: Microsoft (Diamond); Amazon, Bloomberg and Google (Gold); Criteo AI Lab, CISCO, NTENT, Spotify, Yahoo Research and Wikimedia Foundation (Silver); Baidu, DiDi, eBay, Facebook, LinkedIn, Megagon Labs, Mix, Mozilla, Netflix Research, Northeastern University, Pinterest, Quora, Visa Research and Walmart Labs (Bronze); as well as Airbnb, Letgo, Moore Foundation and Webcastor.

Finally, this conference would have not been possible if together with Ashish Goel and Ben Steichen we did not start Web4Good, a California based non-profit company that undersigned the event with IW3C2.

So we hope that you enjoy this week as well as San Francisco!

The Web Conference 2019
Research Chairs' Preface

The research program of this year's edition consists of 12 tracks for refereed research papers (including full papers and short papers), and a demonstrations track. As in previous years, updates were made to ensure that track topics correctly reflect the key research areas of interest to the Web community.

The research tracks attracted submissions from 5042 distinct authors from 53 countries spanning six continents. Submissions were rigorously reviewed by a program committee (PC) comprising 27 track chairs, 69 senior PC members (on three of the tracks), 1112 PC members, and 594 external reviewers. A total of 5280 reviews were provided, with each paper receiving at least three reviews, and many papers receiving four or more reviews.

During the discussion phase, PC members, senior PC members, and track chairs discussed the reviews in detail. Meta-reviews were provided for most submissions, especially for borderline papers and high-scoring rejects, summarizing the reviews and discussion. For consistency across tracks, final decisions on papers were made at the face-to-face PC meeting between track chairs and the PC chairs. We accepted 225 (18%) of the 1247 full papers and 72 (20%) of the 361 short papers submitted to the research tracks. We also accepted a small number of full papers as short papers. New this year, all full and short papers were presented as a poster; some full papers also had an oral presentation.

Additionally, 27 submissions were selected for the demonstrations track after being reviewed by 59 PC members, with each of them reviewing an average of 3.95 papers. The majority of the demos got reviewed by 4 reviewers with a minimum of 3 reviewers per submission.

THE WEB CONFERENCE

Table of Contents

The Web Conference Organization xxix

Research Track Organization xxx

Senior Program Committee xxxi

Keynote Talk

- **Deep Learning for Solving Important Problems** 1
  Jeff Dean *(Google Mountain View, USA)*
- **The Law of the Horse at 20: Phases of the Net** 2
  Lawrence Lessig *(Harvard Law School, USA)*
- **Enlisting the Public to Build a Healthier Web Information Commons** 3
  Claire Wardle *(TED Fellow CIVIC, USA)*

Full Paper

- **Addressing Trust Bias for Unbiased Learning-to-Rank** 4
  Aman Agarwal *(Cornell, USA)*, Xuanhui Wang, Cheng Li, Michael Bendersky, Marc Najork *(Google, USA)*
- **Learning Edge Properties in Graphs from Path Aggregations** 15
  Rakshit Agrawal *(University of California, USA)*, Luca de Alfaro *(UC Santa Cruz, USA)*
- **Evaluating User Actions as a Proxy for Email Significance** 26
  Tarfah Alrashed *(Massachusetts Institute of Technology, USA)*, Chia-Jung Lee *(Microsoft, USA)*, Peter Bailey *(Microsoft, Australia)*, Christopher Lin, Milad Shokouhi, Susan Dumais *(Microsoft, USA)*
- **DDGK: Learning Graph Representations for Deep Divergence Graph Kernels** 37
  Rami Al-Rfou, Bryan Perozzi, Dustin Zelle *(Google AI, USA)*
- **Stereotypical Bias Removal for Hate Speech Detection Task using Knowledge-based Generalizations** 49
  Pinkesh Badjatiya, Manish Gupta, Vasudeva Varma *(IIIT Hyderabad, India)*
- **Personalized Bundle List Recommendation** 60
  Jinze Bai *(Peking University, China)*, Chang Zhou *(Alibaba Group, China)*, Junshuai Song, Xiaoru Qu *(Peking University, China)*, Weiting An, Zhao Li *(Alibaba Group, China)*, Jun Gao *(Peking University, China)*
- **Improving Medical Code Prediction from Clinical Text via Incorporating Online Knowledge Sources** 72
  Tian Bai, Slobodan Vucetic *(Temple University, USA)*
- **No Place to Hide: Catching Fraudulent Entities in Tensors** 83
  Ban Yikun *(Peking University, China)*, Liu Xin *(Tsinghua University, China)*, Huang Ling *(Fintec.ai, China)*, Duan Yitao *(Netease Youdao Inc., China)*, Liu Xue *(McGill University, Canada)*, Xu Wei *(Tsinghua University, China)*
- **Link Prediction in Networks with Core-Fringe Data** 94
  Austin Benson, Jon Kleinberg *(Cornell University, USA)*
- **Spiders like Onions: on the Network of Tor Hidden Services** 105
  Massimo Bernaschi, Alessandro Celestini, Stefano Guarino, Flavio Lombardi, Enrico Mastrostefano *(Istituto per le Applicazioni del Calcolo "Mauro Picone" (IAC - CNR), Italy)*
- **Be Concise and Precise: Synthesizing Open-Domain Entity Descriptions from Facts** 116
  Rajarshi Bhowmik, Gerard de Melo *(Rutgers University, USA)*
- **Navigating the Maze of Wikidata Query Logs** 127
  Angela Bonifati *(Lyon 1 University, France)*, Wim Martens, Thomas Timm *(University of Bayreuth, Germany)*
- **What happened? The Spread of Fake News Publisher Content During the 2016 U.S. Presidential Election** 139
  Ceren Budak *(University of Michigan School of Information, USA)*

- **Unifying Knowledge Graph Learning and Recommendation: Towards a Better Understanding of User Preferences** 151
  Yixin Cao, Xiang Wang, Xiangnan He, Zikun Hu, Tat-Seng Chua *(National University of Singapore, Singapore)*
- **Enriching News Articles with Related Search Queries** 162
  David Carmel *(Amazon Research, Israel)*, Yaroslav Fyodorov *(Yahoo Research, Israel)*, Saar Kuzi *(University of Illinois at Urbana-Champaign, USA)*, Avihai Mejer, Fiana Raiber *(Yahoo Research, Israel)*, Elad Rainshmidt *(Oath, Israel)*
- **Revisiting Opinion Dynamics with Varying Susceptibility to Persuasion via Non-Convex Local Search** 173
  T-H. Hubert Chan, Zhibin Liang *(The University of Hong Kong, Hong Kong)*, Mauro Sozio *(Télécom ParisTech, France)*
- **Trajectories of Blocked Community Members: Redemption, Recidivism and Departure** 184
  Jonathan Chang, Cristian Danescu-Niculescu-Mizil *(Cornell University, USA)*
- **Selling a Single Item with Negative Externalities** 196
  Matheus Xavier Ferreira, S. Matthew Weinberg, Danny Yuxing Huang, Nick Feamster, Tithi Chattopadhyay *(Princeton University, USA)*
- **Revisiting Mobile Advertising Threats with MAdLife** 207
  Gong Chen *(Georgia Institute of Technology, USA)*, Wei Meng *(The Chinese University of Hong Kong, Hong Kong)*, John Copeland *(Georgia Institute of Technology, USA)*
- **Modeling Relational Drug-Target-Disease Interactions via Tensor Factorization with Multiple Web Sources** 218
  Huiyuan Chen, Jing Li *(Case Western Reserve University, USA)*
- **SamWalker: Social Recommendation with Informative Sampling Strategy** 228
  Jiawei Chen, Can Wang *(Zhejiang University, China)*, Sheng Zhou *(ZheJiangUniversity, China)*, Qihao Shi, Yan Feng, Chun Chen *(Zhejiang University, China)*
- **How Serendipity Improves User Satisfaction with Recommendations? A Large-Scale User Evaluation** 240
  Li Chen *(Hong Kong Baptist University, Hong Kong)*, Yonghua Yang *(Alibaba Group, China)*, Ningxia Wang *(Hong Kong Baptist University, Hong Kong)*, Keping Yang *(Alibaba Group, China)*, Quan Yuan *(inspirAI Co. Ltd., China)*
- **Emoji-Powered Representation Learning for Cross-Lingual Sentiment Classification** 251
  Zhenpeng Chen *(Peking University, China)*, Sheng Shen *(University of California, USA)*, Ziniu Hu *(University of California, USA)*, Xuan Lu *(Peking University, China)*, Qiaozhu Mei *(University of Michigan, USA)*, Xuanzhe Liu *(Peking University, China)*
- **Decoupled Smoothing on Graphs** 263
  Alex Chin, Yatong Chen, Kristen M. Altenburger, Johan Ugander *(Stanford University, USA)*
- **Cross-Network Embedding for Multi-Network Alignment** 273
  Xiaokai Chu, Xinxin Fan, Di Yao, Zhihua Zhu, Jianhui Huang, Jingping Bi *(Institute of computing, Chinese Academy of Sciences, China)*
- **Improving Treatment Effect Estimators Through Experiment Splitting** 285
  Dominic Coey, Tom Cunningham *(Facebook, USA)*
- **A Semi-Supervised Active-learning Truth Estimator for Social Networks** 296
  Hang Cui *(University of Illinois, USA)*, Tarek Abdelzaher *(University of Illinois at Urbana-Champaign, USA)*, Lance Kaplan *(Army Research Laboratories, USA)*
- **Dressing as a Whole: Outfit Compatibility Learning Based on Node-wise Graph Neural Networks** 307
  Zeyu Cui *(Institute of Automation, Chinese Academy of Sciences, China)*, Zekun Li *(Institute of Information Engineering, Chinese Academy of Sciences, China)*, Shu Wu *(Institute of Automation, Chinese Academy of Sciences, China)*, Xiao-Yu Zhang *(Institute of Information Engineering, Chinese Academy of Sciences, China)*, Liang Wang *(Institute of Automation, Chinese Academy of Sciences, China)*
- **Are All Successful Communities Alike? Characterizing and Predicting the Success of Online Communities** 318
  Tiago Cunha, David Jurgens *(University of Michigan, USA)*, Chenhao Tan *(University of Colorado Boulder, USA)*, Daniel Romero *(University of Michigan, USA)*

- **Adversarial Training Methods for Network Embedding**.....329
  Quanyu Dai, Xiao Shen *(The Hong Kong Polytechnic University, China)*, Liang Zhang *(JD.com, China)*, Qiang Li *(Y-Lab, Kwai, China)*, Dan Wang *(The Hong Kong Polytechnic University, China)*
- **Local Matching Networks for Engineering Diagram Search**.....340
  Zhuyun Dai *(Carnegie Mellon University, USA)*, Zhen Fan *(Tsinghua University, China)*, Hafeezul Rahman, Jamie Callan *(Carnegie Mellon Univeristy, USA)*
- **Evaluating Anti-Fingerprinting Privacy Enhancing Technologies**.....351
  Amit Datta *(Snap, Inc., USA)*, Jianan Lu *(University of California, USA)*, Michael Carl Tschantz *(International Computer Science Institute, USA)*
- **Heterographic Pun Recognition via Pronunciation and Spelling Understanding Gated Attention Network**.....363
  Yufeng Diao, Hongfei Lin, Liang Yang, Xiaochao Fan, Di Wu, Dongyu Zhang, Kan Xu *(Dalian University of Technology, China)*
- **Evaluating Login Challenges as aDefense Against Account Takeover**.....372
  Periwinkle Doerfler *(NYU, USA)*, Kurt Thomas, Maija Marincenko, Juri Ranieri, Yu Jiang, Angelika Moscicki *(Google, USA)*, Damon McCoy *(NYU, USA)*
- **On Attribution of Recurrent Neural Network Predictions via Additive Decomposition**.....383
  Mengnan Du, Ninghao Liu, Fan Yang, Shuiwang Ji, Xia Hu *(Texas A&M University, USA)*
- **Is a Single Embedding Enough? Learning Node Representations that Capture Multiple Social Contexts**.....394
  Alessandro Epasto, Bryan Perozzi *(Google, USA)*
- **On-Device Algorithms for Public-Private Data with Absolute Privacy**.....405
  Alessandro Epasto, Hossein Esfandiari, Vahab Mirrokni *(Google, USA)*
- **Graph Neural Networks for Social Recommendation**.....417
  Wenqi Fan *(City University of Hong Kong, Hong Kong)*, Yao Ma *(Michigan State University, USA)*, Qing Li *(City University of Hong Kong, Hong Kong)*, Yuan He, Eric Zhao *(JD.com, China)*, Jiliang Tang *(Michigan State University, USA)*, Dawei Yin *(JD.com, China)*
- **Knowledge-Enhanced Ensemble Learning for Word Embeddings**.....427
  Lanting Fang *(Southeast University, China)*, Yong Luo, Kaiyu Feng, Kaiqi Zhao *(Nanyang Technological University, Singapore)*, Aiqun Hu *(Southeast University, China)*
- **Joint Entity Linking with Deep Reinforcement Learning**.....438
  Zheng Fang, Yanan Cao *(Institute of Information Engineering, CAS, China)*, Qian Li *(University of Technology Sydeney, China)*, Dongjie Zhang, Zhenyu Zhang, Yanbing Liu *(Institute of Information Engineering, CAS, China)*
- **Measurement and Early Detection of Third-Party Application Abuse on Twitter**.....448
  Shehroze Farooqi *(University of Iowa, USA)*, Zubair Shafiq *(The University of Iowa, USA)*
- **DPLink: User Identity Linkage via Deep Neural Network From Heterogeneous Mobility Data**.....459
  Jie Feng, Mingyang Zhang, Huandong Wang, Zeyu Yang *(Tsinghua University, China)*, Chao Zhang *(University of Illinois at Urbana-Champaign, USA)*, Yong Li, Depeng Jin *(Tsinghua University, China)*
- **MARINE: Multi-relational Network Embeddings with Relational Proximity and Node Attributes**.....470
  Noriaki Kawamae *(The University of Tokyo, Japan)*
- **Gaps in Information Access in Social Networks**.....480
  Benjamin Fish *(Microsoft, Canada)*, Ashkan Bashardoust *(University of Utah, USA)*, Danah Boyd *(Data & Society, USA)*, Sorelle Friedler *(Haverford College, USA)*, Carlos Scheidegger *(University of Arizona, USA)*, Suresh Venkatasubramanian *(University of Utah, USA)*
- **Cross-domain Recommendation Without Sharing User-relevant Data**.....491
  Chen Gao, Xiangning Chen *(Tsinghua University, China)*, Fuli Feng *(National University of Singapore, Singapore)*, Kai Zhao *(Tsinghua University, China)*, Xiangnan He *(National University of Singapore, Singapore)*, Yong Li, Depeng Jin *(Tsinghua University, China)*
- **Towards Self-Adaptive Metric Learning On the Fly**.....503
  Yang Gao, Yi-Fan Li, Swarup Chandra, Latifur Khan, Bhavani Thuraisingham *(The University of Texas at Dallas, USA)*

- **Knowledge-aware Assessment of Severity of Suicide Risk for Early Intervention**.....514
Manas Gaur, Amanuel Alambo, Joy Prakash Sain, Ugur Kursuncu, Krishnaprasad Thirunarayan *(Kno.e.sis Center, USA)*, Ramakanth Kavuluru *(University of Kentucky, USA)*, Amit Sheth *(Kno.e.sis Center, USA)*, Randy Welton *(Department of Psychiatry, Wright State University, USA)*, Jyotishman Pathak *(Division of Health Informatics, Weill Cornell Medical College, USA)*
- **SpeedReader: Reader Mode Made Fast and Private**.....526
Mohammad Ghasemisharif *(University of Illinois at Chicago, USA)*, Peter Snyder *(Brave Software, USA)*, Andrius Aucinas *(Brave Software, United Kingdom)*, Benjamin Livshits *(Brave Software, Imperial College London, United Kingdom)*
- **Externalities and Fairness**.....538

  Mengfan Yao, Charalampos Chelmis, Daphney-Stavroula Zois *(University at Albany State University of New York, USA)*
- **Enhancing Fashion Recommendation with Visual Compatibility Relationship** 3434
  Ruiping Yin, Kan Li *(Beijing Institute of Technology, China)*, Jie Lu, Guangquan Zhang *(University of Technology, Australia)*
- **Discovering Product Defects and Solutions from Online User Generated Contents** 3441
  Xuan Zhang *(Virginia Tech, USA)*, Zhilei Qiao *(The University of Alabama at Birmingham, USA)*, Aman Ahuja *(Virginia Tech, USA)*, Weiguo Fan *(University of Iowa, USA)*, Edward Fox, Chandan K. Reddy *(Virginia Tech, USA)*
- ***Your Style Your Identity*: Leveraging Writing and Photography Styles for Drug Trafficker Identification in Darknet Markets over Attributed Heterogeneous Information Network** 3448
  Yanfang Ye *(West Virginia University, USA)*, Yiming Zhang, Yujie Fan, Shifu Hou, Xin Li *(West Virginia University, USA)*
- **Abstractive Meeting Summarization via Hierarchical Adaptive Segmental Network Learning** 3455
  Zhou Zhao, Haojie Pan *(Zhejiang University, China)*, Changjie Fan *(NetEase Fuxi AI Lab, China)*, Deng Cai *(Zhejiang University, China)*, Min Yang *(Shenzhen Institutes of Advanced Technology, China)*
- **Adversarial Point-of-Interest Recommendation** 3462
  Fan Zhou, Ruiyang Yin *(University of Science and Technology of China, China)*, Kunpeng Zhang *(University of Maryland, USA)*, Goce Trajcevski *(Iowa State University, USA)*, Ting Zhong, Jin Wu *(University of Science and Technology of China, China)*
- **Context-aware Variational Trajectory Encoding and Human Mobility Inference** 3469
  Fan Zhou, Xiaoli Yue *(University of Science and Technology of China, China)*, Goce Trajcevski *(Iowa State University, USA)*, Ting Zhong *(University of Science and Technology of China, China)*, Kunpeng Zhang *(University of Maryland, USA)*
- **Variational Session-based Recommendation Using Normalizing Flows** 3476
  Fan Zhou, Zijing Wen *(University of Science and Technology of China, China)*, Kunpeng Zhang *(University of Maryland, USA)*, Goce Trajcevski *(Iowa State University, USA)*, Ting Zhong *(University of Science and Technology of China, China)*
- **Improving Top-K Recommendation via JointCollaborative Autoencoders** 3483
  Ziwei Zhu, Jianling Wang, James Caverlee *(Texas A&M University, USA)*

Demos

- **Enlisting the Public to Build a Healthier Web Information Commons** 3490
  Update title and chair/organizer names here *(& their affiliations)*

- **RecBoard: A Web-based Platform for Recommendation System Research and Development** 3493
  Kriti Singh, Mohit Chawla, Longqi Yang, Deborah Estrin *(Cornell University, USA)*
- **CrowdPT: Summarizing Crowd Opinions as Professional Analyst** 3498
  Chung-Chi Chen, Hen-Hsen Huang, Chia-Wen Tsai, Hsin-Hsi Chen *(National Taiwan University, Taiwan)*
- **TIM: A Tool for Gaining Insights into Psychotherapy** 3503
  Ronan Cummins, Michael Ewbank, Alan Martin, Valentin Tablan, Ana Catarino, Andrew Blackwell *(Ieso Digital Health, United Kingdom)*
- **QAnswer: A Question Answering prototype bridging the gap between a considerable part of the LOD cloud and end-users** 3507
  Dennis Diefenbach *(University of Lyon, France)*, Pedro Migliatti *(Universidade Federal de São Carlos, Brazil)*, Omar Qawasmeh *(University of Lyon, France)*, Vincent Lully *(Sorbonne University, France)*, Kamal Singh, Pierre Maret *(University of Lyon, France)*
- **Voyageur: An Experiential Travel Search Engine** 3511
  Sara Evensen *(Megagon Labs, USA)*, Aaron Feng *(Megagon Labs, Japan)*, Alon Halevy, Jinfeng Li, Vivian Li, Yuliang Li, Huining Liu, George Mihaila, John Morales, Natalie Nuno, Ekaterina Pavlovic, Wang-Chiew Tan, Xiaolan Wang *(Megagon Labs, USA)*
- **Tracy: Tracing Facts over Knowledge Graphs and Text** 3516
  Mohamed H. Gad-Elrab *(Max Planck Institute for Informatics, Germany)*, Daria Stepanova *(Bosch Center for Artificial Intelligence, Germany)*, Jacopo Urbani *(Vrije Universiteit Amsterdam, Netherlands)*, Gerhard Weikum *(Max Planck Institute for Informatics, Germany)*
- **LearnerExp: Exploring and Explaining the Time Management of Online Learning Activity** 3521
  Huan He, Qinghua Zheng, Bo Dong *(Xi'an Jiaotong University, China)*
- **Gradual Machine Learning for Entity Resolution** 3526
  Boyi Hou, Qun Chen, Xin Liu, Ping Zhong, Yanyan Wang, Zhaoqiang Chen, Zhanhuai Li *(Northwestern Polytechnical University, China)*
- **Dixit: Interactive Visual Storytelling via Term Manipulation** 3531
  Chao-Chun Hsu, Yu-Hua Chen *(Academia Sinica, Taiwan)*, Zi-Yuan Chen *(IIS, Sinica, Taiwan)*, Hsin Yu Lin *(Institute of Information Science, Academia Sinica, Taiwan)*, Ting-Hao Huang *(The Pennsylvania State University, USA)*, Lun-Wei Ku *(Institute of Information Science, Academia Sinica, Taiwan)*
- **Exam Keeper: Detecting Questions with Easy-to-Find Answers** 3536
  Ting-Lun Hsu, Shih-Chieh Dai, Lun-Wei Ku *(Institute of Information Science, Academia Sinica, Taiwan)*
- **ExQuisiTe: Explaining Quantities in Text** 3541
  Yusra Ibrahim, Gerhard Weikum *(Max Planck Institute for Informatics, Germany)*
- **Can You Give Me a Reason?: Argument-inducing Online Forum by Argument Mining** 3545
  Makiko Ida, Gaku Morio, Kosui Iwasa, Takaki Yasui, Tomoyuki Tatsumi, Katsuhide Fujita *(Tokyo University of Agriculture and Technology, Japan)*
- **UNVEIL: Capture and Visualise WiFi Data Leakages** 3550
  Shubham Jain *(Imperial College London, United Kingdom)*, Eden Bensaid *(Massachusetts Institute of Technology, USA)*, Yves-Alexandre de Montjoye *(Imperial College London, United Kingdom)*
- **SmartDBO: Smart Docker Benchmarking Orchestrator for Web-application** 3555
  Devki Nandan Jha, Michael Nee, Zhenyu Wen *(Newcastle University, United Kingdom)*, Albert Zomaya *(The University of Sydney, Australia)*, Rajiv Ranjan *(Newcastle University, United Kingdom)*
- **R2SIGTP: a Novel Real-Time Recommendation System with Integration of Geography and Temporal Preference for Next Point-of-Interest** 3560
  Xu Jiao, Yingyuan Xiao, Wenguang Zheng *(Tianjin University of Technology, China)*
- **SGX-PySpark: Secure Distributed Data Analytics** 3564
  Do Le Quoc, Franz Gregor *(TU Dresden, Germany)*, Jatinder Singh *(University of Cambridge, United Kingdom)*, Christof Fetzer *(TU Dresden, Germany)*
- **TweetSenti: Target-dependent Tweet Sentiment Analysis** 3569
  Quanzhi Li, Qiong Zhang, Luo Si *(Alibaba Group, USA)*
- **Querying Data Lakes using Spark and Presto** 3574
  Mohamed Nadjib Mami, Damien Graux, Simon Scerri *(Fraunhofer, Germany)*, S??ren Auer *(TIB Leibniz Information Center Science and Technology, Germany)*

- **Automated Fact Checking in the News Room** 3579
  Sebastiao Miranda, David Nogueira, Afonso Mendes *(Priberam, Portugal)*, Andreas Vlachos *(Department of Computer Science and Technology, University of Cambridge, United Kingdom)*, Andrew Secker *(BBC News Labs, United Kingdom)*, Rebecca Garrett *(BBC Monitoring, United Kingdom)*, Jeff Mitchel *(Psychology Department, University of Bristol, United Kingdom)*, Zita Marinho *(Priberam, Portugal)*
- **InfraNodus: Generating Insight Using Text Network Analysis** 3584
  Dmitry Paranyushkin *(Nodus Labs, France)*
- **Bridging Screen Readers and Voice Assistants for Enhanced Eyes-Free Web Search** 3590
  Alexandra Vtyurina *(University of Waterloo, Canada)*, Adam Fourney, Meredith Ringel Morris *(Microsoft, USA)*, Leah Findlater *(University of Washington, USA)*, Ryen W. White *(Microsoft, USA)*
- **Graph-based Interactive Data Federation System for Heterogeneous Data Retrieval and Analytics** 3595
  Xuan-Son Vu, Addi Ait-Mlouk, Erik Elmroth, Lili Jiang *(Department of Computing Science, Umeå University, Sweden)*
- **XFake: Explainable Fake News Detector with Visualizations** 3600
  Fan Yang, Shiva Pentyala, Sina Mohseni, Mengnan Du *(Texas A&M University, USA)*, Hao Yuan *(Washington State University, USA)*, Rhema Linder *(Texas A&M University, USA)*, Eric Ragan *(University of Florida, USA)*, Shuiwang Ji, Xia Hu *(Texas A&M University, USA)*
- **GraviTIE: Exploratory Analysis of Large-Scale Heterogeneous Image Collections** 3605
  Sean Yang, Luke Rodriguez, Jevin West, Bill Howe *(University of Washington, USA)*
- **TaxVis: a Visual System for Detecting Tax Evasion Group** 3610
  Yu Hongchao, Huan He, Qinghua Zheng, Bo Dong *(Xi'an Jiaotong University, China)*
- **Tablepedia: Automating PDF Table Reading in an Experimental Evidence Exploration and Analytic System** 3615
  Wenhao Yu *(University of Notre Dame, USA)*, Zongze Li *(Sichuan University, China)*, Qingkai Zeng, Meng Jiang *(University of Notre Dame, USA)*
- **CityFlow: A Multi-Agent Reinforcement Learning Environment for Large Scale City Traffic Scenario** 3620
  Huichu Zhang, Siyuan Feng, Chang Liu, Yaoyao Ding, Yichen Zhu, Zihan Zhou, Weinan Zhang, Yong Yu, Haiming Jin *(Shanghai Jiao Tong University, China)*, Zhenhui Li *(The Pennsylvania State University, USA)*

Author Index 3625

Conference Organization

Conference Chairs: Ricardo Baeza-Yates (NTENT & Northeastern University, USA)
Leila Zia (Wikimedia Foundation, USA)

Program Chairs: Ling Liu (Georgia Tech, USA)
Ryen White (Microsoft Research, USA)

Local Organizing Chairs: Chris Brooks (University of San Francisco, USA)
Regan Robertson (Executivevents, USA)
Bebo White (SLAC National Accelerator Laboratory, USA)

Treasurer: Fabian Suchanek (Télécom ParisTech University, France)

Tutorial Chair: Ashish Goel (Stanford University, USA)

Workshop Chairs: Sihem Amer-Yahia (CNRS & Université Grenoble Alpes, France)
Mohammad Mahdian (Google, USA)

Demo Chairs: Amin Mantrach (Criteo, USA)
Fabrizio Silvestri (Facebook, UK)

PhD Symposium Chairs: Geert-Jan Houben (TU Delft, The Netherlands)
Kristina Lerman (Information Sciences Institute, USA)

BIG Chairs: Vanja Josifovski (Airbnb, USA)
Liane Lewin-Eytan (Amazon, Israel)

Web of Health Chairs: Evgeniy Gabrilovich (Google, USA)
Nigam H. Shah (Stanford University, USA)

Future of the Open Web Chairs: Stephen LaPorte (Wikimedia Foundation, USA)
Robert West (EPFL, Switzerland)

Designing an Ethical Web Chairs: Sharad Goel (Stanford University, USA)
Deirdre Mulligan (UC Berkeley, USA)

Sponsorship Chairs: Nuria Oliver (Vodafone Research and DataPop Alliance, Spain)
Jie Tang (Tsinghua University, China)
Kuansan Wang (Microsoft, USA)

Student Relations Chair: Ben Steichen (Cal Poly Pomona, USA)

Student Scholarship Chairs: Lora Aroyo (VU Amsterdam, The Netherlands)
Diego Sáez-Trumper (Wikimedia Foundation, Spain)

Communication Chairs: Dawn Anderson (Move It Marketing, UK)
Brent Hecht (Northwestern University, USA)
Xin Fu (Facebook, USA)

Proceedings Chair: Julian McAuley (UC San Diego, USA)

Poster Chairs: Ashton Anderson (University of Toronto, Canada)
Joe DeBlasio (Google, USA)
Reza Zafarani (Syracuse University, USA)

Track Chairs: Tarek Abdelzaher (University of Illinois Urbana-Champaign, USA)
Karl Aberer (École Polytechnique Fédérale de Lausanne, Switzerland)
Omar Alonso (Microsoft, USA)
Elisa Bertino (Purdue University, USA)
Paolo Boldi (University of Milan, Italy)
Carlos Castillo (Pompeu Fabra University, Spain)
Munmun De Choudhury (Georgia Institute of Technology, USA)
Ingemar Cox (University College London, UK)
Nick Craswell (Microsoft, USA)
Debora Donato (Mix, USA)
Aristides Gionis (Aalto University, Finland)
Arun Iyengar (IBM, USA)
Emre Kiciman (Microsoft, USA)
Ashish Kundu (IBM Research, USA)
Edith Law (University of Waterloo, Canada)
Hang Li (Bytedance AI Lab, Hong Kong)
Tie-Yan Liu (Microsoft, China)
Bing Liu (University of Illinois Chicago, USA)
Yoelle Marek (Amazon Research, Israel)
Peter Mika (Independent Consultant, Spain)
Alice Oh (Korea Advanced Institute of Science and Technology, South Korea)
Michael Rabinovich (Case Western Reserve University, USA)
Filip Radlinski (Google, UK)
Pavel Serdyukov (Yandex, Russia)
Sergei Vassilvitskii (Google, USA)
Nalini Venkatasubramanian (University of California Irvine, USA)
Cong Yu (Google, USA)

THE WEB CONFERENCE

Senior Program Committee

Eugene Agichtein (Emory University, USA)
Luca Maria Aiello (Nokia Bell Labs, UK)
Edoardo M. Airoldi (Harvard University, USA)
Omar Alonso (Microsoft, USA)
Andras A. Benczur (Hungarian Academy of Sciences, Hungary)
Shlomo Berkovsky (Commonwealth Scientific and Industrial Research Organisation, Australia)
Francesco Bonchi (ISI Foundation, Italy)
Peter Brusilovsky (University of Pittsburgh, USA)
Ceren Budak (University of Michigan, USA)
Jamie Callan (Carnegie Mellon University, USA)
Pablo Castells (Autonomous University of Madrid, Spain)
Yi Chang (Huawei Research America, USA)
Sanjay Chawla (Qatar Computing Research Institute, Qatar)
Ian Davidson (University of California, Davis, USA)
Brian Davison (Lehigh University, USA)
Nemanja Djuric (Uber, USA)
Alexey Drutsa (Yandex, Russia)
Nadia Fawaz (LinkedIn, USA)
Pierre Fraigniaud (CNRS / University Paris Diderot, France)
Norbert Fuhr (University of Duisburg-Essen, Germany)
David Gleich (Purdue University, USA)
Jennifer Golbeck (University of Maryland, USA)
Mihajlo Grbovic (Airbnb, USA)
Krishna Gummadi (Max Planck Institute for Software Systems, Germany)
Jiafeng Guo (Chinese Academy of Sciences, China)
Ido Guy (eBay, Israel)
Jiawei Han (University of Illinois Urbana-Champaign, USA)
Jake Hofman (Microsoft, USA)
Dietmar Jannach (Alpen-Adria-Universität Klagenfurt, Austria)
Jussi Karlgren (Gavagai and KTH Royal Institute of Technology, Sweden)
George Karypis (University of Minnesota, USA)
Oren Kurland (Technion, Israel)
Mounia Lalmas (Spotify, UK)
Silvio Lattanzi (Google, Switzerland)
Kristina Lerman (University of Southern California, USA)
Liane Lewin-Eytan (Amazon Research, Israel)
Yiqun Liu (Tsinghua University, China)
Qiaozhu Mei (University of Michigan, USA)
Vanessa Murdock (Amazon Research, USA)
Marc Najork (Google, USA)
Wolfgang Nejdl (L3S Research Center and University of Hannover, Germany)
Nuria Oliver (Vodafone Research, Spain)
Alessandro Panconesi (Sapienza University of Rome, Italy)
Dan Pelleg (Yahoo, Israel)
Kira Radinsky (eBay, Israel)
Vladan Radosavljevic (OLX, USA)
Yves Raimond (Netflix, UK)
Steffen Rendle (Google, USA)
Maarten de Rijke (University of Amsterdam, Netherlands)
Alessandra Sala (Bell Labs Ireland, Ireland)
C. Seshadhri (University of California Santa Cruz, USA)
Chirag Shah (Rutgers University, USA)
Milad Shokouhi (Microsoft, UK)
Fabrizio Silvestri (Facebook, UK)
Ian Soboroff (National Institute of Standards and Technology, USA)
Yizhou Sun (University of California Los Angeles, USA)
Evimaria Terzi (Boston University, USA)
Hanghang Tong (Arizona State University, USA)
Panayiotis Tsaparas (University of Ioannina, Greece)
Charalampos Tsourakakis (Harvard University, USA)
Sebastiano Vigna (University of Milan, Italy)
Ji-Rong Wen (Renmin University of China, China)
Jun Xu (Renmin University of China, China)
Elad Yom-Tov (Microsoft, Israel)
Ben Zhao (University of Chicago, USA)

Program Committee

E Philip Abdelmalik (World Health Organization, Switzerland)
Rediet Abebe (Cornell University, USA)
Sami Abu-El-Haija (Google, USA)
Panagiotis Adamopoulos (Emory University, USA)
Eytan Adar (University of Michigan, USA)
Nitish Aggarwal (IBM, USA)
Amr Ahmed (Google, USA)
Nesreen Ahmed (Intel, USA)
Jae-Wook Ahn (University of Pittsburgh, USA)
Qingyao Ai (University of Massachusetts Amherst, USA)
Luca Maria Aiello (Nokia Bell Labs, UK)
Deepak Ajwani (Nokia Bell Labs, Ireland)
Harith Alani (Open University, UK)
Panos Alexopoulos (Textkernel, Netherlands)
Mohammad Allahbakhsh (University of New South Wales, Australia)
Mark Allman (International Computer Science Institute, USA)
Jussara Almeida (Federal University of Minas Gerais, Brazil)
Virgilio Almeida (Federal University of Minas Gerais, Brazil)
Magnus Almgren (Chalmers University of Technology, Sweden)
Kristen Altenburger (Stanford University, USA)
Ismail Sengor Altingovde (Middle East Technical University, Turkey)
Jisun An (Qatar Computing Research Institute and Hamad Bin Khalifa University, Qatar)
Aris Anagnostopoulos (Sapienza University of Rome, Italy)
Avishek Anand (L3S Research Center, Germany)
Ashton Anderson (University of Toronto, Canada)
Renzo Angles (University of Talca, Chile)
Kemafor Anyanwu (North Carolina State University, USA)
Pablo Aragón (Pompeu Fabra University, Spain)
Carlos Buil Aranda (Federico Santa María Technical University, Chile)
Jaime Arguello (University of North Carolina Chapel Hill, USA)
Martin Arlitt (University of Calgary, Canada)
Lora Aroyo (Google, USA)
Ashwin Ashok (Georgia State University, USA)
Cigdem Aslay (Aalto University, Finland)
N. Asokan (Aalto University, Finland)
Manuel Atencia (University of Grenoble Alpes and INRIA, France)
Giuseppe Ateniese (Stevens Institute of Technology, USA)
Medha Atre (University of Oxford, UK)
Sören Auer (TIB Leibniz Information Center Science and Technology and University of Hannover, Germany)
Nathalie Aussenac-Gilles (CNRS / IRIT, France)
Ahmed Hassan Awadallah (Microsoft Research, USA)
Matthew Backus (Columbia University, USA)
Abraham Bagherjeiran (A9 / Amazon, USA)

Xiao Bai (Yahoo Research, USA)
Jinyeong Bak (Korea Advanced Institute of Science and Technology, South Korea)
Saeideh Bakhshi (Georgia Institute of Technology, USA)
Eric Balkanski (Harvard University, USA)
Krisztian Balog (University of Stavanger, Norway)
Zhifeng Bao (RMIT University, Australia)
Pablo Barberá (London School of Economics, UK)
Payam Barnaghi (University of Surrey, UK)
Daniel Barowy (Williams College, USA)
Valerio Basile (University of Turin, Italy)
Justin Basilico (Netflix, USA)
Kinjal Basu (LinkedIn, USA)
Christian Bauckhage (Fraunhofer, Germany)
Luca Becchetti (Sapienza University of Rome, Italy)
Srikanta Bedathur (Indian Institute of Technology Delhi, India)
Zohra Bellahsene (LIRMM, France)
Paolo Bellavista (University of Bologna, Italy)
Alejandro Bellogin (Autonomous University of Madrid, Spain)
Boualem Benatallah (University of New South Wales, Australia)
Michael Bendersky (Google, USA)

Fabricio Benevenuto (Federal University of Minas Gerais, Brazil)
Austin Benson (Cornell University, USA)
Klaus Berberich (Max Planck Institute for Informatics, Germany)
Michele Berlingerio (IBM, Ireland)
Maria Bermudez-Edo (University of Granada, UK)
George Berry (Facebook, USA)
Azer Bestavros (Boston University, USA)
Alex Beutel (Google, USA)
Anastasia Bezzubtseva (Yandex, Russia)
Tijl De Bie (Ghent University, Belgium)
Maria Bielikova (Slovak University of Technology, Slovakia)
Chris Biemann (University of Hamburg, Germany)
Battista Biggio (University of Cagliari, Italy)
Lidong Bing (Tencent, China)
Christian Bizer (University of Mannheim, Germany)
Jeremy Blackburn (University of Alabama Birmingham, USA)
Liad Blumrosen (Hebrew University, Israel)
Fernando Bobillo (University of Zaragoza, Spain)
Uldis Bojars (University of Latvia, Latvia)
Kalina Bontcheva (University of Sheffield, UK)
Ludovico Boratto (Eurecat, Spain)
Cecile Bothorel (Telecom Bretagne, France)
Alessandro Bozzon (Delft University of Technology, Netherlands)
Marco Brambilla (Polytechnic University of Milan, Italy)
Simina Branzei (Purdue University, USA)
Adrian M.P. Brasoveanu (MODUL Technology, Austria)
John Breslin (National University of Ireland Galway, Ireland)
David Buckeridge (McGill University, Canada)
Roman Budylin (Yandex, Russia)
Cody Buntain (University of Maryland, USA)
Keith Burghardt (University of Southern California, USA)
Elena Cabrio (University of Côte d'Azur and INRIA, France)
Jean-Paul Calbimonte (University of Applied Sciences and Arts Western Switzerland HES-SO, Switzerland)
Chico Camargo (University of Oxford, UK)
B. Barla Cambazoglu (RMIT University, Australia)
Jan Camenisch (Dfinity, Switzerland)
Ran Canetti (Boston University, USA; Tel Aviv University, Israel)
Iván Cantador (Autonomous University of Madrid, Spain)
Jiannong Cao (Hong Kong Polytechnic University, Hong Kong)
Cinzia Cappiello (Polytechnic University of Milan, Italy)
Justin Cappos (New York University, USA)
Bogdan Carbunar (Motorola Labs, USA)
Valeria Cardellini (University of Roma Tor Vergata, Italy)
Barbara Carminati (University of Insubria, Italy)
Leslie Carr (University of Southampton, UK)
David Carral (Technical University of Dresden, Germany)
Aniello Castiglione (University of Salerno, Italy)
Dario Catalano (University of Catania, Italy)
Lorenzo Cavallaro (University of London, UK)
James Caverlee (Texas A&M University, USA)
Davide Ceolin (Vrije Universiteit Amsterdam, Netherlands)
Sofia Ceppi (University of Edinburgh, UK)
Suleyman Cetintas (Yahoo Research, USA)
Meeyoung Cha (Korea Advanced Institute of Science and Technology, South Korea)
Augustin Chaintreau (Columbia University, USA)
Kaushik Chakrabarti (Microsoft, USA)
Tanmoy Chakraborty (Indraprastha Institute of Information Technology Delhi, India)
T-H. Hubert Chan (University of Hong Kong, Hong Kong)
Stevie Chancellor (Georgia Institute of Technology, USA)
Ashok Chandrashekar (Netflix, USA)
Kevin Chang (University of Illinois Urbana-Champaign, USA)
Thierry Charnois (LIPN CNRS University of PARIS 13, France)
Keke Chen (Wright State University, USA)
Lei Chen (Hong Kong University of Science and Technology, Hong Kong)
Li Chen (Hong Kong Baptist University, Hong Kong)
Pin-Yu Chen (IBM, USA)

Songqing Chen (George Mason University, USA)
Wei Chen (Microsoft, China)
Xiaojun Chen (Shenzhen University, China)
Zhiyuan Chen (Google, USA)
Zhumin Chen (Shandong University, China)
Gong Cheng (Nanjing University, China)
Ed H. Chi (Google, USA)
Christian Chiarcos (Goethe University, Germany)
Flavio Chierichetti (Sapienza University of Rome, Italy)
Jaegul Choo (Korea University, South Korea)
Richard Chow (Intel, USA)
Sherman S. M. Chow (Chinese University of Hong Kong, Hong Kong)
Omar Chowdhury (University of Iowa, USA)
Konstantina Christakopoulou (University of Minnesota, USA)
Aleksandr Chuklin (Google, Switzerland)
Rumi Chunara (New York University, USA)
Charles Clarke (Facebook, Canada)
Francisco Claude (eBay, USA)
Michael Cochez (Fraunhofer, Germany)
Daniel Cohen (University of Massachusetts Amherst, USA)
Michele Colajanni (University of Modena, Italy)
Michael Cole (LexisNexis, USA)
Pieter Colpaert (Ghent University, Belgium)
Simona Colucci (Polytechnic University of Bari, Italy)
Mauro Conti (University of Padua, Italy)
Olivier Corby (INRIA, France)
Oscar Corcho (Polytechnic University of Madrid, Spain)
Luca Costabello (Accenture Labs, Ireland)
Fabio Cozman (University of São Paulo, Brazil)
Henriette Cramer (Spotify, USA)
Lorrie Cranor (Carnegie Mellon University, USA)
Paolo Cremonesi (Polytechnic University of Milan, Italy)
Pierluigi Crescenzi (University of Florence, Italy)
Bruno Crispo (University of Trento, Italy)
Bruce Croft (University of Massachusetts Amherst, USA)
Mark Crovella (Boston University, USA)
Isabel Cruz (University of Illinois Chicago, USA)
Philippe Cudre-Mauroux (University of Fribourg, Switzerland)
Peng Cui (Tsinghua University, China)
Shane Culpepper (RMIT University, Australia)
Olivier Curé (University of Paris-Est, France)
Enrico Daga (Open University, UK)
Andrew Dai (Google, USA)
Zhuyun Dai (Carnegie Mellon University, USA)
Elizabeth M. Daly (IBM, Ireland)
Claudia d'Amato (University of Bari, Italy)
Florian Daniel (Polytechnic University of Milan, Italy)
Maximilien Danisch (Laboratoire d'Informatique de Paris 6, France)
Mathieu D'Aquin (National University of Ireland Galway, Ireland)
Anirban Dasgupta (Indian Institute of Technology Gandhinagar, India)
Lucas Davi (University of Duisburg-Essen, Germany)
Jérôme David (INRIA, France)
Thierry Declerck (DFKI, Germany)
Jaime Delgado (Polytechnic University of Catalonia, Spain)
Daniele Dell'Aglio (University of Zurich, Switzerland)
Gianluca Demartini (University of Queensland, Australia)
Elena Demidova (L3S Research Center, Germany)
Ronald Denaux (Expert System, Spain)
Hongbo Deng (Google, USA)
Sebastian Deri (Cornell University, USA)
Antoine Desir (INSEAD, France)
Nikhil Devanur (Microsoft, USA)
Dennis Diefenbach (University Jean Monet, France)
Jana Diesner (University of Illinois Urbana-Champaign, USA)
Stefan Dietze (GESIS - Leibniz Institute for the Social Sciences, Germany)
Djellel Difallah (New York University, USA)
Pavel Dmitriev (Outreach, USA)
Juan Manuel Dodero (University of Cadiz, Spain)
Carlotta Domeniconi (George Mason University, USA)
Yuxiao Dong (Microsoft, USA)
Zhicheng Dou (Renmin University of China, China)
Adam Doupé (Arizona State University, USA)
Mauro Dragoni (Fondazione Bruno Kessler, Italy)
Eduard Dragut (Temple University, USA)
Nan Du (Google, USA)
Nick Duffield (Texas A&M University, USA)
Casey Dugan (IBM Research, USA)

Adam Dunn (Macquarie University, Australia)
Schahram Dustdar (Vienna University of Technology, Austria)
Koji Eguchi (Kobe University, Japan)
Maud Ehrmann (École Polytechnique Fédérale de Lausanne, Switzerland)
Carsten Eickhoff (Brown University, USA)
Michael Ekstrand (Boise State University, USA)
Mehdi Elahi (Free University of Bozen-Bolzano, Italy)
Edith Elkind (University of Oxford, UK)
William Enck (North Carolina State University, USA)
Alina Ene (Boston University, USA)
Alessandro Epasto (Google, USA)
Vadim Ermolayev (Zaporizhzhia National University, Ukraine)
Hossein Esfandiari (Harvard University, USA)
Jérôme Euzenat (INRIA and University of Grenoble Alpes, France)

Deep Learning for Solving Important Problems

Jeff Dean
Google
Mountain View, CA, USA, jeff@google.com

ABSTRACT

In this keynote we describe progress in work that our research teams have been doing over the past years, including advances in difficult problems in artificial intelligence, on building large-scale computer systems for machine learning research, and, in collaboration with many teams at Google, on applying our research and systems to dozens of Google products. Our group has open-sourced the TensorFlow system [2], a widely popular system designed to easily express machine learning ideas, and to quickly train, evaluate and deploy machine learning systems. We then highlight some of our research accomplishments, and relate them to the National Academy of Engineering's Grand Engineering Challenges for the 21st Century.

This is joint work with many people at Google.

1 BIOGRAPHY

Jeff Dean [1] joined Google in 1999 and is currently a Google Senior Fellow and SVP of Google AI, Research, and Health. He and his collaborators are working on systems for speech recognition, computer vision, language understanding, and various other machine learning tasks. He has co-designed/implemented many generations of Google's crawling, indexing, and query serving systems, and co-designed/implemented major pieces of Google's initial advertising and AdSense for Content systems. He is also a co-designer and co-implementor of Google's distributed computing infrastructure, including the MapReduce, BigTable and Spanner systems, protocol buffers, the open-source TensorFlow system for machine learning, and a variety of internal and external libraries and developer tools.

Jeff received a Ph.D. in Computer Science from the University of Washington in 1996, working with Craig Chambers on whole-program optimization techniques for object-oriented languages. He received a B.S. in computer science & economics from the University of Minnesota in 1990. He is a member of the National Academy of Engineering, and of the American Academy of Arts and Sciences, a Fellow of the Association for Computing Machinery (ACM), a Fellow of the American Association for the Advancement of Sciences (AAAS), and a winner of the ACM Prize in Computing.

The Law of the Horse at 20: Phases of the Net

Lawrence Lessig
Harvard Law School
Cambridge, MA, USA, lessig@this.is

ABSTRACT

The Internet moves in phases, and we are entering the third in 20 years. In this keynote, using a framework drawn from the Law of the Horse [1], I describe the phase we are entering — the surveillance phase — and the threat it presents to society generally, and democracy in particular. Along the way, I offer an understanding of the Net circa 1999, and the phase that followed it, circa 2009. At each stage, our inability to govern has been a significant liability. In the phase we are entering, it will be devastating.

Enlisting the Public to Build a Healthier Web Information Commons

Claire Wardle
TED Fellow
CIVIC, New York, NY, USA, claire@ted.com

ABSTRACT

Over the past three years, platforms, governments and a plethora of nonprofit initiatives have prioritized fighting online misinformation through a variety of different means. Yet the current framework is too fragmented to deliver global results. The big tech platforms have data, but no public accountability. Governments (mostly) have democratic legitimacy, but little information on what is actually going on in the platforms they're itching to regulate. And nonprofit initiatives too often lack the scale to affect change at the level needed. What if we came up with a dramatically new deliberative process that involves a global community of concerned citizens ready to share information and participate in consultations to improve collective decision-making? What if a more accountable, diverse and verifiable Web were still possible?

ABSTRACT

Existing unbiased learning-to-rank models use counterfactual inference, notably Inverse Propensity Scoring (IPS), to learn a ranking function from biased click data. They handle the click incompleteness bias, but usually assume that the clicks are noise-free, i.e., a clicked document is always assumed to be relevant. In this paper, we relax this unrealistic assumption and study click noise explicitly in the unbiased learning-to-rank setting. Specifically, we model the noise as the position-dependent trust bias and propose a noise-aware Position-Based Model, named TrustPBM, to better capture user click behavior. We propose an Expectation-Maximization algorithm to estimate both examination and trust bias from click data in TrustPBM. Furthermore, we show that it is difficult to use a pure IPS method to incorporate click noise and thus propose a novel method that combines a Bayes rule application with IPS for unbiased learning-to-rank. We evaluate our proposed methods on three personal search data sets and demonstrate that our proposed model can significantly outperform the existing unbiased learning-to-rank methods.

1 INTRODUCTION

Implicit user feedback (such as clicks, dwelling time etc.) is routinely logged in many applications such as web search and personal email search. Using this data for learning-to-rank (LTR) is attractive not only because it is abundantly available, but also because it is the only viable large-scale labeled data for many applications like personal search [32, 33]. Moreover, unlike explicit relevance judgments obtained from experts or crowd-sourcing which can become obsolete quickly, implicit feedback reflects the time-varying preferences of the actual user population and is easy to maintain.

Despite these clear benefits, LTR from implicit feedback, in particular clicks on search results, is challenging due to inherent biases in user behavior. For example, due to position bias, a result displayed at a higher position is more likely to receive clicks than a result at a lower position. Thus directly using clicks as relevance judgments can lead to biased results because (1) clicks are incomplete as relevant documents may be missed non-uniformly and (2) clicks are noisy since a click does not necessarily imply the document is relevant.

Recently, unbiased LTR has been actively studied as a promising approach to learn from biased click logs. It is based on counterfactual inference [21] and has been shown to outperform the traditional click modeling approaches [3]. The commonly used technique in unbiased LTR is Inverse Propensity Scoring (IPS). Different from the traditional IPS approaches used in counterfactual inference where the propensity is known, a key question in unbiased LTR is how to estimate the propensity – the probability that the relevance of a result is observed. Examination-based click models, and the Position-Based Model (PBM) in particular, have been leveraged for this. A nice property of PBM is that the examination bias in it is the propensity needed. Different techniques have been proposed to estimate the examination bias using result randomization [21, 32], random pairs harvesting [2], a regression-based Expectation-Maximization (EM) technique [33], and a dual learning algorithm [3].

Existing PBM methods mainly focus on addressing the click incompleteness bias, by assuming that clicks are noise-free. Such an assumption is unrealistic. How to address click noise for unbiased LTR is still an open question. Joachims et al. [21] showed the robustness of the IPS-based approach when *position-independent constant* noise is present in click data. However, as the user study in [19] showed qualitatively, there is a *trust bias* after examining results, capturing the intuition that users may overestimate (or underestimate) the relevance of a result given its high (or low) position, due to their trust in the effectiveness of the search application to rank relevant documents higher. Thus a non-relevant result may be clicked and a relevant result may not be clicked, and the probabilities are not constant but depend on the position of the result.

Trust bias can be thought of as another form of position bias, but to the best of our knowledge, it has not been quantitatively formulated in the existing literature. In this paper, we introduce a noise-aware PBM, named TrustPBM, to model trust bias in user clicks. The standard PBM model assumes that an examined and relevant document is always clicked. We extend it to capture the following uncertainty: after examination, a relevant document can be missed, and meanwhile a non-relevant document can be clicked. TrustPBM is a click model that gives a rigorous mathematical formulation of the trust bias. However, its bias parameters cannot be estimated based on intervention like the result randomization used for PBM. Even if we can estimate bias parameters in TrustPBM, it is still unclear how to use them for unbiased LTR.

In this paper, we first show that TrustPBM can be effectively estimated using an EM algorithm, inspired by the previous work [33]. Since TrustPBM is no longer a factorization model, a purely IPS method for unbiased LTR is not feasible. We thus derive a novel and mathematically principled Bayes-IPS correction that uses a Bayesian approach for trust bias and IPS for examination bias. Conceptually, the Bayes-IPS method addresses both click incompleteness bias (using IPS) and click noise (using Bayes rule) for unbiased LTR.

We empirically evaluate our method on click logs from search services for Gmail, Google Drive, and Gmail Expert users. Our TrustPBM estimates obtained via the EM algorithm reveal novel insights into the nature of relevance noise present in real settings. Most interestingly, we observe that most of the noise comes from highly ranked irrelevant documents being judged relevant, while relevant documents tend to be judged accurately even at lower positions. Moreover, our results demonstrate that the TrustPBM fits the click data better than the plain PBM. Furthermore, ranking models trained with the Bayes-IPS correction have superior live experiment metrics than those trained with only the IPS correction based on PBM, estimated either via EM or result randomization.

In summary, the contributions of this paper are as follows:

- We propose TrustPBM, a novel click model that captures both position-dependent click incompleteness and click noise.
- We extend the EM algorithm designed for PBM to TrustPBM and show that it can effectively estimate the model parameters for TrustPBM.
- We present a novel Bayes-IPS correction method for unbiased LTR based on the parameters in TrustPBM estimated by the EM algorithm.
- We validate our approach on large-scale click logs. The experimental results show interesting patterns for user behavior and our proposed Bayes-IPS method achieves superior results compared to baselines.

The rest of the paper is organized as follows. In Section 2, we review previous related work. We describe our TrustPBM model in Section 3 and the EM algorithm for its parameter estimation in Section 4. Our Bayes-IPS approach for unbiased LTR is presented in Section 5. We report our evaluation on click logs in Section 6. Finally, we conclude this paper and discuss future work in Section 7.

2 RELATED WORK

Leveraging user interaction data such as clicks has been shown to be quite promising in improving search quality. A simple approach is to use click and non-click information as relevance judgment of results. This can be used for evaluation or to train a new ranking function in the LTR setting. However, such an approach can lead to misleading evaluation results or sub-optimal ranking functions due to various types of bias in click data, e.g., position bias [19], presentation bias [35], and trust bias [19, 25]. In the past, a large amount of research has been devoted to extracting more accurate signals from click data. For example, some heuristic methods have been proposed to address the position bias by utilizing the pairwise preferences between clicked and skipped documents (e.g., SkipAbove) [18–20]. Though these methods have been found to provide more accurate relevance assessments, their data is fundamentally biased. For example, a ranking function trained based on the SkipAbove heuristic tends to reverse the presented order due to its sampling bias [18].

Recently, unbiased LTR has been actively studied to learn a ranking function from click data based on the counterfactual inference framework [21]. With the assumption that feedback is noise-free, it provides an IPS-based correction method which is a provably unbiased and consistent approach to LTR even with biased feedback data. The IPS method requires knowledge of the propensity of obtaining a particular feedback signal. Click modeling, especially PBM, has been used for estimating propensity. Under this model, Wang et al. [32] proposed a result randomization method that randomly shuffles the top n results and uses the average CTR at each position as the propensity. Joachims et al. [21] proposed a pivot-based randomization where position 1 and k are randomly shuffled. The relative propensity between these two positions p_k/p_1 can be derived and this is sufficient for LTR. Wang et al. [33] proposed a RandPair approach where adjacent positions are randomly flipped to obtain p_{k+1}/p_k and a chain rule is used to estimate the ratio p_k/p_1. Wang et al. [32] extended the PBM model to let the propensity depend on query or user contexts, in addition to positions. All of these approaches require interventions.

The more recent development in unbiased LTR is on how to estimate propensity without interventions. Wang et al. [33] proposed a regression-based EM algorithm to fit the PBM model to the regular click logs without interventions. Similarly, Ai et al. [3] presented a framework to jointly learn an unbiased ranker and an unbiased propensity model from regular click data. Agarwal et al. [2] proposed a method for harvesting naturally randomized pairs from logs of multiple rankers in operational systems. All of these methods are based on the standard PBM model and do not address position-dependent click noise.

With the propensity estimated, the IPS-based approach is also used for search quality evaluations, in addition to learning a ranking function. For example, Carterette and Chandar [6] extend the counterfactual inference framework [21] by considering the case of evaluating new rankers that can retrieve previously unseen documents. Chandar and Carterette [7] studied the click-through bias in the cascade model for evaluation.

IPS was developed in causal inference [28] and is a widely accepted technique for handling sampling bias. It has been employed

in unbiased evaluation and learning [1, 11, 22, 23, 29, 30]. The common assumption in most of these studies is that the propensities are under the system's control and are thus known. In the unbiased LTR setting, however, propensities arise from user behavior and thus need to be estimated. While the IPS can be used to address the sample bias or click incompleteness, it is not straightforward for click noise.

Besides PBM, there are many other click models for extracting relevance signals from click data. Click models are parameterized generative models [9] and their parameters are typically estimated via generative maximum likelihood under specific modeling assumptions about user behavior. There are two classic click models: the PBM model [27] and the Cascade model [10]. Based on these two models, more advanced models have been developed. For example, the user browsing model (UBM) [12] extends PBM to condition the examination on a previously clicked position, in addition to the position of the current result. The dynamic Bayesian network model (DBN) [8] and the click chain model (CCM) [15] extend the Cascade model to handle multiple clicks. Both models assume a sequential user behavior over the result list. They focus on modeling the probability that document gets examined depending on the previous documents and differ in their modeling formulation. DBN and CCM are different from PBM and UBM in that the examination of a later document depends on the relevance of previous documents. However, most of these models assume clicks are noise-free. The focus of this paper is on click noise, specifically trust bias. We propose the TrustPBM model by extending the standard PBM model.

Though, in theory, the estimated examination probability in any click model can be used in unbiased LTR, the PBM model is more robust given that the examination does not depend on the relevance of previous documents since estimating relevance is as hard as learning a ranking function and thus leads to high variance of the estimated examination probability. Our TrustPBM model enjoys the same advantage where the trust bias depends on positions only.

The alternate approach of directly using position as a feature is generally not effective for learning a ranking function. This is because the position of a result is highly predictive of its click rate, however, the position feature cannot be used during inference time when a collection of documents must be scored to determine their positions in the presented ranking. Using the position feature in training and then unplugging it during inference leads to worse results [33].

3 TRUST ENHANCED POSITION-BASED MODEL

3.1 Position-Based Model

The Position-Based Model (PBM) is a simple generative model. It has been extensively used in unbiased LTR due to its simplicity. Most existing click models have the *examination hypothesis*. Suppose we have N positions, and for a query q, document d is displayed at position $k \in [1, N]$. A click can be generated only after the user examines the result. In the PBM model, the user clicks the document if and only if they examine the document and the document is relevant. The examination only depends on the position k, but not on q or d. Such a model factors out q and d, and makes the estimation of the probability of examination simpler and more robust, compared to other click models.

Formally, let C be a binary random variable signifying whether the user clicks document d, E whether the user examines the document, R for the true relevance and $\tilde{R}$ to represent the perceived or judged relevance. The PBM makes the following assumptions

$$C = 1 \Leftrightarrow E = 1, \tilde{R} = 1$$
$$R \Leftrightarrow \tilde{R}$$
$$\Pr(E = 1|q, d, k) = \Pr(E = 1|k)$$
$$\Pr(R|q, d, k) = \Pr(R|q, d)$$

Thus, the probability of examining a document only depends on the position k and the perceived relevance is the same as the true relevance. Based on these assumptions, the PBM has the following probability for a click.

$$\begin{aligned}\Pr(C = 1|q, d, k) &= \Pr(E = 1, \tilde{R} = 1|q, d, k) \\ &= \Pr(E = 1, R = 1|q, d, k) \\ &= \Pr(E = 1|k) \Pr(R = 1|q, d) \\ &= \theta_k \gamma_{q,d}\end{aligned}$$

where we use θ_k and $\gamma_{q,d}$ as short-hands for the probabilities.

3.2 Trust Bias

The PBM model and its extensions [32] have a noise-free assumption that perceived relevance is the same as the true relevance. This is not the case in general. How to model the relation between perceived relevance and true relevance is relatively less studied, even in the click models. DBN [8] is one of the few models that incorporates this relation. In DBN, a set of document-dependent parameters α_d are introduced to model the relation between perceived relevance and true relevance:

$$\Pr(R = 1|q, d) = \alpha_d \Pr(\tilde{R} = 1|q, d)$$

where a parameter α_d depend on the document d. The intuition is that the probability of true relevance is a discounted version of perceived relevance and that the discount is document-dependent. As a result, the model has a large number of additional parameters that equals to the number of unique documents in the data.

In this paper, we model the relation between perceived relevance and true relevance based on trust bias introduced in [19]. In this user study, eye tracking was used to monitor examination. The study showed that, after examination, users tend to trust the results presented higher on the result page more, demonstrated by higher click ratio despite the fact that the documents are both examined and their expected relevance is the same. This suggests a position-dependent trust bias in addition to examination bias, due to which higher ranked non-relevant documents may be clicked and lower ranked relevant documents not clicked. However, this has not been mathematically formulated in the past. In this paper, we model the trust bias as follows,

$$\Pr(\tilde{R} = 1|R = 1, E = 1, k) = \epsilon_k^+$$
$$\Pr(\tilde{R} = 1|R = 0, E = 1, k) = \epsilon_k^-$$

Since $C = 1 \Leftrightarrow E = 1, \tilde{R} = 1$, we have $\Pr(C = 1|R = 1, E = 1, k) = \epsilon_k^+$ and $\Pr(C = 1|R = 0, E = 1, k) = \epsilon_k^-$. Intuitively, after

examination, a relevant document at position k can be missed with probability $1-\epsilon_k^+$, but a non-relevant document can be clicked mistakenly with probability ϵ_k^-. Notice that the noise is position-dependent. A similar formulation has been studied in [21] where the noise is constant across positions.

3.3 TrustPBM

We enhance the PBM model by explicitly modeling the trust bias introduced above. We have

$$\begin{aligned}&\Pr(\tilde{R}=1|E=1,q,d,k)\\ =&\Pr(\tilde{R}=1|R=1,E=1,k)\Pr(R=1|q,d)\\ +&\Pr(\tilde{R}=1|R=0,E=1,k)\Pr(R=0|q,d)\\ =&\epsilon_k^+\gamma_{q,d}+\epsilon_k^-(1-\gamma_{q,d})\end{aligned}$$

Thus, in TrustPBM, the probability of a click is given as

$$\begin{aligned}\Pr(C=1|q,d,k)&=\Pr(E=1|k)\Pr(\tilde{R}=1|E=1,q,d,k)\\ &=\theta_k(\epsilon_k^+\gamma_{q,d}+\epsilon_k^-(1-\gamma_{q,d}))\end{aligned}$$

PBM can be viewed as a special case of TrustPBM, where $\epsilon_k^+=1$ and $\epsilon_k^-=0$ to reflect the noise-free assumption. Both PBM and TrustPBM model examination bias in the same way. On the other hand, TrustPBM is different from DBN. The noise depends on position only, not on the document. Compared to PBM, we introduce $2N$ more parameters into the model where N is usually small (e.g., 10), so the model complexity of TrustPBM is much smaller than DBN.

The TrustPBM parameters can be estimated using logged click data. Let $\mathcal{L}$ be the logged data consisting of tuples (q,d,k,c) for each received user query q, each document d displayed at any position k and a binary indicator c for whether the document was clicked or not (i.e. the realized value of the random variable C). Then, the log-likelihood of generating $\mathcal{L}$ (over the randomness in user click behavior) is,

$$\begin{aligned}\log\Pr(\mathcal{L})=&\sum_{(q,d,k,c)\in\mathcal{L}}c\log\theta_k(\epsilon_k^+\gamma_{q,d}+\epsilon_k^-(1-\gamma_{q,d}))\\ &+(1-c)\log(1-\theta_k(\epsilon_k^+\gamma_{q,d}+\epsilon_k^-(1-\gamma_{q,d}))).\end{aligned}$$

In order to find the parameters that maximize the above log-likelihood objective, we use Expectation-Maximization, extending the Regression-based EM method for the plain PBM in [33].

4 ESTIMATION VIA EXPECTATION-MAXIMIZATION

As we will show in Section 5, we only need the parameters θ_k, ϵ_k^+, and ϵ_k^- for unbiased LTR. However, unlike the standard PBM model whose parameters can be estimated based on result randomization, TrustPBM does not allow estimation of these parameters using a randomized data set. In this paper, we extend the previously proposed regression-based EM algorithm [33] to estimate the parameters.

In the standard EM procedure, parameters are estimated by alternating Expectation and Maximization steps until convergence. Suppose $\{\theta_k^{(t)},\epsilon_k^{+(t)},\epsilon_k^{-(t)}:k\in[N]\}$ and $\{\gamma_{q,d}^{(t)}:q,d\in\mathcal{L}\}$ are the parameter estimates at iteration t (initialized appropriately at the first iteration). We will get a new set of parameter estimates after iteration $t+1$.

4.1 Expectation Step

In the Expectation step at iteration $t+1$, the posterior distribution of the hidden variables of examination E and true relevance R given the observed click data $\mathcal{L}$ is expressed in terms of the parameter estimates at iteration t, as shown in Figure 1 (we omit superscript (t) for readability). All the formulas follow directly from Bayes rules. For instance, in the third from last equation, we have

$$\begin{aligned}&\Pr(E=0,R=1|q,d,k,c=0)\\ =&\frac{\Pr(C=0|E=0,R=1,q,d,k)\Pr(E=0,R=1|q,d,k)}{\Pr(C=0|q,d,k)}\\ =&\frac{\Pr(E=0,R=1|q,d,k)}{\Pr(C=0|q,d,k)}\\ =&\frac{\Pr(E=0|k)\Pr(R=1|q,d)}{\Pr(C=0|q,d,k)}\end{aligned}$$

since $\Pr(C=0|E=0,R=1,q,d,k)=1$, and examination and relevance are independent events. Also, a click means that the document must have been examined and thus $\Pr(E=0,R=1|q,d,k,c=1)=0$ in the second equation.

4.2 Maximization Step

In the Maximization step at iteration $t+1$, the parameters are updated to their maximum likelihood values given the click data and the posterior probabilities from the Expectation step as shown in Figure 2. Once again, we drop the superscript $(t+1)$ for clarity in these formulas. Different from PBM model, we have additional ϵ_k^+ and ϵ_k^- parameters updated in this step.

Regression-based EM. For the M-step to work with query-document pairs (q,d), a requirement is that (q,d) should repeat and also be shown in different positions. Since the query-document pairs (q,d) vary arbitrarily, using free parameters $\gamma_{q,d}$ makes the objective very sparse and difficult to learn. Moreover, exposing individual (q,d) identifiers can also pose a privacy or security risk. Therefore, as in [33], we propose to estimate the $\gamma_{q,d}$ parameters in each Maximization step via regression, i.e. fit a function (such as a Gradient Boosted Decision Tree) from features of (q,d) to the derived target value for $P(R=1|c,q,d,k)$ at iteration $t+1$.

More specifically, we assume that there is a feature vector $\mathbf{x}_{q,d}$ representing them and use a function to compute the relevance $\gamma_{q,d}=f(\mathbf{x}_{q,d})$. The Maximization step is then to find a regression function $f(\mathbf{x})$ to maximize the likelihood given the estimation from the Expectation step. Specifically, for each $(q,d,k,c)\in\mathcal{L}$, the expectation step gives a probability $P(R=1|q,d,k,c)$. Intuitively, we can regress the feature vector $\mathbf{x}_{q,d}$ to the probability $P(R=1|c,q,d,k)$. Similar to [33], we convert such a regression problem to a classification problem based on sampling: we sample a binary relevance label $r\in\{0,1\}$ according to $P(R=1|c,q,d,k)$. This conversion allows us to use widely available classification tools to solve our problem. After sampling, we have a training set $\{(\mathbf{x},r)\}$

$$Pr(E=1,R=1|q,d,k,c=1)=\frac{\epsilon_k^+\gamma_{q,d}}{\epsilon_k^+\gamma_{q,d}+\epsilon_k^-(1-\gamma_{q,d})},\qquad \Pr(E=0,R=1|q,d,k,c=1)=0$$

$$Pr(E=1,R=0|q,d,k,c=1)=\frac{\epsilon_k^-(1-\gamma_{q,d})}{\epsilon_k^+\gamma_{q,d}+\epsilon_k^-(1-\gamma_{q,d})},\qquad \Pr(E=0,R=0|q,d,k,c=1)=0$$

$$Pr(E=1,R=1|q,d,k,c=0)=\frac{\theta_k(1-\epsilon_k^+)\gamma_{q,d}}{1-\theta_k(\epsilon_k^+\gamma_{q,d}+\epsilon_k^-(1-\gamma_{q,d}))},\qquad \Pr(E=0,R=1|q,d,k,c=0)=\frac{(1-\theta_k)\gamma_{q,d}}{1-\theta_k(\epsilon_k^+\gamma_{q,d}+\epsilon_k^-(1-\gamma_{q,d}))}$$

$$\Pr(E=1,R=0|q,d,k,c=0)=\frac{\theta_k(1-\epsilon_k^-)(1-\gamma_{q,d})}{1-\theta_k(\epsilon_k^+\gamma_{q,d}+\epsilon_k^-(1-\gamma_{q,d}))},\qquad \Pr(E=0,R=0|q,d,k,c=0)=\frac{(1-\theta_k)(1-\gamma_{q,d})}{1-\theta_k(\epsilon_k^+\gamma_{q,d}+\epsilon_k^-(1-\gamma_{q,d}))}$$

Figure 1: Formulas for computing probabilities of hidden variables in the E-step of the EM algorithm for TrustPBM.

$$\theta_k=\frac{\sum_{(q,d,k',c)\in\mathcal{L}}1\{k'=k\}(c+(1-c)P(E=1|q,d,k,C=0))}{\sum_{(q,d,k',c)\in\mathcal{L}}1\{k'=k\}}$$

$$\gamma_{q,d}=\frac{\sum_{(q',d',k,c)\in\mathcal{L}}1\{q'=q,d'=d\}(c\cdot P(R=1|q,d,k,C=1)+(1-c)P(R=1|q,d,k,C=0))}{\sum_{(q',d',k,c)\in\mathcal{L}}1\{q'=q,d'=d\}}$$

$$\epsilon_k^+=\frac{\sum_{(q,d,k',c)\in\mathcal{L}}1\{k'=k\}\cdot c\cdot P(E=1,R=1|,q,d,k,C=1)}{\sum_{(q,d,k',c)\in\mathcal{L}}1\{k'=k\}(c\cdot P(E=1,R=1|q,d,k,C=1)+(1-c)P(E=1,R=1|q,d,k,C=0))}$$

$$\epsilon_k^-=\frac{\sum_{(q,d,k',c)\in\mathcal{L}}1\{k'=k\}\cdot c\cdot P(E=1,R=0|,q,d,k,C=1)}{\sum_{(q,d,k',c)\in\mathcal{L}}1\{k'=k\}(c\cdot P(E=1,R=0|q,d,k,C=1)+(1-c)P(E=1,R=0|q,d,k,C=0))}$$

Figure 2: Formulas for updating parameters in the M-step of the EM algorithm for TrustPBM, where 1 is the indicator function.

for $f(\mathbf{x})$. The objective function is the log likelihood:

$$\sum_{\{(\mathbf{x},r)\}} r\log(f(\mathbf{x}))+(1-r)\log(1-f(\mathbf{x})),$$

where we use the sigmoid in the objective function

$$f(\mathbf{x})=\frac{1}{1+e^{-F(\mathbf{x})}}$$

$F(x)$ is the log odd of function $f(x)$ and is learned by Gradient Boosted Decision Tree (GBDT) method [13] in this paper.

5 UNBIASED LTR VIA BAYES-IPS CORRECTION

Now we turn to the question of using the parameter estimates of the TrustPBM to learn a new ranking function from the click data in an unbiased way. Specifically, we need to adjust each click signal in the logged data such that it reflects the actual underlying relevance signal in expectation, unconfounded by the inherent examination and trust biases captured by TrustPBM.

In existing work [21, 33] which deals with the standard PBM, this is achieved via Inverse Propensity Scoring (IPS) which corrects for the examination bias factor. Since TrustPBM does not factorize into purely bias (from examination and trust) and relevance terms, a direct IPS correction is not feasible. In the following, we first review the existing unbiased LTR and then present our two-step approach to deal with noise: correct for examination bias via IPS, and then de-noise for trust bias via Bayes law.

5.1 LTR

We begin with a brief overview of the LTR setting. In the standard LTR, a set of labeled data for query and documents are given $\mathcal{L}_U=\{(q,d,r)\}$ where r represents the relevance labels for the (q,d) pair. We also use $\Omega_q=\{d|(q,d)\in\mathcal{L}_U\}$ to represent all documents that are associated with query q. Collection $\mathcal{L}_U$ is *unbiased* and a uniform sample from the space of queries, documents, and relevance. In general, fully supervised LTR algorithms such as LambdaMART and RankingSVM are used to directly or indirectly optimize a performance metric which decomposes as a sum over the (q,d) samples in the training set, as such

$$M=\sum_{(q,d,r)\in\mathcal{L}_U} r\cdot f(q,d,\Omega_q)$$

where f is usually a rank-related function. For instance, Average Relevance Position (ARP) [21, 33, 34] and Discounted Cumulative Gain (DCG) like metrics [17, 33] are shown as below,

$$ARP=\sum_{(q,d,r)\in\mathcal{L}_U} r\,\mathrm{rank}(q,d,\Omega_q)$$

$$DCG=\sum_{(q,d,r)\in\mathcal{L}_U} r\,\frac{1}{\mathrm{rank}(q,d,\Omega_q)}.$$

Note that lower *ACP* and higher *DCG* indicate better ranking performance with more relevant documents at higher ranks. We use a simple DCG definition that uses a binary relevance and a linear function for position discount to be consistent with the rest of paper. But the methodology is applicable to any DCG definitions.

In pairwise learning-to-rank algorithms, scores s are learned for (q, d) pairs by expressing rank as a pairwise objective

$$\begin{aligned} ARP &= \sum_{(q,d,r)\in\mathcal{L}_U} r \,\mathrm{rank}(q, d, \Omega_q) \\ &= \sum_{(q,d,r)\in\mathcal{L}_U} r \,(\sum_{d'\in\Omega_q} \mathbb{I}_{s_{(q,d)}<s_{(q,d')}} + 1) \\ &= \sum_{(q,d,r)\in\mathcal{L}_U} \sum_{d'\in\Omega_q} r\, \mathbb{I}_{s_{(q,d)}<s_{(q,d')}} + const \end{aligned} \tag{1}$$

The loss above can then be upper-bounded by common classification loss functions (e.g., the hinge loss or the logistic loss [16]) as in the RankingSVM method. Moreover, rank-based metrics such as *ARP* and *DCG* can also be optimized in the LambdaLoss framework [34] where LambdaRank and LambdaMART [5] are special cases in the framework.

5.2 Unbiased LTR

The challenge in learning from implicit feedback such as click data is that only the click information c is observed, not the true relevance r for each (q, d) pair. The relation between r and c is captured by click models. The Inverse Propensity Scoring (IPS) technique is used to tackle this issue by de-biasing click data because the examination bias in PBM is equivalent to the propensity of observing relevance labels in the counterfactual framework [21].

Recall that we have logged data $\mathcal{L}$ consisting of tuples (q, d, k, c),

$$\mathbb{E}[C|q, d, k] = \Pr(C = 1|q, d, k) = \theta_k \Pr(\tilde{R} = 1|E = 1, q, d, k)$$

where the expectation is over the randomness in the user click behavior. As in previous work, we can employ IPS to correct for the examination bias in the following way,

$$\begin{aligned} M_{IPS} &= \sum_{(q,d,k,c)\in\mathcal{L}} \frac{c}{\theta_k} f(q, d, \Omega_q) \\ &= \sum_{(q,d,k,c=1)\in\mathcal{L}} \frac{1}{\theta_k} f(q, d, \Omega_q) \end{aligned}$$

M_{IPS} is an unbiased estimation of metric M because

$$\begin{aligned} \mathbb{E}[M_{IPS}] &= \sum_{(q,d,k,c)\in\mathcal{L}} \frac{\mathbb{E}[C]}{\theta_k} f(q, d, \Omega_q) \\ &= \sum_{(q,d,k,c)\in\mathcal{L}} \Pr(\tilde{R} = 1|E = 1, q, d, k) f(q, d, \Omega_q) \end{aligned}$$

In the plain PBM which assumes that $\Pr(\tilde{R} = 1|E = 1, q, d, k) = \Pr(R = 1|q, d)$, i.e. judgment upon examination reflects actual relevance free from noise, interpreting r as $\Pr(R = 1|q, d)$ (the degree of true relevance), M_{IPS} equals M in expectation and thus can be used as a direct unbiased substitute in the learning-to-rank algorithm since it is simply a linear weight modification.

$$\begin{aligned} ARP_{IPS} &= \sum_{(q,d,k,c=1)\in\mathcal{L}} \frac{1}{\theta_k} \,\mathrm{rank}(q, d, \Omega_q) \\ DCG_{IPS} &= \sum_{(q,d,k,c=1)\in\mathcal{L}} \frac{1}{\theta_k} \frac{1}{\mathrm{rank}(q, d, \Omega_q)}. \end{aligned}$$

For instance, the upper-bounding technique shown in Eq 1 still applies with ARP_{IPS} and an IPS-based RankingSVM was derived in [21] and the LambdaMART algorithm can be used to optimize DCG_{IPS}.

5.3 Bayes-IPS Correction

Now, for the TrustPBM, we do not have the equivalence between perceived relevance $\tilde{R}$ and R. The standard IPS approach gives an unbiased estimation of $\tilde{R}$. Note that we only care about the clicked documents in M_{IPS}. To get the estimate of R, we only need to estimate it for $C = 1$, i.e., $\Pr(R = 1|C = 1, q, d, k)$. Such an estimation can involve many parameters due to the dependency on (q, d) pairs. To make it tractable, we thus approximate it by the average relevance at position k: $\Pr(R = 1|C = 1, k)$, i.e., $\Pr(R = 1|\tilde{R} = 1, E = 1, k)$. By Bayes law, we have

$$\begin{aligned} &\Pr(R = 1|\tilde{R} = 1, E = 1, k) \\ &= \frac{\Pr(\tilde{R} = 1|R = 1, E = 1, k) \Pr(R = 1|E = 1, k)}{\Pr(\tilde{R} = 1|E = 1, k)} \\ &= \frac{\epsilon_k^+ \Pr(R = 1|E = 1, k)}{\epsilon_k^+ \Pr(R = 1|E = 1, k) + \epsilon_k^- \Pr(R = 0|E = 1, k)} \\ &= \frac{\epsilon_k^+ \Pr(R = 1)}{\epsilon_k^+ \Pr(R = 1) + \epsilon_k^- \Pr(R = 0)} \\ &= \frac{\epsilon_k^+}{\epsilon_k^+ + \epsilon_k^-} \end{aligned}$$

The first step is based on Bayes law. The second is the definition of ϵ_k^+ and ϵ_k^-. The third step is because R is independent of E and k. The last step is based on a weak uninformative *prior* on actual relevance that $\Pr(R = 1) = \Pr(R = 0) = 0.5$. Putting it all together, we have

$$\begin{aligned} M_{Bayes-IPS} &= \sum_{(q,d,k,c=1)\in\mathcal{L}} \frac{1}{\theta_k} \Pr(R = 1|C = 1, k) f(q, d, \Omega_q) \\ &= \sum_{(q,d,k,c=1)\in\mathcal{L}} \frac{1}{\theta_k} \frac{\epsilon_k^+}{\epsilon_k^+ + \epsilon_k^-} f(q, d, \Omega_q). \end{aligned}$$

Informally, the Bayes-IPS estimate corrects for the examination bias and the likelihood that the result was actually relevant given that it was judged so upon examination. As a sanity check, note that in the noise-free case of the plain PBM, i.e. when $\epsilon_k^+ = 1$ and $\epsilon_k^- = 0$, $M_{Bayes-IPS}$ reduces to M_{IPS}. Moreover, since the proposed correction is simply a change of weights, a learning-to-rank framework with IPS can be easily adapted to use Bayes-IPS weights to replace IPS weights.

6 EMPIRICAL EVALUATION

In this section, we evaluate our proposed TrustPBM click model and the Bayes-IPS correction for unbiased LTR. We first describe our experiment setup and then present our experimental results.

6.1 Experiment Setup

Our experiments are based on both offline evaluation and online experiments. For offline evaluation, we use the standard framework for supervised LTR evaluation [24] by splitting the data into training and test sets. For online experiments, we evaluate our proposed methods through online A/B testing. In this section, we describe

Table 1: Statistics of the three data sets used in offline evaluation.

	Email	File Storage	Email Expert
#Queries per user	> 3	> 3	< 4
#Docs in total	59.69M	50.77M	13.80M
#Docs per query	5.99	5.00	6.00

the data sets and metrics used in offline evaluation as well as the metrics used in online experiments.

6.1.1 Data Sets. For offline evaluation, we use search logs collected from three search services: Gmail for general users (denoted as **Email**), Google Drive for general users (denoted as **File Storage**), and Gmail for expert users (denoted as **Email Expert**). The Email and Email Expert services have the same type of contents, but the users in the Email Expert dataset are more active, as measured by their search activity. The File Storage service has a different type of content compared with the other two. In all services, each query can result in at most a single click of a document because an overlay showing results is displayed as a query is typed and it disappears as a result is clicked. The clicked document is then shown on the screen.

In our data sets, we discard all the queries that did not result in any clicks. No further pre-processing is done. In all these services, ranking features are routinely computed and logged. We collected a sample from the search logs of each service in a two-week period in May 2018. Data from the first week are used for training, and those from the second week are used for testing. Basic statistics for the data sets are shown in Table 1. Each data set contains millions of queries, and between 5 and 6 documents per query. The logs also contain existing ranking features for each query-document pair, which we use in our regression-based EM algorithms and unbiased LTR algorithms.

6.1.2 Offline evaluation metrics. Our offline evaluation consists of two parts. The first part is to compare the PBM and TrustPBM models based on their fitness to the data. For this part, we use the standard log-likelihood on how the models predict clicks in our test data.

$$\text{LogLikelihood} = \frac{1}{|\mathcal{L}|} \sum_{\mathcal{L}} c \log(p) + (1 - c) \log(1 - p) \tag{2}$$

where $p = \theta_k \gamma_{q,d}$ for PBM and $p = \theta_k(\epsilon_k^+ \gamma_{q,d} + \epsilon_k^-(1 - \gamma_{q,d}))$ for TrustPBM. Log-likelihood is commonly used to evaluate click models [9]. It is a negative number and the larger the better.

For the second part, we compared different methods on the effectiveness of learned ranking functions for unbiased LTR. Following [32, 33], we use the weighted version of Mean Reciprocal Rank (MRR) as the evaluation metric for offline experiment. It is an unbiased version of MRR and more suitable than standard MRR for offline evaluation given click bias. Specifically, given a test data set with n queries, the standard MRR is defined as:

$$\text{MRR} = \frac{1}{n} \sum_{i=1}^{n} \frac{1}{\text{rank}_i} \tag{3}$$

where rank_i denotes the rank of the first clicked document of the i-th query in our data sets. Note that since each query can have at most one clicked document, we do not consider more complicated metrics like normalized discounted cumulative gain. We denote weighted MRR [33] by MRR_w, which is defined as:

$$\text{MRR}_w = \frac{1}{\sum_{i=1}^{n} w_i} \sum_{i=1}^{n} w_i \frac{1}{\text{rank}_i} \tag{4}$$

where w_i is the IPS correction weight estimated from our algorithm. Given different propensity estimation methods, the weights are used for both training and offline evaluation.

Table 2: Comparison of PBM and TrustPBM click models based on log-likelihood. The best number per row is in bold face and + means statistically significance based on the student t-test.

	PBM	TrustPBM	Improvement
Email	-0.364	**-0.351**	$3.57\%^+$
File Storage	-0.343	**-0.332**	$3.21\%^+$
Email Expert	-0.356	**-0.339**	$4.78\%^+$

6.1.3 Online experiment metrics. For online experiments, we run A/B testing using ranking functions learned based on different IPS weights. This is the ultimate test of effectiveness of ranking functions. A better ranking function can attract more clicks from users and push the user clicks to higher positions. We thus use the click-through rate (CTR) that is defined as the ratio of queries with clicks and the total number of queries. We also use the standard MRR in Eq 3 for online evaluation to take into account the effect of positions. For any queries without clicks, their MRR values are set to 0 for online experiments.

6.2 Experimental Results

In this section, we report both offline and online experimental results. Our comparisons are conducted for both click modeling and unbiased LTR.

6.2.1 Does the extended model fit the data better? Both PBM and TrustPBM are click models. Our first result is to compare them on how well they can fit our click data. We run our EM algorithms for both PBM and TrustPBM respectively and compare them in terms of log-likelihood in Eq 2. The results on our test data sets are shown in Table 2. From this table, we can see that the TrustPBM model has higher log-likelihood values than the PBM model on all the three data sets. We also report the relative improvement of the log-likelihood in this table. All these improvements are statistically significant based on the student t-test. This means that our proposed method of incorporating click noise in TrustPBM is reasonable since TrustPBM can indeed fit the data significantly better than PBM. In addition, we also study the convergence of the EM algorithms for PBM and TrustPBM in Figure 3, where we plot log-likelihood along with the EM iterations. It can be observed that TrustPBM not only converges to a higher log-likelihood, but also converges faster than PBM at early stages. This confirms that our proposed EM algorithm can estimate parameters for TrustPBM effectively. Overall, this result shows that TrustPBM is better that PBM.

Figure 3: Convergence of EM based on log-likelihood.

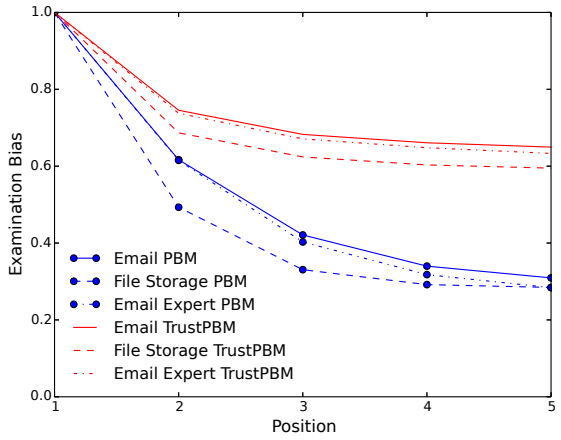

Figure 4: The normalized examination bias estimated from PBM and TrustPBM using EM.

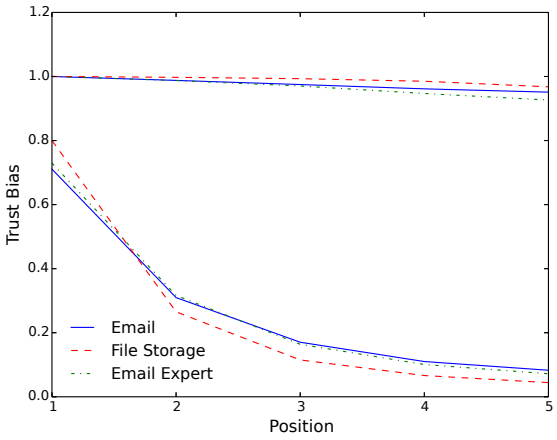

Figure 5: The normalized trust bias estimated for TrustPBM using EM. The upper lines are ϵ_k^+ and the lower lines are ϵ_k^-.

6.2.2 What are the biases estimated from data? We have examination bias for both PBM and TrustPBM. For TrustPBM, we also have the trust bias ϵ_k^+ and ϵ_k^-. We compare these estimated biases from data and show some interesting findings.

The examination biases for PBM and TrustPBM are plotted in Figure 4, where we normalize the bias values by the one at position 1. This figure shows that PBM and TrustPBM give quite different estimation of examination bias, especially for lower ranked documents. TrustPBM shows that there are higher probabilities that users examine lower ranked documents than PBM. This aligns better with the user study in [19] as the user study showed that users examine the surrounding documents before issuing clicks, especially the ones immediately below their clicked ones.

The trust bias estimated by TrustPBM is shown in Figure 5 where we normalize all of them by the ϵ_k^+ for $k = 1$. There are a few interesting observations. (1) All ϵ_k^+ are higher than ϵ_k^-. This means that the probability of clicks given relevant documents is higher than the probability given non-relevant documents after examination. Thus clicks represent reasonable relevance judgments even though they are noisy. (2) ϵ_k^+ are very close to 1 over all positions k, and the difference over positions is very small, showing that relevant documents are not missed often once examined. (3) In contrast, ϵ_k^- varies a lot over positions k. It is much higher at the higher positions (lower values of k) than lower positions, meaning that users are more inclined to click non-relevant documents shown at high positions. This is congruent with the trust bias user study [19], which found that users may place more trust in highly-ranked results. (4) Across different data sets, the trust bias is different. For example, the File Storage data set has a steeper curve for ϵ_k^-, meaning that there is higher trust bias for this service. Overall, this result shows that TrustPBM is better that PBM qualitatively.

6.2.3 Is the Bayes-IPS correction different? We now turn to the unbiased LTR evaluation. The inverse propensity weights estimated by different methods in the Email data set are shown in Figure 7. For result randomization, we use the FairPair approach in [33], that

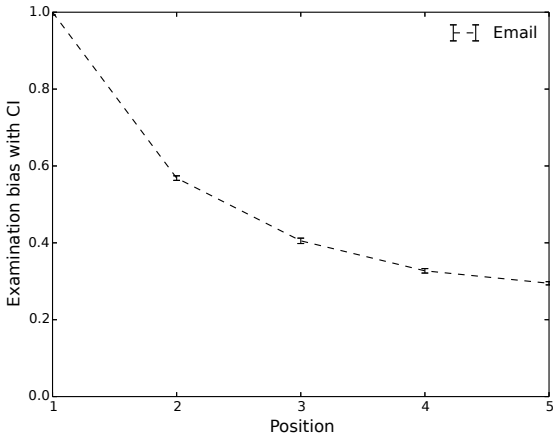

Figure 6: The examination bias and the confidence interval (CI) based on randomization data.

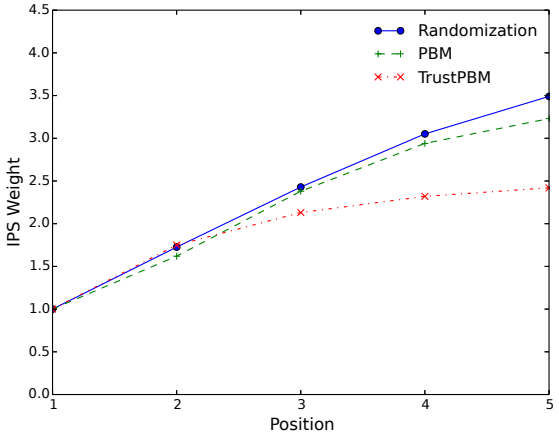

Figure 7: The IPS or Bayes-IPS weights based on Randomization (IPS), PBM (IPS) and TrustPBM (Bayes-IPS).

is, two adjacent documents are randomly swapped before presenting results to users. This method has been shown to be aligned well with other randomization methods for the PBM model. We use Randomization to denote the IPS weights estimated from this method. We use PBM to denote the IPS weights estimated by EM in PBM, and we TrustPBM to denote the Bayes-IPS weights estimated by EM in TrustPBM. Compared with TrustPBM, the EM-based PBM is much closer to Randomization. This result is expected since Randomization is also based on PBM. However, TrustPBM gives much smaller estimation of weights for lower positions. This is because TrustPBM uses a different model that disentangles examination and trust bias, leading to rather different estimation of inverse propensity weights.

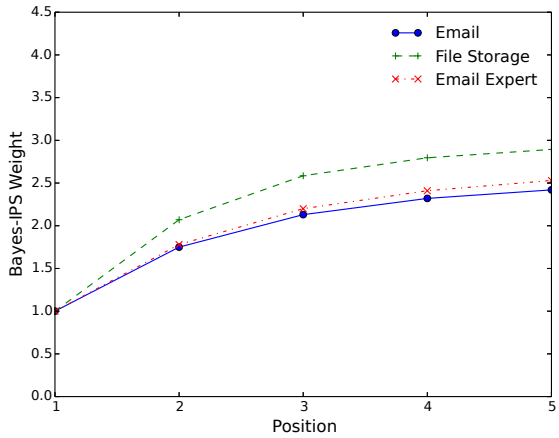

Figure 8: The Bayes-IPS weights estimated for different data sets.

Table 3: Cross offline evaluation to compare IPS weights for training and evaluation.

Training	Evaluation: Weighted MRR in Eq 4			
	NoIPS	Randomization	PBM	TrustPBM
NoIPS	**0.00%**	-0.50%	-0.36%	-0.20%
Randomization	-1.11%	**0.00%**	0.00%	-0.11%
PBM	-0.89%	-0.02%	**0.00%**	-0.06%
TrustPBM	-0.48%	-0.11%	-0.05%	**0.00%**

The lower IPS weights at lower positions in TrustPBM is more desired. As commonly known, IPS-based approaches usually suffer from the problem of the unbounded variance since the variance for a smaller propensity (corresponding to the lower positions in unbiased LTR) can lead to a large difference in IPS weights. Several techniques such as capping methods are developed to address this problem [4, 11, 14, 26, 31]. For Randomization, we compute the variance of our estimated propensity θ_k as follows. We split our randomized data set into 10 folds and use them to estimate the confidence interval (CI). The results are show in Figure 6. From this figure, we see that there is a rather negligible variance based on CI. This means that we have sufficient randomized data for IPS weights estimation. As we will show later that TrustPBM leads to better online experiment results, the result here indicates that PBM is a less accurate model than TrustPBM for extracting relevance from user click behaviors.

In addition, Figure 8 shows the Bayes-IPS weights estimated for different data sets. The weights being different for different data sets means that our method can indeed take click noise into account that varies across data sets.

6.2.4 Can the learning algorithms leverage different IPS weights? We have shown that different methods give different IPS weights. These IPS weights can be used for both evaluation and learning for unbiased LTR. In this sense, we do not have ground-truth IPS

Table 4: Online experiment results based on LambdaMART models learned using different weights. Relative improvement over Randomization is reported, together with the confidence interval (CI). The best number per column is bold and + means the improvement is significant based on student t-test.

	MRR	MRR CI	CTR	CTR CI
Randomization	0.00%	-	0.00%	-
PBM	0.25%	±0.39%	0.26%	±0.40%
TrustPBM	**0.33%**$^+$	±0.29%	**0.33%**$^+$	±0.28%

weights to compare different methods. We rely on the online experiments to do the comparison. Before doing so, we need to make sure that our learning algorithms can effectively leverage the IPS weights during training.

We use an in-house implementation of LambdaMART as our learning algorithm. Table 3 shows the cross comparison using different IPS weights for both training and evaluation. This comparison serves as a sanity check as to whether our training methods can take into account different settings of weights. All the values in Table 3 are relative numbers comparing to the diagonal lines per column. The diagonal values are expected to be the largest numbers per column since both training and evaluation use the same weights. The results in this table confirm that. For example, using the Bayes-IPS weights in TrustPBM, all models trained with different weights show negative relative evaluation numbers. Thus our learning algorithms are able to differentiate different weights to optimize their intended metrics.

6.2.5 Results of online experiments. We compare Randomization, PBM and TrustPBM using the live traffic of the Email service, conducting an online experiment for each method on a portion of the search traffic. These experiments were run for several weeks in August 2018 and our comparisons are based on approximately 100M user queries per experiment. For clarity, we normalize the online evaluation metrics using the Randomization method as the baseline.

We compute online metrics MRR and CTR; the results are shown in Table 4. In this table, we can see that TrustPBM improves over the Randomization method significantly, with MRR and CTR both increased by +0.33%, and these results are statistically significant. In contrast, PBM achieves neutral results compared with the Randomization baseline. Moreover, TrustPBM is more robust than PBM because it has a much smaller confidence interval (CI). This is probably due to the fact that having higher weights on lower positions can lead to higher variance when learning a ranking function for the PBM model. By addressing click noise, TrustPBM is more robust.

7 CONCLUSION

In this paper, we proposed to handle click noise for unbiased LTR. We have introduced an enhanced position bias model called TrustPBM which explicitly models position-dependent click noise, conceptualized as a result of the trust users have in the quality of the search ranking. The parameters of the TrustPBM are estimated from offline click logs via regression-based Expectation Maximization, and the novel Bayes-IPS correction provides a simple weighting scheme for unbiased, de-noised LTR using the estimated parameters. Experiments on three widely used commercial search services revealed new insights about the asymmetry in positive and negative trust bias. Furthermore, the Bayes-IPS correction yielded superior performance metrics over the IPS correction based on the vanilla PBM estimated via EM or randomization.

Future work can include alternate methods for TrustPBM estimation, such as via intervention harvesting [2] which requires click logs from multiple rankers but avoids relevance modeling, and alternate schemes for unbiased LTR that weaken the prior assumption in our Bayes-IPS correction.

ABSTRACT

Graph edges, along with their labels, can represent information of fundamental importance, such as links between web pages, friendship between users, the rating given by users to other users or items, and much more. We introduce LEAP, a trainable, general framework for predicting the presence and properties of edges on the basis of the local structure, topology, and labels of the graph. The LEAP framework is based on the exploration and machine-learning aggregation of the paths connecting nodes in a graph. We provide several methods for performing the aggregation phase by training path aggregators, and we demonstrate the flexibility and generality of the framework by applying it to the prediction of links and user ratings in social networks.

We validate the LEAP framework on two problems: link prediction, and user rating prediction. On eight large datasets, among which the arXiv collaboration network, the Yeast protein-protein interaction, and the US airlines routes network, we show that the link prediction performance of LEAP is at least as good as the current state of the art methods, such as SEAL and WLNM. Next, we consider the problem of predicting user ratings on other users: this problem is known as the edge-weight prediction problem in weighted signed networks (WSN). On Bitcoin networks, and Wikipedia RfA, we show that LEAP performs consistently better than the Fairness & Goodness based regression models, varying the amount of training edges between 10 to 90%. These examples demonstrate that LEAP, in spite of its generality, can match or best the performance of approaches that have been especially crafted to solve very specific edge prediction problems.

1 INTRODUCTION

Graphs and networks provide the natural representation for many real-world systems and phenomena. In social networks, for instance, different users can be represented by nodes in a graph, and each friendship relation can be represented as an edge. Similarly, in physical systems such as railroad networks or communication networks, each terminal or cellular station is a node in the graph connected to several other terminals. In these graphs, each edge can itself contain significant amount of information. For instance, the presence of an edge in a social network gives a binary signal of presence or absence of a relationship, and a weighted edge on the same network can give a numerical measure of the relationship, hence increasing the degrees of available information. A signed network further contains "positive" and "negative" edge weights, indicating the intensity as well as the direction of a relationship.

The presence and properties of edges in graphs are influenced by several structural factors such as the local neighborhood of the edge, the topology of the graph, and properties and labels associated with surrounding edges in the graph, among others. Machine learning methods can be used to predict the existence of edges, or their properties. For instance, the problem of link prediction is a well explored research area where machine learning methods ranging from heuristics to deep neural networks have been experimented. Similarly, problems around predicting specific edge properties or weights in a graph can also be addressed using learning algorithms.

In this paper, we present a general deep learning framework for learning and predicting edge properties in graphs on the basis of the local neighborhood of the edges. The framework uses the concept of aggregating paths in the graph and is named LEAP (Learning Edges by Aggregation of Paths). A distinctive feature of LEAP is its generality: its ability to learn any kind of edge properties without special need for feature extraction.

In LEAP, for a given graph $G = (V, E)$ where V is the set of nodes and E is the set of edges in the graph, and any two given nodes $(u, v) \in V$, we aim at predicting properties associated with the edge $e_{u,v}$ between the two nodes. For instance, in link prediction, we aim at predicting the presence or absence of this edge, whereas in edge weight prediction, our objective is to predict the weight $w_{u,v}$ associated with the edge $e_{u,v}$. LEAP has a modular architecture consisting of three primary modules: path assembler, path vectorizer, and edge learner (Figure 1). Combined together, these three modules form an end-to-end trainable system. The path assembler gathers paths of different lengths between the node pair (u, v). The pact vectorizer uses an aggregator to summarize the information on the paths into a single vector representation. The edge learner uses the vector representation derived from the path vectorizer, and learns a specific objective for any given edge property.

LEAP's modular architecture makes it easy to implement and experiment. The path aggregators used in LEAP are deep learning modules that take as inputs the raw features of the paths, and produce a trainable aggregation, which is akin to an embedding of the edge set into a vector space. The aggregators thus perform — automatically by computing an embedding — the feature engineering that used to be performed manually, for each property of interest (edge prediction, edge weight prediction, and so on). LEAP, while being an end-to-end learning system that learns embeddings for the nodes and paths itself, can also use pre-trained node embeddings [8, 30], node features, and edge features whenever available.

We present four different kinds of aggregators for LEAP. The aggregators, AvgPool, DenseMax, SeqOfSeq, and EdgeConv, use different neural components and operate at different levels of complexity, focusing on properties like the ordered nature of nodes in a path, and the properties of edges in the paths. We use standard neural modules such as Long Short-Term memory (LSTM) [11] networks, Convolutional Neural Networks (CNN) [19], Pooling operations (Max and Average), and Feed-forward neural networks while constructing our aggregators.

We validate our framework on two specific graph problems: link prediction [21], and edge weight prediction in weighted signed networks (WSN) [18]. In link prediction, we evaluate LEAP on eight real world datasets and present comparisons on the Area under the ROC curve (AUC) score with the current state of the art models WLNM [41] and SEAL [42], and more baseline methods. In the WSN edge weight prediction task presented in Kumar et al. [18] , we evaluate LEAP on three user-user interaction datasets. Two of these datasets refer to Bitcoin trading networks where users provide a rating to other users based on trust. In the third dataset, we learn weights for the votes and sentiment scores assigned by users in Wikipedia to other users when one submits a request for adminship (RfA). We show that LEAP performs similar or better on both these problems against dedicated methods crafted for the specific problems.

The primary contributions of this work can be summarized as follows:

- We present and implement a novel deep learning framework, LEAP, for learning and predicting edge properties of graphs. The framework is general, and it requires no feature engineering, as it relies on deep learning to predict edge properties.
- We define several edge aggregators for LEAP, each suited to particular classes of prediction problems, and we illustrate how LEAP can take advantage of any graph embeddings that may be already available.
- We consider two standard graph prediction problems: link prediction (used, e.g., to predict the formation of connections in social networks) and edge weight prediction (used, e.g., to predict user ratings). We show that LEAP, in spite of its generality, closely matches or improves, on the performance of specialized systems that have been built for these tasks.

In the paper, we will first discuss some related methods for edge property prediction in graphs. We then discuss the motivation behind our LEAP framework and the usage of paths. This is followed by the system design and detailed discussion on aggregators. We then present results from an extensive evaluation over several datasets. We conclude the paper with some considerations on the extensibility and modular design of LEAP.

2 RELATED WORK

Graphs have generated intense research interest over the years in machine learning problems. Commonly studied problems include link prediction [21], node classification, and node ranking [31], among others.

With growing interest in deep learning for graphs, several algorithms for learning node representations have been suggested. These include embedding methods such as LINE [33], DeepWalk [30] and node2vec [8]. More neural network based methods for learning node representations include Graph Convolutional Networks [16], GraphSAGE [9], and Graph Attention Networks [35]. These methods are also often adapted for edge-based learning tasks such as link prediction.

Link prediction has been performed with methods ranging from heuristics to deep neural networks. Martinez *et al.* [23] have categorized the existing link prediction methods into the similarity based, probabilistic and statistical, algorithmic, and preprocessing categories. Similarity based methods operate on the intuition of similar nodes having an affinity towards each other. Locally focused methods like Common Neighbors [21] and Adamic-Adar [2] are interpretable simple methods used extensively for link prediction. More complex similarity-based methods include Katz index [14], PageRank [29], and SimRank [13], among others. Al Hasan *et al.* [10] have explored the use of standard machine learning classifiers for link prediction. Factorization method are also used by Menon and Elkan [24] for link prediction.

Weisfeiler-Lehman Neural Machine (WLNM) [41], and Subgraphs, Embeddings, and Attributes for Link prediction (SEAL) [42] present dedicated deep learning systems for link prediction and define the current state of the art in the space.

In weighted signed networks, for predicting edge weights, Kumar et al [18] defined the learning objective and adapted methods like Bias-Deserve [26], Signed Eigenvector Centrality [5], PageRank [29], and more trust based algorithms. Edge based methods are also used in applications such as SHINE [37] and Rev2 [17] where properties from graphs are used in determine dataset specific tasks.

For the tasks of link prediction and edge weight prediction in weighted signed networks, we present comparison of LEAP with many of these methods later in the paper.

3 MOTIVATION

Edges in real world networks are representative of latent properties within the graph as well as properties among the nodes. Intuitively, for any two nodes (u, v) in the graph, the properties of an edge $e_{u,v}$ between them should depend on the characteristics of the nodes themselves. However, the nodes themselves can be characterized by the edges involving these nodes, hence increasing the dependence to neighborhoods. Therefore, $e_{u,v}$ can be affected by several other nodes and edges in the graph and not just the node pair (u, v). In order to learn more about the edge, it is therefore important to explore the neighborhood of u and v.

For example, if the graph represents a professional or social network, the formation of an edge $e_{u,v}$ between u and v may depend on the properties of u and v, and also on the properties of common friends and friend-of-friends, that is, on the properties of paths emanating from u and v. Equally, in a trust network, the amount of trust of a user u on a user v, constituting a label for $e_{u,v}$, can depend not only on the properties of u and v themselves, but also on the other sets of users that trust, and are trusted by, u and v.

In order to learn more about an edge $e_{u,v}$, it is therefore important to explore the neighborhood of u and v, and assemble the nodes and edges from the graph that can impact the edge $e_{u,v}$ the most. In particular, our framework will consider the paths originating at u and ending at v. These paths can involve a large set of nodes and edges, each of which are related to the two nodes by being an intermediary in a path between them. These intermediate nodes and edges give us information on u and v. The framework we present will enable us to learn from this shared neighborhood of u and v when predicting the properties of $e_{u,v}$.

We note that we could also consider paths that originate at u or v, but do not connect u with v; these paths would provide a characterization of one of u and v only. It would be easy to extend our framework to consider these paths also. However, graph embeddings already enable us to summarize properties of individual node neighborhoods; for this reason, our framework considers mainly the *shared* neighborhood around the edge to be predicted.

4 THE LEAP FRAMEWORK

LEAP is an end-to-end deep learning framework for graph edge learning. The core concept driving LEAP is the ability to learn edge properties in a graph simply from the graph structure, without any need for feature engineering. Moreover, in the presence of explicit features, LEAP can use both the available features as well as self-learned representations from the structure of the graph, such as embeddings. The LEAP framework consists of three separate modules: path assembler, path vectorizer, and edge learner; an overview of the system is presented in Figure 2.

LEAP operates on a given graph $G = (V, E)$, where V is the set of vertices (nodes), and $E \subseteq V \times V$ is the set of edges. An edge can be directed or undirected, weighted or unweighted, and signed or unsigned. A path p^l of length l between the two nodes (u, v) consists of a sequence of nodes $u_0, u_1, \ldots, u_l$, with $u_0 = u$ and $u_l = v$. The set of paths $\mathcal{P}^l_{u,v} = \{p^l_1, p^l_2, \ldots, p^l_n\}$ consists of all the paths of length l between the nodes (u, v). For simplicity, we will often use the notation p^l and $\mathcal{P}^l$ when referring to a path $p^l_{u,v}$ and the set of paths $\mathcal{P}^l_{u,v}$ of length l between the vertices (u, v).

The end-to-end learning objective of LEAP is guided by the input of graph G, two specified nodes (u, v), and the target property ρ being predicted about (u, v). For instance, in case of link prediction, where the framework can be used to predict the presence or absence of an edge between the two nodes (u, v), the output prediction $\rho \in [0, 1]$ from the model represents the probability of an edge existing between (u, v). Similarly, in an edge weight prediction task, the model output ρ can be the predicted weight for edge $e_{u,v}$. We now define the separate modules of the framework used for these learning objectives.

4.1 Path Assembler

The first phase of LEAP is an exploration task which gathers data from the graph structure to be used by the subsequent learning modules. Given a graph G and a pair of nodes (u, v), we start by assembling paths of different lengths between the two nodes. As the learning objective is concerned with the pair (u, v), we do not include the possible 1-length path u, v among the paths considered. As a hyper-parameter provided to the system, we define a set $\mathbf{L} = \{l_1, l_2, \ldots, l_k\}$, as the set of path lengths to be used.

For any length $l \in \mathbf{L}$, we now need to collect a set of paths $\mathcal{P}^l$ of length l. For ease of computation, we can limit the size of each subset, as well as the size of $\mathbf{L}$ as required by the problem and the dataset: if there are too many paths between two nodes, a random subset of paths can be extracted for use by the framework. From the perspective of the framework, the processing is independent of these sizes. Once collected, the paths are then made available to the system in the form of k path-sets $\mathcal{P}^l$ with each set consisting of paths of same length l.

The objective of assembling the paths in length-specific sets is to allow our system to learn properties particular to path lengths. For example, when considering paths of length

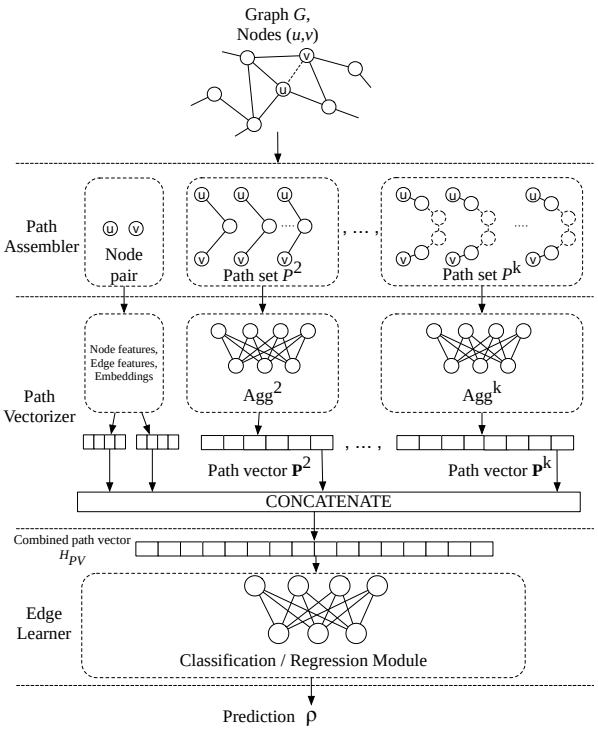

Figure 2: Overview of the LEAP framework

$l = 2$, each path between (u, v) differs only by one vertex. By processing such paths together, we increase the capability of the learning modules to focus on a specific variable property at a time, and therefore capture potential factors affecting the predicted output ρ.

The LEAP framework can be generalized to include the exploration of general paths from u, or to v, rather than only paths from u to v.This can be particularly useful when few (or no) paths connect u to v, while the nodes u and v, individually, belong to many paths.

4.2 Path Vectorizer

At the second phase of LEAP, the assembled paths are passed through a deep learning system. This phase is called the path vectorizer. The objective of this phase is to combine all the available information about the node pair (u, v) using the nodes and the paths, and obtain a vector representation that can be used with different edge learning objectives. This module is inspired by the deep learning architectures capable of learning from complex data structures with different dimensionality. For a graph G with N nodes, each node $x \in V$ is given an integer symbol $x_i \in [1, N]$. In order for LEAP to learn from the graph, these symbolic nodes need to be represented as vectors that can be further processed using neural networks. Different methods of vectorization can be used to represent each node. The simplest notation, which retains the symbolic nature of the nodes, can be to use a one-hot vector of size N. In this notation, node $x_i \in V$ is represented as a vector χ_i of size N where $\chi_i[k] = 1$ if $k = x_i$, and $\chi_i[k] = 0$ otherwise. While this representation allows one to identify each node differently, it does not provide the model with any additional information about the node that can be indicative of its relationship to other nodes or the graph structure. For this purpose, instead of the one-hot vectors, in this paper we use the concept of dense embeddings [8, 9, 25, 30]. We represent each node x_i as a dense vector $\chi_i \in \mathbb{R}^K$ of a fixed dimensionality K. This representation of a node, is obtained through a reference lookup Emb by the entire framework, where $\chi_i = \text{Emb}(x_i)$. Similar to the general use of dense embeddings in deep learning systems, the embeddings can either be trained with the entire system, or can be pre-trained using an embedding generation method first, and then later used with the framework. Additionally, if we have set of node features $\mathcal{N}$ representing engineered feature sets for each node, then they can be used in the framework by combining them with the embeddings. For a node x_i, therefore, the embedding representation used by the system will be $\chi_i \Leftarrow \chi_i | \mathcal{N}(x_i)$, where $(|)$ is a concatenation operation.

The nodes and the paths made available by the path assembler are then used into the path vectorizer using the embedding lookup Emb. Each path, represented as a sequence of nodes in their integer representation is passed through the embedding layer, in order to obtain sequences of vectors, with each sequence of length l representing a path of length $l - 1$. At this stage, we have the two concerned nodes u and v, set of path lengths $\mathbf{L}$, the set of paths $\mathcal{P}^l$ for each length l, and the embedding lookup Emb. In case where edge features $\mathcal{E}$ are available for the graph, LEAP can use these features within the learning module as well. We use Algorithm 1 for obtaining a vector representation H_{PV} from these inputs.

Aggregators. In Algorithm 1, the paths are first converted into their vector representation and then passed through the Aggregator. Aggregators are the primary learning units in LEAP, and are discussed in detail in Section 5. For each path length l, an associated Aggregator Agg_l is responsible for processing the paths and learning a vector representation from them. Initially, in the path vectorizer, path sets of different lengths are provided. Since we aim at learning length-wise significant information from these paths, we process the set for each length separately. An aggregator Agg_l is a deep learning module which takes the path set $\mathbf{P}^l$ as an input, and learns a vector representation $\mathbf{h}_l$. Due to this separate modular structure, LEAP can use several different types of aggregators. The aggregator can also use an edge feature set $\mathcal{E}$ when engineered features for the graph edges are also available. In the path vectorizer, the vectors $\mathbf{h}_l$ learned for each length $l \in \mathbf{L}$ are concatenated together along with the vector representations for the input node pair (u, v) to obtain a final vector representation H_{PV}.

4.3 Edge Learner

The last step of LEAP is to perform problem specific learning on the edge $e_{u,v}$ between the two given nodes (u, v). The

Algorithm 1 PathVectorizer

Input: Node pair (u, v), Path lengths $\mathbf{L}$,
Path sets $\mathcal{P}^l$ for $l \in \mathbf{L}$, Embedding lookup Emb,
Node features $\mathcal{N}$, Edge features $\mathcal{E}$
$\mathbf{u} \leftarrow \text{Emb}(u)|\mathcal{N}(u)$
$\mathbf{v} \leftarrow \text{Emb}(v)|\mathcal{N}(v)$
for l in $\mathbf{L}$ **do**
  $\mathbf{P}^l \leftarrow \text{Emb}(\mathcal{P}^l)|\mathcal{N}(\mathcal{P}^l)$
  $\mathbf{h}_l = \text{Aggregator}(\mathbf{P}^l, \mathcal{E})$
end for
$H_{PV} = \text{Concat}[(\mathbf{u}, \mathbf{v}, \mathbf{h}_l)|l \in \mathbf{L}]$
return H_{PV}

input to the edge learning module is the combined vector H_{PV}. This vector can now be used by any classification or regression method for respective supervised learning problem. For instance, in link prediction problem, where the objective is to detect the presence of an edge between the two nodes (u, v), this module can be used as a binary classifier to classify between *"link exists"* and *"link does not exist"* by predicting a probability $\rho \in [0, 1]$ of a link between (u, v). In general, for any edge based classification, whether binary or multi-class, the module can be used as a classifier with an input vector H_{PV}. The edge learning module can also be used for regression problems. For instance, in edge weight prediction, we can use the output ρ from the module as the predicted weight for the edge. In case of signed edge weight, the same regression module can be used by allowing it to produce both positive and negative values. In multi-class classification, the output ρ can be treated as a vector $\rho \in \mathbb{R}^M$ for M number of classes.

Since the edge learner by itself is simply a classification or a regression module, any corresponding learning algorithm can be used here. For maintaining LEAP as an end-to-end trainable deep learning system, we use feed-forward neural networks for the edge learner. These networks can vary in depth by increasing the number of layers, with the first layer receiving input vector H_{PV} and the final layer predicting the output ρ. Given the vector H_{PV}, and parameter N_{EL} as the number of layers, the process of the edge learner is presented in Algorithm 2

Algorithm 2 EdgeLearner

Input: Combined Path vector H_{PV}, Layer count N_{EL},
$\mathbf{h_{EL}} \leftarrow H_{PV}$
for $c = 1 \ldots N_{EL}$ **do**
  $\mathbf{h_{EL}} \leftarrow \sigma_c(\mathbf{W}_c \cdot \mathbf{h_{EL}} + \mathbf{b}_c)$
end for
$\rho = \sigma_p(\mathbf{W}_p \cdot \mathbf{h_{EL}} + \mathbf{b}_p)$
return ρ

For each layer $c = 1 \ldots N_{EL}$, the weight matrix of the neural network layer is represented by $\mathbf{W}_c$ and the bias of the layer is represented by $\mathbf{b}_c$. σ_c refers to the activation function used by the network layers such as $tanh$, $ReLU$, $sigmoid$ among others. For the final prediction output layer, the weight $\mathbf{W}_p$ and bias $\mathbf{b}_p$ are used. The activation function σ_f for this layer is decided based on the nature of the problem. In case of binary classification, often the $sigmoid \in [0, 1]$ function is used. For multi-class classification, it is common to use the $softmax$ function. In case of normalized edge weight prediction in signed networks, with $w_{u,v} \in [-1, 1]$, we use the $tanh \in [-1, 1]$ activation function to obtain a floating point value representing the predicted signed edge weight.

5 AGGREGATION MODELS

In the previous section, we explained the architecture of LEAP and discussed the requirement of aggregators for performing path vectorization. The concept of using aggregators in graphs is inspired by GraphSAGE [9] where they perform node classification by learning representations for the nodes in a graph. In our system, we have adapted the concept of aggregators for combining paths between two nodes (u, v) and obtaining representations for edges in the graph. Within the path vectorization module, an aggregator Agg_l for paths of length l gets the vectorized path set $\mathbf{P}^l$ as input with an objective of generating output vector $\mathbf{h}_l$.

Since the LEAP framework consists of neural network based layers, each aggregator is itself a deep learning model where the input is a tensor of rank 4 — (batch size, number of paths, path length, node embedding). Each path itself is a sequence of node vectors, and each path set is a set of several such sequences. Therefore, in order to derive single vector representation of the path set, we first need to aggregate all the nodes in the path using aggregator Agg_{node} and then aggregate these paths using the aggregator Agg_{path}. The training of these aggregators is performed with the overall LEAP system using gradient descent based methods. While several other variants are possible, we present four different kinds of aggregators used in this paper.

5.1 AvgPool Aggregator

Our first aggregator follows a simple architecture of combining different vectors together. We call the model for this aggregator AvgPool. This model relies only on the embeddings χ_i for each node x_i under consideration. The model does not have training parameters.

In AvgPool, Agg_{node} concatenates all the node vectors along the path into a single vector. Then, on the set of these derived path vectors, Agg_{path} performs a one-dimensional average pooling operation. The resulting vector $\mathbf{h}_l \in \mathbb{R}^{(l+1)K}$ is therefore a single vector obtained by averaging the paths between the two nodes (u, v) across the paths $k \in K$. The AvgPool aggregator can be summarized as:

$$\mathbf{h}_l = \text{AvgPool}([\overline{(\mathbf{p}_i^l)},\ \forall \mathbf{p}_i^l \in \mathbf{P}^l]) \tag{1}$$

where AvgPool is the one-dimensional average pooling operation, and $\overline{(\cdot)}$ is the vector concatenation operation which

combines multiple vectors by concatenating them together.

$$\overline{([\chi_1, \chi_2, \ldots, \chi_l])} = \chi_1|\chi_2|\ldots|\chi_{l+1} \quad (2)$$

where (|) is the concatenation of two vectors. $\mathbf{P}^l$ is the set of vectorized paths of length l in graph G between the two nodes (u, v). $\mathbf{p}_i^l$, indexed by i is an individual path of length l in set $\mathbf{P}^l$.

AvgPool relies on the embeddings for each node, and represents a path as a fixed size vector of all the nodes combined. Since the first and last node of these paths are the nodes u and v respectively, the only changing bits belong to the nodes within the paths. By performing a bitwise pooling operation over these nodes, we can derive mean vector representations for the changing nodes in the path set. Since the embeddings themselves are still trained by the complete framework, the gradients obtained for updating the node embeddings correspond to these average representations and their influence on the final output ρ.

5.2 DenseMax Aggregator

The DenseMax aggregator is a learning model that uses a dense (feed-forward) neural network layer for each path. Similar to AvgPool, in DenseMax, Agg_{node} obtains the representation for each path by concatenating the node vectors into a single long vector. In this model, at Agg_{path}, the path vector is first passed through a dense neural layer. The resulting activations are then passed through a max-pooling operation which helps derive a single vector representation for the paths of length l. Therefore, Agg_{path} in DenseMax consists of a dense neural network layer and a one-dimensional max pooling operation. The operations of the DenseMax aggregator can be summarized as:

$$\mathbf{h}_l = \textsc{MaxPool}([\sigma(\mathbf{W}_l \cdot \overline{(\mathbf{p}_i^l)} + \mathbf{b}_l), \forall \mathbf{p}_i^l \in \mathbf{P}^l]) \quad (3)$$

where $\mathbf{W}_l$ and $\mathbf{b}_l$ are the weight matrix and bias for the dense neural layer. σ is the activation function used by the dense layer. $\overline{(\cdot)}$ is the vector concatenation operation. MaxPool is the one-dimensional max pooling operation which selects bitwise maximum value from multiple vectors to derive a single final vector. The MaxPool operation is used on these representations in order to capture the most activated bits that can affect the final output ρ.

5.3 SeqOfSeq Aggregator

The sequence of nodes from u to v can hold information relevant to the final prediction. For instance, if the existence of an edge between u and v depends on the presence of a path between the two nodes with consecutively increasing edge weight, the sequential order of nodes contains information which holds significance to the final outcome of the model. Therefore, in SeqOfSeq aggregator, we treat the paths as ordered sequences of nodes. We can further consider the path set as a sequence of different paths, if the paths can be ordered using some characteristics. For example, if the edges are labeled by weights, then the total weight of a path p^l is the sum of edge weights for each edge in the path. If the paths from u to v are then sorted according to their total weights, we can process them in a specified order. To this end, the aggregators Agg_{node} and Agg_{path} would need to be sensitive to the order of the inputs.

In the SeqOfSeq aggregator, we first use an LSTM $\textsc{Lstm}_{inner}$ on each path. From the output activations of $\textsc{Lstm}_{inner}$, we extract a vector representation for the path by performing a max-pooling operation. The aggregator Agg_{node}, in this case, consists of both the $\textsc{Lstm}_{inner}$ and the max-pooling operation. We use a max pool here instead of using only the activation from last timestep of the $lstm_{inner}$: we believe that since our objective is to extract information from the path itself, a max-pooling operation can be more effective in summarizing the path than the final activation. After summarizing each path into a single vector, the sequence of path vectors is processed by a combination of another LSTM $\textsc{Lstm}_{outer}$, followed by a max-pooling operations, as the Agg_{path} aggregator. The SeqOfSeq aggregator can be summarized as:

$$\begin{aligned} H_{inner} &= [\textsc{MaxPool}(\textsc{Lstm}_{inner}(\mathbf{p}_i^l)), \forall \mathbf{p}_i^l \in \mathbf{P}^l] \\ \mathbf{h}_l &= \textsc{MaxPool}(\textsc{Lstm}_{outer}(H_{inner})) \end{aligned} \quad (4)$$

where MaxPool is the one-dimensional max pooling operation, H_{inner} is the intermediate sequence of derived path vectors, and $\textsc{Lstm}_{inner}$ and $\textsc{Lstm}_{outer}$ are the inner and outer LSTMs respectively, used for processing corresponding sequences.

Variants of SeqOfSeq can also be created to use order information only at the paths, or only at the nodes. With the use of sequence learning neural networks such as LSTMs, the SeqOfSeq aggregator is more powerful than the AvgPool or DenseMax aggregators, and it trains a much larger number of parameters.

5.4 EdgeConv Aggregator

Edges of a path can themselves contain significant information. In order to emphasize learning also from the the edges, we propose an aggregator called EdgeConv which focuses on edges while operating over paths. In order to build a learning widget that can operate on the edge, we use a one-dimensional Convolutional Neural Network (CNN) with a window size of 2 that takes as input two consecutive nodes forming an edge. Therefore, when a path is represented as a sequence of nodes, the convolution kernel focuses on all pairs of consecutive nodes along the edge. Given the convolutional results on all pairs of consecutive nodes, we apply a max-pooling operation to compute the overall path label. The aggregator Agg_{node} for EdgeConv, therefore, consists of a one-dimensional CNN and a max-pooling operation. Considering the set of derived paths as an ordered sequence, the Agg_{path} for this case also uses an LSTM and max-pooling operation. Therefore, all the path vectors for paths of length l derived using Agg_{node} are then processed using an LSTM, followed by another max-pooling operation to derive the final vector representation $\mathbf{h}_l$.

EdgeConv can be summarized as :

$$H_{inner} = [\textsc{MaxPool}(\textsc{Conv1D}(\mathbf{p}_i^l)), \forall \mathbf{p}_i^l \in \mathbf{P}^l]$$
$$\mathbf{h}_l = \textsc{MaxPool}(\textsc{Lstm}(H_{inner})) \quad (5)$$

where MaxPool is the one-dimensional max pooling operation, H_{inner} is the intermediate sequence of derived path vectors, and Lstm is the LSTM module used to learn from different path vectors.

Similar to SeqOfSeq, it is not necessary to treat the paths as an ordered sequence, and different variants of EdgeConv can consider the set of derived paths as an unordered set. The sequence of nodes, however, needs to be ordered in EdgeConv, as it operates consecutively over the edges.

5.5 Aggregator Extensions

The four aggregators presented above provide different levels of complexity and use different neural network modules. Together, they illustrate how the modular nature of LEAP allows us to use different neural network architectures as part of the full system for an end-to-end training. We believe that the use of aggregators is key to achieving an extensible and flexible framework. Specialized aggregators can be trained by focusing on significant properties under concern. The aggregators can also include the new deep learning concepts of attention [3, 22] and memory [40]. Similarly, graph specific neural models like Graph Convolutional Networks [16] and Graph Attention Networks [35] can be adapted as aggregators by representing the assembled path sets as subgraphs. While we train the aggregators along with the entire framework, they can be trained separately using any objective function. In case of transfer learning, a well trained model can be transfered into the LEAP framework and can be used simply as a function without training further. Similarly, a partially trained model can be used as an aggregator, and it can further be trained by the learning objective of the complete framework.

6 EVALUATION

The design of the LEAP system, and the use of aggregators, make it an easy to use end-to-end learning system for any kind of graph. For small graphs with fewer nodes, simpler aggregators with few parameters can be used. For very large datasets, we can construct complex aggregators targeted at several latent properties in the graph. In order to demonstrate the learning abilities of this system, we evaluate it on two commonly studied problems in graphs and social networks — link prediction, and edge weight prediction in weighted signed networks.

6.1 Link Prediction

Graphs and networks evolve over time by creation of newer links between the nodes. Given a graph G and a pair of nodes (u, v), the link prediction problem aims at predicting the probability of existence of an edge $e_{u,v}$ between the two nodes.

Table 1: Summary of the datasets used for evaluation

Type	Name	Nodes	Edges
Link Prediction	USAir	332	2,126
	NS	1,589	2,742
	PB	1,222	16,714
	Yeast	2,375	11,693
	C.ele	297	2,148
	E.coli	1,805	14,660
	arXiv	18,722	198,110
	FB	4,039	88,234
Weighted Signed Networks	Bitcoin-OTC	5,881	35,592
	Bitcoin-Alpha	3,783	24,186
	Wikipedia-RFA	9,654	104,554

6.1.1 Learning Objective. In order to learn this objective using LEAP framework, in the Edge Learner module, we can treat it as a binary classification problem. From the graph $G = (V, E)$, the set of edges E can be considered as the positive sample set. Similarly a set of node pairs $(x_1, x_2) \in V$ can be sampled from the graph where edge $e_{x_1,x_2} \notin E$ is the negative set for classification. A label $\tau = 1$, therefore can be associated with positive pairs and a label $\tau = 0$ is associated with the negative pairs.

6.1.2 Datasets. We evaluate the LEAP Link Prediction model on eight real world datasets. The choice of datasets is motivated by the link prediction results presented in two state of the art models — WLNM [41] (Weisfeiler-Lehman Neural Machine) and SEAL [42] (Subgraphs, Embeddings, and Attributes for Link prediction). The datasets used in this paper are listed in Table 1.

USAir [4] is a network graph for US airlines. Network Science (NS) [27] is the collaboration network for researchers in the subject of network science. Political Blogs (PB) [28] is a political blog network form the US. Yeast [36] is a PPI (protein-protein interaction) network for yeast. C.ele is the neural network of the worm Caenorhabditis elegans [38]. E.coli is the dataset of pairwise reaction network of metabolites in E.coli [43]. arXiv [20] is the collaboration network of research papers on arXiv under the Astro Physics category. Facebook (FB) [20] is the dataset of friend lists from the Facebook social network.

6.1.3 Experiment Setup. We performed an extensive set of experiments on the above mentioned datasets in order to evaluate and compare our framework against state of the art methods in link prediction. For each dataset, we sampled a variable number of data samples into the training set and evaluated the model on the remaining samples. The results presented in this paper adopt the partitioning used in the current state of the art method SEAL [42]. For smaller datasets with less than 2500 nodes, we use 90% of the graph edges and an equal number of negative samples for training, and present evaluation results on the remaining 10% edges and equal number of negative

Table 2: Area under the ROC curve (AUC) comparison of LEAP with baselines. Best LEAP results and best dataset results are highlighted. *n2v* refers to the use of node2vec embeddings with LEAP. *OOM* refers to Out-of-Memory.

pairs. For relatively larger datasets with more than at least 4000 nodes, we partition the training and evaluation datasets at 50%.

The LEAP[1] system and the aggregators were written in Python with Keras [7] deep learning framework, using the Tensorflow [1] backend. The hyperparameters for each aggregator were selected using multiple trials. We report the results with the best hyperparameters for each setting individually. In all the reported results, we used the path lengths in set $\mathbf{L} = \{3, 4\}$, and used upto 50 paths for each length selected randomly. All the methods were trained using a loss function of binary cross-entropy and the Adam [15] optimizer for gradient descent with a learning rate of 0.001. Each model was trained for upto 30 epochs with early stopping enabled.

6.1.4 Results. We present the results obtained as per the above mentioned experimental setup for LEAP in table 2. The results comprise of LEAP with the four aggregators — AvgPool, DenseMax, SeqOfSeq, and EdgeConv, discussed in the paper. Additionally, we also compare the ability of our model to learn node embeddings themselves against using pre-trained embeddings. For pre-trained embeddings, similar to SEAL, we use the node2vec [8] method first on the graph to derive node embeddings, and then use them with the LEAP framework without updating them further during the system training. We compare these results with three different kinds of methods used for link prediction. We first use the heuristics including Adamic-Adar [2], Katz index [14], and the PageRank [6] algorithm. For feature learning based models, we use spectral clustering [34], and the node2vec [8] algorithm which learned node embeddings and then performs a link prediction task on them. Finally, we compare our system with subgraph-based link prediction methods, defining the current state of the art. These methods include Weisfeiler-Lehman graph kernel (WLK) [32], Weisfeiler-Lehman Neural Machine (WLNM) [41], and Subgraphs, Embeddings, and Attributes for Link prediction (SEAL) [42]. Performance of all the models is compared using the Area under the ROC curve (AUC) metric. We use the settings and results by Zhang et al. [42] for all our baseline methods.

As can be seen in table 2, LEAP performs best or close-to-best on each dataset. Further, we show that an external method for learning node embeddings like node2vec can easily be used within the system. Similarly we can also incorporate known feature vectors for the nodes whenever available.

In comparison to deep learning methods and current state of the art WLNM and SEAL, LEAP achieves equivalent or better performance with the presented aggregators. However, due to its modular nature, the LEAP framework can be highly extended and adapted for different datasets with different latent properties. Further, SEAL requires two prominent steps of node labeling and embedding generation before the neural network can be trained on the graph. In making a learning framework easily deployable on multiple platforms, it is highly advantageous to have an end-to-end trainable system and LEAP provides this particular ability with sufficient modularity to tune the simplicity of the model as required.

[1]The code is available at https://github.com/rakshit-agrawal/LEAP

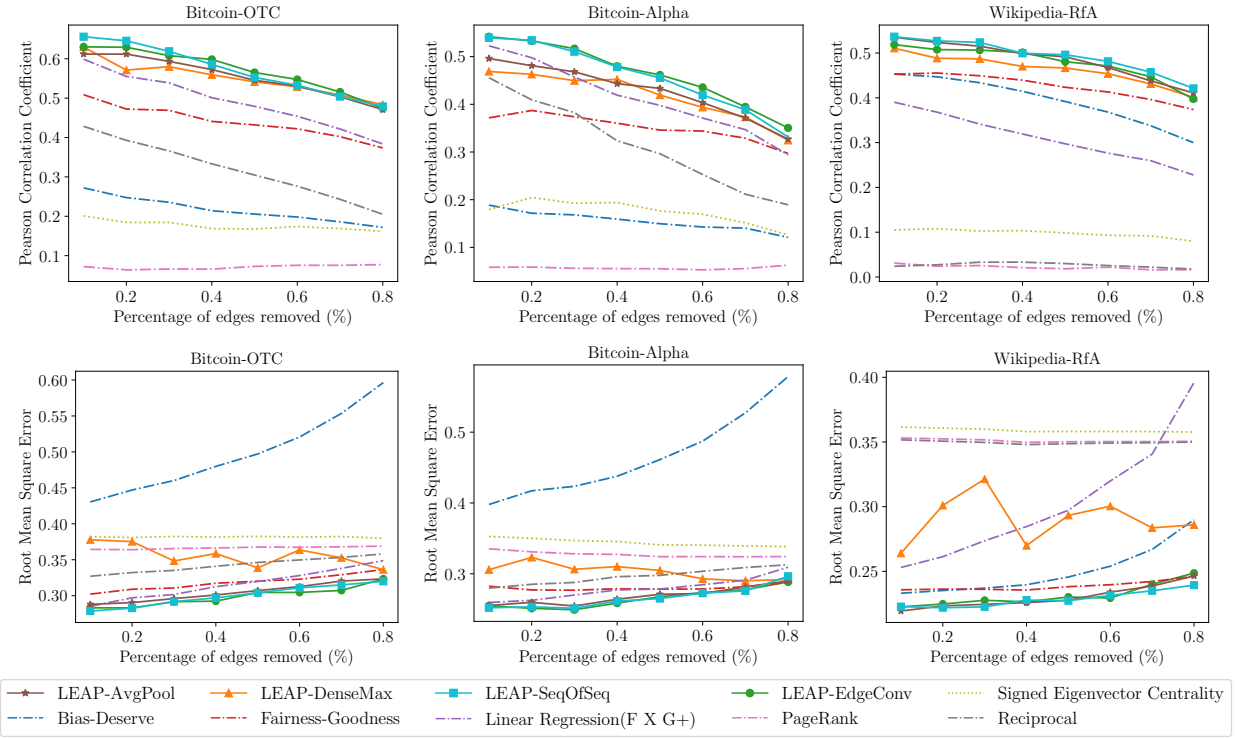

Figure 3: Plots for PCC(top) and RMSE(bottom) on the three datasets for Weighted Signed Networks. The x-axis refers to the percentage of edges removed while training the models. Over all the datasets, and along both the metrics, LEAP based methods show significantly better performance, with the complex aggregators SeqOfSeq and EdgeConv giving the best performance on both the metrics.

6.2 Weighted Signed Networks

In real world datasets representing relations of certain kind among the nodes, the edges can possess different meaningful properties that are of significance to the underlying network. For instance, in a user-user interaction system, each user can have a trust associated with another user. This trust further propagates through the network, affecting the trust between two different users in a certain way. A generalized representation of such networks is obtained through weighted signed networks (WSN). A WSN consists of a graph $G = (V, E)$ where an edge $e_{u,v} \in E$ between two nodes $(u, v) \in V$ has a weight $w_{u,v}$ associated to it. The weight $w_{u,v}$ can be a signed weight, specifying a positive or negative sentiment with a magnitude $|w_{u,v}|$ specifying the intensity of the relation. A WSN graph can either be directed or undirected.

6.2.1 Learning Objective. Kumar et al [18] presented the task of predicting edge weight in WSNs where given a graph G and a node pair (u, v), the objective is to predict the signed edge weight $w_{u,v}$ between the two nodes. For simplicity, the edge weights are normalized to a scale of $w_{u,v} \in [-1, 1]$. In the case of the LEAP framework, the problem of predicting edge weight can be treated as a regression problem for the Edge Learner module. From the graph $G = (V, E)$, we can use the entire set of edges E with the edge nodes $(x_1, x_2) \in V$ for edge $e_{x_1,x_2} \in E$ being the input nodes to the system. Each such node pair can be associated with a regression label $\tau = w_{x_1,x_2}$ using the weights associated with each edge.

6.2.2 Datasets. For evaluation of the LEAP WSN Edge Weight Predictor, we use three real world datasets of user-user interaction networks. These datasets used here are influenced by Kumar et al [18] and are available from SNAP database [20]. The three datasets are listed in Table 1.

Bitcoin-OTC [18] is the "who-trusts-whom" network of people trading Bitcoins on the platform "Bitcoin OTC". The directed signed edge weight between the users on this network refers to the rating given by a user to the other user on the network on a scale from -10 to 10. Bitcoin-Alpha [18] is a similar network for a different trading platform called "Bitcoin Alpha". Wikipedia-RFA [18, 39] is a voting network for Wikipedia request for adminship (RfA). The edges on the network refer to directed votes between users. To associate weights to the signed edges, Kumar et al [18] used the VADER sentiment engine [12] and used the difference between the positive and negative sentiment scores obtained for the vote explanation text in the Wikipedia-RFA dataset.

6.2.3 Experiment Setup. In this evaluation, we present and compare the results for regression on predicting edge weights with $\delta\%$ edges removed. We vary the value of δ between 10% to 80%, with a step size of 10%, specifying the range for partitioning the training and the evaluation datasets.

The system and hyperparameter settings for this task are same as the link prediction model. The only difference in this adaptation of LEAP for a regression task is the choice of loss function. We use the Mean Squared Error (MSE) as the loss function used to compute the gradients for training the Edge Weight Prediction model. The hyperparameter selection was performed using multiple trials, and the best settings were used to report the results.

6.2.4 Results. Similarly to link prediction, we evaluated our system for this objective with the four aggregators — AvgPool, DenseMax, SeqOfSeq, and EdgeConv, discussed in the paper. Neural network based models are not used directly for the task of edge weight prediction in WSN and therefore we compare our results to the heuristic and feature learning based methods previously applied on these datasets.

In the definition of edge weight prediction on WSNs by Kumar et al [18], they adapted several algorithms for this task, providing us with a set of baseline measures on these datasets. We first use a basic method of Reciprocal [18], where the edge weight $w_{u,v}$ is same as that of the reciprocal edge weight $w_{v,u}$ if there exists an edge $e{+}v, u \in E$, and 0 otherwise. We then use two graph algorithms PageRank [29] and Signed Eigenvector Centrality [5]. Each of these algorithms independently learn a score for each node in the graph. The edge weight predicted by these methods simply refers to the difference between the scores obtained for the nodes u and v. Finally, we compare our system with relation specific algorithms used for extracting interaction measures between the nodes. These include Bias-Deserve [26] and Fairness-Goodness [18]. These are iterative algorithms that associate two properties with each node, and learn them by performing sequential iterations on all the nodes in the graph, updating one property at a time. An additional method used in [18] is a Linear Regression model using the above mentioned values as features. This method is identified as Linear Regression (F × G +)

All these methods were evaluated using the experiment setup mentioned above and the results were measures across two standard metrics. We first measure the Root Mean Square Error (RMSE) on the predicted weights to highlight the closeness between predicted and true weights. We then measure the Pearson Correlation Coefficient (PCC) on the predicted weights in order to measure the relative trend in the prediction.

As can be seen in Figure 3, LEAP based methods outperform all the baseline methods on the three datasets, hence defining the new state of the art for edge weight prediction. Moreover, with decreasing number of known edges, the performance of LEAP degrades much slower compared to the other methods.

6.3 Discussion

The results presented above on two edge learning problems prove the ability of LEAP to learn edge properties directly from the structure of the graph. Beyond this, we believe that this framework presents a unique quality of extensibility. LEAP is a highly modular system that can be adapted for any learning objective on the egde properties. In the two tasks presented in the paper, by just making a small change in the edge learner module for each task, the system was able to match the state of the art results. In doing so, it did not require any heuristics or feature extraction methods, and could learn only through the aggregation of paths between the two concerned nodes. Further, LEAP can be trained end-to-end, making it much more convenient to code, use, and maintain, as well as more interpretable since the weights throughout the network are updated using a common objective. The adaptability of LEAP also makes it a potential platform for future research in learning edge properties, and for use of neural networks in graphs.

7 CONCLUSIONS

We presented a novel end-to-end deep learning framework called LEAP for learning edge properties in a graph in this paper. LEAP includes a modular structure consisting of a path assembler, path vectorizer, and an edge learner. For any graph $G = (V, E)$ and two given nodes $(u, v) \in V$, the system learns properties associated with the edge $e_{u,v}$ by aggregating paths between them from the graph. The aggregation is performed using deep learning modules which can be selected based on the dataset and the problem under concern. The system can perform different kinds of supervised learning tasks such as binary or multi-class classification, multi-label classification and regression among others. Being powered by neural modules, the complete framework of LEAP is a layered deep learning model that can be trained end-to-end using gradient descent based methods.

We demonstrate that LEAP can obtain state-of-the-art performance for different learning problems on several real world datasets. For two specific problem of link prediction, and edge weight prediction in weighted signed networks, LEAP shows great performance by matching or improving upon the current state of the art. We also show that the LEAP framework is easily extensible, and can also incorporate node embeddings, node features and edge features into the system. We believe that this system can act as a great platform for experimentation in edge learning, and can be adapted for several different problems. We also believe that the simple architecture of LEAP allows it to be an easily deployable neural model in production environments.

ABSTRACT

Email remains a critical channel for communicating information in both personal and work accounts. The number of emails people receive every day can be overwhelming, which in turn creates challenges for efficient information management and consumption. Having a good estimate of the significance of emails forms the foundation for many downstream tasks (e.g. email prioritization); but determining significance at scale is expensive and challenging.

In this work, we hypothesize that the cumulative set of actions on any individual email can be considered as a proxy for the perceived significance of that email. We propose two approaches to summarize observed actions on emails, which we then evaluate against the perceived significance. The first approach is a fixed-form utility function parameterized on a set of weights, and we study the impact of different weight assignment strategies. In the second approach, we build machine learning models to capture users' significance directly based on the observed actions. For evaluation, we collect human judgments on email significance for both personal and work emails. Our analysis suggests that there is a positive correlation between actions and significance of emails and that actions performed on personal and work emails are different. We also find that the degree of correlation varies across people, which may reflect the individualized nature of email activity patterns or significance. Subsequently, we develop an example of real-time email significance prediction by using action summaries as implicit feedback at scale. Evaluation results suggest that the resulting significance predictions have positive agreement with human assessments, albeit not at statistically strong levels. We speculate that we may require personalized significance prediction to improve agreement levels.

1 INTRODUCTION

It is a truism that email is still one of the most important means of online communication. While individual email volumes vary greatly, we have observed that work email accounts receive more than 100 emails per day on average, while personal email accounts receive an order of magnitude less on average per day, based on a one-week sample of mailboxes from Microsoft Outlook.[1] To assist people with this amount of incoming email, previous work constructs predictive models to direct attention to emails of potentially higher importance or urgency (e.g. [1, 8, 10, 32]). These models tend to focus on predicting whether some set of strong actions such as Reply or Forward will take place. While such predictors have demonstrated value, strong actions such as Reply comprise only a small subset of the possible sets of actions people can take within their email applications [8]. This may create a gap for identifying important emails because strong actions are not the sole actions indicative of importance (e.g. reading an email several times can represent high importance).

In this work, we set out to understand what, if any, relationship exists between the actions carried out on email by people and their perceptions of the significance of those emails. By *significance*, we mean the quality of being worthy of attention that a person accords to an email. Emails that are important, or urgent, or both, are likely to be significant. Other factors may also contribute, such as who it is from or the topic of the email. Our initial analysis based on a large email log sample in Section 3 shows that the actions people perform differ for emails identified as significant versus insignificant. We draw inspiration from an arc of research in the web search community on user actions and inferred document relevance, proceeding from simple clicks [16], to clicks and dwell-time [12], to an entire set of user actions [2].

We conjecture that significance is a quality that exists on a continuous spectrum, and that people make explicit and implicit choices when dealing with their email that reflects this awareness. We also hypothesize that actions carry different semantics and contribute to significance to varying degrees; therefore, diverse actions should be considered when establishing their relationship with significance. Two approaches are investigated for summarizing observed actions

[1] These statistics align with those from a market analysis report by Radicati [22].

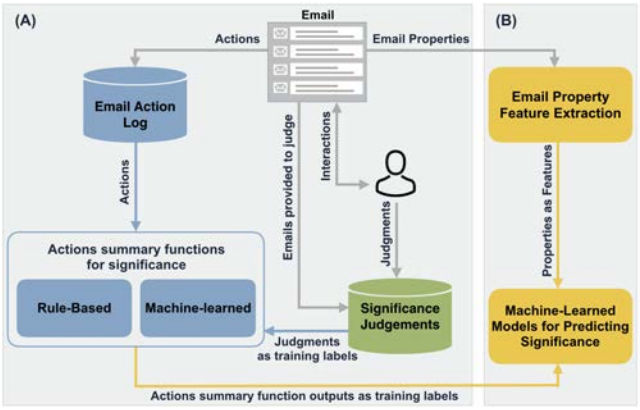

Figure 1: (A) Our framework of evaluating actions as a proxy for email significance, based on action logs and human annotation data. (B) Real-time email significance prediction model trained from actions summary function outputs (§ 7).

in a way that the summaries can then approximate email significance. The first approach presents the notion of weighted action utility (WAU), which is a rule-based fixed-form utility function that summarizes the set of observed actions using a linear combination parameterized on a set of action-specific weights. The second approach attempts to model significance directly using machine learning (ML) techniques.

To evaluate the approaches, we create a human intelligence task (HIT) survey to collect significance judgments from people, including both personal and work accounts. Our results suggest that WAU makes better summaries for determining email significance compared to a reply-only baseline, which is widely adopted as a standard notion for approximating email importance [32] in the literature. As expected, using ML techniques is more effective to make inference over actions and predict email significance. Our follow-up analysis demonstrates that significance prediction using actions varies across users, which may reflect the personalized nature of email activity patterns and significance.

Overall our evaluation results demonstrate that user actions, be it rule-based or machine-learned, can be used as a proxy for users' perceived significance over their own emails. This finding lays an important foundation for downstream tasks such as email prioritization. Building an effective email prioritization predictor with ML usually requires a large quantity of training data, especially given that past research (e.g. [7, 31]) has indicated that email processing is highly personal. Therefore having a means to create unsupervised or semi-supervised training labels at scale is more tractable and practically feasible than aiming for huge quantities of hand-annotated data or explicit user feedback. With the relationship between actions and significance established, we can train such a predictor by leveraging action summaries as a training label, which can be obtained at a low cost by mining action logs. Indeed, in the context of web search, similar ideas of leveraging users' implicit feedback have been studied extensively (e.g. [2, 12, 14, 16]). Specifically, users' actions such as clicks and dwell-time on documents in response to queries have been shown as effective implicit labels of document relevance, based on which standard learning-to-rank techniques are then applicable. To demonstrate this use case, we show an example of how to create a real-time email significance predictor on large-scale email action samples by using the outputs of an action summary function as labels and email properties as features. Our results suggest that the email significance predictions have positive agreement with human assessments, albeit not at statistically strong levels.

To summarize our main contributions, we first evaluate and show that user actions can be used as a proxy for email significance. We consider and conduct extensive experiments on both rule-based and machine-learned techniques to summarize user actions. The results suggest that both approaches outperform a standard reply-only baseline by showing a higher correlation with significance. Figure 1 (A) depicts a high level overview of the process. Furthermore, we identify the analogy between using more than just clicks as implicit feedback for relevance labels in web search and using action summaries as proxies for significance in email processing. In particular, we demonstrate an example of how to leverage an action summary as supervision to train a large-scale email significance predictor, as shown in Figure 1 (B). The predictor can be executed in real-time as it relies on a set of email property features that can be extracted upon email arrival.

2 RELATED WORK

As the volume of email grows and the demand for human attention increases correspondingly, challenges related to email management and retrieval increase [10]. Previous research investigates the different ways that people use and manage their emails in both work and personal settings [6, 11, 31]. As the stream of emails increases, managing email flow is another challenge that has been addressed in the literature [15, 28]. Previous work suggests that with the incoming email flow, people would choose to visit some email messages before others, and spend time selecting which messages to check first [3, 28, 29]. A study has shown that people scan their inbox a couple of times on average before selecting a message to read [4]. Venolia et al. [29] described five stages of email workflow: email flow, triage, task management, archive, and retrieve. Siu et al. [28] extended the work of [29] and their results suggested that people interleave flow, triage and task management, and that handling incoming email involves three steps: glance, scan, and defer. People will usually glance at their inbox several times until a number of new emails have arrived or a message they are expecting has arrived. They would then scan the headers of the new email messages to decide which of these emails need to be read or acted upon. Then they will begin acting on some of these emails messages and/or defer others to return to them later. Although Siu et al. [28] describe the overall steps people take to deal with and manage email flow, it does not address the features people use during the message selecting process and does not describe why people pay more attention to certain email messages over others. Through a user survey and log analysis, Sarrafzadeh et al. [25] investigated how people choose to defer their email for later processing, and whether the decision to defer can be predicted.

Previous work on email prioritization has tried to facilitate the message selection process by including a priority field in messages,

helping people pay attention to important emails easily [21]. Other work focused on allowing the sender to assign a priority to a message by adding a "price" to some messages and not others [19, 23]. However, such approaches were not widely adopted, and the priority field was usually ignored by the users. An analysis to understand why people pay attention to some emails over others is needed to better support the development of such systems. Research by Wainer et al. [30] tried to identify why people attend to some emails and not others based on inbox-level cues about message content. In their think-aloud study, they found that individuals make inferences about message content based on top-level cues and that inferred utility as well as curiosity seem to drive attention to a message. In a controlled laboratory experiment they conducted, in which they investigated the relationship between information gap, utility and demand, they found that curiosity drives attention to email under conditions of low demand, and independent of the marked importance of a message. The work by Wainer et al. is an interesting resource to understand what attracts people's attention to their emails when they arrive; however, more insights are needed to be able to predict such attention. Actions on the other hand, have been used as an indicator in several previous works. Machine learning algorithms to predict the likelihood that a message requires a response are described by Yang et al. [32]. That said, the work by Dabbish et al. [8] found that the need to respond is only one part of defining the importance of an email message, and that people responded to information requests or social messages, even though these messages were unimportant for work.

Other email prioritization work focuses on making a personalized prediction of the significance label of emails [33, 34]. Aberdeen et al. [1] used linear logistic regression models to rank mail in the Gmail mail service by how likely the user was to act on an email without explicit labeling from the user. In that model, they used four categories of features: social, content, thread and label features. Neustaedter et al. [21] described a prototype email client that aggregates social meta-data about email correspondents to support email triage. They define metrics for measuring the social importance of users based on elements like recipients' information and email activities, which can be used for predicting relative email ordering.

The work we are presenting here is similar to this line of research in that we are also interested in understanding email prioritization. However, in our work, we are focused just on whether actions that people take on their emails are related to how they perceive significance, rather than attempting to directly introduce a prioritized email system. Our work follows a similar approach to recent work on email search by Kim et al. [18], in which they mapped explicit *in situ* judgments of email search success and effort to implicit actions that people perform on email; instead, we are mapping our users' judgments to email significance. It is also similar to previous work on web search, in which Huang et al. [14] examined mouse cursor behavior on search engine results pages (clicks, cursor movements and hovers over different page regions), as a proxy for relevance; we are using email interactions, specifically actions performed on emails, as a proxy for email significance.

3 ACTIONS AND IMPLICIT SIGNIFICANCE

In an effort to help users be more productive with their email, popular email services have introduced a number of user experience controls to indicate the significance of individual emails. For example, Gmail's Priority Inbox and Outlook's Focused Inbox both attempt to automatically group emails into two categories of importance. These experiences can often provide interesting insights into users' perceptions of email significance, since they allow users to explicitly move emails from one group to another. In the case of Outlook, users can move emails between the Focused and Other tabs. When a user moves an email to the Focused tab, such explicit interaction can say something about the intention of the user – the current email is likely to be more significant. The reversed operation (i.e., moving an email to the Other tab) may implicitly imply that the user considers this email is less significant. We use these explicit interactions with emails to conduct a quantitative study to investigate if action distributions resemble or differ in the two classes of emails, which we refer to as *implicit significant* and *implicit insignificant*. This helps test if actions can be a good proxy for significance. While we understand emails grouped based on these explicit interactions may not necessarily correspond to a user's notion of significance, this is a close surrogate signal for us based on existing user experiences.

To compare the action distributions, we analyze two random, anonymized action log samples provided by Outlook, one for personal and the other for work email activities. In the personal email sample, we have approximately 500 million users and 17 billion messages, and for work emails, we have 170 million users and 8 billion messages. The email service can be accessed from a number of clients, including native apps for both desktop and mobile as well as browser-based interfaces. The logs did not provide access to any content of the email message, email headers, or email search queries. The logs did contain records of the actions performed against the emails, with corresponding timestamps and other metadata such as the client interface type.

Based on these two samples, we analyze the distribution of actions for these two classes, where we consider diverse actions including but not limited to Read, Reply, Forward, Open an Attachment, Click a Link (in the email), Delete, etc. Figure 2 compares the results. The plot suggests that action distributions for implicit significant and implicit insignificant emails are clearly different. This implies that people interact very differently with emails of different properties, as reflected by the corresponding actions. Particular actions, such as replying to a work email or opening an attachment in a personal email might be good indicators of the significance of this email. Conversely, actions such as deleting an email might indicate it to be of low importance. This observation, to some extent, shows supportive evidence for our hypothesis that using actions as significance proxy is sensible.

4 ACTIONS AS A PROXY FOR SIGNIFICANCE

Next we present approaches for summarizing email significance based on a rule-based function and on machine-learned predictors.

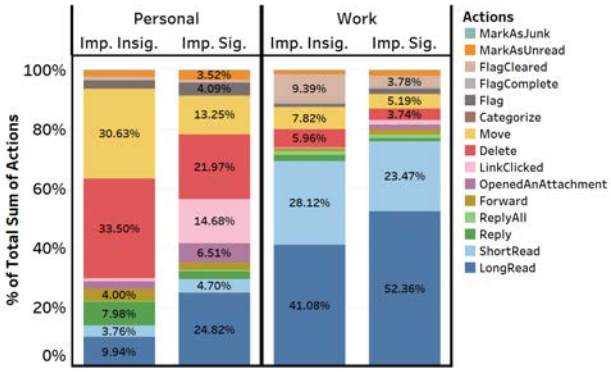

Figure 2: Distribution of actions by implicit insignificant (Imp. Insig.) and implicit significant (Imp. Sig.) emails from a sample of personal and work mailboxes.

4.1 Weighted Action Utility

To summarize the utility obtained from a person's attention on an email, given a set of actions performed on that email, we need some quantity that represents the all-up utility derived from those actions. By *utility* we mean that the attention was useful or beneficial (but not necessarily significant). A naive approach would be to count all actions, giving equal utility for any action. Prior research (e.g. [8]) indicates that different actions (e.g. a Reply to an email vs a Delete) have different degrees of utility. In addition, we can consider that certain compound actions (e.g. a Read followed by a Reply) may indicate that the Read action was more valuable than a Read action in isolation. Thus we also need to allow each type of action (or compound action) to be given a weight.

We propose Weighted Action Utility (WAU), a rule-based fixed-form utility function that summarizes the set of observed actions using a linear combination parameterized on a set of action-specific weights, which is defined as:

$$WAU(e) = \sum_{i=0}^{n} w_{A_i}.A_i \tag{1}$$

where e is an email, $\{A_1, A_2, ..., A_n\}$ is the set of actions performed on e, and w_{A_i} is the weight associated with an action A_i. There are many ways to determine the weights to be associated with each type of action; here we propose two weight configurations:

4.1.1 Authors' weights. Users can benefit from email in many ways, like by gaining information or organizing their thoughts, and this utility is manifested in the logs through their interactions in their email client (e.g. reading emails, writing emails, pinning emails). Thus, our definition of utility first simply assigns utility scores to a set of user actions and sums these scores over every action taken by the user in their email client. Note however, that some actions do not impart utility by themselves, but in combination with whatever item was acted upon. For example, reading an email that teaches the user something has high utility, whereas reading an email to determine that it is spam provides no utility. Thus, we extend our definition of utility by assigning scores to actions that indicate positive utility if they are preceded by a Read. In other words, whereas normally an action like Pin has zero utility, if it is preceded by a Read, then we assign it some positive utility. The way we assign weights to actions is by determining how important and valuable certain actions are compared to others. For example, we believe that Reply and Reply-all actions are important actions, so we assign them higher weights compared to Delete actions which we do not think should be assigned high value.

4.1.2 Crowd-sourced estimates. People might have very different perspectives from us in terms of how they accord utility to their actions. To obtain a broader and more representative estimate of these utility weights, we ask a pool of 40 people from a private crowd-worker service to assign weights to different types of actions commonly carried out on email. We then take the average of these weights and apply them within WAU. By considering these weights alongside the authors' weights, the objective is to see if different sets of weights can give different results for both or either personal and work emails. Our results and findings are discussed in Section 6.

4.2 Predicting Significance using ML

An alternative method that sidesteps WAU altogether is to learn a model from the actions to the significance annotations created by human directly. One challenge here is whether we can obtain sufficient annotation data to learn a model that does not overfit to the available annotations, given the deeply personal nature of email significance. We will describe the details of the annotation data in Section 5.

We compare a number of ML prediction techniques, including Averaged Perceptron [24], Gradient Boosted Trees [13], and logistic regression. To form a set of useful signals for the model training task, we focus on featurizing actions that have been performed on the emails, including:

- Action unigrams – occurrences of actions in isolation.
- Action bigrams – occurrences of pairs of actions observed for an email. While unigrams reflect the occurrence of each type of action, bigrams may capture specific action sequences that may indicate higher significance of emails (e.g. Flag followed by Reply).
- Time information features including: the total time spent on reading; time to reply; time to read; and time to forward.
- The total number of actions.

We note that we only use action-related features for approximating email significance in this section. As discussed in Section 1, having an action summary function derived purely from user actions can benefit the scalability of large production mail systems. Therefore, features such as the historical interactions between sender and receivers or features that require content analysis, although they could be highly useful, should be investigated separately.

The two methods, WAU and ML, are complementary and together provide a better understanding of how actions can indicate significance. Inferring significance using ML bypasses the need to design a summary function and can potentially result in better predictions when interactions between actions are hidden. However, it is important for production systems to have access to an unsupervised or semi-supervised rule-based "labeler" additionally to create training labels for downstream tasks, and this is where WAU can come into play. Ultimately, the performance of supervised ML predictors will be determined by the scale of data available for training, which for human-annotated emails is generally going to

be small-scale and expensive to obtain. Although WAU still poses a few parameters, the simplicity of the formula makes it easy for the weights to be decided elsewhere or heuristically, and also offers high interpretability. A final remark on WAU and ML methods is that they cannot be applied at the time when emails are delivered because at that time no actions are observed. It is similar to web search in that inferring document relevance for a user can only happen after their dwells and clicks. We demonstrate how to apply an action summary in an online prediction task in Section 7.

5 PEOPLE'S PERCEIVED SIGNIFICANCE

Although log data provides implicit characterization of attention utility, people's judgments of the significance of their emails are more valuable for deriving insight. Moreover, as we believe significance is better studied in a continuous spectrum, the fact that current major email clients support only a coarse dichotomy due to binary UI controls is sub-optimal. We developed a human intelligence task (HIT) survey to address these limitations.

The resulting data from HIT can be used as a reference for evaluating action summaries. In the case of an ML action summary, the judgments can also be used as labels in the training phase.

5.1 Email Significance HIT Survey

The email significance HIT survey is a user-email survey that lets people identify or label the absolute significance of individual emails. Each HIT chooses a random email from the most recent 200 emails delivered within the last two months to the user's mailbox, and shows them a rendering of the email's From, Subject, and Body content. It asks them to rate the email by its significance to them at the time they first read it. At the same time, it asks them to select one or more reasons for their decision. Up to 100 emails can be annotated by each person.

Although we believe significance to be a continuous-valued property, for ease of annotation we used a unipolar 5-point Likert scale design. The significance labels ranged from "Insignificant" to "Extremely significant". While the users were seeing their own email messages, we did not record any content of the email. We only collected their significance labels, reasons, and sufficient identifying metadata to let us match the labeled email with its action log record. In addition, we provided users of the HIT survey with the ability to skip any email they felt uncomfortable providing data on to us. While we understand that this might potentially introduce a selection bias towards particular emails, the number of emails that were rated by the users could reduce this bias if any.

Our task guidelines emphasized that rating significance was a personal decision by the participant. We provided suggestions for how to distinguish between different ratings as follows, though not all conditions might exist to select a rating. An "Extremely significant" email is one that communicates essential or important news, or an important and urgent task at work, that the person needed to give their immediate attention to. A "Very significant" email is one that the person would like to pay attention to within the next hour or that the person would return to on multiple occasions within a week after receiving it. A "Moderately significant" email is one the person would like to pay attention to within the next day from receiving it or that they return to at least once. A "Slightly significant" email is one the person would like to pay attention within a week of receiving that email, possibly read or skim the email once, but is unlikely to revisit it again. An "Insignificant" email is an email that the user usually ignored or did not even wish to read.

In the HIT survey we asked people to provide reasons they gave their ratings. The list of reasons we provided to the HIT survey participants includes: Email was from an important person; an Important topic; Part of a conversation I started; Requesting information from me; Information I needed to act on; Of interest but no immediate action; From an organization I often read; I did not have time to pay attention to it; About something I am uninterested in; I usually ignore this sender; and Other. We provided a free-form text field for Other, in case none of the suggested reasons were appropriate. People could select as many reasons as they liked.

5.2 Actions and Perceived Significance

We distributed the survey to both work and personal email participants. For personal emails, we had 118 participants or "judges" and 5774 hits or "judgments". The process of judge selection was managed in a way where bias was minimized, although inevitably they are required to an Outlook user to begin with. Figure 3 shows the distribution of actions (i.e., the percentage of the total number of actions for emails as was ranked "Insignificant" to "Extremely significant"). The most common actions performed on personal emails in all the significance classes are: Read (long and short) and Open an Attachment. A Short Read is one that is 2 seconds or less, to account for read actions that occur when a person is clicking quickly through a list of email, but not stopping to read the content in depth. Long Reads are all reads longer than Short Reads. Separating Short and Long Reads is only one way that attempts to address the complexity of the reading behavior, which is intrinsically affected by different contextual cues such as email length. Both Short and Long Reads are observed at similar rates across different levels of significance. Nevertheless, there is an increase for Open an Attachment actions with the increase of significance, and an increase of the Delete action with decrease of significance. One interesting thing we notice is that Reply and Reply-all have limited impact on how significant an email is. This outcome confirms the results of Dabbish et al. [8] from a study in which they found that the need to respond is only one part of defining the importance of an email message and that people respond to information requests or social messages, even though these messages were unimportant, compared to the work-related messages.

For work emails, we had 24 judges and 560 hits. Figure 4 shows that the distribution of actions for these emails is quite different than their distribution in personal emails shown in Figure 3, as well as the relationship between these actions and the significance of emails. Unlike personal emails, Reply and Reply-all are important actions for work emails. We see an increase of these actions with the increase of the significance of emails.

6 RESULTS AND DISCUSSION

For both WAU and ML predictors, we conduct predictions in two ways. The first casts significance prediction as a binary classification problem, where the outcome directly classifies emails into

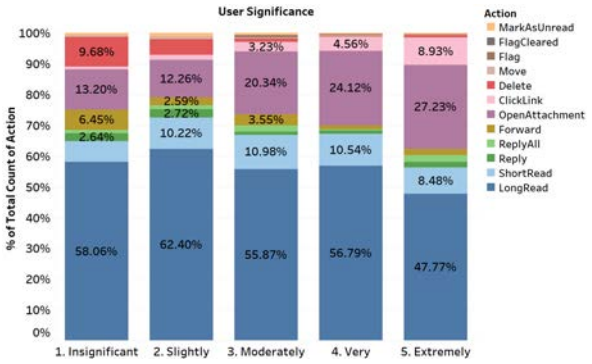

Figure 3: Distribution of actions for personal emails over users' significance

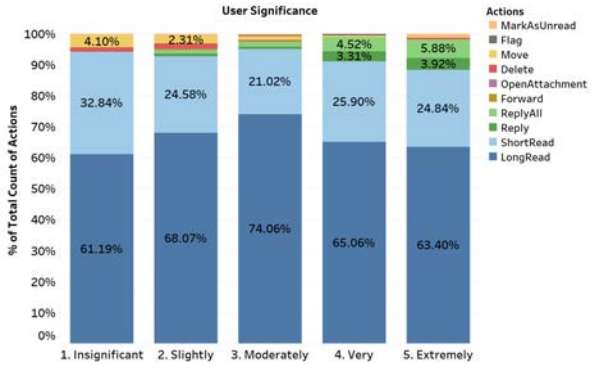

Figure 4: Distribution of actions for work emails over users' significance

positive and negative classes of significance. This task mimics what current solutions popular email services provide today. The second considers predicting the graded significance levels obtained from the HIT Survey data, based on which a partial ordering or even ranking over the emails can be formed.

6.1 Binary Classification

We organize our five significance labels in two different ways for binary classification:

- Binary Classification Low (BC-Low): positive label includes all significant labels, "Extremely", "Very", "Moderately", and "Slightly" significant. The negative class only includes the "Insignificant" label. This division addresses scenarios where missing out any slightly important email may result in a high penalty.
- Binary Classification High (BC-High): positive class includes "Extremely" and "Very" significant labels, and the negative class includes "Insignificant", "Slightly", and "Moderately" significant labels. This division addresses scenarios where only the top significant emails should draw users' attention.

For our baseline analysis, we classify our emails into emails that have at least one Reply or Reply-all as positive and emails that do not as negative. We choose this reply-only baseline because it

Table 1: Precision (P), recall (R), and AUC, for our baseline analysis using both BC-Low and BC-High

	Personal			Work		
BC Type	**P**	**R**	**AUC**	**P**	**R**	**AUC**
BC-Low	0.895	0.023	0.509	1.000	0.097	0.548
BC-High	0.416	0.027	0.507	0.625	0.271	0.619

is widely adopted as a standard notion for approximating email importance [32]. Table 1 shows the precision, recall and AUC for our baseline analysis for both work and personal emails. Overall the AUC for both email types is around 0.5, which is far from ideal. There is one exception for work emails using BC-High (0.619), suggesting that under certain contexts this reply-only predictor can work well, which is consistent with previous findings. The reason why AUC is higher in BC-High compared to BC-Low is that, looking at Figure 4, emails rated "Very" and "Extremely" significant have more Reply and Reply-all actions than the other emails. One drawback of this simple predictor, however, is that it cannot account for 30% of our judges who have no Reply actions at all on the emails that they judged, even though the emails were in fact assigned with different significance labels.

6.1.1 Using Rule-Based WAU. We compute the relationship between the WAU value and the user significance label. We consider the two types of WAU computed using the authors' and crowd-sourced weights. We normalize WAU values using a generalized logistic function. We choose different thresholds (0.1, 0.2, ..., 0.9) to divide the WAU value, where everything beyond the threshold is predicted as positive and everything below is negative. We did not do a train-test split to get an optimal cut because it was important for us to understand the impact of different thresholds.

Table 2 and Table 3 show the prediction results respectively for the tasks BC-Low and BC-High. In both tables, we are only showing 0.4, 0.5, and 0.6 thresholds, due to space limits, and to the fact that extreme thresholds tend to result in more skewed performance (e.g. high precision, low recall). In general, BC-Low appears to be an easier task compared to BC-High (higher precision and AUC values). Among all the thresholds we test, we are getting the highest AUC for both personal and work emails at threshold 0.6. Using BC-Low, the WAU values computed using author's weights can better predict users' significance than the ones computed using crowd-sourced weights in personal emails, and the crowd-sourced weights worked better for work emails. This finding suggests that the same set of weights might not be appropriate to be applied for both types of emails, since personal and work emails tend to have very different action distributions.

6.1.2 Using Machine-Learned Models. We form training and test sets split using 5-fold cross validation on personal and work emails respectively and use McNemar's Test for significance assessment between classifiers. Previous work [33, 34] suggested that personalization is a key factor for improving performance of generically learned models. To study the effects of inter-person variance, when forming the training and test sets, we split the data by either emails or by judges. In both cases, there are no overlapped instances between the splits, and we hypothesize splitting by judges is a more

Table 2: Precision (P), recall (R), and AUC, for authors (A) and crowd-sourced (CS) WAU weights(W), using BC-Low with 0.4, 0.5, and 0.6 thresholds (Th)

		Personal			Work		
W	**Th**	**P**	**R**	**AUC**	**P**	**R**	**AUC**
A	**0.4**	0.772	0.991	0.510	0.735	0.995	0.510
	0.5	0.780	0.914	0.530	0.733	0.904	0.502
	0.6	0.905	0.493	0.661	0.863	0.324	0.592
CS	**0.4**	0.621	1.000	0.500	0.731	1.000	0.500
	0.5	0.621	1.000	0.500	0.731	1.000	0.500
	0.6	0.851	0.282	0.601	0.793	0.723	0.610

Table 3: Precision (P), recall (R), and AUC, for authors (A) and crowd-sourced (CS) WAU weights(W), using BC-High with 0.4, 0.5, and 0.6 thresholds (Th)

		Personal			Work		
W	**Th**	**P**	**R**	**AUC**	**P**	**R**	**AUC**
A	**0.4**	0.123	1.000	0.508	0.165	1.000	0.510
	0.5	0.131	0.972	0.541	0.171	0.945	0.530
	0.6	0.212	0.729	0.677	0.240	0.402	0.580
CS	**0.4**	0.248	1.000	0.500	0.164	1.000	0.500
	0.5	0.248	1.000	0.500	0.164	1.000	0.500
	0.6	0.410	0.340	0.590	0.182	0.7391	0.543

challenging task due to different personal behavior. We experiment with both linear and tree learners, including Averaged Perceptron [24], Boosted Trees [13] and LightGBM [17] for binary classification using off-the-shelf ML libraries. In the following analysis, we present results with Boosted Trees only due to space limit.

Table 4 and Table 5 show the prediction results for the tasks BC-Low and BC-High. Compared to Table 2, the performance of boosted trees is in general better than that of fixed cut-off WAU in terms of AUC with $p\text{-}value < 0.01$, especially for work emails. This highlights that, while WAU describes a good summary of action distributions, the flexibility of incorporating different dimensions of action metadata, such as action sequences and reading time, can further help significance prediction. The same observation can be found in the task BC-High by comparing Tables 3 and 5.

As expected, cross validation with splits by judges tends to be a harder problem, where AUC decreases between 3% – 15% compared to splits by emails. This observation opens up an interesting research question on how we could use personalization strategies for associating actions and significance, which is beyond the scope of this paper and left for future work.

6.2 Multi-Grade Predictions

Next, we present our findings on prediction tasks where multi-grade significance labels are considered. We examine two prediction strategies. Firstly we form a ranking on emails using the continuous WAU, and compare it with the ranked list based on the five classes of significance collected from the HIT Survey. The second strategy casts the prediction problem as a multi-class classification

Table 4: Precision (P), recall (R), and AUC based on Boosted Trees. Average results are reported with 5-fold cross validation split by emails or by judges, for BC-Low

	Personal			Work		
Split By	**P**	**R**	**AUC**	**P**	**R**	**AUC**
Emails	0.622	0.994	0.643	0.793	0.911	0.698
Judges	0.611	0.983	0.638	0.696	0.900	0.666

Table 5: Precision (P), recall (R), and AUC based on Boosted Trees. Average results are reported with 5-fold cross validation split by emails or by judges, for BC-High

	Personal			Work		
Split By	**P**	**R**	**AUC**	**P**	**R**	**AUC**
Emails	0.603	0.157	0.643	0.517	0.212	0.690
Judges	0.468	0.157	0.626	0.300	0.203	0.600

task, where the outcome aims to distinguish emails into the five significance classes.

6.2.1 Using Rule-Based WAU. We first use the WAU value to order the set of annotated emails. Then we compute Spearman's Rho rank correlation coefficient (with correction for ties) between the ordering formed by WAU and the ordering formed by the five classes of users' significance. Both authors' and crowd-sourced weights are considered. Multi-graded prediction is challenging, thus, as we expected, we get low correlation. For both personal and work emails, we get a correlation that ranges from 0.250 to 0.273 using the two different weights. With binary classification results presented in Tables 2 and 3, we are getting better predictions and correlation with user significance, compared to using the 5-class labels. Nevertheless, computing the correlation per judge (discussed in detail in Section 6.3.2), we observe that some judges have high correlation and others have low correlation, supporting our view that perceptions of significance may be highly personal.

6.2.2 Using Machine-Learned Models. Similar to Section 6.1.2, we conduct 5-fold cross validation and split the data by emails or judges. For the learners, we consider again both linear (multi-class logistic regression) and tree (LightGBM) learners. Micro-accuracy and macro-accuracy are two standard metrics for evaluating multi-class classification effectiveness. Micro-accuracy is defined as the ratio of the number of correctly predicted instances to the total number of instances; this metric is more robust towards class size imbalance problems. Macro-accuracy first computes accuracy for each class and reports the average of per-class accuracies. For our task, we first examine micro-accuracy and macro-accuracy in each fold, take the average of the 5 folds, and report the results in Table 6. Spearman's Rho is additionally computed based on the rankings formed by labels and by predicted classes, so as to capture the correlation between the two. Table 6 shows that predicting graded significance tends to be simpler for personal than work emails. This could be because the action distributions appear more distinguishable across different significance classes in personal than in work data, as suggested by Figures 3 and 4. Compared to the results presented in Section 6.2.1, we see that predicting significance with ML models

Table 6: Micro-avg and macro-avg accuracy and Spearman's Rho results based on multi-class logistic regression.

	Personal			Work		
Split By	**Micro**	**Macro**	**Rho**	**Micro**	**Macro**	**Rho**
Emails	0.413	0.275	0.315	0.369	0.279	0.295
Judges	0.391	0.245	0.265	0.308	0.241	0.177

results in higher correlation with the ground truth rankings for data splits by emails, i.e., Rho=0.315 and Rho=0.295 for personal and work respectively. However, when eliminating personal interactions (i.e., split by judges), the correlation is either on par or worse than using WAU. This outcome may suggest that an evaluation metric which focuses on ranking, i.e. Rho, is more heavily impacted by per-person variance.

6.3 Discussion

While we have demonstrated the potential of summarizing actions to predict email significance, based on both WAU and ML, we observe some challenges which are discussed below.

6.3.1 Differentiating perceived significance. Differentiating perceived significance is challenging in general. As mentioned in Section 5.1, we asked our participants to not only judge and rank the significance of their emails, but to also give us feedback on the reasons for their judgments. While there is usually a clear distinction between "Insignificant" and "Extremely" significant, the distinction between "Slightly", "Moderately", and "Very" significant can be more subtle and highly personal. Asking for participants' feedback was one way to make that distinction clearer for us. Figure 5 shows the distribution of the feedback our participants gave in comparison to their email significance ranking for work emails (personal emails have similar distribution). In both types of emails, the reasons the participants gave for the emails they rated "Extremely" are different than the ones rated as "Insignificant". For "Insignificant" rated emails, we notice that the reasons mostly included: something they are not interested in, they usually ignore the sender, or did not have time to pay attention to it. However, for "Extremely" rated emails, the reasons were typically: an important topic or from an important person, or information they needed to act on. The reasons our participants gave for "Very" and "Extremely" rated emails were similar. This similarity could help explain why we obtain better correlation using the binary classification approach. To some extent, this may also explain why the correlation results presented in Section 6.2 based on correlation using the multi-graded labels are worse in comparison to the binary labels in Section 6.1.

Identifying the same level of perceived significance can be challenging even for the same judge on the same email. A subset of emails were judged repeatedly by the personal judges in the HIT survey. In total 998 unique emails were judged multiple times by 101 judges, with each email being displayed on average 4 times. Note that for all the results presented in Section 6, we remove the duplicates and only experiment with those with a single judgment.

To quantify the degree of inconsistency, we calculate entropy for each unique email based on per-significance distribution using

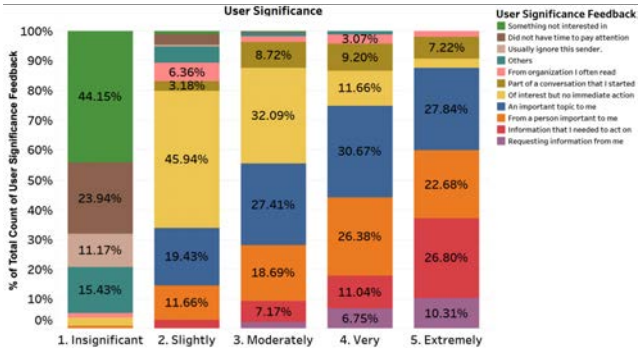

Figure 5: Explanations for the five email significance labels ranked by the HIT Survey participants

$H(x) = -\sum_{s=1}^{5} P(x_s) log_2 P(x_s)$, where s indicates email significance level[2]. If the outcome is certain (i.e. no inconsistency) we would expect entropy of 0. In fact, we see the average entropy is 0.35 for this data, and gets even higher, i.e., 0.41, when the number of repetitions is greater than or equal to 5. This suggests that email owners may have difficulties giving consistent judgments. Scholer et al. [27] also found high rates of intra-judge search relevance judging inconsistency of between 15% and 24% across a range of TREC test collections.

6.3.2 Email significance is highly personal. Another challenge we face is that the significance of emails varies based on the user. To better understand the correlation between our WAU significance values and the judged significance, we compute the correlation for each person. Figure 6 shows the correlation for each of the personal email users in our sample data in comparison to the number of hits. We observe that the number of emails the people are judging has no impact on the the correlation. Some people have a high correlation and others have low correlation. More than half of the people have positive correlation, but some of them have no or negative correlation. The large number of zero correlation scores is due to the tie-adjusted Rho computation.

6.3.3 Action Limitations. Looking at our data, both the log data and the HIT Survey labels, we observed two limitations. The same set of actions performed on emails (e.g. emails that have Long Read and Move) can be rated by the HIT Survey participants with different levels of email significance. That is a major challenge given that we depend on actions as features to predict email significance. These set of actions that have different levels of significance vary in terms of both the numbers of this happening and the different labels assigned to them by the judges. We computed the entropy to better understand the variance of each of the actions sets we have and the judges' assigned labels. We noticed that some of the emails that have common action sets (e.g. Long Read, Short Read) have been labeled "Insignificant" to "Extremely" significant by different users, thus have higher entropy (1.5-2). However, the emails that have a unique set of actions were judged using only one label.

[2] $0log0$ is defined as 0 in information theory.

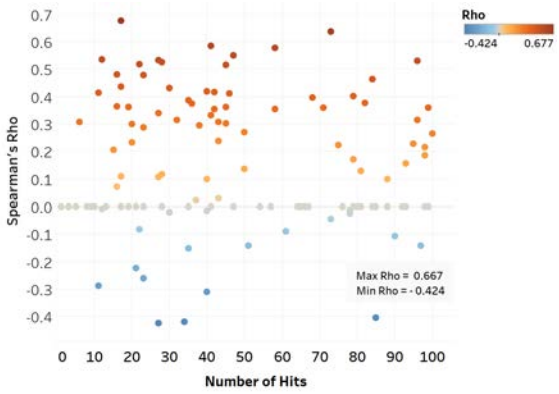

Figure 6: Spearman's Rho for each personal email user over the number of HIT Survey hits

7 REAL-TIME SIGNIFICANCE PREDICTION

Above, We studied how and to what extent user actions on emails can be harnessed as a proxy for email significance. We demonstrated that different action summary functions correlate with significance in varying degrees and overall the correlation is positive. To apply our learning to a practical scenario, we train a machine-learned model based on large scale data for real-time significance prediction, as shown in part (B) of Figure 1. Specifically a regression model is trained to fit the output from an action summary function, which is effectively used as the training label. Then we extract a set of non-action features that can be obtained at the time when an email arrives at a mailbox. In this way, the resulting predictive model can forecast email significance in real-time (i.e., email arrival time) because actions are needed only for offline training.

7.1 Prediction Model

Our goal is to have a predictor that is able to predict email significance in real-time. In an ideal world, a supervised predictor can be trained to reach oracle performance if human significance labels can be obtained at scale at a low cost. However, obtaining large amount of human assessments is impractical in practice; instead leveraging implicit feedback from users as a proxy is commonly a preferred, scalable way. In the search world, one of the most successful examples is to treat users' actions including clicks and dwell-time on documents in response to user queries as positive feedback, and thus the corresponding documents are deemed relevant for training [14]. For email significance prediction, we propose to use the output of action summary functions as implicit significance feedback. In this section, we choose to experiment with the rule-based summarizer WAU as the training label, as we have shown that WAU outperforms a reply-only baseline. Although a machine-learned summary function can be more correlated with significance, the amount of human annotation training data heavily determines the performance of the outcome. To focus on presenting the feasibility of building a real-time predictor, a rule-based summarizer is preferred as it provides high simplicity which in turn benefits production systems.

7.1.1 Model training. We reuse the large-scale log samples described in Section 3 to train two real-time predictors respectively for personal and work accounts. In particular, each of the log sample represents an email e_i. We first compute for each e_i its WAU value as the training label y_i based on the actions performed by actual users. Then we extract a number of non-action features $\boldsymbol{x_i}$, resulting in a dataset of $\{(y_i, \boldsymbol{x_i})\}$. We cast the prediction task as a regression problem with an objective that minimizes the $L2$ distance between the prediction $\hat{y_i}$ and y_i. We adopt LightGBM [17] for regression using an off-the-shelf ML library for training. Two held-out datasets (from different users and time periods) in the same format as the samples are added for validation and parameter selection. Parameters on the number of boosting iterations $\{50, 100, 150, 500, 1000\}$, learning rates, and minimum number of items in leaves $\{10, 20, 50\}$ are swept. Training is done on standard CPU machines without parallelization.

7.1.2 Hand crafted email property features. We adopt a total number of 35 non-action features that may reflect email significance. Not all features are available for both personal and work email; we simply impute 0 for missing values. The features are designed in a way that their values can be extracted during email delivery time, which in turn enables real-time significance prediction.

- Sender-related. Binary features that capture if the sender is of high impact, such as if a sender is in the address book or if a sender is more senior in the management chain.
- Recipient-related. Features that capture if the recipient receives an email as a user on the To, CC or BCC field.
- Historical interactions between sender and recipient. Features that reflect in the past how often the sender and recipient interact with each other (e.g., email read rate).
- Binary classifiers. Output from in-house classifiers that predict if the content of an email may belong to a category (i.e., a newsletter, a promotion or a purchase).

We note that any future user action performed on a current email is not considered in this feature list. That is, there is no leak or overlap between the features on email properties and the actual actions that may be performed on this current email at a future time. We should also emphasize that the focus of this section is not to develop a comprehensive set of email property features, but instead to show how online prediction is possible by leveraging output from action summary functions as supervision for ML.

7.2 Evaluation

We compare the real-time prediction $\hat{y_i}$ and the ground truth label $L(e_i)$ on both the personal and work human judgment sets. One way is to compute Spearman's Rho between the rankings formed by predictions and labels as is done in Section 6.2. On the personal set the Rho value is 0.265, and on the work set, it is 0.370. Compared to the results in Section 6.2, we see overall an increase in the correlation for both data sets. One reason for this improvement is that the real-time prediction models tend to create more continuity in the predictions than WAU and the action-features-only models. This continuity breaks ties for emails of similar user responses; the direction of separation usually aligns with the judgments.

In addition to Rho, we also report Krippendorf's α [20] for evaluation on pairwise data formed from the human judgment sets. In

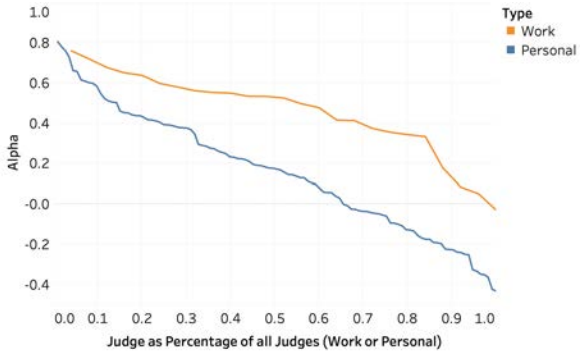

Figure 7: Krippendorf's α for each personal and work email user over their email pairs for significance labels and model prediction scores. The x-axis is the pool size normalized to lie between 0 and 1; agreement rates decline faster with personal judges.

the search literature, the amount of quality relevance assessments is key to training an effective ranker. To increase the amount of training data, a common approach is to permute pairs of labelled observations (within some group, such as a query) and incorporate pairwise comparisons in the objective function for optimization (e.g. [5]). In our work, although our goal is not to facilitate learning-to-rank training, we leverage pairwise data generated from the human sets to obtain more observations. Based on that, we can provide evaluation in more detail using Krippendorf's α.

Krippendorf's α is commonly used for assessing agreements between target and reference distributions for various data types (e.g., ordinal, interval and ratio), and deals with ties and missing values naturally. Given a pair of emails $(e_i, e_j), i \neq j$, our goal is to quantify how often the model predictions agree with ground truth ordering. To this end, α is used to assess the degree of consistency between the difference in model scores, $M(e_i) - M(e_j)$, and the difference in human significance labels, $L(e_i) - L(e_j)$. Consistency is higher when the difference in model scores resembles that in labels. For example, when a user regards e_i to be "Very significant" (4) and e_j to be "Insignificant" (1), a model that gives a large positive difference in predictive scores will result in high consistency. The α scores range from -1 (complete anti-agreement) to 1 (complete agreement), where the middle point 0 is effectively random agreement.

We calculate α as the agreement measure on both personal and work judgment data, for all possible pairs of emails belonging to each person. Values for α in aggregate are 0.131 and 0.339 respectively. Overall, we can see that the work data has better agreement in ordering than the personal data, which is consistent with the Rho results. In neither case do the scores show strong levels of agreement; indeed for the personal email corpus it is close to random levels of agreement. (As a comparison, inter-rater agreement for search relevance has also been found to vary considerably, ranging from lows of 0.15 in one study of 180 raters [26] to highs of 0.557–0.705 (depending on condition and scale) in another study involving 16 raters [9], both involving university students.) Search relevance is a challenging labeling task for judges and email significance is also hard for models to predict, based on these outcomes.

In addition to the overall α, we calculate α values on a per person basis. Figure 7 shows these sorted by decreasing α values, and normalized (as a percentage of the pool size) in the x-axis to allow easier comparison between personal and work judges. We see as previously that there is a wide range of agreement according to individuals. Approximately 20% of the work judges and 10% of the personal judges have α values above the 0.667 threshold, which is considered "possibly reliable" for agreement. In the personal case, around a third of the judges start to be anti-correlated. All these findings suggest that, for future work, studying user engagement in depth in personal emails will be important. Indeed, Cecchinato et al [7] found that in personal accounts, people usually looked for order confirmations, travel or money related emails etc. For these cases, it is hard to separate observed user engagement such as reading from other less significant emails such as promotions, given that people also read promotions.

8 CONCLUSIONS

Managing email flow is something that people carry out often. Some emails require more attention than others, and hence, different actions are performed on them accordingly. We investigated our hypothesis that the cumulative set of actions on an email can be considered as a proxy for people's perceived significance of the email using two approaches. The rule-based approach WAU was simple and made better summaries for significance compared to a reply-only baseline; meanwhile the machine-learned approach can more effectively summarize actions and predict email significance.

We found that there are differences in actions between significant and insignificant emails in aggregate. Our analysis also showed that the degree of correlation between actions and significance varies across personal and work accounts as well as across people. Nevertheless, email processing is a much more complex task than traditional web search, in which mapping actions to relevance in search has been shown to have a strong correlation. Thus we carried out more analysis and discussed a number of challenges in our framework, including the fact that the same sets of actions can be observed for emails from different classes of significance. Overall, our results suggest that the cumulative set of actions on any email can be treated as a partial proxy for the email's perceived significance, at least for some people or account types.

Although action summaries are not perfectly correlated with human significance judgments, using actions as a proxy still has potential to be used in predicting significance on emails in real-time, which is similar to modeling document relevance using clicks and dwell time in the context of web search. Specifically, we presented an example of using a rule-based action summary function, WAU, as supervision for training an email significance predictor based on large-scale email action samples, where the resulting predictor can be executed upon email arrival. Evaluation of this predictor showed reasonable correlation with human assessments, more so for work accounts.

Our work provides insights on how the different actions performed on emails can have an impact on the significance of these emails, and how to apply the findings to create a real-time predictor for email prioritization. Future work is required to understand how

the personalized nature of significance can be more accurately modeled, including by collecting substantially more annotation data, conducting deeper feature engineering and analysis, or performing *in situ* surveys.

ACKNOWLEDGEMENTS

We gratefully thank Kshitiz Gupta for his help in creating the HIT survey codebase and the anonymous personal and work judges for their judging work.

ABSTRACT

Can neural networks learn to compare graphs without feature engineering? In this paper, we show that it is possible to learn representations for graph similarity with neither domain knowledge nor supervision (i.e. feature engineering or labeled graphs). We propose Deep Divergence Graph Kernels, an unsupervised method for learning representations over graphs that encodes a relaxed notion of graph isomorphism. Our method consists of three parts. First, we learn an encoder for each anchor graph to capture its structure. Second, for each pair of graphs, we train a cross-graph attention network which uses the node representations of an anchor graph to reconstruct another graph. This approach, which we call *isomorphism attention*, captures how well the representations of one graph can encode another. We use the attention-augmented encoder's predictions to define a divergence score for each pair of graphs. Finally, we construct an embedding space for all graphs using these pair-wise divergence scores.

Unlike previous work, much of which relies on 1) supervision, 2) domain specific knowledge (e.g. a reliance on Weisfeiler-Lehman kernels), and 3) known node alignment, our unsupervised method jointly learns node representations, graph representations, and an attention-based alignment between graphs.

Our experimental results show that Deep Divergence Graph Kernels can learn an unsupervised alignment between graphs, and that the learned representations achieve competitive results when used as features on a number of challenging graph classification tasks. Furthermore, we illustrate how the learned attention allows insight into the the alignment of sub-structures across graphs.

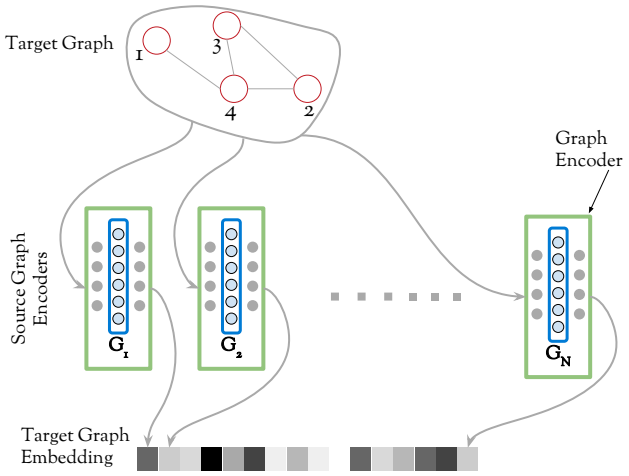

Figure 1: Our method of learning graph representations by measuring the divergence of a target graph across a population of source graph encoders. First, we train a graph encoder for each graph in our source graph population {G_1, G_2, ..., G_N}. Second, for each of these encoders we measure the divergence of the target graph from the associated source graph. Finally, these divergence scores are used to compose the vector representation of the target graph.

1 INTRODUCTION

Deep learning methods have achieved tremendous success in domains where the structure of the data is known a priori. For example domains like speech and language have intrinsic sequential structure to exploit, while computer vision applications have spatial structure (images) and perhaps temporal structure (videos). In all these cases, our intuition guides us to build models and learning algorithms based on the structure of the data. For example, translation invariant convolution networks might search for shapes regardless of their physical position in an image, or recurrent neural networks might share a common latent representation of a concept across distant time steps or diverse domains such as languages. In contrast, graph learning represents a more general class of problems because the structure of the data is free from any constraints. A neural network model must learn to solve both the desired task at hand (e.g. node classification) and to represent the structure of the problem itself – that of the graph's nodes, edges, attributes, and communities.

Despite the challenges, there has been a recent surge of interest in applying neural network models to such graph-structured data

[26, 30, 40, 50, 63]. While initial approaches like DeepWalk [40] focused on generic representations of graph primitives (e.g. a graph's nodes [40] or edges [1]), present approaches ignore learning general graph and node representations in favor of maximizing accuracy on a set of narrow classification tasks. These approaches, broadly referred to as Graph Neural Networks (GNNs), seek to leverage the structure between data items as a scaffolding to perform computation (e.g. message passing, gradient updates, etc). The parameters and the activations, use the structure during training, but are tuned primarily to classify the graph's nodes, edges, and/or attributes.

While much effort has focused on unsupervised learning of node representations [12, 24, 40, 48], edge representations [1], or latent community structure [13, 52, 62], relatively little work has focused on the unsupervised learning of representations for entire graphs – a problem of practical interest in domains such as information retrieval, biology, and natural language processing [5, 23]. In cases where GNNs have been applied to the task of learning similarity between graphs, the approaches considered generally come in two flavors: an end-to-end *supervised graph classification* or *graph representation learning*.

In supervised graph classification, the task is to solve an end-to-end whole-graph classification problem (i.e. the problem of assigning a label to the entire graph). These supervised approaches [33, 36, 45, 61] learn an intermediate representation of an entire graph as a precondition in order to solve the classification task. This learned representation can be used to compare similarity between graphs, but is heavily biased towards maximizing performance on the classification task of interest.

The second class of approaches focuses on the more general problem of learning graph representations [43]. While much exciting progress has been made in this area, the existing approaches suffer from one or more of the following limitations. First, many existing methods rely on feature engineering, such as the graph's clustering coefficient, its motif distribution, or its spectral decomposition, to represent graphs [6, 47, 56]. By limiting the features that they consider, these methods are limited to composing only known graph signals. Second, many of these approaches [36, 61] have sought to encode algorithmic heuristics from the graph isomorphism literature (especially the intuition encoded in the Weisfeiler Lehman algorithm [42]). Relying heavily on existing heuristics to solve a hard problem raises an important question: how well can a learning-only approach solve a classic algorithmic problem? Finally, other work in this area of graph similarity assumes that identical nodes in both graphs share the same id (i.e. the alignment is already given). While this can be useful for calculating a similarity score, we find the general problem more compelling.

In this work, we propose a method of learning graph representations driven by the similarity between a pair of graphs as measured by the divergence in their structures. We show the representations learned through our method, Deep Divergence Graph Kernels (DDGK), capture the attributes of graphs by using them as features for several classification problems. In addition, we show that our representations capture the local similarity of graph pairs and the global similarity across families of graphs.

DDGK has three key differentiators. First, it makes no assumptions about the structure of the matching problem. In order to solve the matching problem, we propose an attention mechanism: *isomorphism attention* to align the nodes across graph pairs. Second, DDGK does not rely on any existing heuristics for graph similarity. Instead, we learn the kernel method jointly with the node representation and alignment networks. This allows the model the freedom to learn representations that best preserve the graph, and does not impose artificial oversights. Finally, as an unsupervised method, the representations it learns emphasize structural similarity, and does not correlate with a downstream labeling tasks. This is especially useful for ranking tasks where labeling may not be available.
To summarize, our main contributions are:

- **Deep Divergence Graph Kernels**: A novel method for learning unsupervised representations of graphs and their nodes. Our kernel is learnable and does not depend on feature engineering or domain knowledge.
- **Isomorphism Attention**: A cross-graph attention mechanism to probabilisticly align representations of nodes between graph pairs. These attention networks allow for great interpretablity of graph structure and discoverablilty of similar substructures.
- **Experimental results**: We show that DDGK both encodes graph structure to distinguish families of graphs, and when used as features, the learned representations achieve competitive results on challenging graph classification problems like predicting the functional roles of proteins.

2 LEARNING GRAPH REPRESENTATIONS

In this section, we lay out the problem definition of representing graphs and the connection between our representations and the kernel framework.

2.1 Problem Definition

A graph is defined to be a tuple $G = (V, E)$, where V is the set of vertices and E is the set of edges, $E \subseteq (V \times V)$. A graph G can have an attribute vector Y for each of its nodes or edges. We denote the attributes of node v_i as y_i, and denote the attributes of an edge (v_i, v_j) as y_{ij}.

Given a family of graphs G_0, G_1, ..., G_N we aim to learn a continuous representation for each graph $\Psi(G) \in \mathbb{R}^N$ that encodes its attributes and its structure. For this representation to be useful, it has to be comparable to other graph representations. However, it is likely that our method of graph encoding will produce one of many equally good representations each time we run it. For example we can get two different, but equal, representations by permuting the dimensions of the first one. Those representations are not comparable given they exist in two different spaces.

To avoid this problem, we seek to develop an equivalence class across all possible encodings of a graph. Essentially, two encodings of a graph are equivalent if they lead to the same pair-wise similarity scores when used to compare the graph to all other graphs in the set. We note that this issue arises when working with embedding based representations across domains, and several equivalence methods have been proposed [3, 58].

2.2 Embedding Based Kernels

In this work, we study the development of graph kernels, which are functions to compute the pairwise similarity between graphs. Specifically, given two graphs G_1, G_2, a classic example of a kernel defined over graph pairs is the geometric random walk kernel [9] as shown in Eq. 1:

$$k_\times(G_1, G_2) = e^T (I - \lambda A_\times)^{-1} e, \tag{1}$$

where $A_\times$ is the adjacency matrix of the product graph of G_1 and G_2, and λ is a hyper-parameter which encodes the importance of each step in the random walk. We aim to learn an embedding based kernel function $k()$ as a similarity metric for graph pairs, defined as the following:

$$k(G_1, G_2) = ||\Psi(G_1) - \Psi(G_2)||^2 \tag{2}$$

For a dataset of N *source*[1] graphs $\mathcal{S}$ and M *target* graphs ($\mathcal{T}$), for any member of the target graph set we define the i^{th} dimension of the representation $\Psi(G \in \mathcal{T}) \in \mathbb{R}^N$ to be:

$$\Psi(G)_i = \sum_{v_j \in V_T} f_{g_i}(v_j), \tag{3}$$

where $g_i \in \mathcal{S}$ and $f_{g_i}()$ is a predictor of some structural property of the graph G but parameterized by the graph g_i. We note that the source and target graphs sets $(\mathcal{S}, \mathcal{T})$ could be disjoint, overlapping, or equal.

3 LEARNING TO ALIGN GRAPH REPRESENTATIONS

We propose to learn a graph representation by comparing it to a population of graphs. To compare the similarity of a pair of graphs (*source*, *target*), we rely on deep neural networks to measure the divergence between their structure and attributes. First, we learn the structure of the source graph by passing it through a graph encoder. Second, to measure how much the target graph diverges from the source graph, we use the source graph encoder to predict the structure of the target graph. If the pair is similar, we expect the source graph encoder to correctly predict the target graph's structure. In this section, we develop the three key components necessary to learn the similarity between a pair of graphs.

First, in Section 3.1, we discuss encoding graphs. The quality of the graph representation depends on the extent to which the encoder of each source graph is able to discover its structure.

Second, in Section 3.2, we propose a cross-graph attention mechanism to learn a soft alignment between graphs. This is necessary because a target graph may not share its vertex ids with any of the source graphs – indeed, they could even have differing number of nodes! Therefore, we need to learn an alignment between the nodes of the target graph and each source graph. This leads to an alignment that is not necessarily a one-to-one correspondence.

Third, in Section 3.3 we introduce additional constraints on the cross-graph attention learning. For example, let us assume that $v_i \in V_{G_1}$ is assigned to $u_j \in V_{G_2}$. While both v_i and u_j may be structurally similar, they may belong to different node classes as indicated by their attributes. These attributes may be of significant

[1]In this paper, we use source and anchor interchangeably when referring to the encoded graph.

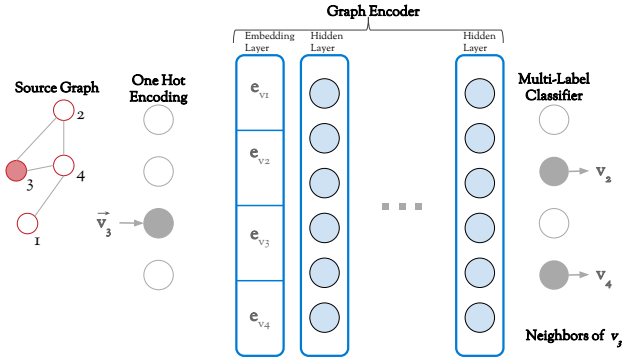

Figure 2: A Node-To-Edges Encoder. Here the input graph contains 4 vertices, and the encoder has to predict the neighbors of vertex v_3. First, v_3 is represented by a one-hot encoding $\vec{v}_3$. Second, $\vec{v}_3$ is multiplied by a linear embedding layer. Third, this embedding $\mathbf{e}_{v_3}$ is passed to a DNN which produces scores for each vertex in V. Finally, these scores are normalized using the *sigmoid* function to produce the final predictions, in this case, $\{v_2, v_4\}$.

importance to the nature of the graph. For instance, swapping one element for another in a graph representing a molecule could drastically change its chemical structure.

We will see how these pairwise alignments can produce divergence scores suitable for Graph Kernels in Section 4.

3.1 Graph Encoding

To learn the structure of a graph, we train an encoder capable of reconstructing such structure given partial or distorted information. In this paper, we choose a *Node-To-Edges* encoder (Figure 2) for its simplicity, but we note that additional choices are certainly possible (see Section 7 for more discussion).

Node-To-Edges Encoder. - In this setup, an encoder is given a single vertex and it is expected to predict its neighbors. This can be modeled as a multilabel classification task since the predictions are not mutually exclusive. Specifically, we are maximizing the following objective function $J(\theta)$,

$$J(\theta) = \sum_i \sum_{\substack{j \\ e_{ij} \in E}} \log \Pr(v_j \mid v_i, \theta). \tag{4}$$

Each vertex v_i in the graph is represented by one-hot encoding vector $\vec{v}_i$. Then to embed the vertex we multiply its encoding vector with a linear layer $\mathbf{E} \in \mathbb{R}^{|V| \times d}$ resulting in an embedded vertex $\mathbf{e}_{v_i} \in \mathbb{R}^d$, where $|V|$ is the number of vertices in the graph, and d is the size of the embedding space.

For graphs with a large number of nodes, we can replace this multiplication with a table lookup, extracting one row from the embedding matrix. This embedding vector represents the feature set given to the encoder tasked with predicting all adjacent vertices. Our encoder H, is implemented as a fully connected deep neural network (DNN) with an output layer of size $|V|$ and trained as a multilabel classifier.

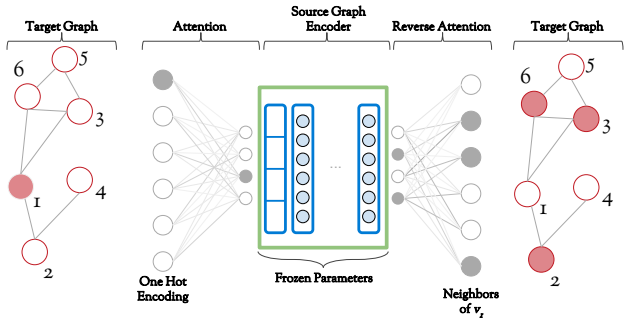

Figure 3: Attention layers mapping the target graph nodes onto the source graph. The augmented encoder has to predict the neighbors of node 1 in the target graph. First, node 1 is passed to the attention layer which assigns it mainly to node 3 of the source graph. Second, the source graph encoder learned earlier (in Figure 2) that the neighbors of node 3 are {2, 4}. Finally, the reverse attention network maps nodes {2, 4} of the source graph to nodes {2, 3, 6} of the target graph which are the neighbors of node 1.

3.2 Cross-Graph Attention

So far, we have developed a utility to encode individual graphs. However, we seek to develop a method which can compare pairs of graphs, which may differ in size (differing node sets) and structure (differing edge sets). For this to happen we need a method of learning an alignment between the graphs. Ideally this method will operate in the absence of a direct mapping between nodes.

In other areas, attention models have been proposed to align structured data. For example, attention models have been proposed to align pairs of images and text [55], pairs of sentences for translation [49], and pairs of speech and transcription [16]. Inspired by these efforts, we formalize the problem of aligning two graphs as that of attention. We propose an attention mechanism, *isomorphism attention*, that aligns the nodes of a target graph against those of a source graph.

3.2.1 Isomorphism Attention. Given two graphs S (*source graph*) and T (*target graph*), we propose a model that allows bi-directional mapping across the pair's nodes. This requires two separate attention networks. The first network allows nodes in the target graph to *attend* to the nodes in the source graph. The second network, allows neighborhood representations in the source graph to *attend* to neighborhoods in the target graph.

We denote the first attention network as ($\mathcal{M}_{T\to S}$), which assigns every node in the target graph ($u_i \in T$) a probability distribution over the nodes of the source graph ($v_j \in S$). This attention network will allow us to pass the nodes of the target graph as an input to the source graph encoder. We implement this attention network using a multiclass classifier,

$$\Pr(v_j \mid u_i) = \frac{e^{\mathcal{M}_{T\to S}(v_j, u_i)}}{\sum_{v_k \in V_S} e^{\mathcal{M}_{T\to S}(v_k, u_i)}}. \tag{5}$$

The second network is a *reverse attention* network ($\mathcal{M}_{S\to T}$) which aims to learn how to map a neighborhood's representation in the source graph to a neighborhood in the target graph. By adding both attention networks to the source graph encoder, we will be able to construct a target graph encoder that is able to predict the neighbors of each node – but utilizing the structure of the source graph. We implement the reverse attention as a multilabel classifier,

$$\Pr(u_j \mid \mathcal{N}(v_i)) = \frac{1}{1 + e^{-\mathcal{M}_{S\to T}(u_j, \mathcal{N}(v_i))}}. \tag{6}$$

Figure 3 shows the attention network ($\mathcal{M}_{T\to S}$) receiving a one-hot encoding vector representing a node (u_i) in the target graph and mapping it onto the most structurally similar node (v_j) from the source graph. The source graph encoder, then, predicts the neighbors of v_j, $\mathcal{N}(v_j)$. The *reverse attention* network ($\mathcal{M}_{S\to T}$), takes $\mathcal{N}(v_j)$ and maps them to the neighbors of u_i, $\mathcal{N}(u_i)$.

Both attention networks may be implemented as linear transformations $\mathbf{W}_A \in \mathbb{R}^{|V_Q|\times|V_P|}$. In the case that either $|V_P|$ or $|V_Q|$ are prohibitively large, the attention network parameters can be decreased by substituting a DNN with hidden layers of fixed size. This will reduce the attention network size from $\Theta(|V_P| \times |V_Q|)$ to $\Theta(|V_P| + |V_Q|)$.

3.3 Attributes Consistency

Labeled graphs are not defined only by their structures, but also by the attributes of their nodes and edges. The attention network assigns each node in the target graph a probability distribution over the nodes of the source graph. There might be several, equally good, nodes in the source graph with similar structural features. However, these nodes may differ in their attributes. To learn an alignment that preserves nodes and edges attributes, we add regularizing losses to the attention and reverse-attention networks.

More specifically, we refer to the nodes as v and u for the source and target graphs, respectively. We refer to the set of attributes as $\mathcal{Y}$ and the distribution of attributes over the graph nodes as ($Q_n = \Pr(y_i \mid u)$). Given that the attention network $\mathcal{M}_{T\to S}$ learns the distribution $\Pr(u_k \mid v_j)$, we can calculate a probability distribution over the attributes as inferred by the attention process as the following:

$$Q_n(y_i|u_j) = \sum_k \mathcal{M}_{T\to S}(y_i|v_k) \Pr(v_k \mid u_j). \tag{7}$$

We define, the attention regularizing loss over the nodes attributes to be the average cross entropy loss between the observed distribution of attributes and the inferred one (See Eq. 8).

$$L = \frac{1}{|V_T|} \sum_j^{|V_T|} \sum_i \Pr(y_i \mid u_j) \log(Q_n(y_i|u_j)), \tag{8}$$

where $|V_T|$ is the number of nodes in the target graph.

For preserving edge attributes over nodes, we define $Q_e(y_i \mid u) = \Pr(y_i \mid u)$ to be the normalized attributes count over all edges connected to the node u. For instance, if a node u has 5 edges with 2 of them colored red and the other three colored yellow, $Q_e(red \mid u) = 0.4$ By replacing Q_n with Q_e in Equations 7 and 8, we create a regularization loss for edge attributes.

We also introduce these regularization losses for *reverse attention* networks. Reverse attention networks maps a neighborhood in the source graph to a neighborhood in the target graph. The distribution of attributes over a node's neighborhood will be the frequency of

each attribute occurrence in the neighborhood normalized by the number of attributes appearing in the neighborhood. For edges, the node's neighborhood edges are the edges appearing at 2-hops distance from the node. Similarly, we can define the probability of the edges attributes by normalizing their frequencies over the total number of attributes of edges connected to the neighborhood.

4 DEEP DIVERGENCE GRAPH KERNELS

So far, we have proposed a method for learning representations of graphs, and an attention mechanism for aligning graphs based on a set of encoded graph representations. Here we discuss our proposed method for using the alignment to construct a graph kernel based on divergence scores. First, in Section 4.1, we show how we can utilize the divergence scores to construct a full graph representation. Divergence is driven by the target graph structure and attribute prediction error as calculated using a source graph encoder. Next we introduce DDGK, our method for learning graph representations for Deep Divergence Graph Kernels in Section 4.3. Then in Section 4.4 we discuss how we train these representations. Finally we discuss the scalability of this approach in Section 4.5.

4.1 Graph Divergence

In Section 3 we presented a method to align two graphs by using a source graph encoder, augmented with attention layers, to encode a target graph. Here, we propose to use the ability of the augmented encoder at predicting the structure of the target graph as a measure of those graphs similarity. To explain, let us assume the trivial case where both the source and target graphs are identical. First, we train the source graph encoder. Second, we augment it with attention networks and train it to predict the structure of the target graph. The attention networks will (ideally) learn the identity function. Therefore, the source graph encoder is able to encode the target graph as accurately as encoding itself. We would reasonably conclude that these graphs are similar.

We aim to learn a metric that measures the divergence score between a pair of graphs $\{S, T\}$. If two graphs are similar, we expect their divergence to be correspondingly low. We refer to the encoder trained on a graph S as H_S and the divergence score given to the target graph T to be

$$\mathcal{D}'(T \parallel S) = \sum_{v_i \in V_T} \sum_{\substack{j \\ e_{ji} \in E_T}} -\log \Pr(v_j \mid v_i, H_S) \tag{9}$$

Given that H_S is not a perfect predictor of the graph S structure, we can safely assume that $\mathcal{D}'(S \parallel S) \neq 0$. To rectify this problem we define

$$\mathcal{D}(S \parallel T) = \mathcal{D}'(S \parallel T) - \mathcal{D}'(S \parallel S), \tag{10}$$

which sets $\mathcal{D}(S \parallel S)$ to zero.

We note that this definition is not symmetric (as $\mathcal{D}(T \parallel S)$ might not necessarily equal to $\mathcal{D}(S \parallel T)$). If symmetry is required, we can define $\mathcal{D}(S, T) = \mathcal{D}(S \parallel T) + \mathcal{D}(T \parallel S)$.

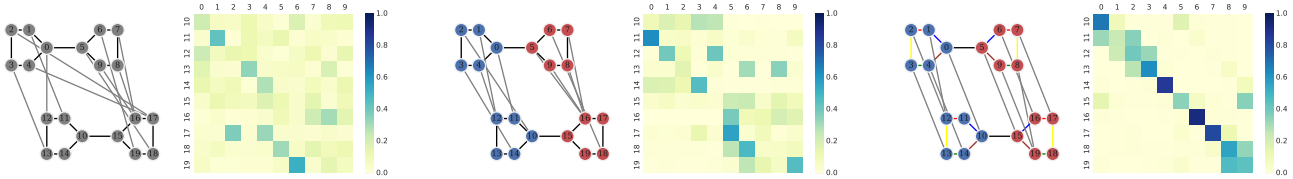
4.2 Graph Embedding

Given a set of source graphs, we can establish a vector space where each dimension corresponds to one graph in the source set. Target graphs are represented as points in this vector space where the value of the i_{th} dimension for a given target graph T_j is $\mathcal{D}(T_j \parallel S_i)$.

More formally, for a set of N source graphs we can define our target graph representation to be:

$$\Psi(G_T) = [\mathcal{D}(T \parallel S_0), \mathcal{D}(T \parallel S_1), \ldots, \mathcal{D}(T \parallel S_N)] \tag{11}$$

To create a kernel out of our graph embeddings, we use the Euclidean distance measure as outlined in Eq 2. This distance measure will guarantee a positive definite kernel [25, 54].



input : Set of N source graphs $\mathcal{S}$
Set of M target graphs $\mathcal{T}$

Algorithm 1: DDGK: An unsupervised algorithm for learning graph representations.

4.3 Algorithm : DDGK

We present pseudo-code for DDGK in Algorithm 1. The algorithm has two parts. First, a *Node-To-Edges* encoder is trained for all source graphs (Algorithm 1 line 5 and line 6). Second, cross-graph attentions are learned for all target-source graph pairs (Algorithm 1 line 15, line 16 and line 17). We implement DDGK using a deep neural network for its *Node-To-Edges* encoder and linear transformations for its isomorphism attention.

(a) No attributes. (b) Labeled nodes. (c) Labeled nodes and edges.

Figure 4: The effect of attributes preserving losses on the attention networks. Our method is given a pair of identical graphs, the upper graph represents the target and the other represents the source graph. Each graph consists of two rings of size 5 connected with one edge ((0, 5) and (10, 15) respectively). We visualize the strongest attention weights as cross-graph edges. On the right of each figure we visualize the rest of the attention weights as a heatmap. When the graph attends to itself without attribute preserving losses, there are several solutions that are equally good because of several symmetries available. Once we add the nodes attributes, we can see an immediate effect where the nodes from the same label class attend only to each other. This behavior further intensifies after also adding the edge attributes.

4.4 Training

We implement our models using TensorFlow [44], calculate our gradients using backpropagation, and update our parameters using Adam [29]. We train each source graph on its adjacency matrix for a constant number of iterations.

4.4.1 Target Graph Encoding. Here, the augmented encoder has to predict the neighboring vertices for each vertex in the target graph with the help of the attention and reverse-attention layers. To learn the augmented target graph encoder (which consists of the source graph encoder with the additional attention layers), we use the following procedure:

(1) First, freeze the parameters of the source graph encoder.
(2) Second, add two additional networks, one for attention and another for reverse attention mapping between the target graph nodes to the source graph nodes and vice versa.
(3) Third, add the regularizing losses to preserve the nodes or edges attributes if they are available.
(4) Fourth, train the augmented encoder on the input, which is the adjacency matrix of the target graph, and a node attribute and/or edge attribute matrix (if available).

Finally, once the training of the attention layers is done, we use the augmented encoder to compute the divergence between the graph pair as discussed in 4.1.

4.5 Scalability

We start by defining the following quantities: N the number of source graphs in the dataset, M the number of target graphs in the dataset, V the average number of nodes, τ the number of epochs to encode source graphs, ρ the number of epochs to encode target graphs, l the number of encoder hidden layers, m the number of attention hidden layers, and d the embedding and hidden layer size

Our method relies on pairwise similarity, therefore, we will have $M \times N$ computations that each involves scoring a target graph against one source graph. Training a source graph encoder requires τ steps that each involves $2\times V\times d+l\times d^2$ computations. In addition to running the source graph encoder, the target graph alignment learns the attention networks which represents $\rho\times(2\times d\times V+m\times d^2)$. If we define $T = max(\rho, \tau)$, $k = max(l, m)$, and $M = N$ then the total computation cost is $\Theta(N^2 \times T \times (V \times d + k \times d^2)$. Because V is likely much larger than d^2, we interpret the computational complexity as $O(TN^2V)$.

In Section 5.4, we explore the effect of sampling to hasten DDGK's runtime on large datasets. We show that not all $M \times N$ comparisons are necessary to achieve high performance: empirically, it seems that less than 20% of source graphs are required, significantly speeding our approach.

5 EXPERIMENTS

In this section, we demonstrate our method through a series of qualitative and quantitative experiments. First, we show how our attention based alignment works under different conditions. Then, we show how our representations are capable of capturing the structure of the space of graphs by applying hierarchical clustering on the kernel space. Finally, we show that the learned graph embeddings represent a sufficient feature set to predict the graph label on several challenging classification problems in real-world biological datasets.

5.1 Cross-Graph Attention

In this qualitative experiment, we seek to understand how two graphs are related to each other. Comparing different patterns between different graphs is an important application in domains such as biology.

Figure 4a shows two identical unlabeled barbell graphs. Each graph consists of two rings of size 5 connected with the edge (0, 5) and (10, 15). The upper graph represents the target graph while the lower one represents the source graph. The edges connecting the source and target graphs represent the strongest attention weights for each node in the target graph. The heatmap shows the full attention matrix for more thorough analysis. Aligning these identical graphs is an easy task for the naked eye. However, our method can find many possible symmetries to exploit while still achieving perfect predictions. For example, nodes in the left ring can attend to the right ring of the source graph and vice versa.

Figure 4b shows the previous setup with labeled graph nodes. This introduces a regularizing loss to preserve the node attributes. The attention heat map shows significant weights for the upper

left and lower rights quadrants. The right ring does not attend to nodes in the left ring anymore, and vice versa. Still we can see the method exploiting symmetries within the same ring.

Finally, by also adding edge labels, the alignment problem is constrained enough that the attention heatmap is concentrated along the diagonal (See Figure 4c). We can observe that the attention edges correspond in a one-to-one relationship between the target and source graphs. This synthetic experiment shows the effect of attribute preserving losses on learning the alignment between graphs.

5.2 Hierarchical Clustering

To understand the global structure of the graph embedding space, we explore it qualitatively using hierarchical clustering. First, we create a dataset which is a composition of 6 different families of graphs. Three graph families are mutated graphs and three families are subset of a larger set of realistic graphs. From each family we sample 5 graphs, creating a universe of 30 graphs. Then, we embed the graphs using our method constructing a graph embedding space. Finally, we cluster the embeddings according to their pairwise euclidean distances.

5.2.1 Mutated Graphs. For these datasets we start with a known graph and generate a sequence of mutations to produce a family of graphs. In particular, we consider the following graphs.

- C. Elegans [53]: represents the neural network of the C. Elegans worm.
- Karate Club [60]: social network of friendships between 34 members of a karate club.
- Word Network [35]: adjacency network of common adjectives and nouns in the novel David Copperfield by Charles Dickens.

In order to generate a family $G_1 \cdots G_k$ for each original graph G_0, we employ the following mutation procedure. At each of the k time steps, there is a $p = 0.5$ chance of performing an edge deletion or addition. For additions, we select the two nodes to connect from any unlinked nodes according to the preferential attachment model characterized by G_0 [17]. For deletions, we select an edge at random and remove it. We run this procedure for 4 times with $k = 50$ time steps, creating a family of 5 related graphs. The initial seed for any of these mutations is denoted by the suffix "-0".

5.2.2 Realistic Graphs. We randomly pick 5 graphs from three of the real-world families of graphs we consider (**D&D**, **PTC**, and **NCI1**). See Section 5.3.2 for more information about these graphs.

Figure 5 shows the result of clustering the pairwise distances between our graph embeddings. We are able to retrieve perfect clusters of {`c-elegans`, `words`} where there are clusters of size of 5 that consist only of graphs of the same type. For {**NCI1**, **D&D**}, we can cluster 4 graphs out of 5 before adding a graph which is out of the family.

5.3 Graph Classification

Our learned graph representations respect both attributes and structure. They can be used for graph classification tasks where the graph structure, node attributes, and/or edge attributes convey meaning or function. To demonstrate this, we use DDGK representations of several chemo- and bio- informatics datasets as features for classification tasks. We report our results against both unsupervised and supervised methods.

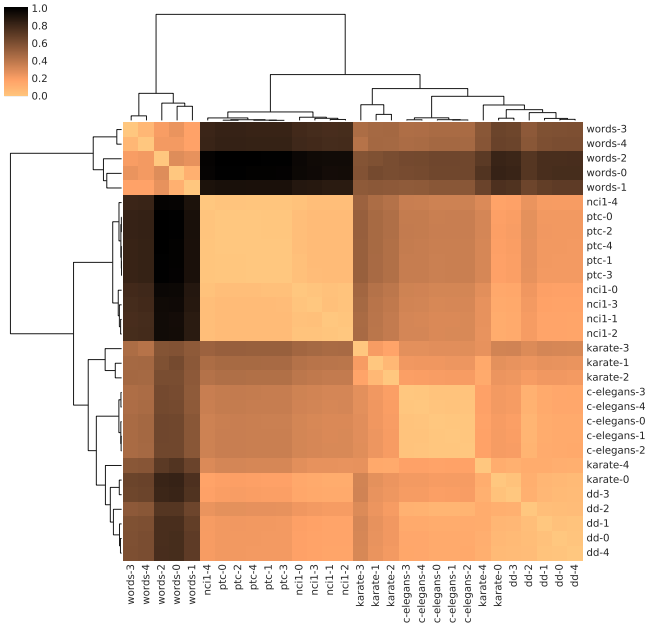

Figure 5: A hierarchical clustering of the graph kernel space for several different graph families. It shows 30 graphs that belong to 6 different families. The values of the matrix are the pairwise Euclidean distances between the graph embeddings.

Hyper-Parameter	Values
Node embedding	2, 4, 8, 16, 32
Encoder layers	1, 2, 3, 4
Learning rate	10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}, 1
Encoding epochs	100, 300, 600
Scoring epochs	100, 300, 600
Node preserving loss coefficient	0, 0.25, 0.5, 1.0, 1.5, 2.0
Edge preserving loss coefficient	0, 0.25, 0.5, 1.0, 1.5, 2.0

Table 1: Values used during our grid search for DDGK graph representations learning hyper-parameters.

5.3.1 Hyper-parameters Search. To choose DDGK hyperparameters (See Table 1), we perform grid searches for each dataset. We create splits of each dataset to avoid over-fitting, they are: {`train`, `dev`, `test`}. We use the scikit-learn SVM [39] as our classifier, and we vary the kernel choices between {`linear`, `rbf`, `poly`, `sigmoid`} and the regularization coefficient C between 10 and 10^9. We choose the hyper-parameters of both DDGK and the classifier that maximize the accuracy on the `dev` dataset.

	# Graphs	Average Nodes	Average Edges	# Labels	# Node Labels	# Edge Labels
D&D	1178	284	716	2	89	–
NCI1	4110	30	32	2	37	–
PTC	344	14	15	2	18	4
MUTAG	188	18	20	2	7	4

Table 2: Statistics of the chemo- and bio-informatics datasets.

5.3.2 Datasets. Four benchmark graph classification datasets from chemo- and bio-informatics domains are used. The datasets include **D&D**, **NCI1**, **PTC** and **MUTAG**. All datasets include node labels. The **PTC** and **MUTAG** datasets also include edge labels. Table 2 shows network statistics for each dataset. The datasets:

- **D&D** [20]: contains 1178 proteins labeled as enzymes or non-enzymes.
- **NCI1** [51]: contains 4110 chemical compounds labeled as active or inactive against non-small cell lung cancer.
- **PTC** [46]: contains 344 chemical compounds labeled according to their carcinogenicity in male rats.
- **MUTAG** [19]: contains 188 mutagenic aromatic and heteroaromatic compounds labeled according to their mutagenic effect on a specific gram negative bacterium.

5.3.3 Results. The results of these experiments are presented in Table 3. We see that DDGK is quite competitive, with higher average performance on both the **D&D** and **MUTAG** datasets than any of the baselines. This is especially surprising given that the supervised methods have additional information available to them. We note that DDGK achieves its strong results without engineered features, or access to information from Weisfeiler-Lehman kernels. For **PTC**, we also see that DDGK attains competitive performance against all other methods, only being outperformed by 2 of the 9 baselines. Finally, on **NCI1**, we see that DDGK performs better than the method using the most similar kind of information (`node2vec`), but find that baselines using the WL kernel perform best on this dataset (indeed, the WL kernel itself takes the top two spots). We find this dependence quite interesting, and will seek to characterize it better in future work.

5.4 Dimension Sampling

So far, we have been setting the source graphs set to be equal to the target graphs set. This pairwise computation is quite expensive for large datasets. To reduce the computational complexity of our method, we study the effect of sub-sampling the dimensions of our graph embedding space on the quality of graph classification.

To do that, we construct a source graph set that is a subset of the original graph set. We learn divergence scores for all target graphs against this subset. We use the reduced embeddings as features to predict graph categories. Figure 6 shows that we are able to achieve stable and competitive results with less than 20% of the graphs being used as source graphs.

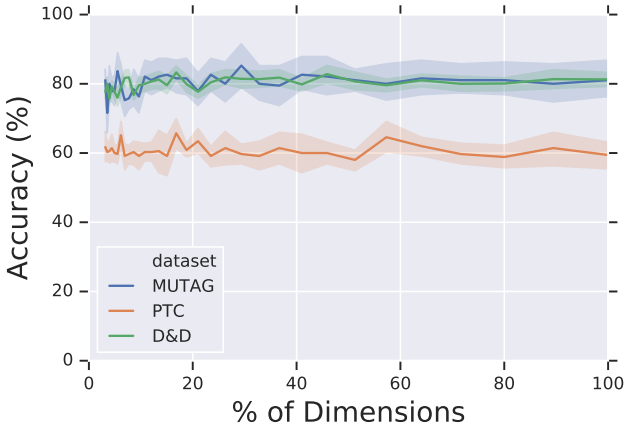

Figure 6: Effect of sub-sampling source graphs on graph classification tasks. Here we vary the number of source graphs available to each method, and observe that very few dimensions are needed to achieve our final classification performance (less than $< 20\%$ of the dimensions for the datasets considered).

6 RELATED WORK

The main differences between our proposed method and previous work can be summarized as follows:

(1) We are an unsupervised method, taking only a graph as input.
(2) We use no domain-specific information about what primitives are important in a graph, using only the edges.
(3) We use no algorithmic insights from the literature in graph isomorphism (e.g. the Weisfeiler-Lehman kernel).
(4) We assume nothing about the mapping of node ids between graphs, instead learning the alignment.

While many approaches exist that contain at least one of these differentiators, we are, to the best of our knowledge, the only proposed method that meets all four of these conditions. In this section we will briefly cover related work in graph similarity and other applications of neural networks to graph representation.

6.1 Unsupervised Graph Similarity

We divide our brief survey of the literature into three kinds of unsupervised methods for graph similarity. The first seeks to explicitly define a kernel over graph features, or use the intuition from such a kernel as part of the representation learning process. The second focuses on the representation of individual elements of the graph, learning primitives that maximize some kind of reconstruction of the graph. The third group of work constructs a similarity function between graphs by an explicit vector of statistical features constructed by the graph.

Traditional Graph Kernels: There has been considerable work done on unsupervised methods for graph kernel learning. Initial efforts in the area focused on theoretical views of the problem, defining graph similarity via the Graph Edit Distance [22] or the size of the Maximum Common Subgraph [11] between graphs.

Method		Unsupervised	No Weisfeiler-Lehman	No Feature Engineering	D&D	NCI1	PTC	MUTAG
PSCN	[36]				76.27 ± 2.64	76.34 ± 1.68	62.29 ± 5.68	88.95 ± 4.37

Table 3: Average accuracy in ten-fold cross validation on our graph classification task. Methods are grouped by their level of supervision during the similarity metric learning, whether they use algorithm insights the Weisfeiler-Lehman algorithm, and whether they use feature engineering (e.g. graph motifs, random walks, etc.). Baseline results taken from [32, 36, 43] (missing results are missing from these works). We note that DDGK performs surprisingly competitively for an unsupervised method with no hard-coded insights.

Unfortunately these problems are both NP-Complete in the general case, require a known correspondence between the nodes of the two graphs of interest.

Many approaches are built around the graph similarity measure computed by the Weisfeiler-Lehman (WL) subtree graph kernel [32, 42]. At its core, the WL algorithm collapses the labels of a node's neighbors into a ordered sequence, and then hashes that sequence into a new label for the node. This process repeats iteratively to average information over the neighborhood together. Other functions that use different types of predefined features for graph similarity, such as shortest-paths kernels [8], and random walk kernels [28] have also been proposed, but their naive implementations suffer from high asymptotic complexity ($O(n^4)$ and $O(n^6)$, respectively). Faster implementations of these kernels have been proposed [10, 27]. Some unsupervised methods also focus on extending the algorithm intuition of these classic approaches to the problem. For instance [43] learns a representation for each position in a WL ordering jointly while learning a graph representation.

Unlike all of these approaches, our method deliberately avoids algorithmic insights. Our proposed isomorphism attention mechanism allows capturing higher-order structure between graphs (beyond immediate neighborhoods).

Node embedding methods: Since DeepWalk [40] proposed embedding the nodes via a sequence of random walks, the problem of node representation learning has received considerable attention [2, 7, 15, 21, 24, 41, 48]. In general, all of these methods utilize insights about similarity functions which are important to the graph. While these methods seek the best way to represent nodes, the representations are learned independently between graphs, which makes them generally unsuitable for graph similarity computations. For more information on this area, we recommend recent surveys in the area [14, 18]. Unlike these methods, our goal is to learn representations of graphs, not of nodes.

Graph statistics: Finally, another family of unsupervised graph similarity measures define a hand-engineered feature vector to compute graph similarity. The NetSmilie method [6] operates by constructing a fixed size feature value of graph statistics and uses this as a similarity embedding over graphs. Similarly, DetlaCon [31] defines the similarity over two graphs with known node-to-node mapping via the similarity in their propagation of belief, and [38] proposes a number of similarity measures over directed web graphs.

Unlike these methods, DDGK does not explicitly engineer its features for the problem. Instead, the similarity is learned function directly from the edges present in the adjacency matrix, with no assumptions about which features are important for the application task.

6.2 Supervised Graph Similarity

The first class of supervised methods uses some supervision to inform a similarity function constructed over different hand-engineered graph features.

A number of supervised approaches also utilize intuitions from the Weisfeiler-Lehman graph kernel. `Patchy-SAN` [37] proposes an approach for convolutional operations on graph structured data. The core of their method uses the ordering from the WL kernel to order the nodes of a rooted subgraph into a sequence, and then apply standard 1-dimensional convolutional filters. This approach is further generalized by [61], who use the WL ordering to sort a graph sample in a pooling layer. Another branch of work has focused on extending the Graph Convolutional Networks (GCNs) proposed by [30] to perform supervised classification of graphs. Proposed extensions include a pooling architecture that learns a soft clustering of the graph [59], or a two-tower model which frames graph similarity as link prediction between GCN representations [4]. Interestingly, it has been shown that many of these methods

are not necessarily more expressive than the original Weisfeiler-Lehman subtree kernel itself [33].

Unlike all of these approaches, our method learns representations of graphs without supervision — we use no labels about the class label of a graph, and no external information about which pairs of graphs are related. Our proposed isomorphism attention mechanism allows capturing higher-order structure between graphs (beyond immediate neighborhoods).

7 EXTENSIONS & FUTURE WORK

Here we briefly discuss a number of areas of future investigation for our method.

7.1 Graph Encoders

Given the choice of input and reconstructed output, several additional graph encoders are possible, in addition to the Nodes-To-Edges encoder which we used in this work. To mention a few options:

Edge-To-Nodes Encoder. - This encoder is trained to predict the source and destination vertices given a specific edge. Similar to the *Node-To-Edges* encoder, this could be expressed as a multilabel classification task with the following objective function,

$$J(\theta) = \sum_{e_{ij} \in E} \log \Pr(v_i \mid e_{ij}, \theta) + \log \Pr(v_j \mid e_{ij}, \theta) \tag{12}$$

Note that the number of edges in a graph could grow quadratically, therefore, iterating over the edges is more expensive than the nodes.

Neighborhood Encoder. - In this case, the encoder is trained to predict a set of vertices or edges that are beyond the immediate neighbors. Random walks could serve as a mechanism to calculate a neighborhood around a specific node or edge. Given a partial random walk, the encoder has to predict the vertices that could have been visited within a specific number of hops.

$$J(\theta) = \sum_{\substack{(v_1, v_2, \cdots, v_i) \\ \sim RandomWalk(G,E,V)}} \log \Pr\Big(v_j \mid (v_1, v_2, \cdots, v_i, \theta)\Big) \tag{13}$$

7.2 Attention Mechanism

We proposed a simple attention mechanism which uses node-to-node alignment. As we discussed in Section 4.5, we could replace the linear layer with a deep neural network to reduce the size of the model if scability is an issue. While node-to-node alignment enhances the interpretability of our models, subgraph alignment could lead to better and easier understanding of how two graphs are similar. Hierarchical attention models [57] could lead to higher levels of abstractions which could learn community structure and which communities are similar across a pair of graphs. Hierarchy has already been used within the context of learning better node embeddings, for example [59] showed that a better understanding of the graph substructure can lead to better graph classification. Therefore, we believe extending the work beyond node-to-node alignment will significantly improve our results.

7.3 Regularization

We proposed attribute based losses to regularize our isomorphism attention mechanism. The graph encoder capacity was adjusted according to the source graph size. However, the source graph encoder could still suffer from overfitting which would reduce its utility in recognizing similar target graphs. Therefore, further research is necessary to understand the relation between the encoder training characteristics and the quality of the generated divergence scores

7.4 Feature Engineering

In this work we have focused on developing an approach for representing graphs that operated without any feature engineering or algorithmic insights. While this willful ignorance has allowed us to design a new paradigm for graph similarity, we suspect that there are many fruitful combinations of this idea with other approaches for graph classification. For example, the graph embeddings we learn could be used as additional features for approaches based on learning supervised classifiers over graphs.

8 CONCLUSION

In this work, we have shown that neural networks can learn powerful representations of graphs without explicit feature engineering. Our proposed method, Deep Divergence Graph Kernels, learns an encoder for each graph to capture its structure, and uses a novel *isomorphism preserving attention mechanism* to align node representations across graphs without the use of supervision. We show that representing graphs by their divergence from different source graphs provides a powerful embedding space over families of graphs. Our proposed model is both flexible and amenable to extensions. We illustrate this by proposing extensions to handle many commonly occurring varieties of graphs, including graphs with attributed nodes, and graphs with attributed edges.

Our experimental analysis shows that despite being trained with only the graph's edges (and no feature engineering) the learned representations encode a variety of local and global information. When the representations produced by DDGK are used as features for graph classification methods, we find them to be competitive with challenging baselines which use at least one of graph labels, engineered features, or the Weisfeiler-Lehman framework. In addition to being powerful, DDGK models are incredibly informative. The learned isomorphism attention weights allow a level of insight into the alignment between a pair of graphs, which is not possible with other deep learning methods developed for graph similarity.

Unsupervised representation learning for graphs is an important problem, and we believe that the method of Deep Divergence Graph Kernels we have introduced here is an exciting step forward in this area. As future work, we will investigate 1) enhanced method for choosing informative source from the space of all graphs, 2) improving the architecture of our encoders and attention models, 3.) making it easier to reproduce research results in the area of graph similarity, and 4) making graph similarity models even easier to understand.

ABSTRACT

With the ever-increasing cases of hate spread on social media platforms, it is critical to design abuse detection mechanisms to proactively avoid and control such incidents. While there exist methods for hate speech detection, they stereotype words and hence suffer from inherently biased training. Bias removal has been traditionally studied for structured datasets, but we aim at bias mitigation from unstructured text data.

In this paper, we make two important contributions. First, we systematically design methods to quantify the bias for any model and propose algorithms for identifying the set of words which the model stereotypes. Second, we propose novel methods leveraging knowledge-based generalizations for bias-free learning.

Knowledge-based generalization provides an effective way to encode knowledge because the abstraction they provide not only generalizes content but also facilitates retraction of information from the hate speech detection classifier, thereby reducing the imbalance. We experiment with multiple knowledge generalization policies and analyze their effect on general performance and in mitigating bias. Our experiments with two real-world datasets, a Wikipedia Talk Pages dataset (WikiDetox) of size ~96k and a Twitter dataset of size ~24k, show that the use of knowledge-based generalizations results in better performance by forcing the classifier to learn from generalized content. Our methods utilize existing knowledge-bases and can easily be extended to other tasks.

1 INTRODUCTION

With the massive increase in user-generated content online, there has also been an increase in automated systems for a large variety of prediction tasks. While such systems report high accuracy on collected data used for testing them, many times such data suffers from multiple types of unintended biases. A popular unintended bias, stereotypical bias (SB), can be based on typical perspectives like skin tone, gender, race, demography, disability, Arab-Muslim background, etc. or can be complicated combinations of these as well as other confounding factors. Not being able to build unbiased prediction systems can lead to low-quality unfair results for victim communities. Since many of such prediction systems are critical in real-life decision making, this unfairness can propagate into government/organizational policy making and general societal perceptions about members of the victim communities [13].

In this paper, we focus on the problem of detecting and removing such bias for the hate speech detection task. With the massive increase in social interactions online, there has also been an increase in hateful activities. Hateful content refers to "posts" that contain abusive speech targeting individuals (cyber-bullying, a politician, a celebrity, a product) or particular groups (a country, LGBT, a religion, gender, an organization, etc.). Detecting such hateful speech is important for discouraging such wrongful activities. While there have been systems for hate speech detection [1, 9, 16, 21], they do not explicitly handle unintended bias.

*Author is also a Principal Applied Researcher at Microsoft. (gmanish@microsoft.com)

We address a very practical issue in short text classification: that the mere presence of a word may (sometimes incorrectly) determine the predicted label. We thus propose methods to identify if the model suffers from such an issue and thus provide techniques to reduce the undue influence of certain keywords.

Acknowledging the importance of hate speech detection, Google launched Perspective API [1] in 2017. Table 1 shows examples of sentences that get incorrectly labeled by the API (as on 15^{th} Aug 2018). We believe that for many of these examples, a significant reason for the errors is bias in training data. Besides this API, we show examples of stereotypical bias from our datasets in Table 2.

Traditionally bias in datasets has been studied from a perspective of detecting and handling imbalance, selection bias, capture bias, and negative set bias [14]. In this paper, we discuss the removal of stereotypical bias. While there have been efforts on identifying a broad range of unintended biases in the research and practices around social data [18], there is hardly any rigorous work on principled detection and removal of such bias. One widely used technique for bias removal is sampling, but it is challenging to obtain instances with desired labels, especially positive labels, that help in bias removal. These techniques are also prone to sneak in further bias due to sample addition. To address such drawbacks, we design *automated* techniques for bias detection, and *knowledge-based generalization* techniques for bias removal with a focus on hate speech detection.

Enormous amounts of user-generated content is a boon for learning robust prediction models. However, since stereotypical bias is highly prevalent in user-generated data, prediction models implicitly suffer from such bias [5]. To de-bias the training data, we propose a two-stage method: Detection and Replacement. In the first stage (Detection), we propose skewed prediction probability and class distribution imbalance based novel heuristics for bias sensitive word (BSW) detection. Further, in the second stage (Replacement), we present novel bias removal strategies leveraging knowledge-based generalizations. These include replacing BSWs with generalizations like their Part-of-Speech (POS) tags, Named Entity tags, WordNet [17] based linguistic equivalents, and word embedding based generalizations.

We experiment with two real-world datasets – WikiDetox and Twitter of sizes ~96K and ~24K respectively. The goal of the experiments is to explore the trade-off between hate speech detection accuracy and stereotypical bias mitigation for various combinations of detection and replacement strategies. Since the task is hardly studied, we evaluate using an existing metric Pinned AUC, and also propose a novel metric called PB (Pinned Bias). Our experiments show that the proposed methods result into proportional reduction in bias with an increase in the degree of generalization, without any significant loss in hate speech detection task performance.

In this paper, we make the following important contributions.

- We design a principled two-stage framework for stereotypical bias mitigation for hate speech detection task.
- We propose novel bias sensitive word (BSW) detection strategies, as well as multiple BSW replacement strategies and show improved performance on existing metrics.
- We propose a novel metric called PB (Pinned Bias) that is easier to compute and is effective.
- We perform experiments on two large real-world datasets to show the efficacy of the proposed framework.

The remainder of the paper is organized as follows. In Section 2, we discuss related work in the area of bias mitigation for both structured and unstructured data. In Section 3, we discuss a few definitions and formalize the problem definition. We present the two-stage framework in Section 4. We present experimental results and analysis in Section 5. Finally, we conclude with a brief summary in Section 6.

2 RELATED WORK

Traditionally bias in datasets has been studied from a perspective of detecting and handling imbalance, selection bias, capture bias, and negative set bias [14]. In this paper, we discuss the removal of stereotypical bias.

2.1 Handling Bias for Structured Data

These bias mitigation models require structured data with bias sensitive attributes ("protected attributes") explicitly known. While there have been efforts on identifying a broad range of unintended biases in the research and practices around social data [18], only recently some research work has been done about bias detection and mitigation in the fairness, accountability, and transparency in machine learning (FAT-ML) community. While most of the papers in the community relate to establishing the existence of bias [3, 20], some of these papers provide bias mitigation strategies by altering training data [10], trained models [12], or embeddings [2]. Kleinberg et al. [15] and Friedler et al. [11] both compare several different fairness metrics for structured data. Unlike this line of work, our work is focused on unstructured data. In particular, we deal with the bias for the hate speech detection task.

2.2 Handling Bias for Unstructured Data

Little prior work exists on fairness for text classification tasks. Blodgett and O'Connor [3], Hovy and Spruit [13] and Tatman [20] discuss the impact of using unfair natural language processing models for real-world tasks, but do not provide mitigation strategies. Bolukbasi et al. [4] demonstrate gender bias in word embeddings and provide a technique to "de-bias" them, allowing these more fair embeddings to be used for any text-based task. But they tackle only gender-based stereotypes while we perform a very generic handling of various stereotypes.

There is hardly any rigorous work on principled detection and removal of stereotypical bias from text data. Dixon et al.'s work [8] is most closely related to our efforts. They handle stereotypical bias using a dictionary of hand-curated biased words, which is not generalizable and scalable. Also, one popular method for bias correction is data augmentation. But it is challenging to obtain instances which help in bias removal, and which do not sneak in further bias. To address such drawbacks, we design *automated* techniques for bias detection, and *knowledge-based generalization* techniques for bias removal with a focus on hate speech detection.

[1] https://www.perspectiveapi.com/

Sample	Classification prob. (Prediction)	Inference
kat is a woman alice is a woman	0.63 (Hateful) 0.23 (Neutral)	Replacing the name from Kat to Alice should not have resulted in such a difference in prediction probability.
that's just fucking great, man. that's just sad man. shit, that's just sad man.	0.80 (Hateful) 0.24 (Neutral) 0.85 (Hateful)	Use of the word "fucking" somehow makes the sentence hateful. Similarly, use of the word "shit" abruptly increases the hate probability.
rt @ABC: @DEF @GHI @JKL i don't want to fit anything into their little boxes ...	0.80 (Hateful)	In the training dataset, the word "@ABC" is mentioned in 17 tweets of which 13 (76%) are "Hateful". Hence, the classifier associates @ABC with "Hateful"
my house is dirty i gotta go damn, my house is dirty. i gotta go and clean it	0.86 (Hateful) 0.71 (Hateful) 0.99 (Hateful)	The words "dirty" and "gotta" are present heavily in instances labeled as hateful in the training dataset. This resulted in the classifier learning to wrongfully infer the sentence as being hateful.

Table 2: Examples of Incorrect Predictions from our Datasets described in Section 5.1

3 PROBLEM FORMULATION

In this section, we present a few definitions and formulate a formal problem statement.

3.1 Preliminary Definitions

We start by presenting definitions of a few terms relevant to this study in the context of hate speech detection task.

Definition 3.1. Hate Speech: Hate speech is speech that attacks a person or group on the basis of attributes such as race, religion, ethnic origin, national origin, sex, disability, sexual orientation, or gender identity. Its not the same as using certain profane words in text. A sentence can use profane words and still might not be hate speech. Eg, *Oh shit! I forgot to call him*

Definition 3.2. Hate Speech Detection: Hate Speech Detection is a classification task where a classifier is first trained using labeled text data to classify test instances into one of the two classes: Hateful or Neutral.

Definition 3.3. Stereotypical Bias (SB): In social psychology, a stereotype is an over-generalized belief about a particular category of people. However, in the context of hate speech detection, we define SB as an over-generalized belief about a word being Hateful or Neutral.

For example, as shown in Table 2, "kat" and "@ABC" have a bias of being associated with "Hateful" class. Typical stereotype parameters represented as strings could also pertain to stereotypical bias in the context of hate speech detection, e.g. "girls", "blacks", etc.

Definition 3.4. Feature Units: These are the smallest units of the feature space which are used by different text processing methods.

SB in the context of hate speech detection can be studied in terms of various feature units like character n-grams, word n-grams, phrases, or sentences. In this work, although we focus on words as feature units, the work can be easily generalized to other levels of text.

Definition 3.5. Bias Sensitive Word (BSW): A word w is defined as a bias sensitive word for a classifier if the classifier is unreasonably biased with respect to w to a very high degree.

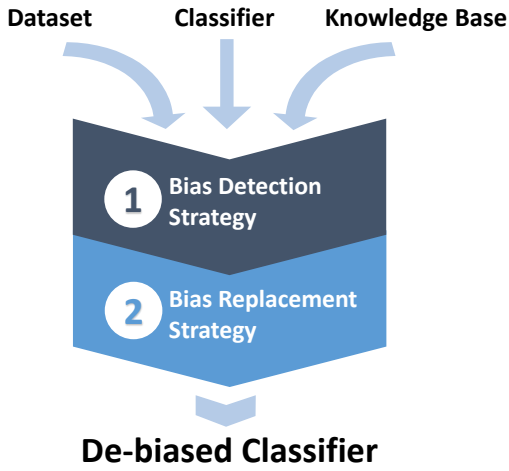

Figure 1: Conceptual Diagram for the proposed 2-Stage De-biasing Framework

For example, if a classifier labels the sentence with just a word "muslims" as "Hateful" with probability 0.81, then we say that the word "muslims" is a BSW for the classifier. Similarly, if a classifier predicts the sentence *'Is Alex acting weird because she is a woman ?'* with much higher probability than *'Is Alex acting weird because he is a man ?'* as Hateful, then the words "woman" and "she" are BSWs for that classifier.

3.2 Problem Formulation

Given: A hate speech detection classifier.
Find:

- A list of BSW words from its training data.
- De-biased dataset to mitigate the impact of BSWs.

We propose a two-stage framework to solve the problem. In the first stage (Detection), we propose biased-model prediction based novel heuristics for bias sensitive word (BSW) detection. Further, in the second stage (Replacement), we present novel bias removal strategies leveraging knowledge-based generalizations. Figure 1 shows the basic architecture diagram of the proposed framework.

4 TWO-STAGE DE-BIASING APPROACH

In this section, we first discuss the first stage of the proposed framework which deals with detection of BSWs. Next, we discuss choices related to bias correction strategies that we could employ. Finally, as part of the second stage, we propose multiple knowledge generalization based BSW replacement strategies.

4.1 Stage 1: Identifying BSWs

Many text-related tasks (e.g., gender profiling based on user-written text, named entity recognition) can extract strong signals from individual word occurrences within the text. However, higher order natural language processing tasks like hate speech detection, sentiment prediction, sarcasm detection cannot depend on strong signals from individual word occurrences; they need to extract signals from a combination of such words. Consider the sentence "Pakistan is a country with beautiful mountains". Here it is good for a named entity recognition classifier to use its knowledge about the significant association between the word "Pakistan" and a label "location". But it is not good for a hate speech detection classifier to use its knowledge about associating the word "Pakistan" with label "Hateful" which it might have unintendedly learned from the training data.

Note that although it is important to identify BSWs, it is important to ensure that obvious hateful words should not be removed while doing bias mitigation. Using a standard abusive word dictionary, one can easily ignore such words from being considered a BSW. To identify stereotypical bias and avoid the classifier from propagating the bias from training data to its parameters, we propose the following three strategies for identifying BSWs.

4.1.1 Manual List Creation. Dixon et al. [8] manually created a set of 50 terms after performing analysis on the term usage across the training dataset. The selected set contains terms of similar nature but with disproportionate usage in hateful comments. Examples: lesbian, gay, bisexual, transgender, trans, queer, lgbt, etc.

4.1.2 Skewed Occurrence Across Classes (SOAC). If a word is present a significant number of times in a particular class (say Hateful), the classifier is highly likely to learn a high probability of classifying a sentence containing that word into that particular class. Hence, we define the skewed occurrence measure to detect such BSWs.

For the hate speech detection task, consider the two classes: Hateful (+) vs Neutral (-). Let $tf(w)$ be the total term frequency of the word w in the training dataset. Let $df(w)$ be the total document frequency, $df^+(w)$ be the document frequency of the word for documents labeled as Hateful, and $df^-(w)$ be the document frequency of the word for documents labeled as Neutral. Then, we can use the procedure mentioned in Algorithm 1 to rank the BSWs.

Algorithm 1 BSW Detection based on 'Skewed Occurrence Across Classes' detection strategy in Training Dataset

1: S is a ordered list of words, tf is term-frequency of these words, df is document-frequency values of these words, ϕ is the cutoff tf threshold.
2: $S^* \leftarrow \{w | w \in S \text{ and } tf(w) > \phi \text{ and } df^+(w) > df^-(w)\}$
3: Sort S^* in non-ascending order by $(df(w), df^+(w)/df(w))$.

Filtering based on just the high frequency would not be enough as that would include stopwords as well, hence we add additional constraints to filter these unnecessary terms.

Essentially, Algorithm 1 ranks a word higher if (1) it occurs with a minimum ϕ frequency in the entire dataset (2) it occurs in many training dataset documents (3) it occurs in Hateful documents much more than in Neutral documents. The drawback of this method is that we need to have access to the exact training corpus.

4.1.3 Skewed Predicted Class Probability Distribution (SPCPD). Let $p(c|w)$ denote the classifier prediction probability of assigning a sentence containing only word w to class c. Let c_ϕ denote a "Neutral" or an "Others" class, or any such "catchall" class. Then, we define the SPCPD score as the maximum probability of w belonging to one of the classes excluding c_ϕ.

$$SPCPD(w) = \max_{\forall c \in C, c \neq c_\phi} p(c|w) \quad (1)$$

Note that a high value of $SPCPD(w)$ means that the classifier has stereotyped the word w to belong to the corresponding class. For example, if a classifier labels the sentence with just a word "muslims" as "Hateful" with probability 0.81, $SPCPD_{muslims}$=0.81. A word w is called bias sensitive word (BSW) if $SPCPD(w) \geq \tau$, where τ is a threshold, usually close to 0.5 (for binary classification).

In settings where Hateful class is further sub-divided into multiple subtypes, using the maximum probability of classification amongst the positive target classes allows us to identify words that force the decision of the model towards a target class. Instead, an ideal classifier should predict a uniform probability distribution on the target classes except for the neutral class. The advantage of this bias detection strategy is that it does not need access to the original training dataset and can be used even if we just have access to the classifier prediction API.

The *SOAC & SPCPD* bias sensitive words detection strategies return an ordered list of BSWs with scores. We can pick the top few BSWs from each of these strategies, and subject them to bias removal as detailed in the remainder of this section.

Both the *SOAC & SPCPD* bias sensitive words detection strategies can be used for n-grams as well. Considering that higher word-n-grams would require considerable computation power, we focus on unigrams only. Additionally, using prediction on single-word documents might seem trivial but later, in Section 5, we show that such a simple intuitive strategy can be quite effective in identifying BSWs.

4.2 Choices for Bias Correction Strategy

For removing bias from a biased training dataset, we can do the following:

(1) **Statistical Correction:** This includes techniques that attempt to uniformly distribute the samples of every kind in all the target classes, augmenting the train set with samples to balance the term usage across the classes. "Strategic Sampling" is a simple statistical correction technique which involves strategically creating batches for training the classifier with aim of normalizing the training set. Data Augmentation is another technique that encourages adding new examples instead of performing sampling with replacement.

Example: Hatespeech corpus usually contains instances where 'women' are getting abused in huge proportion as compared to 'men' getting abused. Statistical correction can be useful in balancing this disproportion.

(2) **Data Correction:** This technique focuses on converting the samples to a simpler form by reducing the amount of information available to the classifier. This strategy is based on the idea of Knowledge generalization, when the classifier should be able to decide if the text is hateful or not based on the generalized sentence, not considering the private attribute information, as these attributes should not be a part of decision making of whether the sentence is hateful or not. Some popular examples of private attributes include Gender, Caste, Religion, Age, Name etc.
Example: For a sentence, *That Indian guy is an idiot and he owns a Ferrari*, private attribute information should not be used while learning to classify as abuse. The new generalized sentence after removing private attributes should look like: *That <NATIONALITY> guy is an idiot and he owns a <CAR>*.

(3) **Model Correction or Post-processing:** Rather than correcting the input dataset or augmenting, one can either make changes to the model like modifying word embeddings or post-process the output appropriately to compensate for the bias.
Example: A simple technique would involve denying predictions when the sentence contains private attributes to reduce false positives.

In this paper, we direct our effort towards effective data correction based methods to counter bias in learning. This is mainly because of the following reasons: (1) for statistical correction, it is challenging to obtain instances which help in bias removal, and which do not sneak in further bias. In other words, the additional words in augmented instances can skew the distribution of existing words, inducing new bias. (2) for model correction, the strategy could be very specific to the type of classifier model.

We consider dataset augmentation or statistical correction as a baseline strategy. In order to prevent differential learning, we can add additional examples of neutral text in the training set containing the BSWs forcing the classifier to learn features which are less biased towards these BSWs. Dixon et al. [8] use this strategy to balance the term usage in the train dataset thereby preventing biased learning.

4.3 Stage 2: Replacement of BSWs

Next, we propose multiple knowledge generalization based BSW replacement strategies as follows.

4.3.1 Replacing with Part-of-speech (POS) tags. In order to reduce the bias of the BSWs, we can replace each of these words with their corresponding POS tags. This process masks some of the information available to the model during training inhibiting the classifier from learning bias towards the BSWs.

Example: Replace the word 'Muhammad' with POS tag 'NOUN' in the sentence - *Muhammad set the example for his followers, and his example shows him to be a cold-blooded murderer.* POS replacement substitutes specific information about the word 'Muhammad' from the text and only exposes partial information about the word, denoted by its POS tag 'NOUN', forcing it to use signals that do not give significant importance to the word 'Muhammad' to improve its predictions.

4.3.2 Replacing with Named-entity (NE) tags. Consider the sentence - *Mohan is a rock star of Hollywood.* The probability of the sentence being hateful or not does not depend on the named entities 'Mohan' and 'Hollywood'. However, classifiers are prone to learn parameters based on the presence of these words. Hence, in this strategy, we replace the named entities with their corresponding entity type tag. This technique generalizes all the named-entities thus preventing information about the entities from being exposed to the classifier.

We use the standard set of NE tags which includes PERSON, DATE, PRODUCT, ORGANIZATION etc.

4.3.3 K-Nearest Neighbour. Given a word embedding space (say GloVe [19]) and a BSW w, we find K nearest neighbors for w in the embedding space. Let the $N_K(w)$ indicate the set of these K nearest neighbors plus the word w. For every occurrence of w in the training dataset, we randomly replace this occurrence with a word selected from $N_K(w)$. The intuition behind the strategy is as follows. If we replace all instances of a word with another word then it may not decrease the bias. But if we replace some sentences with other variants of the word, then it should add some variance in the sentences, and hence reduce the bias.

This strategy should serve as an equivalent of adding additional examples in the text to reduce the class imbalance.

4.3.4 Knowledge generalization using lexical databases. Replacing surface mentions of entities with their named entity types holds back important information about the content of the sentence; it generalizes the content too much. A more general approach would involve replacing BSWs with the corresponding generalized counterparts. A major reason for learning bias is because of differential use of similar terms. Consider the terms, 'women' and 'man'. For the domain of hate speech, the term 'women' would be present more frequently as compared to 'man', even though they represent similar, if not same, groups.

We leverage WordNet [17] database to obtain semantically related words and the lexical relations in order to find a suitable candidate for replacement. In this strategy, words are replaced with their corresponding hypernym as obtained from the WordNet. A hypernym is a word with a broad meaning constituting a category into which words with more specific meanings fall; a superordinate. For example, *colour is a hypernym of red.* A BSW might have multiple hypernyms and therefore different paths leading to a common root in WordNet. We perform a Breadth-First-Search (BFS) over the sets of synonyms, known as synsets, from the child node as obtained from the WordNet for a BSW. A synset contains lemmas, which are the base form of a word. We then iterate over all the lemmas in the synset to obtain the replacement candidate. This allows us to identify the lowest parent in the hypernym-tree which is already present in the training dataset vocabulary.

We try out all the words in the synonym-set to select a suitable candidate for replacement. Replacing a word with a parent which is not present in the text won't be of any importance since it will not help reduce bias when learning the classifier. Hence, we ignore such

words. Not every word can be located in WordNet, especially the ones obtained from casual conversational forums like Twitter. To obtain better performance, we use spell correction before searching for the suitable synset in the WordNet.

4.3.5 Centroid Embedding. All the above techniques exploit the information in the text space either by using NLP tools or lexical databases. In order to leverage the complex relationships in the language in embedding space, we can use the existing word embeddings which sufficiently accurately capture the relationship between different words.

In the centroid embedding method, we replace a bias sensitive word with a dummy tag whose embedding we compute as follows. We find the POS tag for that occurrence of the word, and then find similar words from the word embeddings with similar POS usage. Further, we compute the centroid of the top k neighbors, including the original word to obtain the centroid embedding. We set k to 5 in our experiments.

The centroid represents the region of the embedding space to which the bias sensitive word belongs. So, rather than using the exact point embedding of the word, we smooth it out by using the average embedding of the neighborhood in which the point lies. This strategy is a continuous version of the WordNet-based strategy as the generalizations happen in the embedding space rather in text or word space. Additionally, computing the centroid of sufficient number of words helps in obtaining bias-free vector representations giving improved performance (as shown in Section 5).

5 EXPERIMENTS

In this section, we first discuss our datasets and metrics. Next, we present comparative results with respect to hate speech detection accuracy and bias mitigation using different BSW detection and replacement strategies.

5.1 Datasets

In order to measure the efficacy of the proposed techniques, we use the following datasets to evaluate the performance.

WikiDetox Dataset [22]: We use the dataset from the Wikipedia Talk Pages containing 95,692 samples for training, 32,128 for development and 31,866 for testing. Each sample in the dataset is an edit on the Wikipedia Talk Page which is labeled as 'Neutral' or 'Hateful'.

Twitter Dataset [7]: We use the dataset consisting of hateful tweets obtained from Twitter. It consists of 24,783 tweets labeled as hateful, offensive or neutral. We combine the hateful and offensive categories; and randomly split the obtained dataset into train, development, and test in the ratio 8:1:1 to obtain 19,881 train samples, 2,452 development samples, and 2,450 test samples.

"Wiki Madlibs" Eval Dataset [8]: For the Dataset augmentation based bias mitigation baseline strategy, we follow the approach proposed by Dixon et al. [8]. For every BSW, they manually create templates for both hateful instances and neutral instances. Further, the templates are instantiated using multiple dictionaries resulting into ~77k examples with 50% examples labeled as Hateful. For example, for a BSW word "lesbian", a template for a neutral sentence could be "Being lesbian is ⟨adjectivePositive⟩." where ⟨adjectivePositive⟩ could be a word from dictionary containing "great, wonderful, etc." A template for a Hateful sentence could be "Being lesbian is ⟨adjectiveNegative⟩." where ⟨adjectiveNegative⟩ could be a word from dictionary containing "disgusting, terrible, etc.".

5.2 Metrics

5.2.1 ROC-AUC Accuracy. For the hate speech detection task, while we mitigate the bias, it is still important to maintain a good task accuracy. Hence, we use the standard ROC-AUC metric to track the change in the task accuracy.

5.2.2 Pinned AUC Equality Difference. In order to empirically measure the performance of the de-biasing procedures, Dixon et al. [8] proposed the Pinned AUC Equality Difference ($pAUC$) metric to quantify the bias in learning for the dataset augmentation strategy only.

For a BSW w, let D_w indicate the subgroup of instances in the "Wiki Madlibs" eval dataset containing the term w. Let $\overline{D_w}$ be the instances which do not contain the term w such that $|D_w| = |\overline{D_w}|$. Further, the classifier is used to obtain predictions for the entire subgroup dataset $\{D_w \cup \overline{D_w}\}$. Let $AUC(w)$ denote the subgroup AUC obtained using these predictions. Further, let AUC denote the AUC obtained using predictions considering the entire "Wiki Madlibs" dataset $\{\sum_{\forall w}(D_w \cup \overline{D_w})\}$. Then, a good way to capture bias is to look at divergence between subgroup AUCs and the overall AUC. Dixon et al. [8] thus define the Pinned AUC Equality Difference ($pAUC$) metric as follows,

$$pAUC = \sum_{w \in BSW} |AUC - AUC(w)| \tag{2}$$

A lower $pAUC$ sum represents less variance between performance on individual term subgroups and therefore less bias. However, the $pAUC$ metric suffers from the following drawbacks:

- Computation of $pAUC$ requires creating a synthetic dataset with balanced examples for each bias sensitive word (BSW) w, making it challenging to compute and scale with the addition of new BSWs as it would require an addition of new examples with desired labels.
- The "Wiki Madlibs" Eval dataset is synthetically generated based on templates defined for BSWs. The pinning to the AUC obtained on such a dataset is quite ad hoc. An ideal metric should be independent of such relative pinning.

5.2.3 Pinned Bias (PB). To address the above-mentioned drawbacks with $pAUC$, we propose a family of metrics called Pinned Bias Metric (PB) that is better able to capture the stereotypical bias. Note that small values of PB are preferred.

Let T represent the set of BSW words. Let $p(\text{"}Hateful\text{"}|w)$ be the prediction probability for a sentence which contains only word w. We define PB as the absolute difference in the predictions 'pinned' to some predictive value for the set T. This captures the variation in Bias Probability of the classifier for the given set of words with respect to the pinned value. Keeping these intuitions in mind, we define the general PB metric as follows.

Detection Strategy	WikiDetox Dataset	Twitter Dataset
Skewed Occurrence Across Classes	get, youre, nerd, mom, yourself, kiss, basement, cant, donkey, urself, boi	lol, yo, my, ya, girl, wanna, gotta, dont, yall, yeah
Skewed Predicted Class Probability Distribution	pissed, gotta, sexist, righteous, kitten, kidding, snake, wash, jew, dude	feelin, clap, lovin, gimme, goodnight, callin, tryin, screamin, cryin, doin

Detection Strategy	WikiDetox Dataset
Manually curated set of words	lesbian, gay, bisexual, transgender, trans, queer, lgbt, lgbtq, homosexual, straight, heterosexual, male, female, nonbinary, african, african american, black, white, european, hispanic, latino, latina, latinx, mexican, canadian, american, asian, indian, middle eastern, chinese, japanese, christian, muslim, jewish, buddhist, catholic, protestant, sikh, taoist, old, older, young, younger, teenage, millenial, middle aged, elderly, blind, deaf, paralyzed

Table 3: BSWs obtained using the Bias Detection strategies on the WikiDetox and Twitter dataset. The words in the order from left to right are ranked based on the strategy specific ranking criteria.

Table 4: Hate Speech Detection Accuracy and Bias Mitigation Results Across Multiple Detection and Replacement Strategies on Twitter Dataset. The best replacement strategy is highlighted in *bold* while the 2^{nd} best is *<u>underlined</u>* for each metric.

$$PB = \sum_{w \in T} \frac{|p(\text{“}Hateful\text{”}|w) - \phi|}{|T|} \tag{3}$$

, where ϕ is the pinned value which differs for different metrics in the PB family. Next, we define three specific members of the PB family as follows.

- PB_{mean}: For a similar set of terms, it is important to have consistency in the predictions. To capture this deviation in prediction from the general classifier consensus, we pin the metric with respect to the mean prediction. For this metric, ϕ in Eq. 3 is set as follows.

$$\phi = \sum_{w \in T} \frac{p(\text{“ Hateful ”}|w)}{|T|} \tag{4}$$

- PB_{sym}: PB_{mean} is not effective in situations where the terms are of varied nature or from diverse domains. Also pinning it relative to the general consensus of the classifier again can introduce errors.
  Hence, for this metric, ϕ in Eq. 3 is set as ϕ=0.5 for binary classification. In case of k classes, ϕ can be set to $\frac{1}{k}$.
- PB_{asym}: Intuitively, prediction probability of 0.70 being hateful as compared to probability of 0.30 being hateful for a BSW should not be considered equal as a degree of being hateful is much more sensitive as compared to a degree of being neutral.
  A high value of $p(\text{“}Hateful\text{”}|w)$ should be penalized much more than a value less than 0.50 (for binary classification; $\frac{1}{k}$ for k-class classification). Hence, for this metric, ϕ in Eq. 3 is set as follows.

$$\phi = \min(p(\text{“}Hateful\text{”}|w),\ 0.5) \tag{5}$$

The PB metrics, in general, represent the average deviation of the probability scores from the ideal pinning value. Eg, A score of $PB_{sym} = 0.2$ would mean that the probabilities have an average deviation of 0.2 from the ideal value of 0.5. The PB metrics can be modified, if needed, to incorporate the bias in n-grams.

5.3 Experimental Settings

We perform multiple experiments to test different BSW identification and bias mitigation strategies. We experiment with multiple classification methods like Logistic Regression, Multi-layer Perceptron (MLP), Convolutional Neural Network (CNN), an ensemble of classifiers. Since we obtained similar results irrespective of the classification method, we report results obtained using CNNs in this section.

We use identical Convolutional Neural Network (CNN) [8] implemented in Keras [6] for all the experiments. Fig. 2 shows the architecture diagram of the neural network. We use 100D GloVe [19]

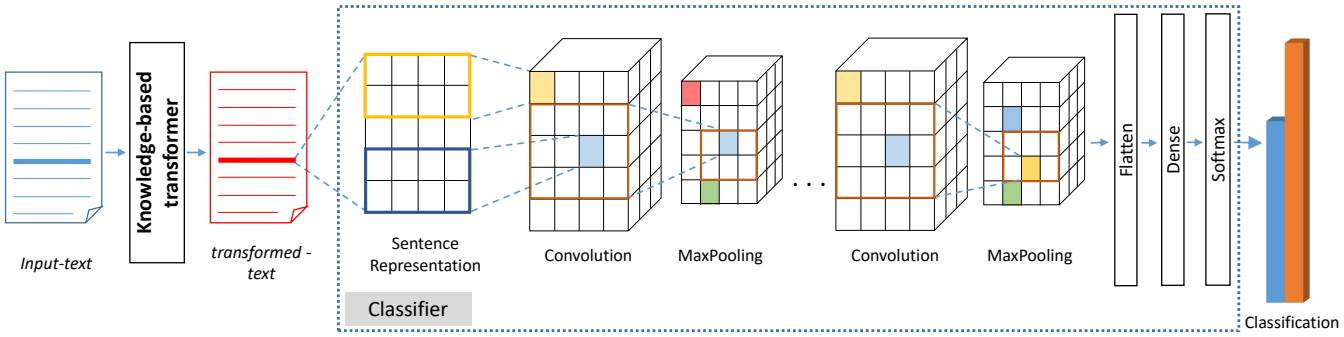

Figure 2: Model Architecture Diagram

embeddings to encode text and CNN architecture with 128 filters of size 5×5×5 for each convolution layer, dropout of 0.3, max-sequence length as 250, categorical-cross-entropy as the loss function and RMSPROP as optimizer with learning-rate of 0.00005. We use the best parameter setting as described in Dixon et al. [8] and train the classifiers for our task with batch size 128 and early stopping to a maximum of 20 epochs, keeping other hyperparameters constant throughout the experiments.

We use the spaCy [2] implementation of POS tagger and NER tool. More details about the experiments can be found in the source code [3].

5.4 Results

Table 5: Bias Mitigation Results using pAUC metric and ROC-AUC across Multiple Replacement Strategies on Wiki Madlibs Dataset. The best replacement strategy is highlighted in *bold* while the 2^{nd} best is <u>*underlined*</u> for each metric.

5.4.1 BSWs identified by Various Strategies. Table 3 shows the list of BSWs obtained using different Bias Detection strategies. The words obtained from both the SOAC and SPCPD detection strategies are not obvious and differ from the manual set of words as the distribution of the terms in the training set can be arbitrary, motivating us to design detection strategies. In case of the Twitter Dataset, in Table 3, we do not show results for the 'Manual List Creation' detection strategy because we do not have a manual dataset of bias sensitive words for Twitter. The simple strategy of detecting biased words using Skewed Predicted Class Probability Distribution (SPCPD) is effective and works for arbitrary classifiers as well. The words obtained from the SPCPD detection strategy are not very obvious but the prediction on sentences that contain those words have very high discrepancy than expected prediction scores.

The BSWs obtained using the detection strategies are better than the ones obtained using the 'Manual List Creation' strategy because of the high PB_{asym} scores for the 'Biased' classifier for different detection strategies as tabulated in Table 6. Additionally, the PB_{asym} scores for BSWs from the manual list are very low in spite of a large number of words which suggests that the classifier is not biased towards these terms. For the Twitter dataset, the PB_{asym} score for the SOAC detection strategy is the lowest, but in WikiDetox where the training dataset size is large, the skewness in distribution reduces resulting in the PB_{asym} scores for the SPCPD detection strategy to be the lowest.

5.4.2 Effectiveness of various Bias Detection-Replacement Strategies. Tables 4, 5 and 6 show the hate speech detection accuracy and bias mitigation results across various bias detection and bias replacement strategies (averaged over 10 runs because of high variance) for the Twitter, Wiki Madlibs and WikiDetox datasets. 'Biased' replacement strategy indicates the biased classifier, i.e., the one where no bias has been removed. For Wiki De-bias bias removal strategy, we do not have results for non-manual detection strategies since they require template creation (like 'Wiki Madlibs') and dataset curation. We train the 'Wiki De-bias' [8] baseline using the additional data containing 3,465 non-toxic samples as part of the dataset augmentation method as proposed in the original paper. For Wiki Madlibs dataset (Table 5), we show results using only manual list creation but across multiple bias replacement strategies, using $pAUC$ metric only since it is meant for this combination alone. WordNet-i denotes the WordNet strategy where the starting synset level for finding hypernyms was set to i levels up compared to the level of the bias sensitive word. For Tables 4 and 6, we use the ROC-AUC scores for comparing the general model performance while the PB_{asym} metric for bias evaluation. We do not use $pAUC$ for these tables because they need manual generation of a dataset like Wiki

Table 6: Hate Speech Detection Accuracy and Bias Mitigation Results Across Multiple Detection and Replacement Strategies on WikiDetox Dataset. The best replacement strategy is highlighted in *bold* while the 2^{nd} best is *underlined* for each metric.

Madlibs. Finally, note that the scores in the Table 4 and Table 6 are vertically grouped based on different detection strategies which involve varying set of BSWs making the results non-comparable across the detection strategies in general.

As seen in Table 5, for the Wiki Madlibs dataset, Centroid Embedding strategy performs the best beating the state-of-the-art technique (Wiki De-Bias) on both ROC-AUC as well as pAUC metrics. Additionally, POS tags and WordNet-based strategies also perform better than the Wiki De-bias strategy on the *pAUC* metric with just a minor reduction in $ROC - AUC$ accuracy. The POS tags strategy performs better because the replaced words mostly belong to the same POS tag resulting in high generalization.

For the Twitter dataset, Centroid Embedding replacement method works best across all the detection strategies and across different metrics. The overall general classification performance for all the strategies remain almost similar, though the WordNet-3 replacement strategy works best. WordNet based replacement strategy is not as effective as the PB_{asym} scores gradually increase with the increase in generalization, due to the absence of slang Twitter words in WordNet. The WordNet-based replacement strategies also show decreasing PB_{asym} scores as the strategy is unable to find a suitable generalized concept that is already present in the Twitter dataset because of its small vocabulary size.

The WordNet and Centroid Embedding replacement strategies work best for the WikiDetox dataset. For the WordNet strategy, the best results vary based on detection strategy, but it performs either the best or gives comparable results to the best strategy. It also has an added benefit of deciding on the level of generalization which can be tweaked as per the task. For "manual list creation" detection strategy, Centroid Embedding provides unexpectedly low *PB* scores because most of the words in the list are nouns. The non-zero PB_{mean} metric in case of manual-list-creation detection strategy along with POS tags replacement strategy is due to the fact that the words like 'gay' are marked as Adjective instead of Noun, which is expected.

Finally, note that bias mitigation usually does not lead to any significant change in the ROC-AUC values, if performed strategically, while generally, it reduces bias in the learning.

5.4.3 Details of WordNet-based bias removal strategy. Table 7 shows WordNet-based replacement examples for the manual set of words with different values of the start synset level.

Original Word	**Replaced Words**					
	Level 0	**Level 1**	**Level 2**	**Level 3**	**Level 4**	**Level 5**
sikh	disciple		follower	person	cause	entity
homosexual	homosexual	person	cause	entity		object
queer	faggot	homosexual		person	cause	entity
gay	homosexual	person	cause	entity		object
straight	homosexual	person	cause	collection	entity	object
muslim	person			cause	entity	
deaf	deaf	people	group	abstraction	entity	-
latino	inhabitant			person	cause	entity

Table 7: WordNet based bias correction examples for the 'Manual List Creation' detection strategy with different start Synset Levels

Fig. 3 shows details about WordNet based replacement. As we traverse from right-to-left along the edges, we obtain generalizations for each of the words. The figure highlights two sets of similar words where one set (denoted by ▭) is highly prone towards getting stereotypically biased, while all the highlighted terms (denoted by ⬭) represent "a group of people with specific attributes". Each node represents the term which can be used for BSW replacement. In the case of multiple generalizations, the selection was made randomly.

Wordnet-based strategy often leads to the best results across our datasets. However, the results could be improved further using an appropriate normalization scale that captures generalization to different levels. For example, *Hindu* requires three levels of generalization, while *Muslim* requires two (see Fig. 3). This requires a generalization scheme that considers the inconsistency in the sibling nodes and performs differential normalization.

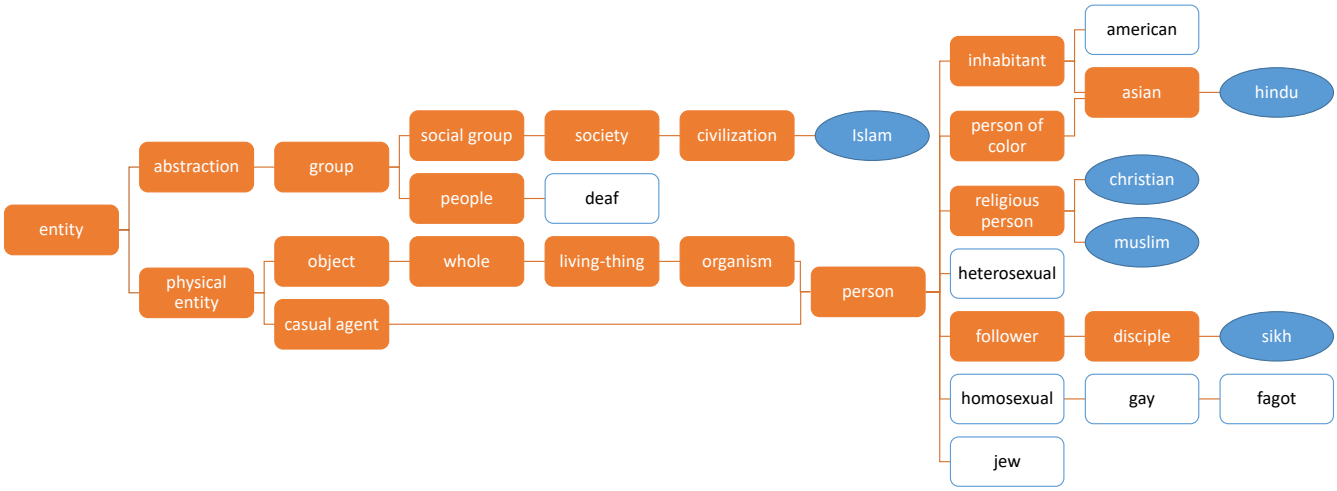

Figure 3: Horizontal representation of the WordNet Hypernym Hierarchy for BSWs.

5.4.4 Case Studies. In order to evaluate the effectiveness of the Bias Detection strategy in identifying BSWs, we perform an experiment on a publicly accessible classifier, the Perspective API [4]. We leverage the vocabulary of size 400k of GloVe vectors and obtain hate (toxicity) scores for each word in the vocabulary and rank them using the Skewed Predicted Class Probability Distribution Bias Detection strategy. This allows us to identify the set of bias sensitive words allowing us to create examples to test the quality of the obtained words. Some of these examples are tabulated in Table 1 where the API gives incorrect scores. The obtained examples show the effectiveness of the obtained BSWs.

Further, Table 8 shows some examples which were wrongly predicted as being "hateful" by the original 'Biased' classifier and the corresponding prediction scores after bias removal using the above strategies. These simple manually created examples clearly show the efficacy of our proposed method.

Examples	**Toxicity Predictions**	
	before bias removal	**after bias removal**
are you a **nerd** ?	0.928	0.294
he hit the **donkey**	0.289	0.021
he is a **gay**	0.786	0.493
One of John brothers was **homosexual** while the other is a **black transgender**	0.690	0.048
katrina is a **female african** who is **sikh**	0.782	0.535

Table 8: Examples for predictions on sentences before and after the classifier had undergone the bias correction stage using the Centroid Embedding strategy for the manually constructed sentences containing identified BSWs. Bias Sensitive Words are marked in bold. The ideal prediction probabilities in all the cases should be less than 0.5

[4]https://www.perspectiveapi.com/

5.4.5 Unigrams versus higher order ngrams. In this paper, we experimented with unigrams only. From our experiments, we observed that the SB bias in unigrams propagates to word n-grams and char-n-grams as well. E.g., SB towards a word 'women' propagates to the char n-grams 'wom, omen, wome' as the distribution of char n-grams is similar to that of the corresponding word and also similar to the word n-grams, *women are*, *womens suck*, etc. Thus, considering unigrams is reasonably sufficient. That said, the PB metrics rely on the probability scores and thus can be easily used for bias sensitive *n-grams* as well.

6 CONCLUSIONS

In this paper, we discussed the problem of bias mitigation for the hate speech detection task. We proposed a two-stage framework to address the problem. We proposed various heuristics to detect bias sensitive words. We also proposed multiple novel knowledge generalization based strategies for bias sensitive word replacement which can be extended to other short-text classification tasks as well. Using two real-world datasets, we showed the efficacy of the proposed methods. We also empirically show that the data-correction based removal techniques can reduce the bias without reducing the overall model performance.

We also demonstrate the effectiveness of these strategies by performing the experiment on Google Perspective API and perform a qualitative analysis to support our observations using multiple examples.

ABSTRACT

Product bundling, offering a combination of items to customers, is one of the marketing strategies commonly used in online e-commerce and offline retailers. A high-quality bundle generalizes frequent items of interest, and diversity across bundles boosts the user-experience and eventually increases transaction volume. In this paper, we formalize the personalized bundle list recommendation as a structured prediction problem and propose a bundle generation network (BGN), which decomposes the problem into quality/diversity parts by the determinantal point processes (DPPs). BGN uses a typical encoder-decoder framework with a proposed feature-aware softmax to alleviate the inadequate representation of traditional softmax, and integrates the masked beam search and DPP selection to produce high-quality and diversified bundle list with an appropriate bundle size. We conduct extensive experiments on three public datasets and one industrial dataset, including two generated from co-purchase records and the other two extracted from real-world online bundle services. BGN significantly outperforms the state-of-the-art methods in terms of quality, diversity and response time over all datasets. In particular, BGN improves the precision of the best competitors by 16% on average while maintaining the highest diversity on four datasets, and yields a 3.85x improvement of response time over the best competitors in the bundle list recommendation problem.

1 INTRODUCTION

A bundle is a collection of products or services for sale as a whole, and the bundle list recommendation is to recommend a personalized list of bundles. Traditional business domains, e.g., communication services, offline retailers and supermarkets, take bundling as a critical marketing strategy, and they usually make bundles by human insights or non-personalized mining methods [2]. Modern e-commerce websites and online service business, e.g., Amazon, Taobao, Steam and Netflix, also deploy new applications [22, 32], which recommend and sale a list of bundles rather than a list of items.

Customers, sellers, as well as the recommendation platform, could benefit from the personalized bundle recommendation service. For customers, high-quality bundles broaden user interests and indicate the complementary products directly in the shortest path after purchase. It is well known in classic marketing research that carefully-designed bundle brings mutual promotions.

For sellers, bundling increases per customer transaction. The average order size for walmart.com is 2.3 [36]. By attaching some highly correlated products, the seller can launch more products and increase gross merchandise volume (GMV). Besides, buying a bundle of products may cost less than buying each product separately for both customers and sellers. For example, it is a common practice to waive shipping fee if the items in one order exceed a certain amount in e-commerce websites.

For the recommendation system, bundling is a more efficient way to organize and present products. The recommendation list is structured by bundles where the products are highly correlated

Figure 1: Bundle List Recommendation Example

in contrast to the list of items, and multiple diversified bundles avoid monotonous choices for users. The recommendation system shows bundle as a whole and thus presents more products per unit area. It is crucial to reduce swipe-up operations for improving user experiences for the mobile application.

In Figure 1, we illustrate a bundle list example. The items in the bundle should be highly correlated. Besides, diversity across bundles becomes a critical metric as an interpretable, business-oriented goal, which is independent of click-through rate (CTR) and precision, trying to avoid tedious choices and quantify the user-experience in bundle recommendation system. The identical high-quality item tends to be generated in different bundles [22], which compose the confusing and monotonous bundle list, so there is a trade-off between precision/likelihood and diversity. Other meaningful problems, e.g., how to set the price discount for maximizing the profit, how to compose the picture of the bundle, are beyond the scope of this paper and can be the future work. Our paper focuses on how to generate high-quality and diversified bundles.

There are several challenges for the personalized bundle recommendation problem. First, the recommendation system should generate high-quality bundles automatically and flexibly without manual involvement. Frequent itemsets mining algorithms provide high-quality bundling but are not personalized. For modeling the distribution of bundle, we use the co-purchase data or pre-defined bundles to supervise the quality of bundles with the user context. However, the sequence generation methods suffer from inadequate representation for rich features in bundle recommendation scenario, because the weight matrix of traditional softmax only considers the item_id. Besides, in practice, we may need the larger size of bundles for the purpose of sellers' promotion, but seq2seq usually suffers from generating short sequences [14].

Second, diversity across bundles emerges as a critical metric for bundle recommendation. Different bundles with the same high-quality item may reach high ranking scores at the same time, so duplicated items tend to be seen in these generated bundle list [22]. Besides duplication, similar items due to the similarity of features may produce confusing and tedious bundle list and decrease user interest. A bundle recommendation system should consider the cross-bundle diversity considering both duplication and similarity of items. Here, the diversity is a explicit metric instead of some hidden relationships of similarity learned from data. The explicit similarity pre-defined by side information and prior knowledge provides the exact signal for the purpose of measurement and adjustment. We use the determinantal point processes (DPPs) as the objective function which considers the global negative correlations during inference to decompose the quality and diversity.

Last, compared to the traditional item list recommendation, the search space is the doubly exponential number of items for the bundle recommendation, since a bundle can contain arbitrary-length combination theoretically and a list contains multiple bundles [9]. Bundle sparsity should be carefully considered because the training data in the form of co-purchase contains few bundle ground truths w.r.t. the whole search space. Most of the bundles in search space are low-quality, so we need a method to generate high-quality candidate bundles efficiently for each user, instead of the ranking method applied in all the possible bundles.

In this paper, we aim to the problem of the personalized bundle list recommendation and propose a **Bundle Generation Network (BGN)**. We summarize the contributions of this paper as follows:

- It is the first attempt to address the bundle list recommendation problem by the sequence generation approach considering both the quality and diversity. We decompose the generation model based on determinantal point processes, and integrate the neural network with DPP selection to produce the high-quality and diversified bundle list.
- We propose a feature-aware softmax in bundle recommendation scenario, for making up the inadequate representation of traditional seq2seq for rich features, which improves the modeling of quality significantly. The loss of feature-aware softmax is a generalization of optimizing BPR loss at each step.
- We conduct extensive experiments on both the real-world dataset and public datasets. Our model improves the precision of the best baseline by 16% on average while maintaining the highest diversity on four datasets, and shows the fastest response time in the bundle list recommendation problem. Besides, BGN can control the bundle size with a tolerable reduction in precision.

2 RELATED WORKS

We present the existing bundle recommendation approaches and introduce the sequence generation model (Seq2seq) and Determinantal Point Processes (DPPs) as related works.

2.1 Bundle Recommendation

Product bundling is one of the marking strategies commonly used in both offline retailers and online e-Commerce websites. Frequent itemsets mining algorithms like Apriori [2] provide high-quality bundling but are not personalized. Parameswaran et al. [21] study some complex constraints like cross-item dependencies in personalized curriculum bundling. The complexity of top-K bundle recommendation is discussed comprehensively in [9]. All above only use frequency of items, which cannot utilize rich features and fail to generalize on similar items and users.

For the single bundle recommendation, Zhu et al. [36] propose a personalized method based on integer quadratic programming. This method considers the first and the second terms of cross-item dependencies. However, the estimation of the second term is heuristic, and this method ignores the higher order terms of cross-item dependencies, which gives a sub-optimal result. The bundle recommendation problem to groups rather than users is investigated by [23]. For the bundle list recommendation, Xie et al. [32] generate top-k bundles via sampling and preference elicitation. This method uses an additive utility function with a linear combination of the corresponding (aggregate) feature values, which fails to capture the complicated dependencies. In [22], Pathak and Gupta build an optimization criterion upon the latent factor model, Bayesian Personalized Ranking (BPR) [24], with the mean pair-wise Pearson correlation of the items. This method generates personalized bundles by a two-stage approach, combining the corresponding preference scores with a greedy annealing schedule, which might be caught in the local optimum due to randomness and instability of annealing.

2.2 Sequence Generation Approaches

In recent years, sequence generation methods achieve great successes in many tasks like Machine Translation [26] and Dialog Generation [29]. They adopt an encoder-decoder architecture to generate sequences, and use the beam search strategy [30] to produce the maximum possible sequences approximately.

In recommendation systems, some works based on RNN, CNN, attention extract the user embedding from the behaviors for each user [31, 33, 34]. The recurrent model and the memory network are also adopted for sequential recommendation [7, 18]. The difference between the sequential recommendation and the bundle recommendation is that, the former uses the encoder only, while the latter uses the encoder to model the user context and uses the decoder to model the bundle distribution. The decoder usually has separate trainable parameters without sharing with the encoder. Besides, The bundle recommendation produces multiple bundles, so we need to know when to end the generation and control diversity of bundles.

2.3 Determinantal Point Processes

Determinantal Point Processes (DPPs), first introduced to model fermion behavior, have gained popularity due to their elegant balancing of quality and diversity. DPPs have been studied for their theoretical properties [11, 16], and their machine learning applications including summarization [5, 17], object retrieval [1] and conversation generation [25]. Structured Determinantal Point Processes (SDPPs) [15] extend the DPP model to handle an exponentially-sized set of particles (structures) via a natural factorization combined with the second-order message passing, which leads to tractable algorithms for inference.

Recent works use DPPs for item list recommendation in [10, 35] to solve cross-item diversity, but to the best of our knowledge, there are no studies about cross-bundle diversity. In this paper, we use SDPP as the tool to decompose the quality/diversity term.

3 PERSONALIZED BUNDLE LIST RECOMMENDATION

Notation. Let $\mathcal{I}$ be the whole set of items that one could select from and $|N|$ be the number of all items. A bundle b is any combination out of $\mathcal{I}$ which consists of items, and T denotes the number of items in a bundle. The items are unordered in bundles. When regarding the bundle as a sequence, we usually give the order by sorting the items of the bundle in terms of their prices in a descendant order, because the cheaper items are more substitutable for the bundle and could endure more exposure bias in the sequence generation model. Let $\mathcal{B}$ be the set of all possible bundles, so $|\mathcal{B}|$ equals $\sum_{t=1}^{T}\binom{N}{t}$ with the fixed maximum bundle size T, where $\binom{N}{t} = \frac{N!}{t!(N-t)!}$ is the combination of t out of N.

$$\mathcal{I} = \{1, 2, \ldots, N\} \qquad |\mathcal{I}| = N$$

$$\mathcal{B} = \{b = \{i_1, i_2, \ldots, i_T\} | i \in \mathcal{I}\} \qquad |b| = T,\ |\mathcal{B}| = \sum_{t=1}^{T}\binom{N}{t}$$

$$\mathcal{Y} = \{y = \{b_1, b_2, \ldots, b_K\} | b \in \mathcal{B}\} \quad |y| = K,\ |\mathcal{Y}| = \binom{|\mathcal{B}|}{K}$$

Here K is the size of a recommended bundle list y. Still, we consider the order does not matter in the bundle list. Let $\mathcal{Y}$ be the set of all possible bundle list. The user context C_u is usually represented as the item sequence he/she has clicked/bought in the history.

Problem Formalization. Let $\tilde{\mathcal{P}}(\cdot,\cdot) : \mathcal{Y} \times \{C_u\} \to \mathbb{R}^+$ be a universal compatibility function measuring the score (compatibility) of the bundle list y and the user context C_u, and we refer $\tilde{\mathcal{P}}(y|C_u)$ to a unnormalized conditional probability of y given C_u. Then, the personalized bundle list recommendation problem can be formalized as a structured prediction problem [3], which tries to find the bundle list $\hat{y}$ satisfying:

$$\hat{y} = \arg\max_{y \in \mathcal{Y}} \tilde{\mathcal{P}}(y = \{b_1, b_2, \ldots, b_K\} | C_u) \tag{1}$$

Let $\mathcal{P}(y|C_u)$ be the normalized conditional probability of $\tilde{\mathcal{P}}$ over y. $\mathcal{P}(y|C_u)$ is actually modeling a distribution over the *doubly exponential* number of N, so there are $\binom{\sum_{t=1}^{T}\binom{N}{t}}{K}$ possible structures of y given C_u naively, which poses an extreme computational challenge. In this paper, we consider the compatibility function $\tilde{\mathcal{P}}$ related to both the quality and diversity.

The bundle list recommendation is a generalization of the single bundle recommendation problem and single-item list recommendation problem. When each bundle is independent given the user context, we have $\mathcal{P}(y = \{b_1, b_2, \ldots, b_K\}|C_u)) = \prod_k \mathcal{P}(b_k|C_u)$. In this case, there are no correlations among the bundle list, and the

problem becomes the single bundle recommendation problem [36], sometimes considered as the personalized bundle ranking problem [22]. Furthermore, when the bundle size T equals one it is the single-item list recommendation problem.

4 BUNDLE GENERATION NETWORK

Here we propose a *Bundle Generation Network* (BGN) to solve the personalized bundle list recommendation problem considering both the quality and diversity.

In the following subsections, we introduce how to decompose the bundle list probability into the quality/diversity part by SDPP and factorize them respectively. Then, we illustrate the measurement of diversity and design an improved neural network with the feature-aware softmax to learn the quality part. Besides, we propose a masked beam search to control the bundle size and avoid duplicated items. Finally, we demonstrate how to integrate these parts to BGN to tackle the process of generation for the bundle recommendation.

4.1 SDPP-based Bundle Generation Model

We define a *structured determinantal point process* (SDPP) [15] on the probability space $(\mathcal{B}, \mathcal{Y}, \mathcal{P})$. When Y is a random variable of bundle recommendation list drawn according to the probability mass function (PMF) $\mathcal{P}$, the distribution is given by:

$$\mathcal{P}(\mathrm{Y} = y) \triangleq det(L_y)/Z \tag{2}$$

Here, L is a symmetric positive semi-definite kernel of SDPP, with the size of $|\mathcal{B}| * |\mathcal{B}|$. L_y denotes the restriction of L to the entries indexed by elements of y, and $Z = \sum_{y' \in \mathcal{Y}} det(L_{y'})$ is the normalization constant. There is an intuitive geometric interpretation of the kernel L, that is, $\det(L_y)$ is the square of the volume spanned by its associated feature vectors [16]. Notice that, each element of y refers to a bundle which has a certain structure, so we consider that the DPP is structured.

One of the benefits of defining a DPP probability model is that we can decompose quality and diversity in a very natural way. For any element L_{ab} of positive semi-definite matrix L we could always find a quality/diversity decomposition:

$$\begin{aligned} L_{ab} &= q(a)\phi(a)^T\phi(b)q(b) \\ &= q(a)S(a,b)q(b) \end{aligned} \tag{3}$$

where $a, b \in \mathcal{B}$, L_{ab} denotes the element indexed by bundle a and b, $q(b) \in \mathbb{R}$ denotes the quality term of bundle, and $\phi(b) \in \mathbb{R}^D$ denotes the normalized diversity feature with $||\phi(b)||_2 = 1$. Here we define a similarity function/metric $S(a,b) : \mathcal{B} \times \mathcal{B} \to \mathbb{R}$ which satisfies $S(a,b) = \phi(a)^T\phi(b)$ and keeps the corresponding similarity matrix S positive semi-definite. We reformalize Equation (3) in the matrix way as

$$L = QSQ \tag{4}$$

where Q denotes a diagonal matrix $\mathrm{diag}\{q(b)_{b \in \mathcal{B}}\}$. The decomposition balances the quality and the diversity. Then, the optimization criterion of the personalized bundle list recommendation is to find a bundle list y maximizing the $\mathcal{P}(y|C_u;\theta)$ given the user context C_u:

$$\arg\max_{y} \ \det(S_y) \cdot \prod_{b \in y} q^2(b|C_u;\theta) \tag{5}$$

One major challenge for solving the personalized bundle list recommendation is that, the optimization criterion of the bundle list has the complexity over doubly exponential number of N. According to the decomposition in Equation (5), we reduce the complexity to a quality term q over the measure space $\mathcal{B}$, and a diversity term S over the measure space $\mathcal{B} \times \mathcal{B}$. However, both of the terms still have exponential space which is intractable.

SDPP considers that any elements in measure space $\mathcal{B}$ can factorize over a set of factors F [15], where a factor $\alpha \in F$ is a small subset of the parts of a structure. Then, we continue to factorize the quality term and the diversity term respectively:

$$q(b) = \prod_{\alpha \in F} q_\alpha(b_\alpha) \qquad \phi(b) = \sum_{\alpha \in F} \phi_\alpha(b_\alpha) \tag{6}$$

The factorization defines how we interpret the model structure and keeps the model tractable. Then we shall specify the factorization for the diversity and quality respectively, and integrate them to produce high-quality and diversified bundle list.

4.2 The Measurement and Factorization of Diversity

The diversity we measure in our work is a interpretable metric/goal, trying to quantify the user-experience in bundle recommendation system, which is independent of the likelihood from data. This implicit relationship learned from data may not be the same 'diversity' as we target, and the correlations among items from data have been considered into the quality part. Whereas, the explicit similarities defined by side information and prior knowledge provide exact signals for the purpose of the measurement and adjustment. Besides, the recommendation system is usually lake of the diversity-labeled ground-truth list, which makes it hard to supervise the complete likelihood.

With Equation (3) and Equation (6) and , we factorize the bundle similarity function to the item similarity function:

$$\begin{aligned} S(a,b) &= \phi(a)^T\phi(b) \\ &= (\sum_{\alpha \in F} \phi_\alpha(a_\alpha)^T)(\sum_{\beta \in F} \phi_\beta(b_\beta)) \\ &= \sum_{\alpha,\beta} \phi_\alpha(a_\alpha)^T\phi_\beta(b_\beta) \\ &= \sum_{i \in a, j \in b} s_{a,b}(i,j) \end{aligned} \tag{7}$$

Here, $s_{a,b}(i,j)$ measures the similarity of items rather than bundles, which is independent of user context. The similarity funciton usually should be consistent with the metrics of diversity predefined according to domain knowledge. For example, in our experiments the $s_{a,b}(i,j)$ is given by Jaccard similarity of bundle:

$$s_{a,b}(i,j) = \frac{1}{|a \cup b|}\delta(i = j) \tag{8}$$

where $\delta(\cdot)$ denotes the indicator function. Note that the bundles do not contain duplicated items inside. This function can maintain the positive semi-definition of L [4] and prevent the identical items shown in the different bundles. The function keeps consistent local measurement with Equation (19), and SDPP optimizes the global negative correlations. Besides, the metric of diversity could also be

defined by calculating the similarity of attributes, which provides the fine-grained diversity of attributes.

4.3 Modeling the Quality Part with Feature-Aware Softmax

Here, we focus on modeling the quality part $q(b|C_u;\theta)$ by a typical *Encoder-Decoder* framework, where the encoder extracts the information from the user context and the decoder generates the high-quality candidate bundle list with a proposed feature-aware softmax.

For the encoder, the user context can be represented as the purchase history of items. We use a text-CNN [13] to extract the information, which has recently been shown of effectiveness in text classification and information extraction [33, 34]. We show the basic network architecture in Figure 2 and omit the discussion of the details because it is not one of our main contributions. The text-CNN is parallelizable and faster than bi-LSTM, and it could also be easily improved by Transformer [27] based on the self-attention architecture in the future work.

For the decoder, the quality of a bundle $q(b|C_u;\theta)$ is an unnormalized joint probability parameterized in terms of a generic θ, so we factorize it in the Bayesian formula way. Note that the Bayesian formula always holds and models the complete distribution of quality, the assumption here is sharing the parameters in a sequence way.

$$\begin{aligned} q(b|C_u;\theta) &\propto p(b=\{i_1,i_2,\ldots,i_T\}|C_u;\theta) \\ &= \prod_{t=1}^{T} p(i_t|i_1,...,i_{t-1},C_u;\theta) \end{aligned} \tag{9}$$

In Equation (9), we factorize the joint probabilities of any bundle by multiplying all conditional probabilities for each of its elements. By sharing the same weights of those conditional probabilities, we use a sequence generation model with the (stacked) LSTM cell with the well-known Luong Attention [19] to calculate the probability. Let x_t be the decoder's input and t be the item position in the bundle. We initialize h_0 with the encoder's output. Still, we omit the common details of LSTM and attention.

$$\begin{aligned} h_0 &= \text{text-CNN}(C_u) \\ x_t &= [\text{item_emb}(i_t), \text{cate_emb}(i_t), ...] \\ h_t &= \text{stacked-LSTM-attention}(h_{t-1}, x_{t-1}, C_u) \\ p(i_t|i_1,...,i_{t-1},C_u;\theta) &= \text{feature-aware-softmax}(h_t)_{i_t} \end{aligned} \tag{10}$$

The traditional softmax layer contains a weight matrix $W^{(h+1)*N} = [w_1, w_2, ..., w_N]$, where w_i could be considered as an embedding of item_id of i. Note that, we eliminate the bias term here just for writing convenience.

$$\text{softmax}(h_t, W)_j = \frac{exp(h_t^T w_j)}{\sum_{\hat{j}=1}^{N} exp(h_t^T w_{\hat{j}})} \tag{11}$$

However, the item candidates in recommendation system usually have more belonging features rather than just item_id. The traditional softmax could result in inadequate representation for weight matrix owing to the lack of features.

Inspired by pointer network [28], we propose **feature-aware (FA) softmax**, which modifies the softmax operator with feature-aware weight matrix instead of a stationary weight matrix, and makes the softmax sensitive to dynamic information. Feature-aware softmax uses the dynamic weight matrix built by $F(x_i)$, where F is a nonlinear transformation function for all kinds of features, so that the softmax could be sensitive to features besides item_id.

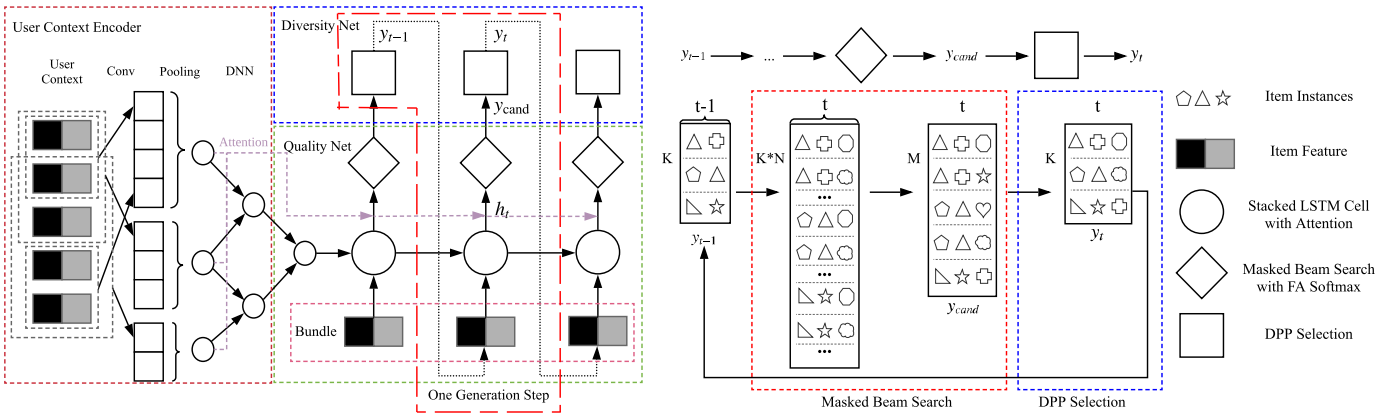
$$\begin{aligned} E^{(h+1)*N} &= [e_1, e_2, ..., e_N]^1, \qquad e_i = F(x_i) \\ \text{feature-aware-softmax}(h_t)_j &= \text{softmax}(h_t, E)_j \end{aligned} \tag{12}$$

We use the co-purchased data $\mathcal{D} = \{b, C_u\}_{1:|\mathcal{D}|}$ to guide the learning process. The loss could be defined as the mean cross entropy for the softmax layer of each step, which guarantees the same form as Equation (9) and the model is to maximize the likelihood of a single bundle.

$$\mathcal{L}_{\text{MLE}} = -\frac{1}{T}\sum_{t=1}^{T} \log p(i_t|i_1,...,i_{t-1},C_u;\theta) \tag{13}$$

However, the feature-aware softmax might be time-consuming during training owing to constructing the weight matrix E dynamically. So we apply feature-aware softmax with sampled softmax loss [12], denoted as the sampled feature-aware softmax loss, which accelerates the training process.

We show that the sampled feature-aware softmax is a generalization of optimizing the average BPR [24] at each step. The sampled feature-aware softmax samples a part of negative items at each step plus the ground truth of the next step, and then builds the corresponding weight matrix. We regard h_t as the user vector of BPR, e_{i_t} as the positive item vector, and e_{s_t} as the negative item vector, where s_t is the sampled negative item at step t. When setting the sample number to be 1, the loss of the sampled feature-aware softmax is given by:



$$\begin{aligned} \mathcal{L}_{\text{sample-1}} &= -\frac{1}{T}\sum_{t=1}^{T} \log \frac{exp(h_t^T e_{i_t})}{exp(h_t^T e_{i_t}) + exp(h_t^T e_{s_t})} + \lambda_\theta ||\theta||^2 \\ &= -\frac{1}{T}\sum_{t=1}^{T} \log \sigma(h_t^T (e_{i_t} - e_{s_t})) + \lambda_\theta ||\theta||^2 \\ &= -\frac{1}{T}\sum_{t=1}^{T} \log p(\theta| \geq_{t,C_u}) = \frac{1}{T}\sum_{t=1}^{T} \mathcal{L}_{\text{BPR}}(t) \end{aligned} \tag{14}$$

where $\sigma(\cdot)$ is the logistic sigmoid function, and $\geq_{t,C_u}$ is the pairwise preference at each step as [24]. So the feature-aware softmax with one negative item is equivalent to optimizing average BPR at each time in equation (14).

4.4 Overall Process of Bundle Generation

The goal of bundle list recommendation is to generate the high-quality and diversified bundles list y maximizing the $p(y|C_u)$ in Equation (5). We integrate and summarize the overall process of bundle generation in this subsection.

Figure 2(a) shows the overall inference process of BGN. We initialize h_0 with the output of text-CNN and then produce the bundle list by expanding the generated prefix of bundles at each step. Figure 2(b) shows how the bundle list y_t expands at each generation step. Each small shape icon denotes an item, each row

a. Overall Inference Process

b. One Generation Step

Figure 2: Inference Process of Bundle Generation Network.

of the rectangular block is a generated bundle prefix, and t indicates the aligned size of the generated bundle prefix. At each generation step, we use the beam search to produce $K * N$ candidate bundles. Beam search [30] is a heuristic search algorithm that explores the search space by expanding the most promising item in a limited set, which is widely used [26] in sequence generation approaches. Here, we use the beam search to prune the low-quality ones down to y_{cand} with width M, which is crucial for the efficiency. The submodular assumption [16] of DPPs is widely used during inference in practice including recommendation systems [6, 10], where one can find the solution in polynomial time. Following Equation (5), we choose the bundle b from y_{cand} one by one maximizing $P(y \cup \{b\})$, which is given by:

$$\begin{aligned} &\arg\max_{b \in y_{\text{cand}}} \log\det S_{y\cup\{b\}} + \sum_{\beta \in y \cup \{b\}} \log q^2(\beta|C_u) \\ \Leftrightarrow &\arg\max_{b \in y_{\text{cand}}} \log p(b|C_u) + \lambda \log\det S_{y\cup\{b\}} \end{aligned} \tag{15}$$

Here, λ is a hyper-parameter controlling the tradeoff between quality and diversity. When we increase λ, we pay more attention to the diversity among the generated bundles than the precision of the final list, and vice versa.

In addition, we need to avoid duplicated items in the bundle, and would like to generate bundles with the larger size in practice. Usually, We add a particular end token of an item to mark the end of bundle generation so that we can produce the various-length bundle. However, BGN uses the co-purchase data or pre-defined bundles to supervise the quality part. The distribution of groundtruth bundle size may not be consistent with expected distribution for target applications. In practice, one may need larger bundle size due to sellers' promotion. Besides, the traditional beam search often has a significant length bias and squeezes the distribution of bundle size to a much more skewed one that prefers shorter size, as we show in Figure 4(b) in our experiments. If we simply select the dataset with larger bundle size when training, it could cause more sparsity issue owing to the reduction of the training set.

For controlling the distribution of bundle size, as well as eliminating duplicated items, we improve the softmax with masks during beam search, which denotes the masked beam search. The masked beam search subtracts a mask vector $m_t \in \mathbb{R}^N$ to the logits for decreasing the probability in beam search during inference, which is given by:

$$\text{masked_softmax}(h_t, E, m_t)_j = \frac{exp(h_t^T e_j - m_{t,j})}{\sum_{\hat{j}=1}^{N} exp(h_t^T e_{\hat{j}} - m_{t,\hat{j}})} \tag{16}$$

where $m_{t,j}$ is the j-th element of m_t. Notice that, the mask vector reduces the certain unnormalized probabilities exponentially. In the bundle recommendation problem, we set m_t to be:

$$m_{t,j} = \begin{cases} \max(C - t, 0) & \text{j is the end token} \\ +\infty & \text{j has been generated before } t \\ 0 & \text{otherwise} \end{cases} \tag{17}$$

where C is a positive hyper-parameter for shifting the distribution of the bundle size, which gives a threshold for end token. The reduction effect due to the shifting hyper-parameter C decays exponentially with time step and dribbles away after C steps. Besides, the mask vector can avoid the duplicated elements in the bundle. We can set $m_{t,j}$ to be infinity when we definitely don't want to generate the item j at time step t.

The overall algorithm is shown in Algorithm 1, where line 5-15 show the single generation step and line 10-12 show the DPP selection according to Equation (15). Each generation step consists of the stacked LSTM cell, the masked beam search with feature-aware softmax, and the DPP selection. We consider the hidden dimension of LSTM cell is constant here. The time complexity of generating candidate list y_{cand} using beam search is $O(TMN)$, and we usually choose M larger than K to ensure that the candidate set is sufficiently diversified. The time complexity of the DPP selection at each step is $O(MK^\omega)$ where the K^ω term comes from the determinant calculation and ω denotes 2.37. Note that we do not need $O(N^2)$ space to compute and store all item pair's similarity because we only compute S_y rather than entire S. The total time complexity of inference process for BGN is $O(TMN + TMK^\omega)$.

5 EXPERIMENT

We organize the experiment section as follows. First, we clarify the experiment setup, measurement metrics, and all competitors. Second, we illustrate the performance gain of feature-aware softmax

Algorithm 1 Bundle Generation Network during Inference

Input: User context C_u, Similarity function $S(a, b)$, Quality/diversity hyper-parameter λ, Maximum bundle size T, Beam search width M, Output list size K
Output: Diversified bundle list y with size K
$h_0 \leftarrow$ text-CNN(C_u)
$y_0 \leftarrow \varnothing$
Building the weight matrix E of the feature-aware softmax according to Equation (12)
for $t \in [1, ..., T]$ **do**
    $h_t \leftarrow$ Stacked LSTM Cell with Attention(h_{t-1}, y_{t-1}, C_u)
    $y_{\text{cand}} \leftarrow$ Masked Beam Search with FA Softmax(h_t, E, m_t)
    // y_{cand} contains M bundles with maximum size t
    $y_t \leftarrow \varnothing$
    // DPP Selection
    while $|y_t| \neq K$ **do**
        Choose b from y_{cand} according to Equation (15)
        $y_{\text{cand}} \leftarrow y_{\text{cand}} - \{b\}$
        $y_t \leftarrow y_t \cup \{b\}$
    end while
    //y_t has K bundles with maximum bundle size t
end for
return $y \leftarrow y_T$

and the performance impact of the masked beam search. Then, we show the balances the diversity and the precision. Finally, we compare with all competitors to see the advantages of our methods on metrics of precision, diversity, response time for generation and AUC for ranking.

5.1 Experiment Setup

Dataset. We use three public datasets and one industrial dataset: Electro and Clothe are two public datasets of Amazon in [20] where bundles are generated from co-purchase records synthetically. Steam is a public dataset where bundles are extracted from video game distribution network in [22]. Taobao is an industrial dataset where we collect the real sales transaction of bundles from the online bundle list recommendation services. We show the statistics for each dataset in Table 1.

Dataset	Electro	Clothe	Steam	Taobao
Items	63,001	23,033	10,978	104,328
Users	192,403	39,387	88,310	2,767
Categories	801	484	-	3,607
Records	1,689,188	278,677	87,565	54,344
Bundles	327,874	72,784	615	1,236
Average Bundle Size	1.50	2.47	5.73	4.06

Table 1: Statistics of each dataset.

Amazon Dataset[1]. We use two subsets (Electro and Clothe) of Amazon product data in [20], which have already been reduced to satisfy the 5-core property, such that each of the remaining users and items has five reviews. We regard the co-purchase items as a bundle, where items are sorted in terms of their prices in a descendant order. The behavior history of each user can be represented as $(b_1, b_2, ..., b_k, ..., b_K)$ where b_k is a bundle consisting of co-purchase items. We make the first k bundle behaviors of each user as the user context to predict the $k+1$ th bundle behavior in the training set and validation set, where $k = 1, 2, ..., K-2$, and we use the first $K-1$ bundle behaviors to predict the last one in the test set. The average bundle size is 1.50 for Electro and is 2.47 for Clothe, and we notice that many bundles consist of only one item in these two datasets. For alleviating the sparsity of bundle purchase records and keeping enough training records, we consider the bundles with one item is valid in training set. However, in the test set, we only use bundles consisting of more than one items to measure the performance, which isolates the measurement from the single-item list recommendation. The features that we use contain user id, item id, category id, and bundle id. The category is a feature of items.

Steam Dataset[2]. This dataset is collected in [22] from the Steam video game distribution platform. The item is a certain game in this dataset. We partition all purchase records into 70%/10%/20% training/validation/test splits. As in Amazon dataset and Taobao dataset, Some combinations of items in the test set may never be seen in the training set, which leads to the difficulty in generation. Note that there is no feature of the category in the Steam dataset.

Taobao Dataset. This dataset is collected from an online bundle list recommendation service of a commercial e-business, Taobao[3]. Different from the synthetic bundles consisting of co-purchase items in Amazon dataset, the bundles in the Taobao dataset are predefined manually by the sellers. Correspondingly, they have higher quality and longer average bundle size. We conduct the careful collection which guarantees that each user has at least three bundle behaviors. We use the last one of bundle behaviors in the test set and the others in the training set. The user context consists of items which users have purchased. The features that we use contain user id, item id, category id, and bundle id.

Measurements. For the bundle generation problem, the metrics we mainly consider are the top-k precision ***pre@k*** measuring the quality and the cross-bundle diversity ***div***. The *pre@k* is the average precision with the ground truth over each user and each position in the final bundle list. The *div* is defined as 1 − Jaccard Similarity over each pair of the final bundle list.

$$pre@k = \frac{1}{|U|} \sum_{u} \frac{1}{|K|} \sum_{b \in y_u} \frac{|b \cap gt_u|}{|b \cup gt_u|} \tag{18}$$

$$div = \frac{1}{|U|} \sum_{u} \frac{1}{|K|(|K|-1)} \sum_{a,b \in y_u} (1 - \frac{|a \cap b|}{|a \cup b|}) \tag{19}$$

where gt_u is the ground truth bundle that a user buys or clicks. According to the dataset setup above, there is only one bundle in gt_u for the Amazon and Taobao dataset, and there are multiple bundles in gt_u for the Steam dataset. Let y_u be the final recommendation bundle list with size K, U be all users in the test set. These two metrics can be applied to any case no matter whether the bundle is predefined. Note that, the repeated items belonging to different

[1] http://jmcauley.ucsd.edu/data/amazon

[2] http://jmcauley.ucsd.edu/data/steam.tar.gz

[3] https://www.taobao.com

bundles hit the ground truth and increase the *pre@k*, but they decrease *div*.

For studying whether our method can adapt to the bundle ranking problem, we use the **AUC** to evaluate the performance, which is given by:

$$AUC = \frac{1}{|U|} \sum_{u} \frac{1}{|gt_u|} \sum_{b^+ \in gt_u} \delta(\hat{p_{u,b^+}} > \hat{p_{u,b^-}}) \tag{20}$$

where $\hat{p_{u,b}}$ is the predicted probability that a user may act on a bundle and $\delta(\cdot)$ denotes an indicator function. Note that, b^- is sampled uniformly from all valid bundles in the dataset, which are all co-purchase records consisting of more than two items for the Amazon dataset and all pre-defined bundles for the Steam and Taobao dataset.

Competitors. We mainly consider six methods as below:

- **BGN**. This denotes our Bundle Generation Network method. For CNN encoder of user context, we use various filters with the window size of $\{1, 2, 4, 8, 12, 16, 32, 64\}$, and each filter contains 12 output channels, so the final dimension of output channel is 96. The other latent dimension is set to be 64. We use two layers' stacked LSTM cell with attention in the decoder. The batch size is set to be 16. We use l2-loss in the training process, and the weight is set to be 5e-5. Adam is adopted as the optimizer. The beam search width is set to be 50. The sample number of sampled feature-aware softmax is set to be 1024. We use Equation (8) as the similarity function. λ is the quality/diversity hyper-parameter ranging from 0.0 to 5.0 with step 0.25. C is the shifting hyper-parameter controlling the distribution of bundle size, which ranges from 0 to 20 with step 1.0.
- **Freq**. This is a well-known frequent itemsets mining algorithm introduced in [2], and we generate bundles according to frequent itemsets discovered in co-purchase or pre-defined bundles. Then we recommend the most frequent k bundles to users. Note that this is not a personalized method.
- **BRP**. *BRP* (Bundle Recommendation Problem) [36] is a personalized single bundle recommendation algorithm, which optimizes the expected reward based on Mixed-Integer Quadratic Programming (MIQP). We use matrix factorization as the probability model which has the best performance in the original paper, and use Gurobi[4], one of the fastest public mathematical programming solver, to optimize the MIQP problem.
- **BBPR**. *BBPR* (Bundle Bayesian Personalized Ranking) is proposed by [22]. It builds the optimization criterion upon the Bayesian Personalized Ranking(BPR) [24], with the mean pair-wise Pearson correlation of the items. Combined with traditional matrix factorization techniques, it utilizes both item and bundle information including bundle size and item compatibility for better performance. As for the bundle generation, it proposes a greedy algorithm following an annealing schedule to give personalized bundles, which avoids ranking for all possible bundles. In the Steam dataset, we maintain the setup of typer-parameters as the original paper, and in other datasets, we deploy a small range of fine-tuning and report the best results.
- **RankAll**. *RankAll* ranks all the existing bundles in the training set and returns the top-K results, and we consider it as a strong baseline to validate whether the ranking methods are good enough for the bundle generation task regardless of the consumption of time and space. Note that, *RankAll* refers to rank all the existing bundles in the training set, instead of ranking all possible bundles in $\mathcal{B}$, which is too large to enumerate even for modern machines. Specifically, *RankAll* adopts the same loss as *BBPR*, but utilizes two text-CNN networks to extract the user context and the bundle information respectively. The hyper-parameter setting of text-CNN is agree with *BGN*. Ranking all the existing bundles in the training set is time-consuming and usually is unacceptable in practice.

Environment. All experiments are conducted on a machine with one GPU (NVIDIA Tesla P100 16G) and 96 CPUs (Intel Xeon Platinum 2.50GHz). We use Tensorflow [5] as the main toolkit of neural network.

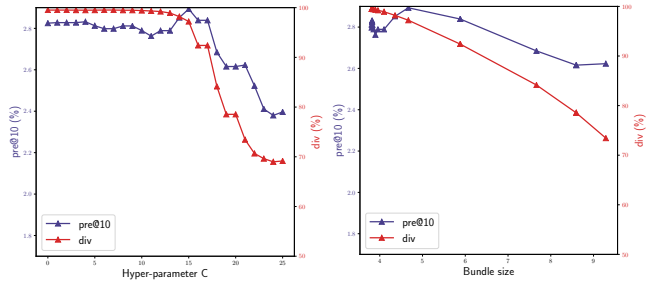
5.2 Feature-Aware Softmax Performance Gain

The feature-aware softmax combines more features besides the item_id in the weight matrix of softmax. We demonstrate the performance gain of all datasets in Table 2, where 'w/o FA' denotes 'without feature-aware' and 'w/ FA' denotes 'with feature-aware' for short.

Dataset		Electro	Clothe	Steam	Taobao
pre@10	BGN w/o FA	0.32%	0.13%	-	1.75%
	BGN w/ FA	0.60%	0.38%	9.65%	2.82%
pre@5	BGN wo/ FA	0.38%	0.12%	-	1.83%
	BGN w/ FA	0.67%	0.43%	14.96%	3.09%

Table 2: Feature-Aware (FA) softmax Performance Gain

In Table 2, we observe that the proposed feature-aware softmax can improve the precision significantly, which yields the improvements on *pre*@10 by 0.87x, 1.92x and 0.61x on Electro, Clothe and Taobao dataset respectively. The gain brought by feature-aware softmax indicates that, compared to the traditional softmax, the feature-aware softmax considers more features in the weight matrix and alleviates the sparsity issue of item_id effectively in bundle generation. The performance gain also verifies the importance of features for recommendation tasks as in [8]. Note that there is no feature of categories in the Steam dataset, so there is no difference with feature-aware softmax.



Note that all competitors except *Freq* consider the same complete features as BGN, but BGN with feature-aware softmax performs better because we factorize the bundle probability as a sequence of conditional probability, which is equivalent to optimizing generalized BPR loss directly at each step as shown in Equation (14).

[4] http://www.gurobi.com/

[5] https://tensorflow.org

5.3 Performance Impact due to controlling the Bundle Size

The distribution of the training data may not be consistent with the distribution of the bundle size for the target application. According to the masked beam search, we study the performance impact due to controlling the Bundle Size.

(a) Hyper-parameter C (b) Bundle Size

Figure 3: Performance Impact of the Masked Beam Search (Taobao)

The masked beam search controls the distribution of bundle size by changing a shifting typer-parameter C according to Equation (17), which reduces the unnormalized probabilities exponentially of generating the end token. We show in the Taobao dataset how the distribution of bundle size is altered in Figure 4 and the effect on the precision and diversity in Figure 3.

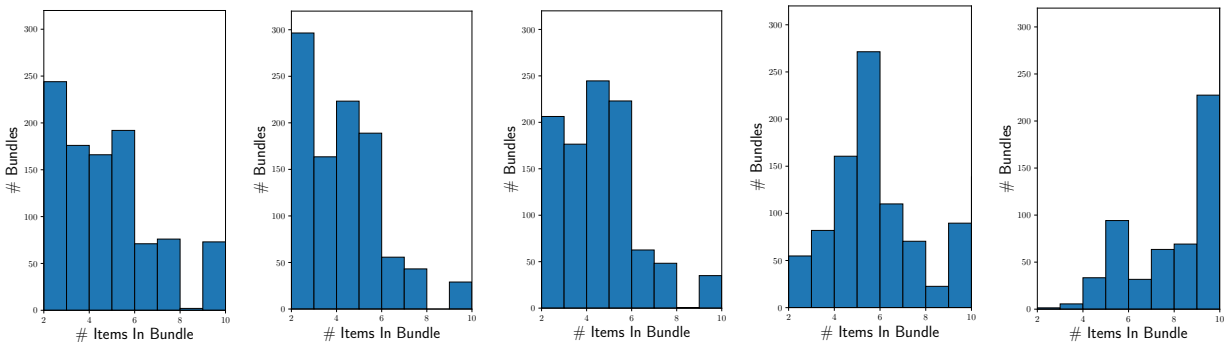
In Figure 4, we notice that the masked beam search does shift the distribution of bundle size. The distribution shifts significantly compared to the original beam search when setting C to be 14, and with the increase of C the average bundle size shifts as we expected. However, the shifting parameter C enforces the network to generate the most likely items, although the generation should have ended. As shown in Figure 3, C is set from 0 to 20 with step 1.0, which leads to the bundle size varying from 3.8 to 9.2, then we show the performance impact about the precision and diversity respectively for the C and bundle size. We notice that the precision still holds when we shift the bundle size from 3.8 to 6.0, but both the precision and diversity decrease if we continue shifting. Though our shifting strategy is simple, it is good enough to control the distribution in a small range in practice and it might be promoted in the future work through considering the long-term reward in advance by reinforcement learning.

5.4 Balance Between Precision and Diversity

According to Algorithm 1, we produce the diversified bundle list by combining the beam search and DPPs, which chooses the item maximizing the objective function of the quality and diversity in Equation (15). The hyper-parameter λ balances between the precision and the diversity. The metric of diversity is a separate metric from CTR and precision, trying to quantify the user-experience in a bundle recommendation system. When we increase λ, we pay more attention to the diversity among the generated bundles than the precision of the final list, and vice versa. We select K bundles from M candidates generated from the beam search with $M = 50$, $K = 10$ at each step, and λ is set from 0 to 5 with step 0.25 and C is set to be 0.

We show in Figure 5 that in all datasets, the precision decreases along with the growth of diversity as we expected. We also mark the other competitors' results as points in the figure, and we omit the competitors whose precision is too poor. Feature-aware softmax and beam search guarantee that BGN has a high precision base, meanwhile, DPP selection ensures to improve the diversity steadily with a tolerable reduction in precision. With adjustment of the λ, the curve formed by BGN is completely at the top right of all competitors. We achieve the highest precision and diversity in contrast with all competitors in all datasets.

5.5 Comparison in the Bundle Generation Problem



By comparing the proposed BGN against the other competitors including, *Freq*, *BRP*, *BBPR*, *RankAll*, *Seq2seq*, we report and analyze their performance in terms of the precision metric *pre@k*, the diversity metric *div*, and the average response time per user of these methods during inference, denoted by *avg-time* in Table 3. Note that the shifting hyper-parameter C of BGN is set to be 0 in this part becasue we have shown the performance results of shifting the bundle size in Figure 3.

Freq performs poorly in term of precision on all datasets, because it is a non-personalized method, but *Freq* performs quite diverse in Amazon dataset. We think that it is because the bundles of two Amazon datasets are generated synthetically by co-purchase records, which contain more diversified bundles naturally, whereas, the bundles of Steam and Taobao dataset is pre-defined by sellers.

BRP produces only one bundle, so there is no diversity reported. We repeat the results K times to produce the list for achieving the higher precision, which is well-defined because our metric of precision averages on each position. With regard to precision, *BRP* performs better than *Freq* owing to the personalization and consideration of the the first and second cross-item dependencies, but it ignores the higher order terms and gives a sub-optimal result. Besides, compared with other methods, solving the mixed-integer quadratic programming (MIQP) problem is time-consuming.

BBPR produces a personalized list of bundles instead of one. This method utilizes both item and bundle information including bundle size and the pair-wise Pearson correlation of the items, which performs better than *Freq* and *BRP* on most of the dataset. However, the annealing schedule leads to randomness in generating bundles and is easily caught in the local optimum due to instability of annealing.

RankAll performs better than *BBPR* and *BRP* on the metrics of precision and diversity on all datasets, because it uses CNN as a context extractor capturing more combinatorial generalization of features. But for the response time, *RankAll* is the most time-consuming approach on almost all datasets. Because the inference time of *RankAll* is approximately proportional to the number of bundles, whereas, other methods are approximately proportional to the number of items. Essentially, *RankAll* is not a generative model, but a ranking model which ranks the existing bundles to give the final recommendation list. It wastes most of the time scoring the low-quality bundles and it is not scalable in practice. Furthermore, it

BRP	0.324%	-	4.85s	0.149%	-	3.96s	6.750%	-	0.44s	0.332%	-	5.47s
BBPR	0.308%	95.87%	0.68s	0.122%	85.56%	0.34s	7.168%	87.32%	0.29s	0.357%	95.49%	1.27s
RankAll	0.443%	88.87%	55.97s	0.280%	89.23%	7.94s	9.497%	97.63%	0.11s	1.540%	98.19%	1.38s
BGN ($\lambda = 0$)	**0.607%**	87.22%	**0.05s**	**0.387%**	81.63%	**0.03s**	**9.655%**	98.01%	**0.04s**	**2.825%**	99.50%	**0.24s**
BGN ($\lambda = 5$)	0.469%	**96.68%**	0.09s	0.235%	**95.75%**	0.06s	9.617%	**99.08%**	0.06s	2.739%	**99.88%**	0.28s

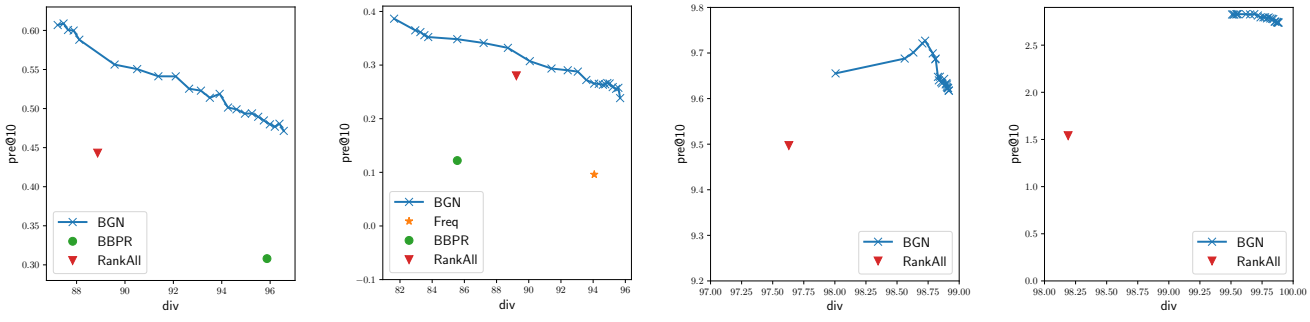

Table 3: *pre*@10, *div*, *avg-time* of Different Methods in the Bundle List Recommendation Problem.

could not produce new bundles beyond the existing ones in training data, which limits the precision.

BGN achieves the best precision, diversity and fastest response time at the same time on all datasets. The high precision benefits from the the feature-aware softmax. However, when setting λ to be 0, BGN has low diversity especially in the synthetic bundle because traditional seq2seq is easy to generate similar sentences. When we simply set the λ to be 5, BGN balances the quality and diversity, which improves the precision of the best baselines by 16% on average while maintaining the highest diversity on four datasets. Besides, BGN is a sequnce generation approach without ranking or recursive searching. The time complexity of BGN during inference is proportional to the number of items. So our model achieves fastest response time in bundle list recommendation problem. Specifically, BGN improves the response time by 6.5x, 4.6x, 0.8x, 3.5x on four datasets respectively over the best competitors when λ equals 5.

5.6 Comparison in the Bundle Ranking Problem

BGN is designed for the bundle list generation problem. However, we can adopt it in the bundle ranking problem, by feeding the candidate bundles to the inputs of the decoder and taking the negative loss as the ranking score, so that we compare with other competitors in the bundle ranking problem. Note that, the absolute values of the AUC in the bundle ranking problem are usually lower than the one in the item ranking problem because the sample space for bundles is larger and more sparse.

(a) Electro (b) Clothe (c) Steam (d) Taobao

Figure 5: Balance between Precision and Diversity.

AUC	Electro	Clothe	Steam	Taobao
BBPR	74.85%	66.20%	90.27%	60.24%
RankAll	75.51%	66.97%	**99.66%**	60.93%
BGN	**78.11%**	**69.99%**	99.36%	**61.27%**

Table 4: AUC Tests in the Bundle Ranking Problem.

In Table 4, we show the measurement of AUC for different methods, and BGN improves the best baseline by 2.04% on average on four datasets. Actually, in the bundle ranking setup, all competitors in Table 4 can be regarded as the encoder-decoder framework, where the encoder extracts the user context information and the decoder extracts the bundle information. The major differences are the architectures of specific neural network and the loss function. With the help of the feature-aware softmax, BGN is good at utilizing the feature information, because the weight matrix of softmax is built dynamically and its loss is a generalization of optimizing the average BPR at each step. The Steam dataset has no category feature, so BGN is worse than *RankAll* slightly on this dataset.

6 CONCLUSIONS

This paper studies a problem of personalized bundle list recommendation and proposes a bundle generation network (BGN). BGN decomposes the problem into the quality/diversity part to produce the high-quality and diversified bundle list. The proposed feature-aware softmax makes up the inadequate representation of traditional sequence generation for rich features in bundle recommendation scenario, which improves the modeling of quality significantly. We conduct extensive experiments on three public datasets and one industrial dataset. BGN achieves the best state-of-the-art results on the metrics of precision, diversity and response time on all datasets. Besides, BGN can control the bundle size with a tolerable reduction in precision.

ABSTRACT

Clinical notes contain detailed information about health status of patients for each of their encounters with a health system. Developing effective models to automatically assign medical codes to clinical notes has been a long-standing active research area. Despite a great recent progress in medical informatics fueled by deep learning, it is still a challenge to find the specific piece of evidence in a clinical note which justifies a particular medical code out of all possible codes. Considering the large amount of online disease knowledge sources, which contain detailed information about signs and symptoms of different diseases, their risk factors, and epidemiology, there is an opportunity to exploit such sources. In this paper we consider Wikipedia as an external knowledge source and propose **K**nowledge **S**ource **I**ntegration (KSI), a novel end-to-end code assignment framework, which can integrate external knowledge during training of any baseline deep learning model. The main idea of KSI is to calculate matching scores between a clinical note and disease related Wikipedia documents, and combine the scores with output of the baseline model. To evaluate KSI, we experimented with automatic assignment of ICD-9 diagnosis codes to the emergency department clinical notes from MIMIC-III data set, aided by Wikipedia documents corresponding to the ICD-9 codes. We evaluated several baseline models, ranging from logistic regression to recently proposed deep learning models known to achieve the state-of-the-art accuracy on clinical notes. The results show that KSI consistently improves the baseline models and that it is particularly successful in assignment of rare codes. In addition, by analyzing weights of KSI models, we can gain understanding about which words in Wikipedia documents provide useful information for predictions.

1 INTRODUCTION

Clinical notes are free-text documents generated by healthcare professionals documenting clinical status of patients during hospital stay or outpatient care. Clinical notes contain various nuanced information such as a history of illness, lifestyle, symptoms, treatment, and medications. Clinical notes are used to facilitate communication between medical professionals treating the same patient over time, to provide a basis for billing, and to create a record trail in case of legal issues. Medical coding, which refers to translating a clinical note into a set of medical codes from a medical ontology, is necessary to obtain reimbursement for the provided healthcare services. The most popular medical coding ontology is the International Classification of Diseases (ICD, with the most recent versions ICD-9 and ICD-10), whose codes provide alphanumeric encoding of diagnoses and treatments as shown in Table 1. Interestingly, beyond their primary billing purpose, medical codes have been widely used in healthcare research such as predictive modeling [1, 3, 4, 8, 33, 34] and retrospective epidemiologic studies [24, 36, 40]. The reason for popularity of medical codes in research is that it abstracts away fine details of care from the free-text clinical notes and normalizes a patient encounter to a standardized computer-readable format.

Medical coding is typically performed by professional staff trained to understand clinical notes containing complex medical terminology with frequent misspellings and abbreviations and transcribe the notes into a limited set of appropriate medical codes from a large menu of options (e.g., ICD-10 contains more than 100,000 codes). Thus, medical coding is an expensive, time consuming, and inexact process. Due to these issues, there has been a significant interest in developing automatic code assignment models and it has been a long-standing research challenge [6, 10, 11, 13, 22, 25, 29–31, 35, 37, 39].

Recently, deep neural networks with attention mechanism have been shown to achieve the state-of-the-art performance on automatic code assignment task [6, 29, 35, 39]. The attention mechanism [2, 26] uses one or more layers of neurons to identify words indicative of a specific disease and assigns them large weights. The success of the attention mechanism could be attributed to the property of medical code assignment: the relevant information for a specific medical code is often located in a small portion of a clinical note.

Despite the success of deep neural networks with the attention mechanism, there are still outstanding challenges that remain to be addressed. In this paper we address an issue related to recognition of rare codes. To illustrate the issue, let us consider MIMIC-III [18], the largest publicly-available database containing 59,652 discharge notes from the Beth Israel Deaconess Medical Center's Intensive Units. There are 942 unique 3-digit ICD-9 codes occurring in the dataset in a highly unbalanced way, where the most common 10

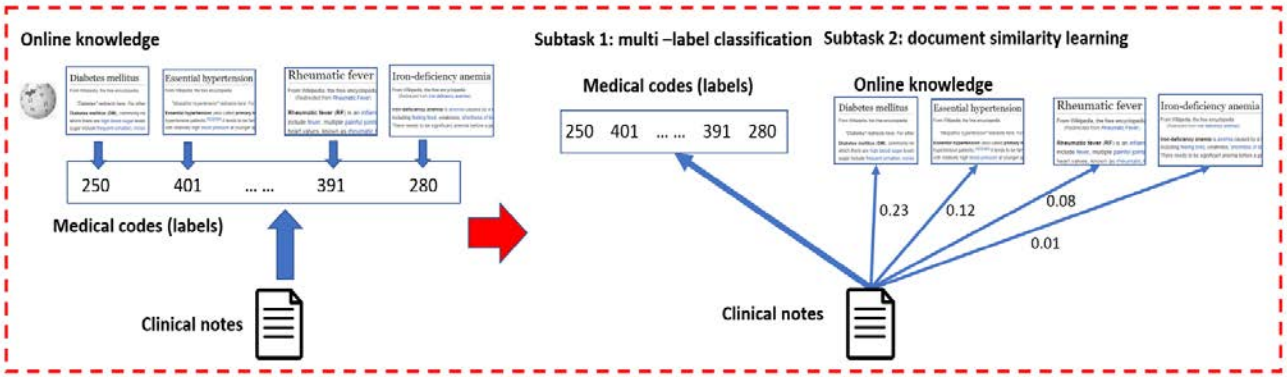

Figure 1: Our main goal is to predict medical codes from clinical notes by taking advantage of online knowledge sources. We decompose the task into two parallel subtasks: the first subtask is traditional multi-label classification and the second subtask is document similarity learning.

Table 1: Examples of 3-digit ICD-9 codes and their descriptions (249-259).

ICD-9 code	Description
249	Secondary diabetes mellitus
250	Diabetes mellitus
251	Other disorders of pancreatic internal secretion
252	Disorders of parathyroid gland
253	Disorders of the pituitary gland and its hypothalamic control
254	Diseases of thymus gland
255	Disorders of adrenal glands
256	Ovarian dysfunction
257	Testicular dysfunction
258	Polyglandular dysfunction and related disorders
259	Other endocrine disorders

Table 2: Wikipedia webpage for ICD-9 code "250" (partially shown).

ICD-9 code: 250 (Diabetes mellitus)
Diabetes mellitus Diabetes mellitus (DM), commonly referred to as diabetes, is a group of metabolic disorders in which there are high blood sugar levels over a prolonged period. Symptoms of high blood sugar include frequent urination, increased thirst, and increased hunger. If left untreated, diabetes can cause many complications. Acute complications can include diabetic ketoacidosis, hyperosmolar hyperglycemic state, or death. Serious long-term complications include cardiovascular disease, stroke, chronic kidney disease, foot ulcers, and damage to the eyes.

codes account for 26% of all code occurrences and the least common 437 codes account for only 1% of the occurrences. Thus, there is highly limited information available for training a neural network to recognize such rare codes. The rare codes problem is particularly severe considering the length of clinical notes: each MIMIC-III discharge note contains an average of 1,596 words. Even with the attention mechanisms, it would be very difficult to learn to identify relevant portions of text from only a few examples.

In this paper we consider exploiting online knowledge sources to improve accuracy of medical code prediction from clinical notes. There are rich disease-related online knowledge sources such as Mayo Clinic, Wikipedia, and Medscape, which contain detailed information such as signs, symptoms, and epidemiology useful for differentiating different diseases in the clinical notes. For example, as shown in Table 2, from a Wikipedia article introducing diabetes, we learn that the typical signs of diabetes include frequent urination, increased thirst, and increased hunger. If a clinical note also mentions in a passage that a patient is having these symptoms, then the passage could be used as an evidence for diabetes. In this paper we use Wikipedia, because it is an easily accessible online resource with loose license constraints that has already been widely studied in the research community. In order to take advantage of the existing state of the art neural networks for medical code prediction, instead of building a completely new model, we develop a framework called **K**nowledge **S**ource **I**ntegration (KSI), which is able to enhance the state of the art neural networks with information from the external knowledge sources. As illustrated in Figure 1, the proposed architecture consists of two components. The first component is directly predicting codes from a note, and it could be any of the state of the art neural networks. Our main contribution is the second component, which is a neural network whose objective is to learn similarity scores between a note and Wikipedia articles about various diseases. Each similarity score measures how closely a clinical note is associated with a corresponding medical code. Finally, the proposed architecture combines the similarity scores with the output of the first subtask and learns to optimize both components to minimize the loss between the predictions and the true labels.

Using Wikipedia as an external knowledge source for analyzing clinical notes poses a couple of challenges. First, there are significant differences between content of Wikipedia articles and clinical notes. Wikipedia articles are mostly carefully edited and the terminology used is optimized toward the general audience. Since Wikipedia can be edited by anyone with Internet access, there is a certain risk that the provided information is incorrect. On the contrary, clinical

notes are written by medical professionals in a hurry and contain a lot of non-standard abbreviations, misspellings and specialized medical terminology. Second, the coverage of Wikipedia and clinical notes are very different. As a knowledge base, Wikipedia elaborates different aspects of diseases including pathophysiology, prevention, history, and social impact, which are unlikely to appear in clinical notes. On the other hand, clinical notes contain patient conditions, including medications on admission and allergies, which are unlikely to occur in Wikipedia articles. In summary, these two types of documents have very different data distributions, which makes unsupervised document similarity measures such as Word Mover's Distance [21] unsuitable, as we need to carefully deal with noise and misleading information in the documents and focus on aspects important for medical code prediction.

In order to properly handle the above challenges, in this paper we develop a supervised document similarity learning model, which is designed to measure the similarity of two types of documents with very different data distributions. To accomplish this, we first take intersection of a clinical note and a Wikipedia document. The intersection operation discards disparate parts of the text and focuses on the common aspects of the two documents. Then, we project the intersection into a low dimensional vector space to reduce dimensionality. Since terms remaining in the intersection might have different importance for medical code prediction, next we apply an attention mechanism to weight the terms. Finally, the weighted intersection vector is transformed into a matching score, which measures the similarity between the two documents. All matching scores are combined with the output of the baseline neural network model and trained to predict medical codes.

In our experiments we selected a variety of baseline models, from simple logistic regression to a recently proposed attention based deep neural network, which achieves the state-of-the-art performance. We show that our KSI framework of incorporating external knowledge sources consistently improves the baseline models. Moreover, thorough analysis shows that KSI significantly improves accuracy of rare code prediction. Finally, by analyzing attention values and weights of the model, our framework reveals which words in Wikipedia documents are the most influential to the prediction, which is important for understanding the reasoning behind the prediction.

Our work makes the following contributions:

- We propose a novel end-to-end framework to integrate external knowledge sources with any end-to-end baseline neural network model for the task of medical code prediction from clinical notes.
- We empirically show that our framework improves a variety of baseline models, including the state of the art attention based neural networks, and that the improvement is particularly large on rare codes.
- We demonstrate that our framework allows interpretability via analyzing attention values and weights of the model, which sheds light on the connection between the external knowledge source and clinical text.

We organize the rest of the paper as follows: in Section 2 we discuss the related previous work. Section 3 presents our KSI framework. In Section 4 we explain the experiment design. The results are shown and discussed in Section 5.

2 RELATED WORK

2.1 Prediction of Medical Codes from Clinical Notes

Automatic assignment of medical codes is a long-standing research area dating back to 1990s [11]. [11] represents clinical notes and ICD-9 codes as two TF-IDF vectors and calculates cosine similarity in the joint vector space. Later, a variety of methods were applied to this area, ranging from rule-based methods [10, 13] to machine learning methods such as K-nearest-neighbor, relevance feedback, Bayesian independence classifiers [22] and support vector machines [25]. In [30, 31] the authors develop methods which exploit the hierarchical tree structure of ICD-9 ontology. More recent models combine neural networks with attention mechanism. In [6], the authors apply hierarchical attention networks [41], which calculate both word-level attention and sentence-level attention while predicting medical codes. In [35], the authors apply character-aware neural network to generate hidden representations of ICD-9 codes and diagnosis section in clinical notes and use the attention mechanism to match these two hidden representations. Their ICD-9 descriptions are quite short (typically, less than 10 words), while in our case a Wikipedia document contains thousands of words providing multiple views of a disease. In [37] the authors propose a modified GRU, where each dimension in the hidden vector corresponds to a specific label, and use their model on medical code prediction. In [29], the authors combine the attention mechanism with a convolutional neural network [19] and report state-of-the-art accuracy on a medical prediction task. In [39], the authors project both words and labels into the same low-dimensional vector space and calculate the compatibility/attention between them. Then, they combine the attention values with word embeddings to get the final document representation. None of the above approaches incorporate external knowledge sources on the task of medical code prediction.

In [32], the authors use memory network to infer clinical diagnosis from clinical notes. While they also use Wikipedia as knowledge source, their work is different from ours in several ways: first, their focus is on a different task, which uses a much smaller diagnosis label set directly derived from clinical notes, while we use accurate medical codes as labels. Second, their memory network is highly specialized and hard to generalize, while our framework can incorporate knowledge into any end-to-end neural network model developed in this field. Lastly, their model is hard to interpret, while our attention based model sheds light on how knowledge source and notes are connected.

2.2 Attention Mechanism

The attention mechanism was first proposed in machine translation [2, 26] to select the most relevant words in a source sentence while predicting the next word in the target sentence. Typically, a neural network is applied to the context vector, generated by either Recurrent Neural Network (RNN) or Convolutional Neural Network (CNN), and attention values are expected to capture the importance

of the context vectors. Final sentence or document representations are simply the sum of context vectors weighted by the attention values. The attention mechanism is widely used in natural language processing [2, 6, 29, 35, 38, 39, 41] and sequence modeling in healthcare domain [5, 9, 27, 33]. Our variable-level attention mechanism is the most similar to [9] because we compute attention on different vector elements. Our work is different in a way that we focus on learning attention of clinical words, instead of medical codes.

2.3 Document Similarity Learning

Document similarity computation transforms two documents into a score depicting how similar the two documents are. Documents are typically transformed into vectors, with each dimension corresponding to the statistic of a word (count, occurrence or TF-IDF [16]) in the vocabulary. Then, similarity between two documents is calculated as the cosine similarity between the two vectors. Other methods transform documents into low-dimensional vectors which capture semantics of documents, such as singular vector decomposition [12] or latent dirichlet allocation [7]. More recently, doc2vec [23] uses architecture similar to word2vec [28] in order to learn document emebddings. Word Mover's Distance [21] exploits high quality word embeddings and treats the document distance as an instance of Earth Mover's Distance. The above approaches are unsupervised. Supervised approaches such as supervised Word Mover's Distance [17] and neighborhood components analysis [14] consider label information while learning similarity between two vectors. However, there is no explicit way to handle the situation where each instance has multiple labels. Moreover, as mentioned before, Wikipedia and clinical notes have very different distributions, thus making direct measurement of the similarity unsuitable. On the contrary, our approach first calculates the overlap between two documents and then uses the attention mechanism to select the most informative parts for medical code prediction.

3 METHODOLOGY

In this section we describe the proposed KSI framework. We first introduce the problem setup and our goal. Then, we describe the details of the proposed approach. Finally, we show how to interpret the learned model via analyzing attention values and weights of neural network associated with words in clinical notes and Wikipedia documents.

3.1 Basic Problem Setup

Assume our dataset is a collection of clinical notes. Each note N consists of a sequence of words. N is accompanied with a set of medical codes M corresponding to the note. We denote the size of word vocabulary $W = \left\{w_1, w_2, ..., w_{|W|}\right\}$ as $|W|$ and the size of medical code vocabulary $C = \left\{c_1, c_2, ..., c_{|C|}\right\}$ as $|C|$. In addition, we have an external knowledge source K which contains a set of documents $K = \left\{k_1, k_2, ..., k_{|C|}\right\}$ in which each document k_i is a sequence of words. Each unique medical code c_i in the medical code vocabulary C has a corresponding document k_i in K. Given a clinical note N, our goal is to predict associated medical codes M when knowledge source K is available. This is naturally a multi-label text classification problem.

3.2 KSI Framework

As shown in Figure 1, when each label (*i.e.*, medical code) c_i has a document k_i in knowledge source K, we can calculate the likelihood of label c_i as the similarity between document k_i and note N. Therefore, we decompose the prediction task into two parallel subtasks. As shown in Figure 2, the first subtask is to directly predict codes from notes, which can be achieved by any end-to-end multi-label classification model in this field. We denote the baseline model as f, which is a mapping from notes N to the label space. The last layer of f is a vector $o_1 \in \mathbb{R}^{|C|}$

$$o_1 = f(N). \tag{1}$$

Since the task is multi-label classification, a sigmoid activation function is applied to o_1 and the i-th dimension in the resulting vector represents the probability that code c_i is the true label. Loss values are calculated between the output and the true labels. In KSI framework o_1 is combined with the output of subtask 2 to get the final output. We select a variety of baseline models and describe the details in the next section. Our main focus is the second subtask, *i.e.*, to learn similarity scores between Wikipedia documents and a note.

First, we represent note N as binary vector $q \in \{0,1\}^{|W|}$ and Wikipedia document k_i as binary vector $x_i \in \{0,1\}^{|W|}$. Binary vectors encode the presence of words. If word occurs in the document, then the corresponding element has value 1, otherwise it is 0. By encoding documents as binary vectors we lose the frequency information. However, as mentioned before, the frequency does not necessarily reflect the importance of words for code prediction since these two types of documents have very different data distributions, *e.g.*, in the Wikipedia document about "influenza", word "birds" has high frequency because there is one section in the document talking about "bird flu". As we formulate the similarity learning in a supervised framework, we expect the network to be able to assign large weights to important words for the task.

After we represent both N and k_i as binary vectors, we calculate their element-wise multiplication as

$$z_i = x_i \odot q, \tag{2}$$

where $z_i \in \{0,1\}^{|W|}$ represents the intersection of two documents. Value of words that appear in both documents equals 1, otherwise it is 0. By taking the intersection operation, we discard irrelevant parts in two documents and focus on the common content between them.

Then, we use an embedding matrix $W_e \in \mathbb{R}^{m \times |W|}$ to transform the high-dimensional sparse vector z_i into a low-dimensional vector space

$$e_i = W_e z_i, \tag{3}$$

where $e_i \in \mathbb{R}^m$ denotes the embedding of z_i and m is the dimensionality of the embedding space. e_i is expected to capture the semantic information about the intersection set. In e_i, each element has its own latent meaning and represents a hidden topic. Since not all topics are relevant to the prediction task, we use a variable-level attention mechanism to weight variables in the vector. We use weight matrix $W_a \in \mathbb{R}^{m \times m}$ to calculate the attention values as

$$\alpha_i = sigmoid(W_a e_i) \tag{4}$$

$$v_i = \alpha_i \odot e_i, \tag{5}$$

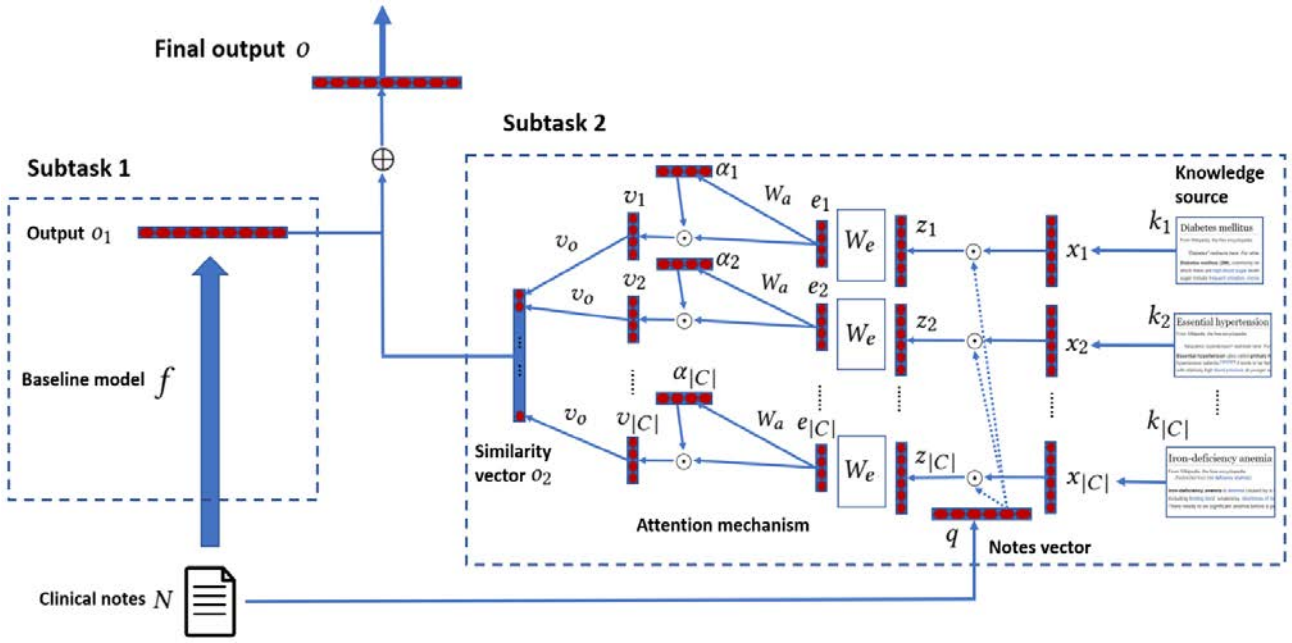

Figure 2: The illustration of our KSI framework. First, it represents document k_i and clinical note N as binary vectors x_i and q. Then, it performs element-wise multiplication of x_i and q to obtain the intersection vector z_i. Next, it projects z_i into a low-dimensional vector e_i. Next, the attention mechanism is used to transform e_i into a weighted vector v_i. Finally, it projects v_i into a similarity score and the concatenation of all scores is combined with the output of baseline model to get the final output.

where $\alpha_i \in \mathbb{R}^m$ is the attention weight vector and $sigmoid()$ is the sigmoid activation function. $v_i \in \mathbb{R}^m$ is the weighted embedding which is the element-wise multiplication of α_i and e_i.

Next, we use a vector $v_o \in \mathbb{R}^m$ to transform v_i into a similarity score s_i as

$$s_i = v_o^T v_i + b_o, \tag{6}$$

where s_i depicts how similar Wikipedia document k_i and note N are and b_o is a scalar bias term. We concatenate the similarity scores for all $k_i \in K$ to get the similarity vector $o_2 \in \mathbb{R}^{|C|}$,

$$o_2 = [s_1, s_2, ..., s_{|C|}]. \tag{7}$$

Finally, the similarity vector o_2 is combined with the output of the baseline model o_1 to get the final output vector $o \in \mathbb{R}^{|C|}$ as

$$o = o_1 + o_2 \tag{8}$$

$$\hat{y} = sigmoid(o), \tag{9}$$

where $\hat{y} \in \mathbb{R}^{|C|}$ is the predicted label vector. True labels are also represented as a binary vector $y \in \{0,1\}^{|C|}$ and the training procedure minimizes the binary cross-entropy loss between the predicted values and the true values,

$$L_{BCE}(N, y) = -(\sum_{i=1}^{|C|} y_i \log(\hat{y_i}) + (1 - y_i) \log(1 - \hat{y_i})), \tag{10}$$

where we sum the binary cross entropy errors over all dimensions of $\hat{y}$. Note that equation (10) is the loss for one note. In our implementation, we calculate the average loss for multiple notes. We use Adam optimizer [20] to minimize the above loss values. For deep learning based models (CNN and RNN based models), it typically takes a long time to converge. Therefore, in our training, we first deactivate the document similarity learning part of the model to let the baseline model converge. We activate the document similarity learning part and disable parameters updating in the baseline model when the performance of baseline model stops increasing on the validation set as the early stopping criteria.

3.3 Interpreting KSI framework

Interpretability is a model's ability to provide rationale behind its behavior. In KSI framework, the larger the s_i is, the more evidence Wikidedia knowledge source provides for predicting code c_i. To understand what evidence Wikipedia knowledge source provides, we need to calculate the contribution of each variable in x_i to the final similarity score. By combining equations (6) and (5), we get

$$s_i = v_o^T v_i + b_o = v_o^T (\alpha_i \odot e_i) + b_o. \tag{11}$$

Since α_i are weights of e_i, we keep them fixed and decompose e_i. As in equation (3), e_i is the sum of the columns of W_e weighted by each variable in z_i, and we can rewrite equation (11) as

$$\begin{aligned} s_i &= v_o^T (\alpha_i \odot (\sum_{j=1}^{|W|} z_{i,j} W_e[:, j])) + b_o \\ &= \sum_{j=1}^{|W|} v_o^T (\alpha_i \odot W_e[:, j]) z_{i,j} + b_o. \end{aligned} \tag{12}$$

Using equation (2), we can further decompose $z_{i,j}$ as the product of $x_{i,j}$ and q_j,

$$s_i = \sum_{j=1}^{|W|} v_o^T(\alpha_i \odot W_e[:,j]q_j)x_{i,j} + b_o. \quad (13)$$

Since $x_{i,j}$ is a binary value indicating the presence of word w_j in document k_i, $\lambda(x_{i,j}) = v_o^T(\alpha_i \odot W_e[:,j]q_j)$ is the coefficient for $x_{i,j}$ and measures how much word w_j in k_i contributes to final similarity s_i.

4 EXPERIMENTAL SETUP

4.1 DataSets

In our experiments we use clinical notes in MIMIC-III dataset and Wikipedia pages of ICD-9 diagnosis codes. Both datasets are publicly available. The source code of KSI is available at https://github.com/tiantiantu/KSI.

Clinical notes dataset: MIMIC-III Critical Care Database [18] is the largest publicly available electronic health records dataset which contains de-identified health records of 46,518 patients who stayed in the Beth Israel Deaconess Medical Center's Intensive Units from 2001 to 2012. We use all discharge summary notes and the accompanying ICD-9 diagnosis codes. The total number of discharge summary notes is 59,652. For each patient visit, we aggregated all discharge summary notes. The number of aggregated discharge summary notes is 52,722. On average, in each aggregated note there are 1,596 words. During preprocessing we lowercased all tokens and removed punctuations, stop words, words containing only digits, and words whose frequency is less than 10. The final word vocabulary contains 47,965 unique words. We extracted all listed ICD-9 diagnosis codes for each visit and grouped them by their first three digits. On average, each visit has 11 medical codes. The code vocabulary contains 942 codes. Of those codes, we selected a subset of 344 codes for which we found the corresponding Wikipedia document and used those codes in our experiments.

Wikipedia knowledge dataset: Wikipedia maintains a web page including all ICD-9 diagnosis codes and links to their web pages if available[1]. Out of the 389 Wikipedia pages available for the first three digits ICD-9 diagnosis codes, we found 344 of them in MIMIC-III medical code vocabulary. We extracted Wikipedia documents for these 344 medical codes and transformed them into pure text. Then we removed punctuations and lowercased all tokens. On average each processed document has 1,058 words. The size of the word vocabulary of Wikipedia documents is 60,968, out of which only 12,173 are also in the word vocabulary of MIMIC-III clinical notes, showing that the two types of documents have very different word distributions.

4.2 Baseline model selection

We selected 5 baseline models f for this study. In our experiments, we use them stand-alone and as a component of the KSI framework that incorporates Wikipedia knowledge in order to evaluate the improvement the KSI framework brings. We briefly introduce the selected baseline models below.

[1]https://en.wikipedia.org/wiki/List_of_ICD-9_codes

Logistic regression (LR). First, we represent note N as binary bag-of-words vector $n \in \{0,1\}^{|W|}$. Then, we use a weight matrix $W_{LR} \in \mathbb{R}^{|C|\times|W|}$ to map feature space to label space as

$$o_1 = W_{LR}n. \quad (14)$$

For all baseline models, when combined with the KSI framework we use equations (8) and (9) to get the predicted values. When used as a stand-alone model, we apply sigmoid function to its output,

$$\hat{y} = sigmoid(o_1). \quad (15)$$

Recurrent neural network (RNN). We first project each word in note N to a low-dimensional vector $emb \in \mathbb{R}^m$. Then we transform the sequence of words into a sequence of word embeddings and feed it to a recurrent neural network,

$$h_1, h_2, ..., h_{|N|} = RNN(emb_1, emb_2, ..., emb_{|N|}), \quad (16)$$

in which hidden vector $h_i \in \mathbb{R}^{d_o}$ captures the context information of emb_i. Then, max-pooling is used to compute the sequence vector $g \in \mathbb{R}^{d_o}$ and transform it into output o_1 as

$$g(i) = \max_k h_{k,i} \quad (17)$$

$$o_1 = W_{RNN} \cdot g + b_{RNN}, \quad (18)$$

where $W_{RNN} \in \mathbb{R}^{|C|\times d_o} \in$ and $b_{RNN} \in \mathbb{R}^{|C|}$. In our experiments we use the long short-term memory network [15] as the specific RNN selection.

RNN with attention (RNNatt). Instead of using max-pooling of hidden vectors as the sequence vector, we can apply label-specific attentions to them. Let $H = [h_1, h_2, ..., h_{|N|}]$. For each label $c_j \in C$ we use $u_j \in \mathbb{R}^{d_o}$ to calculate the attention as

$$\alpha_j = softmax(H^T u_j), \quad (19)$$

where $softmax = \frac{\exp(x)}{\sum_i \exp(x_i)}$ and $\exp(x)$ is the element-wise exponentiation of x. Then we calculate vector representation for label c_j as

$$p_j = \sum_{k=1}^{|N|} \alpha_{j,k} h_k, \quad (20)$$

and the final likelihood for label c_j in o_1 is

$$o_1(j) = \beta_j^T p_j + b_j, \quad (21)$$

in which $\beta_j \in \mathbb{R}^{d_o}$ and b_j is a scalar bias.

Convolutional neural network (CNN) [19]. As in the RNN case, we first project each word in note N to a low-dimensional vector $emb \in \mathbb{R}^m$ and transform the sequence of words into a sequence of word embeddings. Next, we use a convolutional filter $W_{CNN1} \in \mathbb{R}^{k\times m\times d_o}$ to aggregate context information, where k is the filter width and d_o is the size of filter output. Then for each word embedding emb_n, we use W_{CNN1} to capture its context as

$$h_n = ReLU(W_{CNN1} * emb_{n:n+k-1} + b_{CNN1}), \quad (22)$$

where $*$ is the convolution operator, $ReLU$ is the rectified linear unit and $b_{CNN1} \in \mathbb{R}^{d_o}$ is the bias. We pad both sides of the input to make $H = [h_1, h_2, ..., h_{|N|}] \in \mathbb{R}^{d_o\times|N|}$. Here, as in the RNN case, H is the matrix capturing context information of each word. In [19], max-pooling is used to compute the sequence vector as

$$g(i) = \max_k h_{k,i}. \quad (23)$$

Table 3: Label frequency distribution

Frequency range	Number of unique codes	Percentage of code occurrences
1-10	80	0.1%
11-50	73	0.6%
51-100	25	0.6%
101-500	82	6.7%
>500	84	92.0%

Finally, $g \in \mathbb{R}^{d_o}$ is mapped to the label space:

$$o_1 = W_{CNN2} \cdot g + b_{CNN2}, \tag{24}$$

where $W_{CNN2} \in \mathbb{R}^{|C| \times d_o}$ and $b_{CNN2} \in \mathbb{R}^{|C|}$.

Convolutional Attention (CAML) [29]: CAML combines the attention mechanism with CNN and achieves the state-of-the-art performance on medical code prediction. After calculating context matrix H in equation (22), instead of applying max-pooling in equation (23), CAML applies label-specific attentions following equations (19) (20) (21). For each label $c_j \in C$, we use $u_j \in \mathbb{R}^{d_o}$ to calculate the attention as

$$\alpha_j = softmax(H^T u_j). \tag{25}$$

Then we can calculate vector representation for label c_j as

$$p_j = \sum_{k=1}^{|N|} \alpha_{j,k} h_k, \tag{26}$$

and the final likelihood for label c_j in o_1 as

$$o_1(j) = \beta_j^T p_j + b_j, \tag{27}$$

where $\beta_j \in \mathbb{R}^{d_o}$ and b_j is a scalar bias.

4.3 Evaluation metric

In order to properly evaluate different models, we report six different metrics: average loss value, top-10 recall, macro-averaged AUC, micro-averaged AUC, macro-averaged F1 and micro-averaged F1. The average loss value is the average of binary cross-entropy defined in equation (10) over all test notes. Top-10 recall is defined as the number of correct medical codes ranked in the top $\max(10, |M|)$ in $\hat{y}$ divided by $|M|$, where $|M|$ is the number of medical codes for the note, and averaged over all test notes. This metric is motivated by the potential use case in computer-aided coding where the system recommends several codes for human experts to review. AUC (area under ROC curve) measures the probability that a classifier ranks a randomly chosen positive instance higher than a randomly chosen negative instance. F1 score is defined as the harmonic mean between the precision and the recall. Micro-averaged values are calculated by aggregating instances of all classes and calculating the average metric over all instances. Therefore, this metric will be dominated by the most frequent medical codes. Medical codes in our dataset (3-digit ICD-9 codes which have Wikipedia webpage) are highly imbalanced. As shown in Table 3, the most common 84 codes account for 92% of all code occurrences. On the other hand, the macro-averaged metric first calculates the value for each medical code separately and then takes the average over all the codes. Since a frequent class is weighted the same as a rare class, the macro-averaged metrics puts a higher emphasis on rare medical code prediction.

Implementation details. All models are implemented with Pytorch. We randomly divide the dataset into training, validation and test sets in a 0.7, 0.1, 0.2 ratio. Early stopping on the validation set is used to determine when to stop training. Training terminates if top-10 recall does not improve in the next 5 epochs and the model with the highest top-10 recall is used on the test set. Each batch contains 32 notes. We use Adam optimizer with the learning rate of 0.001 to minimize the loss function. The dimensionality of word embedding m and hidden vector of RNN and CNN d_o are set to 100 and 200, respectively.

5 EXPERIMENTAL RESULTS

5.1 Predictive results

We show the accuracies of the baseline models alone and with the KSI framework in Table 4. From the table we can see that regardless of the baseline model, KSI framework consistently improves the accuracy. Although different metrics measure different aspect of model performance, the KSI framework improves most of them. Overall, the micro-averaged score is much higher than the macro-averaged score, as expected because the macro-averaged score emphasizes performance on the rare medical codes on which the number of available training examples is too small for accurate learning. On the other hand, in the micro-averaged scores medical codes contribute proportionally to their frequency and the frequent medical codes such as diabetes and essential hypertension provide more examples for accurate learning.

Overall, deep learning models outperform the logistic regression model, and KSI framework improves these complicated models further, showing the effectiveness of exploiting external online knowledge sources. The attention mechanism based models (RNNAtt and CAML) outperform other models while CAML achieves the best overall performance compared to the other baseline models. The success of CAML and RNNatt could be attributed to their multi-label attention mechanism. For each label, both models use a label-specific weight matrix to generate label specific attentions over all words in the text. Therefore, they are able to pay attention to locations of text segments which refer to a specific disease, which is important for medical notes since evidence about different diseases can occur in different parts of clinical notes.

It is worth noting that KSI framework improves all macro F1 and macro AUC of all models by a large margin. For macro AUC: 4.8% for LR, 3.1% for RNN, 3.0% for RNNatt, 3.4% for CNN and 3.6% for CAML. As macro AUC is the unweighted average AUC over all labels we hypothesize that the KSI framework is able to improve AUC for labels which are not so frequent in the dataset. In particular, since the frequent medical codes have a larger number of examples for accurate learning, they stand to benefit less from the external sources. On the contrary, the rare codes lack examples and are benefiting greatly from the external sources.

To validate this, we divide medical codes into 5 groups based on their frequencies in the dataset: [1, 10], [11, 50], [51, 100], [101, 500] and [500, $+\infty$). Then, we calculate macro-averaged AUC of each medical code group for RNN, RNNatt, CNN, and CAML baselines

Table 4: The predictive performance of baseline models alone and with KSI framework.

Method	Macro AUC	Micro AUC	Macro F1	Micro F1	Test loss value	Top-10 recall
LR	0.716	0.956	0.167	0.554	**0.048**	0.724
KSI+LR	**0.764**	**0.961**	**0.196**	**0.557**	0.055	**0.738**
RNN	0.854	0.972	0.204	0.653	0.032	0.772
KSI+RNN	**0.885**	**0.978**	**0.244**	**0.662**	**0.030**	**0.798**
RNNatt	0.850	0.973	0.264	0.647	0.035	0.791
KSI+RNNatt	**0.880**	**0.976**	**0.300**	**0.659**	**0.033**	**0.802**
CNN	0.825	0.968	0.214	0.626	0.040	0.753
KSI+CNN	**0.859**	**0.973**	**0.237**	**0.637**	**0.039**	**0.775**
CAML	0.855	0.978	0.257	0.656	0.032	0.806
KSI+CAML	**0.891**	**0.980**	**0.285**	**0.659**	0.032	**0.814**

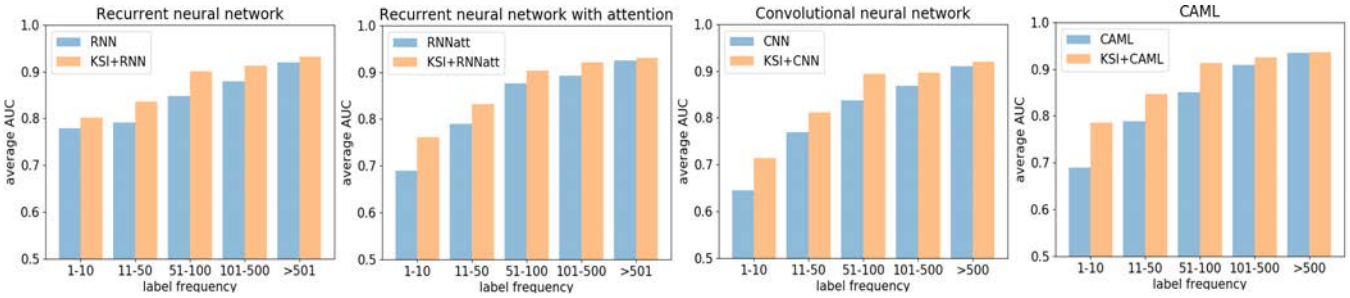

Figure 3: Macro-averaged AUC by label frequency group for RNN, RNNatt, CNN and CAML. x-axis denotes the label frequency group and y-axis denotes the macro-averaged AUC for each group.

and their counterparts under the KSI framework. The results are summarized in Figure 3.

As shown in the figure, different methods perform differently on each medical code group. Overall, the average AUC of medical code prediction increases with the code frequency. For the least frequent group (occurring less than 10 times), the average AUC of medical codes is less than 0.8. For the most common group of medical codes (occurring more than 500 times), all methods achieve an averaged AUC of more than 0.9. The figure also shows the trend in which the KSI improvement decreases with the frequency of medical codes in the dataset. For example, for CAML model, KSI framework brings 9.6% improvement of AUC on the least common [1-10] group. On the [11-50] and [51-100] groups, KSI brings 5.8% and 6.3% improvement, respectively. On the more common groups [101-500] and [500,+∞), the KSI framework only increases AUC by 1.5% and 0.1% respectively. The benefit of the KSI framework on rare medical codes can intuitively be explained in the following way. An intersection of a note and a Wikipedia document can be viewed as a feature selection; it significantly narrows down the feature space and makes it easier for the attention mechanism to find the evidence for the rare medical codes. To validate this, in the following paragraph we take a look at the contribution coefficient we derived in section 3.3.

5.2 Informative evidence extraction

The success of medical code prediction depends on the ability to extract evidence for inferring the specific codes. In equation (13), we can calculate coefficient $\lambda(x_{i,j})$ of each word w_j for document k_i. $\lambda(x_{i,j})$ depicts the contribution of each word to predicting code c_i. We calculate the coefficient for each word in the document and sort the words by their values. We study 10 words with the highest coefficients in order to gain insight into the performance of the KSI framework. In Table 5 we show the top 10 words according to the document similarity learning sub-network (subtask 2) and we also show the top 10 substrings extracted by the baseline sub-network (subtask 1). For the table, we used CAML as our baseline sub-network since it outperformed other baseline models. In equation (25), CAML calculates the attentions α_j for all words in a clinical note. These attentions are specific to medical code $c_j \in C$, the higher the attentions, the more the underlying words contribute to predicting c_j. Since in equation (22) CAML uses a convolutional layer to aggregate context information for a given word, the attentions are generated on top of the n-grams, where n equals to the filter size. Since in our experiments we set the filter size n to 3, the table is showing the top 10 trigrams with the highest attentions.

In Table 5 we show results for three representative diseases, both frequent and rare ones in order to better understand how KSI framework creates its two sub-networks.

As shown in the table, the first medical code is “250" (diabetes mellitus), which is one of the most frequent codes in our dataset. Since CAML sub-network alone is able to predict this disease with AUC as high as 0.97, the similarity sub-network cannot improve the performance any further. By checking the trigrams with the highest coefficients, we find that CAML sub-network finds highly meaningful substrings for inferring diabetes such as “failure diabetes mellitus" and “significant diabetes mellitus". By contrast, the similarity sub-network assigns the largest weight to word “name" rather than to some words that are more directly related to diabetes.

Table 5: Words/trigrams with highest contribution by document similarity learning (subtask 2) and baseline model alone (subtask 1) for medical codes 250, 138 and 501.

Code: 501 (Asbestosis) Count: 115			
Subtask 2 Final AUC: 0.96		**Subtask 1 (CAML) Final AUC: 0.76**	
Word	Weight	Trigram	Weight
asbestosis	5.21	asbestos exposure hyperlipidemia	0.95
transferred	0.68	medical history cad	0.01
inhalation	0.53	discharge diagnosis cad	0.01
illness	0.45	history cad sp	0.004
condition	0.30	one day five	0.003
two	0.17	cad sp pci	0.002
breath	0.16	cad sp pci	0.002
family	0.10	disp50 tablets refills	0.002
shortness	0.08	date date birth	0.002
current	0.01	homecare discharge diagnosis	0.002

This can be explained as follows: since there are many notes in the training dataset to allow the CAML sub-network to achieve high accuracy, errors back-propagated into the similarity sub-network are small and the impact of code “250" on any of its weights is small. Next, we take a look at two less common diseases on which CAML sub-networks achieves smaller accuracy.

The second medical code shown in the table is “138" (polio, late effects). This code occurs only in 68 notes. AUC of the CAML sub-network is only 0.74. The similarity sub-network is very helpful and it results in increasing the AUC to 0.98. Among the top 10 trigrams of the CAML sub-network, we see that only “hypotension" is vaguely related to poliomyelitis. On the other hand, the similarity sub-network identifies highly important terms such as “polio", “puncture" and “constipation", which are all related to poliomyelitis problems. These words are mentioned both in Wikipedia document about “poliomyelitis" and in the clinical notes and are assigned large coefficients.

Table 6: Intersection of a clinical note and Wikipedia document for medical code “214" (Lipoma; count: 33) and final coefficient for each word.

After taking intersection (containing only 35 words):
known surgical present cm last first prior one medical family physical exam soft results blood disease possible identified multiple greater diagnosis condition internal years size tissue obese include removed wound common tumors minor lipomas
Final weights for words in intersection set:
obese: 1.42 lipomas: 0.70 tumors: 0.48 minor: 0.30 soft: 0.29 last: 0.24 wound: 0.22 tissue: 0.13 ... ...

Finally, we look at another rare code “501" (asbestosis). CAML sub-network recognizes important word “asbestos". The similarity sub-network identifies related words “asbestosis", “inhalation", “breath" and “shortness", which are all symptoms of asbestosis. The similarity sub-network improves the AUC for this disease from 0.76 to 0.96.

The strengths of the KSI framework in finding the important evidence can be explained by the way it works: the main obstacle to finding evidence in clinical notes for rare medical codes is that they do not have enough occurrences for models to select useful features from a large feature space. For example, an average note contains 1,596 words and CAML calculates an attention value for each word in the document. Thus, it is difficult for CAML to learn the attention values among more than a thousand words when medical codes are rare. On the other hand, external knowledge sources such as Wikipedia contain important words (signs, symptoms, typical treatments) for each disease, which can be used to narrow down the feature space. On average, each clinical note contains 407 unique words and each Wikipedia document contains 517 unique words. After taking their intersection, the resulting intersection set only contains an average of 64 words, which is much smaller than the original feature space. Then, the KSI framework learns weight for each word in the intersection set, which is much easier compared to learning weights from the original feature space. An example intersection set and final weights are shown in Table 6. Even for very rare labels such as “lipoma" the KSI framework is able to learn large weights for relevant words. We will also show the effectiveness of the intersection process in the next subsection.

5.3 Ablation study

To study contribution of each component in the KSI framework to learning the document similarity score, we compare our method to several variations of the framework. To focus on accuracy of different variations, in this subsection we fix the baseline model to be CAML and we study the effect of changing components of document similarity learning part on accuracy. We consider the following variations:

Table 7: The predictive performance of KSI and its variations.

Method	Macro AUC	Micro AUC	Macro F1	Micro F1	Test loss value	Top-10 recall
KSI-attention	0.871	0.978	0.255	0.654	0.032	0.807
KSI-intersection	0.864	0.979	0.263	**0.662**	0.032	0.809
KSI	**0.891**	**0.980**	**0.285**	0.659	0.032	**0.814**

KSI-attention. In order to study the effect of variable-level attention mechanism, we remove the attention vector in equation (5) and directly use e_i as input to the next layer.

KSI-intersection. In section 5.2 we analyzed the advantage of taking intersection of clinical note vector q and Wikipedia document vector k_i. In this variation we swap the order of element-wise multiplication and embedding. We first embed both q and k_i into low-dimensional vector space as

$$e_q = W_e q \tag{28}$$

$$e_{x_i} = W_e x_i, \tag{29}$$

where $e_q \in \mathbb{R}^m$ and $e_{x_i} \in \mathbb{R}^m$. Both e_q and e_{k_i} contain information about all words in the respective documents. Then we calculate element-wise multiplication of e_q and e_{x_i} as

$$e_i = e_q \odot e_{x_i}, \tag{30}$$

where e_i is used as in equations (4) and (5).

The results are shown in Table 7. From the table we can see that KSI outperforms other variations. Since the baseline model is fixed to CAML, which performs well on frequent labels, all accuracies are similar on micro-averaged metric. However, for macro-averaged metric, we can observe sizable differences. KSI significantly outperforms other methods on macro AUC and macro F1. KSI-intersection performs the worst on macro AUC, showing the importance of the intersection on inferring rare medical codes. KSI-attention also underperforms KSI by 2.0% and 3.0% on macro AUC and macro F1, respectively, showing the effectiveness of attention mechanism on selecting important features for prediction.

5.4 Qualitative insights from coefficients of KSI

Recent research about medical codes prediction [29, 35] observed improved performance by incorporating words in ICD-9 code descriptions into prediction model. These ICD-9 code descriptions are typically very short, with less than 10 words (e.g., "secondary diabetes mellitus with hyperosmolarity"). Nonetheless, it would be very promising to design a small knowledge base specialized for providing evidence for medical code prediction. To design such a knowledge base, it is important to understand which evidence is the most helpful for the task.

Besides serving as a framework that incorporates knowledge into other end-to-end models, the KSI could provide an insight into how Wikipedia helps clinical code prediction. As we showed by calculating coefficient λ, we are able to see which words in the intersection set are influencing the final prediction. We calculated the average coefficient of each word for a given Wikipedia document. Words with high average coefficients are influential and should be considered for future specialized knowledge base construction. We show words with the highest average coefficients for four Wikipedia documents in Table 8.

Table 8: Words with highest average coefficients for four disease Wikipedia documents.

Wiki documents	Words with highest coefficients
Episodic mood disorders	lithium bipolar affective dysregulation mdd manic anxiety psychiatrist hypomanic behavior
Lipoma	lipoma lipomatosis lipomas malignant tumor wound repeat tumors subcutaneous obese
Mild intellectual disabilities	epilepsy retardation service supervision abuse benzodiazepines psychiatry cerebral threatened
Kaposi's sarcoma	sarcoma aids tumor haart kaposi ks antiretroviral chemotherapy meical hiv viral

As shown in the table, the influential words include representative symptoms for a disease such as "dysregulation", "anxiety", "manic" and "retardation". The full name and abbreviation of diseases are other types of highly informative words such as "lipoma", "ks" and "mdd". Besides, risk factors such as "hiv" and "obese" are also important evidence for inferring medical codes. These results shed light on the connection between the knowledge source and clinical notes, which provides guideline for future specialized knowledge-based design.

6 CONCLUSION

Medical code prediction from clinical notes is an active research area. The success of the task depends on finding evidence to infer diagnosis. However, it is challenging to learn what is the corresponding evidence in the notes when medical codes are rare. In this paper we propose a framework called KSI which is able to incorporate an external online knowledge source into any neural network multi-label predictive model. The key component of the KSI framework is to take intersection of a clinical note and external knowledge document, then use an attention mechanism to select important features in the intersection set. Finally, it calculates a matching score between the note and each knowledge document. KSI framework consistently improves the baseline model, especially when predicting rare codes. KSI framework also provides an insight into the evidence from an external source that was useful for the prediction. While our work uses medical codes which have Wikipedia web pages as labels, there is still a substantial number of medical codes without Wikipedia documentation. Our results suggest that it would be worthwhile for the Wikipedia community to create pages for all major ICD-9 and ICD-10 codes to not only enhance the health knowledge of public, but also to bring benefits to predictive modeling of clinical notes.

ABSTRACT

Many approaches focus on detecting dense blocks in the tensor of multimodal data to prevent fraudulent entities (e.g., accounts, links) from retweet boosting, hashtag hijacking, link advertising, etc. However, no existing method is effective to find the dense block if it only possesses high density on a subset of all dimensions in tensors. In this paper, we novelly identify dense-block detection with dense-subgraph mining, by modeling a tensor into a weighted graph without any density information lost. Based on the weighted graph, which we call information sharing graph (ISG), we propose an algorithm for finding multiple densest subgraphs, D-Spot, that is faster (up to 11x faster than the state-of-the-art algorithm) and can be computed in parallel. In an N-dimensional tensor, the entity group found by the ISG+D-Spot is at least 1/2 of the optimum with respect to density, compared with the 1/N guarantee ensured by competing methods. We use nine datasets to demonstrate that ISG+D-Spot becomes new state-of-the-art dense-block detection method in terms of accuracy specifically for fraud detection.

1 INTRODUCTION

Fraud represents a serious threat to the integrity of social or review networks such as Twitter and Amazon, with people introducing fraudulent entities (e.g., fake accounts, reviews, etc.) to gain more publicity/profit over a brief period. For example, on a social network or media sharing website, people may wish to enhance their account's popularity by illegally buying more followers [27]; on e-commerce websites, fraudsters may register multiple accounts to benefit from "new user" promotions.

Consider the typical log data generated from a social review site (e.g., Amazon), which contains four-dimensional features: users, products, timestamps, rating scores. These data are often formulated as a tensor, in which each dimension denotes a separate feature and an entry (tuple) of the tensor represents a review action. Based on previous studies [12, 30], fraudulent entities form dense blocks (subtensors) within the main tensor, such as when a mass of fraudulent user accounts create an enormous number of fake reviews for a set of products over a short period. Dense-block detection has also been applied to network intrusion detection [20, 30], retweet boosting detection [12], bot activities detection [30], and genetics applications [20, 26].

Various dense-block detection methods have been developed. One approach uses tensor decomposition, such as CP decomposition and higher-order singular value decomposition [20]. However, as observed in [32], such methods are outperformed by search-based techniques [12, 30, 32] in terms of accuracy, speed, and flexibility regarding support for different density metrics. Furthermore, [30, 32] provide an approximation guarantee for finding the densest/optimal block in a tensor.

We have examined the limitations of search-based methods for dense-block detection. First, these methods are incapable of detecting *hidden-densest blocks*. We define a hidden-densest block as one that does not have a high-density signal on all dimensions of a tensor, but evidently has a high density on a subset of all dimensions. Moreover, existing methods neglect the data type and distribution of each dimension on the tensor. Assuming that two dense blocks A and B have the same density, however, A is the densest on a subset of critical features, such as IP address and device ID, whereas B is the densest on some trivial features such as age and gender. Can we simply believe that A is as suspicious as B? Unfortunately, the answer when using existing methods is 'yes.'

To address these limitations, we propose a dense-block detection framework and focus on entities that form dense blocks on tensors. The proposed framework is designed using a novel approach. Given a tensor, the formation of dense blocks is the result of value sharing (the behavior whereby two or more different entries share a distinct value (entity) in the tensor). Based on this key point, we propose a novel *Information Sharing Graph (ISG)* model, which accurately captures each instance of value sharing. The transformation from dense blocks in a tensor to dense subgraphs in ISG leads us to propose a fast, high-accuracy algorithm, D-Spot, for determining fraudulent entities with a provable guarantee regarding the densities of the detected subgraphs.

In summary, the main contributions of this study are as follows:

1) **[Graph Model].** We propose the novel ISG model, which converts every value sharing in a tensor to the representation of weighted edges or nodes (entities). Furthermore, our graph model considers diverse data types and their corresponding distributions based on information theory to automatically prioritize multiple features.

2) **[Algorithm].** We propose the *D-Spot* algorithm, which is able to find multiple densest subgraphs in one run. And we theoretically prove that the multiple subgraphs found by D-Spot must contain some subgraphs that are at least 1/2 as dense as the optimum. In real-world graphs, D-Spot is up to 11× faster than the state-of-the-art competing algorithm.

3) **[Effectiveness].** In addition to dense blocks, ISG+D-Spot also effectively differentiates hidden-densest blocks from normal ones. In experiments using eight public real-world datasets, ISG+D-Spot detected fraudulent entities more accurately than conventional methods.

2 BACKGROUND

2.1 Economics of Fraudsters

As most fraudulent schemes are designed for financial gain, it is essential to understand the economics behind the fraud. Only when the benefits to a fraudster outweigh their costs will they perform a scam.

To maximize profits, fraudsters have to share/multiplex different resources (e.g., fake accounts, IP addresses, and device IDs) over multiple frauds. For example, [13] found that many users are associated with a particular group of followers on Twitter; [36] identified that many cases of phone number reuse; [4] observed that the IP addresses of many spam proxies and scam hosts fall into a few uniform ranges; and [38] revealed that fake accounts often conduct fraudulent activities over a short time period.

Thus, fraudulent activities often form dense blocks in a tensor (as described below) because of this resource sharing.

2.2 Related Work

Search-based dense-block detection in tensors. Previous studies [12, 20, 30] have shown the benefit of incorporating features such as timestamps and IP addresses, which are often formulated as a multi-dimensional tensor. Mining dense blocks with the aim of maximizing a density metric on tensors is a successful approach. CrossSpot [12] randomly chooses a seed block and then greedily adjusts it in each dimension until the local optimum is attained. This technique usually requires enormous seed blocks and does not provide any approximation guarantee for finding the global optimum. In contrast to adding feature values to seed blocks, M-Zoom [30] removes feature values from the initial tensor one by one using a similar greedy strategy, providing a $1/N$-approximation guarantee for finding the optimum (where N is the number of dimensions in the tensor). M-Biz [31] also starts from a seed block and then greedily adds or removes feature values until the block reaches a local optimum. Unlike M-Zoom, D-Cube [32] deletes a set of feature values on each step to reduce the number of iterations, and is implemented in a distributed disk-based manner. D-Cube provides the same approximation guarantee as M-Zoom.

Table 1: ISG+D-Spot vs. existing dense-block detection methods.

	MAF [20]	CrossSpot [12]	M-zoom [30]	M-biz [31]	D-cube[32]	ISG+D-Spot
Applicable to N-dimensional data?	√	√	√	√	√	√
Catch densest blocks?	√	√	√	√	√	√
Catch hidden-densest blocks?	×	×	×	×	×	√
%-Approximation Guarantee?	×	×	1/N	×	1/N	1/2

Tensor decomposition methods. Tensor decomposition [17] is often applied to detect dense blocks within tensors [20]. Scalable algorithms, such as those described in [23, 33, 37], have been developed for tensor decomposition. However, as observed in [12, 32], these methods are limited regarding the detection of dense blocks, and usually detect blocks with significantly lower densities, provide less flexibility with regard to the choice of density metric, and do not provide any approximation guarantee.

Dense-subgraph detection. A graph can be represented by a two-dimensional tensor, where an edge corresponds to a non-zero entry in the tensor. The mining of dense subgraphs has been extensively studied [18]. Detecting the densest subgraph is often formulated as finding the subgraph with the maximum average degree, and may use exact algorithms [10, 16] or approximate algorithms [6, 16]. Fraudar [11] is an extended approximate algorithm that can be applied to fraud detection in social or review graphs. CoreScope [29] tends to find dense subgraphs in which all nodes have a degree of at least k. Implicitly, singular value decomposition (SVD) also focuses on dense regions in matrixes. EigenSpoke [24] reads scatter plots of pairs of singular vectors to find patterns and chip communities, [7] extracts dense subgraphs using a spectral cluster framework, and [14, 27] use the top eigenvectors from SVD to identify abnormal users.

Other anomaly/fraud detection methods The use of belief propagation [3, 22] and HITS-like ideas [8, 9, 13] is intended to catch rare behavior patterns in graphs. Belief propagation has been used to assign labels to the nodes in a network representation of a Markov random field [3]. When adequate labeled data are available, classifiers can be constructed based on multi-kernel learning [2], support vector machines [35], and k-nearest neighbor [34] approaches.

3 DEFINITIONS AND MOTIVATION

In this section, we introduce the notations and definitions used throughout the paper, analyze the limitations of existing approaches, and describe our key motivations.

3.1 Notation and Formulations

Table 2 lists the notations used in this paper. We use $[N] = \{1, ..., N\}$ for brevity. Let $\mathbf{R}(A_1, ..., A_N, X) = \{t_0, ..., t_{|X|}\}$ be a relation with N-dimensional features, denoted by $\{A_1, ..., A_N\}$, and a dimensional entry identifiers, denoted by X. For each entry (tuple) $t \in \mathbf{R}$, $t = (a_1, ..., a_N, x)$, where $\forall n \in [N]$, we use $t[A_n]$ to denote the value of A_n in t, $t[A_n] = a_n$ and $t[X]$ to denote the identification of t, $t[X] = x$, $x \in X$. We define the mass of $\mathbf{R}$ as $|\mathbf{R}|$, which is the total number of such entries, $|\mathbf{R}| = |X|$. For each $n \in [N]$, we use $\mathbf{R}_n$ to

Table 2: Symbols and Definitions

Symbol	Interpretation
N	number of dimensions in a tensor
$[N]$	set {1,..., N}
$\mathbf{R}(A_1, \ldots, A_N, X)$	relation representing a tensor
A_n	n-th dimensional values of $\mathbf{R}$
$\mathbf{R}_n$	set of distinct values of A_n of $\mathbf{R}$
$t = (a_1, \ldots, a_N, x)$	an entry (tuple) of $\mathbf{R}$
$\mathcal{B}(\mathcal{A}_1, \ldots, \mathcal{A}_N, \mathcal{X})$	a block in $\mathbf{R}$
$\mathcal{B}_n$	set of distinct values of $\mathcal{A}_n$ of $\mathcal{B}$
U	target dimension in $\mathbf{R}$
$\mathbf{V} = \{u_1, \ldots, u\}$	set of distinct values of U
$\mathbf{G} = (\mathbf{V}, \mathbf{E})$	Information Sharing Graph
$\mathcal{S}_{i,j}$	$\mathcal{S}$-score between u_i and u_j
$\mathcal{S}_i$	$\mathcal{S}$-score of u_i
$\mathcal{G} = (\mathcal{V}, \mathcal{E})$	subgraph in $\mathbf{G}$
$\mathcal{F}$	density metric

denote the set of distinct values of A_n. Thus, $\mathbf{R}$ naturally represents an N-dimensional tensor of size $|\mathbf{R}_1| \times \ldots \times |\mathbf{R}_N|$.

A block $\mathcal{B}$ in $\mathbf{R}$ is defined as $\mathcal{B}(\mathcal{A}_1, \ldots, \mathcal{A}_N, \mathcal{X}) = \{t \in \mathbf{R} : t[X] \in \mathcal{X}\}$ and $\mathcal{X} \subseteq X$. Additionally, the mass $|\mathcal{B}|$ is the number of entries of $\mathcal{B}$ and $\mathcal{B}_n$ is the set of distinct values of $\mathcal{A}_n$. Let $\mathcal{B}(a, A_n) = \{t \in \mathbf{R} : t[A_n] = a\}$ represent all entries that take the value a on A_n. The mass $|\mathcal{B}(a, A_n)|$ is the number of such entries. A simple example is given as follows.

Example 1 (Amazon review logs). *Assume a relation* $\mathbf{R}(\underline{user}, \underline{product}, \underline{timestamp}, X)$*, where* $\forall t \in \mathbf{R}$*,* $t = (a_1, a_2, a_3, x)$ *indicates a review action where user* a_1 *reviews product* a_2 *at timestamp* a_3*, and the identification of the action is* x*. Because* a_1 *may review* a_2 *at* a_3 *(we assume that* a_3 *represents a period) multiple times,* X *helps us distinguish each such action. The mass of* $\mathbf{R}$*, denoted by* $|\mathbf{R}|$*, is the number of all review actions in the dataset. The number of distinct users in* $\mathbf{R}$ *is* $|\mathbf{R}_1|$*. A block* $\mathcal{B}(a_1, user)$ *is the set of all rating entries operated by user* a_1*, and the number of overall entries of* $\mathcal{B}(a_1, user)$ *is* $|\mathcal{B}(a_1, user)|$*.*

First, we present a density metric that is known to be useful for fraud detection [30, 32]:

Definition 1. (Arithmetic Average Mass ρ). Given a block $\mathcal{B}(\mathcal{A}_1, \ldots, \mathcal{A}_N, \mathcal{X})$, the arithmetic average mass of $\mathcal{B}$ on dimensions $\mathcal{N}$ is

$$\rho(\mathcal{B}, \mathcal{N}) = \frac{|\mathcal{B}|}{\frac{1}{|\mathcal{N}|}\sum_{n \in \mathcal{N}} |\mathcal{B}_n|},$$

where $\mathcal{N}$ is a subset of $[N]$ and obviously $\rho \in [1.0, +\infty)$.

If block $\mathcal{B}$ *is dense in* $\mathbf{R}$*, then* $\rho(\mathcal{B}, [N]) > 1.0$.

Other density metrics listed in [32] are also effective for fraud detection. It is broadly true that all density measures are functions of the cardinalities of the dimensions and masses of $\mathcal{B}$ and $\mathbf{R}$. In $\mathbf{R}$, previous studies [12, 30–32] have focused on detecting the top-k densest blocks in terms of a density metric. In the remainder of this paper, we use the density metric ρ to illustrate our key points.

3.2 Shortcomings of Existing Approaches and Motivation

In practice, the blocks formed by fraudulent entities in $\mathbf{R}$ may be described by *hidden-densest blocks*. To illustrate hidden-densest blocks, we present the following definitions and examples.

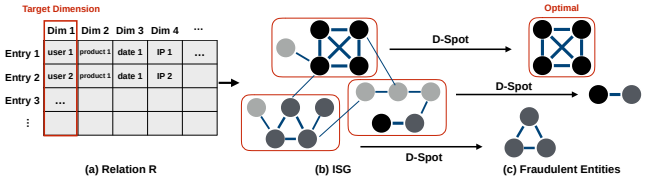

Figure 1: Workflow of ISG+D-Spot.

Definition 2. In $\mathbf{R}(A_1, \ldots, A_N, X)$, we say that $\mathcal{B}(\mathcal{A}_1, \ldots, \mathcal{A}_N, \mathcal{X})$ is the densest on a dimension A_n if $\rho(\mathcal{B}, \{n\})$ is the maximal value of all possible $\rho(\hat{\mathcal{B}}, \{n\})$, where $\hat{\mathcal{B}}$ is any possible block in $\mathbf{R}$.

Definition 3. (Hidden-Densest Block). In $\mathbf{R}(A_1, \ldots, A_N, X)$, $\mathcal{B}(\mathcal{A}_1, \ldots, \mathcal{A}_N, \mathcal{X})$ is the hidden-densest block if $\mathcal{B}$ is the densest on a small subset of $\{A_1, \ldots, A_N\}$.

Example 2 (Registration logs). *In a registration dataset with 19 features, fake accounts only exhibit conspicuous resource sharing with respect to the IP address feature.*

Example 3 (TCP dumps). *The DARPA dataset [1] has 43 features, but the block formed by malicious connections is only the densest on two features.*

Thus, catching hidden-densest blocks has a significant utility in the real world. Unfortunately, the problem is intractable using existing approaches [12, 30–32].

First, assuming that the hidden-densest block $\mathcal{B}(\mathcal{A}_1, \ldots, \mathcal{A}_N, \mathcal{X})$ is only the densest on dimension A_N, we have that

$$\rho(\mathcal{B}, [N-1]) = \frac{|\mathcal{B}|}{\frac{1}{N-1}\sum_{n \in [N-1]} |\mathcal{B}_n|} \approx \rho(\mathcal{B}, [N]) = \frac{|\mathcal{B}|}{\frac{1}{N}\sum_{n \in [N]} |\mathcal{B}_n|}$$

when N is sufficiently large. Assuming $\rho(\mathcal{B}, [N-1])$ is very low, then the methods in [12, 30–32], which try to find the block $\mathcal{B}$ that maximizes $\rho(\mathcal{B}, [N])$, have a limited ability to detect the hidden-densest block.

Second, consider a block $\mathcal{B}$ formed by fraudulent entities, in which $\mathcal{B}$ is only the densest on $\{A_2, A_3, A_5\}$, and thus $\rho(\mathcal{B}, \{2, 3, 5\})$ is maximal. However, the techniques of [12, 30–32] cannot find $\{A_2, A_3, A_5\}$ when the feature combinations are exploded.

Furthermore, in $\mathbf{R}(A_1, \ldots, A_N, X)$, consider two blocks $\mathcal{B}_1$ and $\mathcal{B}_2$, where $\mathcal{B}_1$ is the densest on A_i, $\mathcal{B}_2$ is the densest on A_j, and $\rho(\mathcal{B}_1, [N]) = \rho(\mathcal{B}_2, [N])$. Does this indicate that $\mathcal{B}_1$ and $\mathcal{B}_2$ are equally suspicious? No, absolutely not, because A_i could be the IP address feature and A_j could be a trivial feature such as the user's age, location, or gender.

[Value Sharing]. Based on the considerations above, we design our approach from a different angle. The key reason behind the formation of dense blocks is value sharing. Given $t_1 \in \mathbf{R}$, a dimension A_n, and $t_1[A_n] = a$, we can identify value sharing when $\exists t_2 \in \mathbf{R}$, $t_2 \neq t_1$, and $t_2[A_n] = a$.

Obviously, if a block $\mathcal{B}$ is dense, $\rho(\mathcal{B}, [N]) > 1.0$, then value sharing must be occurring, i.e., **value sharing results in dense blocks**.

Therefore, detecting dense blocks is equivalent to catching value sharing signals. We propose ISG based on information theory and design the D-Spot algorithm to leverage graph features, allowing us to catch fraudulent entities within dense blocks and overcome the limitations mentioned above.

4 ISG BUILDING

In this section, we present the Information Sharing Graph (ISG), which is constructed on the relation $\mathbf{R}$.

4.1 Problem Formulation

Catching fraudulent entities is equivalent to detecting a subset of distinct values in a certain dimension. Let U denote the target dimension in which a subset of distinct values form the fraudulent entities we wish to detect. In $\mathbf{R} = (A_1, ..., A_N, X)$, **we choose a dimension and set it as U, and denote the remaining $(N-1)$ dimensions as K dimensions**, $\underline{k \in [K]}$, for brevity. We build the ISG of U, i.e., the weighted-undirected graph $\mathbf{G} = (\mathbf{V}, \mathbf{E})$, in which $\mathbf{V} = \{u_1, ..., u_n\}$ is the set of distinct values of U.

In Example 1, $\mathbf{R}(\underline{user}, \underline{product}, \underline{timestamp}, X)$, we set $U = \underline{user}$ if we wish to detect fraudulent user accounts. In Example 2, we set $U = \underline{account}$ if we would like to identify fake accounts. In Example 3, we set $U = \underline{connection}$ to catch malicious connections.

To specifically describe the process of value sharing, we present the two following definitions:

Definition 4. (Pairwise Value Sharing). Given $u_i, u_j \in \mathbf{V}$ and $a \in A_k$, we say that u_i and u_j share value a on A_k if $\exists t_1, t_2 \in \mathbf{R}$ such that $t_1[U] = u_i, t_2[U] = u_j$ and $t_1[A_k] = t_2[A_k] = a$.

Pairwise value sharing occurs when a distinct value is shared by multiple individual entities. Given a value sharing process in which a is shared by $\mathcal{V} \subset \mathbf{V}$, we denote this as $\frac{|\mathcal{V}|(|\mathcal{V}|-1)}{2}$ pairwise value sharing.

Definition 5. (Self-Value Sharing). Given $t_1 \in \mathbf{R}$, where $t_1[U] = u_i, u_i \in \mathbf{V}$, and $t_1[A_k] = a$, we say that u_i shares value a on A_k if $\exists t_2 \in \mathbf{R}$ and $t_2 \neq t_1$ such that $t_2[U] = u_i$ and $t_2[A_k] = a$.

Another type of value sharing occurs when the distinct value a is shared n times by an entity u_i, which can be represented by n instances of self-value sharing.

In ISG $\mathbf{G} = (\mathbf{V}, \mathbf{E})$, for some edge $(u_i, u_j) \in \mathbf{E}$, $\mathcal{S}_{i,j}$ represents the information between u_i and u_j derived from the other K dimensions, and for some node $u_i \in \mathbf{V}$, $\mathcal{S}_i$ denotes the information of u_i calculated from the other K dimensions. From the definitions and notations defined in the previous section, Problem 1 gives a formal definition of how to build the ISG of a tensor.

Problem 1 (Building a pairwise information graph). **(1) Input:** *a relation* $\mathbf{R}$*, the target dimension* U*,* **(2) Output:** *the information sharing graph* $\mathbf{G} = (\mathbf{V}, \mathbf{E})$.

4.2 Building an ISG

Given a dimension A_k, the target dimension U, any $u_i \in \mathbf{V}$, and an entry $t_1 \in \mathbf{R}$ for which $t_1[U] = u_i$, then for each $a \in A_k$, we assume that the probability of $t_1[A_k] = a$ is $p^k(a)$.

Edge Construction. Based on information theory [28], the self-information of the event that u_i and u_j share a is:

$$\mathcal{I}^k_{i,j}(a) = \log(\frac{1}{p^k(a)})^2. \tag{1}$$

To compute the pairwise value sharing between u_i and u_j across all K dimensions, we propose the metric $\mathcal{S}$-score as the edge weight of ISG:

$$\mathcal{S}_{i,j} = \sum_{k=1}^{K} \sum_{a \in H_k(u_i, u_j)} \mathcal{I}^k_{i,j}(a), \tag{2}$$

where $H_k(u_i, u_j)$ is the set of all values shared by u_i and u_j on A_k. Note that $\mathcal{S}_{i,j} = 0.0$ if $\bigcup_{k=1}^{K} H_k(u_i, u_j) = \emptyset$.

Intuitively, if u_i and u_j *do not* have any shared values, which is to be expected in normal circumstances, we have zero information. Otherwise, we obtain some information. Thus, the higher the value of $\mathcal{S}_{i,j}$ is, the more similar u_i is to u_j. In practice, the $\mathcal{S}$-score has a large variance. For example, fraud user pairs sharing an IP subnet and device ID will have a high $\mathcal{S}$-score, whereas normal users are unlikely to share these values with anyone, and will thus have an $\mathcal{S}$-score close to zero. Additionally, the information we obtain for u_i and u_j sharing the value a is related to the overall probability of that value. For example, it would be much less surprising if they both follow Donald Trump on Twitter than if they both follow a relatively unknown user.

Node Setting. For a node $u_i \in \mathbf{V}$, let $\mathcal{B}(a, A_k, u_i, U)$ be the set $\{t \in \mathbf{R} : (t[A_k] = a) \wedge (t[U] = u_i)\}$. When $|\mathcal{B}(a, A_k, u_i, U)| \geq 2$. The information of forming $\mathcal{B}(a, A_k, u_i, U)$ is:

$$\mathcal{I}^k_i(a) = \log(\frac{1}{p^k(a)})^{|\mathcal{B}(a, A_k, u_i, U)|}. \tag{3}$$

We now define $\mathcal{S}_i$ to compute the self-value sharing for u_i across all K dimensions:

$$\mathcal{S}_i = \sum_{k=1}^{K} \sum_{\mathcal{B} \in H_k(u_i)} \mathcal{I}^k_i(a), \tag{4}$$

where $H_k(u_i)$ is the set $\{\mathcal{B}(a, A_k, u_i, U), \forall a \in \mathbf{R}_k\}$ and $\mathbf{R}_k$ is the set of distinct values of A_k. Note that $\mathcal{S}_i = 0.0$ if $\bigcup_{k=1}^{K} H_k(u_i) = \emptyset$.

In effect, self-value sharing occurs in certain fraud cases. For instance, a fraudulent user may create several fake reviews for a product/restaurant on Amazon/Yelp [25] over a few days. In terms of network attacks [19], a malicious TCP connection tends to attack a server multiple times.

Determining [$p^k(a)$]. We can extend the $\mathcal{S}$-score to accommodate different data types and distributions.

It is difficult to determine $p^k(a)$, as we do not always know the distribution of A_k. In this case, for dimensions that are attribute features, we assume a uniform distribution and simply set

$$p^k(a) = 1/|\mathbf{R}_k|. \tag{5}$$

This approximation works well for many fraud-related properties such as IP subnets and device IDs, which usually follow a Poisson distribution [12].

However, the uniform assumption works poorly for low-entropy distributions, such as the long-tail distribution, which is common in dimensions such as items purchased or users followed. Low entropy implies that many users behave similarly anyway, independent of frauds. Intuitively for such distributions, there is no surprise in following a celebrity (head of the distribution), but considerable information if they both follow someone at the tail. For example, 20% of users correspond to more than 80% of the "follows" in online social networks. The dense subgraphs between celebrities and their fans are very unlikely to be fraudulent. If feature A_k has a long-tail distribution, its entropy is very low. For example, the entropy of the uniform distribution over 50 values is 3.91, but the entropy of a

long-tail distribution with 90% of probabilities centered around one value is only 0.71. Therefore, we set $p^k(a)$ based on the empirical distribution as

$$p^k(a) = |\mathcal{B}(a, A_k)|/|\mathbf{R}|, \tag{6}$$

when the values in A_k have low entropy. We also provide an interface so that users can define their own $p^k(a)$ function.

Optimization of ISG Construction. In theory, a graph with $|\mathbf{V}|$ nodes has $O(|\mathbf{V}|^2)$ edges. Naively, therefore, it takes $O(|\mathbf{V}|^2)$ time for graph initialization and traversal.

To reduce the complexity of building the ISG, we use the *key-value* approach. The *key* corresponds to a value a on A_k and the *value* represents the block $\mathcal{B}(a, A_k)$. Let $\mathcal{V} \subseteq \mathbf{V}$ denote the entities that occur in $\mathcal{B}(a, A_k)$. As each pair $(u_i, u_j) \in \mathcal{V}$ shares a, we increase the value of $\mathcal{S}_{i,j}$ by $\mathcal{I}^k_{i,j}(a)$. Additionally, for each $u_i \in \mathcal{V}$, there exists some $\mathcal{B}(a, A_k, u_i, U) \subseteq \mathcal{B}(a, A_k)$. Thus, we increase the value of $\mathcal{S}_i$ by $\mathcal{I}^k_i(a)$ if $|\mathcal{B}(a, A_k, u_i, U)| \geq 2$.

To build the ISG, we compute all *key-value* pairs across K dimensions by traversing $\mathbf{R}$ in parallel. Thus, it takes $O(K|\mathbf{R}| + |\mathbf{E}|)$ time to build the graph $\mathbf{G} = (\mathbf{V}, \mathbf{E})$. Note that we only retain positive $\mathcal{S}_{i,j}$ and $\mathcal{S}_i$. In practice, $\mathbf{G}$ is usually sparse, which is discussed in Section 6.1.

4.3 Key Observations on ISG

Given a relation $\mathbf{R} = (A_1, ..., A_N, X)$ in which we set $U = A_N$, we construct the ISG of U, $\mathbf{G} = (\mathbf{V}, \mathbf{E})$. Assuming there is a **fraudulent block** $\mathcal{B}$ in $\mathbf{R}$, $\mathcal{B} = (\mathcal{A}_1, ..., \mathcal{A}_N, \mathcal{X})$ is transformed into a subgraph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ in $\mathbf{G}$, where $\mathcal{V}$ is the set of distinct values of $\mathcal{A}_N$ and an edge $\mathcal{S}_{i,j} \in \mathcal{E}$ denotes the information between u_i and u_j calculated from the other K dimensions. Then, $\mathcal{V}$ is the fraud group comprised of fraudulent entities that we wish to detect.

We summarize three critical observations of $\mathcal{G}$ that directly lead to the algorithms presented in Section 5.2. Given $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, we define the **edge density** of $\mathcal{G}$ as

$$\rho_{edge}(\mathcal{G}) = \frac{|\mathcal{E}|}{|\mathcal{V}|(|\mathcal{V}| - 1)}$$

1) The value of $\mathcal{S}_{i,j}$ or $\mathcal{S}_i$ is unusually high. Value sharing may happen frequently, but sharing across certain features, even certain values, is more suspicious than others. Intuitively, it might be suspicious if two users share an IP address or follow the same random "nobody" on Twitter. However, it is not so suspicious if they have a common gender, city, or follow the same celebrity. In other words, certain value sharing is likely to be fraudulent because the probability of sharing across a particular dimension, or at a certain value, is quite low. Thus, the information value is high, which is accurately captured by $\mathcal{S}_{i,j}$ and $\mathcal{S}_i$.

2) $|\mathcal{V}|$ is usually large. Fraudsters perform the same actions many times to achieve economies of scale. Thus, we expect to find multiple pairwise complicities among fraudulent accounts. A number of studies have found that large cluster sizes are a crucial indicator of fraud [5, 38]. Intuitively, while it is natural for a few family members to share an IP address, it is highly suspicious when dozens of users share one.

3) The closer $\rho_{edge}(\mathcal{G})$ is to 1.0, the more suspicious $\mathcal{G}$ is. Fraudsters usually operate a number of accounts for the same job, and thus it is likely that users manipulated by the same fraudster will share the same set of values. Thus, the $\mathcal{G}$ formed by the fraud group will be well-connected.

Appearance of legitimate entities on ISG. In $\mathbf{G} = (\mathbf{V}, \mathbf{E})$, given some u_i that we assume to be **legitimate**, let $h(u_i)$ denote the set of its neighbor nodes. We have two findings. (1) For u_i, $\mathcal{S}_i + \sum_{u_j \in \mathbf{V}} \mathcal{S}_{i,j} \to 0$ because u_i is unlikely to share values with others. Even if exists, the shared values should have a high probability (see observation 1) and therefore small $\mathcal{S}_{i,j}$. (2) The subgraph $\mathcal{G}$ induced by $h(u_i)$ is typically not well-connected, as resource sharing is uncommon in the real world. If $\mathcal{G}$ is well-connected, $|h(u_i)|$ is quite small compared with the fraud group size (see observation 2).

In summary, the techniques described in [12, 20, 30–32] work directly on the tensor, indicating that they consider value sharing on each dimension, and even certain values, as equivalent. In contrast, ISG assigns each instance of value sharing a theoretical weight based on the edges and nodes of the ISG, which is more effective for identifying the (hidden-) densest blocks (comparison in Sec.6.2).

5 SPOTTING FRAUD

Based on the observations in Section 4.3, we now describe our method for finding objective subgraphs in $\mathbf{G}$. This section is divided into two parts: first, we define a density metric $\mathcal{F}_\mathcal{G}$, and then we illustrate the proposed D-Spot algorithm.

5.1 Density Metric and Problem Definition

To find the objective $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, we define a density metric $\mathcal{F}_\mathcal{G}$ as [6, 11]:

$$\mathcal{F}_\mathcal{G} = \frac{\sum_{(u_i,u_j)\in\mathcal{E}} \mathcal{S}_{i,j} + \sum_{u_i \in \mathcal{V}} \mathcal{S}_i}{|\mathcal{V}|}. \tag{7}$$

The form of $\mathcal{F}_\mathcal{G}$ satisfies the three key observations of $\mathcal{G}$ in Section 4.3.

(1) Keeping $|V|$ fixed, we have that $\sum_{(u_i,u_j)\in\mathcal{E}} \mathcal{S}_{i,j} + \sum_{u_i \in \mathcal{V}} \mathcal{S}_i \uparrow \Rightarrow \mathcal{F}_\mathcal{G} \uparrow$.
(2) Keeping $\mathcal{S}_{i,j}$, $\mathcal{S}_i$, and $\rho_{edge}(\mathcal{G})$ fixed, we have that $|V| \uparrow \Rightarrow \mathcal{F}_\mathcal{G} \uparrow$.
(3) Keeping $\mathcal{S}_{i,j}$, $\mathcal{S}_i$, and $|\mathcal{V}|$ fixed, we have that $\rho_{edge}(\mathcal{G}) \uparrow \Rightarrow \mathcal{F}_\mathcal{G} \uparrow$.

Thus, our subgraph-detection problem can be defined as follows:
Problem 2 (Detecting dense subgraphs). **(1) Input:** *the information sharing graph* $\mathbf{G} = (\mathbf{V}, \mathbf{E})$. **(2) Find:** *multiple subgraphs of* $\mathbf{G}$ *that maximize* $\mathcal{F}$.

5.2 D-Spot (Algorithm 1-3)

In real-world datasets, there are usually numerous fraud groups forming multiple dense subgraphs. Based on the considerations described above, we propose D-Spot (Algorithms 1–3). Compared with other well-known algorithms for finding the densest subgraph [6, 11], D-Spot has two differences:

(1) D-Spot can detect multiple densest subgraphs simultaneously. D-Spot first partitions the graph, and then detects a single densest subgraph in each partition.
(2) D-Spot is faster. First, instead of removing nodes one by one, D-Spot removes a set of nodes at once, reducing the number of iterations. Second, it detects the single densest subgraph

in partition $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, rather than in graph $\mathbf{G} = (\mathbf{V}, \mathbf{E})$, where $|\mathcal{V}| << |\mathbf{V}|$ and $|\mathcal{E}| << |\mathbf{E}|$.

D-Spot consists of two main steps: (1) Given $\mathbf{G}$, divide $\mathbf{G}$ into multiple partitions (Algorithm 1); (2) In each $\mathcal{G}$, find a single dense subgraph (Algorithms 2 and 3).

Algorithm 1: graph partitioning. Let $\hat{\mathcal{G}}$ be a dense subgraph formed by a fraud group that we are about to detect. In $\mathbf{G}$, there are usually multiple $\hat{\mathcal{G}}$s, where each $\hat{\mathcal{G}}$ should be independent or connected with others by small values of $\mathcal{S}_{i,j}$. Thus we let $\mathcal{G}$s be the connected components of $\mathbf{G}$ as partitions (line 6). For each $\mathcal{G} \in \mathcal{G}s$, we run Algorithms 2 and 3 (lines 7–9) to find $\hat{\mathcal{G}}$. Finally, Algorithm 1 returns multiple dense subgraphs $\hat{\mathcal{G}}$s (line 10). Note that there is a guarantee that $\hat{\mathcal{G}}$s must contain the $\hat{\mathcal{G}}$ that is at least 1/2 of the optimum of $\mathbf{G}$ in terms of $\mathcal{F}$ (proof in Sec.6.3).

Information pruning (recommended). As mentioned before, Fraud entities usually have surprising similarities that are quantified by $\mathcal{S}_{i,j}$. We want to delete edges with regular weights and thus we provide a threshold for removing edges:

$$\theta = \frac{\sum_{(u_i,u_j)\in\mathbf{E}} \mathcal{S}_{i,j}}{|\mathbf{V}|(|\mathbf{V}|-1)} \tag{8}$$

It is easy to see that θ (conservative) is the average information of all possible pairs (u_i, u_j). Thus, we iterate through all edges in $\mathbf{G}$, and remove those for which $\mathcal{S}_{i,j} < \theta$ (lines 3–5). In all experiments of this paper, we used θ and get the expected conclusion that the performance of D-Spot using θ is hardly different from no pruning but using θ is able to significantly decrease the running cost of D-Spot.

Algorithm 1 *find multiple dense subgraphs* in $\mathbf{G}$

Require: $\mathbf{G} = (\mathbf{V}, \mathbf{E})$, θ (Eq.8), $w()$ (Eq. 9)
Ensure: $\hat{\mathcal{G}}$s
1: $\hat{\mathcal{G}}$s $\leftarrow \emptyset$
2: **if** needed **then**
3: **for** each $\mathcal{S}_{i,j} \in \mathbf{E}$ **do**
4: **if** $\mathcal{S}_{i,j} < \theta$ **then**
5: remove $\mathcal{S}_{i,j}$
6: $\mathcal{G}$s $\leftarrow$ connected components of $\mathbf{G}$
7: **for** each $\mathcal{G} \in \mathcal{G}$s **do**
8: $\hat{\mathcal{G}} \leftarrow$ *find a dense subgraph* $(\mathcal{G}, w())$
9: $\hat{\mathcal{G}}$s $\leftarrow \hat{\mathcal{G}}$s $\cup \{\hat{\mathcal{G}}\}$
10: **return** $\hat{\mathcal{G}}$s

Algorithms 2 and 3: find a dense subgraph. Initially, let $\mathcal{V}_c$ be a copy of $\mathcal{V}$. In each iteration (lines 5–14), we delete *a set of nodes* (R, line 6) from $\mathcal{V}_c$ until $\mathcal{V}_c$ is empty. Of all the $\mathcal{V}_c$ constructed during the execution of the algorithm, that maximizing $\mathcal{F}$ ($\hat{R}$, line 15) is returned as the output of the algorithm.

Given a subgraph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, for some $u_i \in \mathcal{V}$, we define $w(u_i, \mathcal{G})$ as

$$w(u_i, \mathcal{G}) = \sum_{(u_j\in\mathcal{V})\wedge((u_i,u_j)\in\mathcal{E})} \mathcal{S}_{i,j} + \mathcal{S}_i. \tag{9}$$

Lines 1–4 initialize the parameters used in the algorithm. *Dict*2 records the w value of each node. *Dict*1 records the order in which the nodes are deleted (line 10), which allows us to determine the value of $\hat{R}$ that maximizes $\mathcal{F}$. Line 6 determines which R are deleted in each iteration. R is confirmed by $\{u \in \mathcal{V} : w(u, \mathcal{G}) \le \overline{w}\}$ (line 6), where the average $\overline{w}$ is given by:

$$\begin{aligned}\overline{w} &= \frac{\sum_{u\in\mathcal{V}} w(u,\mathcal{G})}{|\mathcal{V}|} \\ &= \frac{2\sum_{(u_i,u_j)\in\mathcal{E}} \mathcal{S}_{i,j} + \sum_{u_i\in\mathcal{V}} \mathcal{S}_i}{|\mathcal{V}|} \le 2\mathcal{F}_{\mathcal{G}},\end{aligned} \tag{10}$$

because each edge $\mathcal{S}_{i,j}$ is counted twice in $\sum_{u\in\mathcal{V}} w(u, \mathcal{G})$. In lines 7–14, the nodes in R are removed from $\mathcal{V}_c$ in each iteration (In contrast, [11] recomputes all nodes and finds those with the minimal w after deleting a node). As removing a subset of R may result in a higher value of $\mathcal{F}$, D-Spot records each change of $\mathcal{F}$, as if the nodes were removed one by one (lines 8–14). Algorithm 3 describes how the edges are updated after a node is removed, requiring a total of $|\mathcal{E}|$ updates. Finally, Algorithm 2 returns the subgraph $\hat{\mathcal{G}}$ induced by $\hat{R}$, the set of nodes achieving $\mathcal{F}^{max}$, according to *top* and *Dict*1 (line 15).

Summary. As R contains at least one node, the worst-case time complexity of Algorithm 2 is $O(|\mathcal{V}|^2 + |\mathcal{E}|)$. In practice, the worst case is too pessimistic. In line 6, R usually contains plenty of nodes, significantly reducing the number of scans of $\mathcal{V}_c$ (see Section 7.2).

Algorithm 2 *find a dense subgraph*

Require: $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, $w()$(Eq. 9)
Ensure: $\hat{\mathcal{G}}$
1: $\mathcal{V}_c \leftarrow copy(\mathcal{V})$
2: $\mathcal{S}_{sum} \leftarrow \sum_{(u_i,u_j)\in\mathcal{E}} \mathcal{S}_{i,j} + \sum_{u_i\in\mathcal{V}} \mathcal{S}_i$
3: $\forall u \in \mathcal{V}, Dict1[u] \leftarrow 0, Dict2[u] = w(u, \mathcal{G})$
4: $index \leftarrow 0,\ \mathcal{F}^{max} \leftarrow \frac{\mathcal{S}_{sum}}{|\mathcal{V}_c|},\ top \leftarrow 0$
5: **while** $\mathcal{V}_c \neq \emptyset$ **do**
6: $R \leftarrow \{u \in \mathcal{V}_c : Dict2[u] \le \frac{2\sum_{(u_i,u_j)\in\mathcal{E}} \mathcal{S}_{i,j} + \sum_{u_i\in\mathcal{V}_c} \mathcal{S}_i}{|\mathcal{V}_c|}\}$ (Eq. 10)
7: sort R in increasing order of $Dict2[u]$
8: **for** each $u \in R$ **do**
9: $\mathcal{V}_c \leftarrow \mathcal{V}_c - u,\ \mathcal{S}_{sum} \leftarrow \mathcal{S}_{sum} - Dict2[u]$
10: $index \leftarrow index + 1, Dict1[u] \leftarrow index$
11: $\mathcal{F} = \frac{\mathcal{S}_{sum}}{|\mathcal{V}_c|}$
12: **if** $\mathcal{F} > \mathcal{F}^{max}$ **then**
13: $\mathcal{F}^{max} \leftarrow \mathcal{F},\ top \leftarrow index$
14: $Dict2 \leftarrow$ *update edges* $(u, \mathcal{V}_c, Dict2, \mathcal{G})$
15: $\hat{R} \leftarrow \{u \in \mathcal{V} : Dict1[u] > top\}$
16: **return** $\hat{\mathcal{G}}$ (the subgraph induced by $\hat{R}$)

Algorithm 3 *update edges*

Require: $u_i, \mathcal{V}_c, Dict2, \mathcal{G} = (\mathcal{V}, \mathcal{E})$
Ensure: *Dict*2
1: **for** each $u_j \in \mathcal{V}_c$ **do**
2: **if** $(u_i, u_j) \in \mathcal{E}$ **then**
3: $Dict2[u_j] \leftarrow Dict2[u_j] - \mathcal{S}_{i,j}$
4: remove (u_i, u_j) from $\mathcal{E}$
5: **return** *Dict*2

6 ANALYSIS

6.1 Complexity.

In the graph initialization stage, it takes $O(K|\mathbf{R}| + |\mathbf{E}|)$ time to build $\mathbf{G}$ based on the optimization in Section 4.2. In D-Spot, the cost of partitioning $\mathbf{G}$ is $O(|\mathbf{E}|)$, and detecting a dense block in a partition $\mathcal{G}$ requires $O(|\mathcal{E}|+|\mathcal{V}|^2)$ operations, where $|\mathcal{E}| << |\mathbf{E}|$, $|\mathcal{V}| << |\mathbf{V}|$. Thus, the complexity of ISG+D-Spot is linear with respect to $|\mathbf{E}|$.

In the worst case, admittedly, $|\mathbf{E}| = |\mathbf{V}|^2$ when there is some dimension A_k in which $|\mathbf{R}_k| = 1$. However, that is too pessimistic. In the target fraud attacks, fraud groups typically exhibit strong value sharing while legit entities should not. Hence, we expect $\mathbf{G}$ to be sparse because the u_i only have positive edges with a small subset of $\mathbf{V}$. We constructed a version of $\mathbf{G}$ using several real-world datasets (see Fig. 3), and the edge densities were all less than 0.06.

6.2 Effectiveness of ISG+D-Spot

Theorem 6. *(Spotting the Hidden-Densest Block). Given a dense block $\mathcal{B}(\mathcal{A}_1, ..., \mathcal{A}_N, \mathcal{X})$ in which the target dimension $U = A_N$ and $\mathcal{V}$ denotes the set of distinct values of $\mathcal{A}_N$, a shared value a exists in $\mathcal{B}$ such that, $\forall u \in \mathcal{V}$, $\exists t \in \mathcal{B}$ satisfying $(t[U] = u) \wedge (t[A_k] = a)$. Then, $\mathcal{B}$ must form a dense subgraph $\mathcal{G}$ in $\mathbf{G}$.*

Proof. Using the optimization algorithm in Section 4.2, we build $\mathbf{G}$ by scanning all values in $\mathbf{R}$ once. Hence, the block $\mathcal{B}(a, A_k)$ must be found. Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be the subgraph induced by $\mathcal{V}$ in $\mathbf{G}$. Then, $\forall(u_i, u_j) \in \mathcal{E}$, the edge $\mathcal{S}_{i,j} \geq \mathcal{I}^k_{i,j}(a)$. Hence, $\rho_{edge}(\mathcal{G}) = 1.0$ and $\mathcal{F}_{\mathcal{G}} = \frac{\sum_{\forall(u_i,u_j)\in\mathcal{E}} \mathcal{S}_{i,j}+\sum_{u_i\in\mathcal{V}} \mathcal{S}_i}{|\mathcal{V}|} \geq \frac{|\mathcal{V}|(|\mathcal{V}|-1)\mathcal{I}^k_{i,j}(a)}{|\mathcal{V}|} = (|\mathcal{V}| - 1)\mathcal{I}^k_{i,j}(a)$. □

Observation. (Effectiveness of ISG+D-Spot) Consider a hidden-densest block $\mathcal{B}(\mathcal{A}_1, ..., \mathcal{A}_{N-1}, \mathcal{A}_N, \mathcal{X})$ of size $|\mathcal{X}| \times ... \times |\mathcal{X}| \times 1$ and $|\mathcal{B}| = |\mathcal{X}|$, i.e., $\mathcal{B}$ is the densest on A_N by sharing the value a. Then, assuming the target dimension $U = A_1$ and the fraudulent entities $\mathcal{V}$ are distinct values of $\mathcal{A}_1$, ISG+D-Spot captures $\mathcal{V}$ more accurately than other algorithms based on tensors (denoted as Tensor+Other Algorithms).

Proof. Let us consider a non-dense block $\hat{\mathcal{B}}(\hat{\mathcal{A}}_1, ..., \hat{\mathcal{A}}_N, \mathcal{X})$ of size $|\mathcal{X}| \times ... \times |\mathcal{X}|$, $|\hat{\mathcal{B}}| = |\mathcal{X}|$, and let $\hat{\mathcal{V}}$ denote the distinct values of $\hat{\mathcal{A}}_1$. Denoting legitimate entities as $\hat{\mathcal{V}}$ and fraudulent entities as $\mathcal{V}$, we now discuss the difference between ISG+D-Spot and Tensor+Other Algorithms.

[*Working on the tensor*]. On $\mathbf{R}$, $\hat{\mathcal{B}}$ is not dense and thus $\rho(\hat{\mathcal{B}}, [N]) = 1$. For $\mathcal{B}$, because $\{|\mathcal{B}_1|, ..., |\mathcal{B}_{N-1}|, |\mathcal{B}_N|\} = \{|\mathcal{X}|, ..., |\mathcal{X}|, 1\}$, we have $\rho(\mathcal{B}, [N]) = \frac{|\mathcal{B}|}{\frac{1}{N}\sum_{n\in[N]}|\mathcal{B}_n|} \approx 1$ for sufficiently large N.

[*Working on ISG*]. On $\mathbf{G}$, let $\hat{\mathcal{G}}$ denote the subgraph induced by $\hat{\mathcal{V}}$ and $\mathcal{G}$ denote the subgraph formed by $\mathcal{V}$. We know that $\hat{\mathcal{G}}$, $\mathcal{F}_{\hat{\mathcal{G}}} = 0$, because $\hat{\mathcal{B}}$ does not have any shared values. For $\mathcal{G}$, $\mathcal{F}_{\mathcal{G}} = (\mathcal{V} - 1)\mathcal{I}^k_{i,j}(a)$ according to Theorem 6.

[*Other Algorithms*]. M-Zoom[30] and D-Cube [32] are known to find blocks that are at least $1/N$ of the optimum in term of ρ on $\mathbf{R}$ ($\frac{1}{N}$-Approximation guarantee).

[*D-Spot*]. In Section 6.3, we will show that the subgraph detected by D-Spot is at least 1/2 of the optimum in term of $\mathcal{F}_{\mathcal{G}}$ on ISG ($\frac{1}{2}$-Approximation guarantee).

In summary, Tensor+Other Algorithms vs. ISG+D-Spot corresponds to:

$$\left(\rho(\hat{\mathcal{B}}, [N]) = 1 \mid \rho(\mathcal{B}, [N]) \approx 1 \ + \ (\frac{1}{N}\text{-Approximation})\right)$$
$$vs. \left(\mathcal{F}_{\hat{\mathcal{G}}} = 0 \mid \mathcal{F}_{\mathcal{G}} = (\mathcal{V} - 1)\mathcal{I}^k_{i,j}(a) \ + \ (\frac{1}{2}\text{-Approximation})\right)$$

Therefore, ISG+D-Spot catches fraudulent entities within hidden-densest blocks more accurately than Tensor+Other Algorithms. □

From the observation, ISG+D-Spot can effectively detect hidden-densest blocks. Similarly, when $\mathcal{B}$ becomes denser, the $\mathcal{G}$ formed by $\mathcal{B}$ will also be much denser, and thus ISG+D-Spot will be more accurate in detecting the densest block.

6.3 Accuracy Guarantee of D-Spot

For brevity, we use $[\mathcal{V}]$ to denote a subgraph induced by the set of nodes $\mathcal{V}$.

Theorem 7. *(Algorithm 1 Guarantee). Given $\mathbf{G} = (\mathbf{V}, \mathbf{E})$, let $\mathcal{G}s = \{\mathcal{G}_1, ..., \mathcal{G}_n\}$ denote the connected components of $\mathbf{G}$. Let $\mathcal{F}_i^{opt}$ denote the optimal $\mathcal{F}$ on $\mathcal{G}_i$, i.e., $\nexists \mathcal{G}' \subseteq \mathcal{G}_i$ satisfying $\mathcal{F}_{\mathcal{G}'} > \mathcal{F}_i^{opt}$. Then, if $\mathcal{F}_n^{opt}$ is the maximal value of $\{\mathcal{F}_1^{opt}, ..., \mathcal{F}_n^{opt}\}$, $\mathcal{F}_n^{opt}$ must be the optimum in terms of $\mathcal{F}$ on $\mathbf{G}$.*

Proof. Given any two sets of nodes $\mathcal{V}_1$ and $\mathcal{V}_2$ and assuming there are no edges connecting $\mathcal{V}_1$ and $\mathcal{V}_2$, we assume that $\mathcal{F}_{[\mathcal{V}_1]} > \mathcal{F}_{[\mathcal{V}_2]} \Rightarrow \frac{c_1}{|\mathcal{V}_1|} > \frac{c_2}{|\mathcal{V}_2|} \Rightarrow c_1|\mathcal{V}_2| > c_2|\mathcal{V}_1|$. Then,

$$\mathcal{F}_{[\mathcal{V}_1]} - \mathcal{F}_{[\mathcal{V}_1\cup\mathcal{V}_2]} \Rightarrow \frac{c_1}{|\mathcal{V}_1|} - \frac{c_1 + c_2}{|\mathcal{V}_1| + |\mathcal{V}_2|}$$
$$\Rightarrow \frac{c_1|\mathcal{V}_2| - c_2|\mathcal{V}_1|}{|\mathcal{V}_1|(|\mathcal{V}_1| + |\mathcal{V}_2|)} > \frac{c_2|\mathcal{V}_1| - c_2|\mathcal{V}_1|}{|\mathcal{V}_1|(|\mathcal{V}_1| + |\mathcal{V}_2|)} = 0.$$

Thus, for any $\mathcal{V}_1$ and $\mathcal{V}_2$ that are not connected by any edges, it follows that $\mathcal{F}_{[\mathcal{V}_1\cup\mathcal{V}_2]} \leq \max(\mathcal{F}_{[\mathcal{V}_1]}, \mathcal{F}_{[\mathcal{V}_2]})$ (Conclusion 1).

In $\mathcal{G}_n = (\mathcal{V}_n, \mathcal{E}_n)$, we use $\hat{\mathcal{V}}$ to denote the set of nodes satisfying $\hat{\mathcal{V}} \subseteq \mathcal{V}_n$ and $\mathcal{F}_{[\hat{\mathcal{V}}]} = \mathcal{F}_n^{opt}$. Let $\mathcal{V}'$ be a set of nodes satisfying $\mathcal{V}' \subset \mathbf{V}$ and $\mathcal{V}' \cap \hat{\mathcal{V}} = \emptyset$. Now, let us consider two conditions.

First, if $\mathcal{V}' \subset \mathcal{V}_n$, then $\mathcal{F}_{[\mathcal{V}']} \leq \mathcal{F}_{[\hat{\mathcal{V}}]}$ and $\mathcal{F}_{[\mathcal{V}'\cup\hat{\mathcal{V}}]} \leq \mathcal{F}_{[\hat{\mathcal{V}}]}$ because $\mathcal{F}_{[\hat{\mathcal{V}}]}$ is the optimum on $\mathcal{G}_n$.

Second, if $\mathcal{V}' \cap \mathcal{V}_n = \emptyset$, then $\mathcal{F}_{[\mathcal{V}']} \leq \mathcal{F}_{[\hat{\mathcal{V}}]}$ and $\mathcal{F}_{[\mathcal{V}'\cup\hat{\mathcal{V}}]} \leq \mathcal{F}_{[\hat{\mathcal{V}}]}$ by Conclusion 1 and because $\mathcal{F}_{[\hat{\mathcal{V}}]}$ is the maximum of $\{\mathcal{F}_1^{opt}, ..., \mathcal{F}_n^{opt}\}$.

If $\mathcal{V}' \cap \mathcal{V}_n \neq \emptyset$, then $\mathcal{V}'$ can be divided into two parts conforming with the two conditions stated above.

Therefore, $\nexists \mathcal{V}' \subset \mathbf{V}$ satisfies $\mathcal{F}_{[\mathcal{V}']} > \mathcal{F}_{[\hat{\mathcal{V}}]}$ or $\mathcal{F}_{[\mathcal{V}'\cup\hat{\mathcal{V}}]} > \mathcal{F}_{[\hat{\mathcal{V}}]}$. We can conclude that $\mathcal{F}_n^{opt} = \mathcal{F}_{[\hat{\mathcal{V}}]}$ must be the optimum in terms of $\mathcal{F}$ on $\mathbf{G}$. □

Theorem 8. *(Algorithm 2 Guarantee). Given a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, let Q^* be a subset of nodes maximizing $\mathcal{F}_{[Q^*]}$ in $\mathcal{G}$. Let $[Q]$ be the subgraph returned by Algorithm 2 with $\mathcal{F}_{[Q]}$. Then, $\mathcal{F}_{[Q]} \geq \frac{1}{2}\mathcal{F}_{[Q^*]}$.*

Proof. Consider the optimal set Q^*. We know that, $\forall u \in Q^*$, $w(u, [Q^*]) \geq \mathcal{F}_{[Q^*]}$, because if we remove a node u for which

$w(u, [Q^*]) < \mathcal{F}_{[Q^*]}$,

$$\mathcal{F}' = \frac{|Q^*|\mathcal{F}_{[Q^*]} - w(u, Q^*)}{|Q^*| - 1} > \frac{|Q^*|\mathcal{F}_{Q^*} - \mathcal{F}_{Q^*}}{|Q^*| - 1} = \mathcal{F}_{[Q^*]},$$

which contradicts the definition of Q^*.

Denote the first node that Algorithm 2 removes from Q^* as u_i, $u_i \in R$, and denote the node set before Algorithm 2 starts removing R as Q'. Because $Q^* \subseteq Q'$, we have $w(u_i, [Q^*]) \leq w(u_i, [Q'])$. According to Algorithm 2 (line 6), $w(u_i, [Q']) \leq 2\mathcal{F}_{[Q']}$ (Eq. 10). Additionally, Algorithm 2 returns the best solution when deleting nodes one by one, and so $\mathcal{F}_{[Q]} \geq \mathcal{F}_{[Q']}$. We conclude that

$$\mathcal{F}_{[Q]} \geq \mathcal{F}_{[Q']} \geq \frac{w(u_i, [Q'])}{2} \geq \frac{w(u_i, [Q^*])}{2} \geq \frac{\mathcal{F}_{Q^*}}{2}.$$

□

In summary, let $\{\mathcal{G}_1, ..., \mathcal{G}_n\}$ be the subgraphs returned by D-Spot, and $\{\mathcal{F}_{\mathcal{G}_1}, ..., \mathcal{F}_{\mathcal{G}_n}\}$ be the corresponding scores. Then, based on Theorems 7 and 8, $\mathcal{F}^{max} = max(\mathcal{F}_{\mathcal{G}_1}, ..., \mathcal{F}_{\mathcal{G}_n})$ is at least 1/2 of the optimum in terms of $\mathcal{F}$ on $\mathbf{G}$ (1/2-Approximation guarantee).

7 EVALUATION

A series of evaluation experiments were conducted under the following conditions:

Implementation. We implemented ISG+D-Spot in Python, and conducted all experiments on a server with two 2.20 GHz Intel(R) CPUs and 64 GB memory.

Baselines. We selected several state-of-the-art dense-block detection methods (M-Zoom [30], M-Biz [31], and D-Cube [32]) as the baselines (using open source code). To obtain optimal performance, we run three different density metrics from [32] for each baseline: ρ **(ari)**, Geometric Average Mass **(geo)**, and Suspiciousness **(sus)**.

Suspiciousness Score Setting. For the baselines, we considered a detected block $\mathcal{B}(\mathcal{A}_1, ..., \mathcal{A}_N, \mathcal{X})$ and let $\theta = \rho(\mathcal{B}, N)$. For any unique value a within $\mathcal{B}$, we then set the suspiciousness score of a to θ. If a occurred in multiple detected dense blocks, we chose the one with the maximal value of θ. Regarding ISG+D-Spot, given a detected subgraph $\hat{\mathcal{G}} = (\hat{\mathcal{V}}, \hat{\mathcal{E}})$, for a unique value $a \in \hat{\mathcal{V}}$, we set the suspiciousness score of a to $w(a, \hat{\mathcal{G}})$ (Eq. 9). Finally, we evaluated the ranking of the suspiciousness scores of unique values using the standard area under the ROC curve (AUC) metric.

7.1 Datasets

Table 3 summarizes the datasets used in the experiments.

Synthetic is a series of datasets we synthesized using the same method as in [12]. First, we generated random seven-dimensional relations $\mathbf{R}(A_1, ..., A_7, X)$, in which $|\mathbf{R}| = 10000$ and the size of $\mathbf{R}$ is $1000 \times 500 \times ... \times 500$. In $\mathbf{R}$, we assume that A_1 corresponds to users and the other six dimensions are features. To specifically check the detection performance of the hidden-densest block using each method, we injected a dense block $\mathcal{B}(\mathcal{A}_1, ..., \mathcal{A}_7, \mathcal{X})$ into $\mathbf{R}$ five separate times, with each injection assigned a different configuration to generate five datasets. For $\mathcal{B}$, $|\mathcal{B}_1| = 50$ and $|\mathcal{B}| = 500$. We introduce the parameter λ, which denotes the number of dimensions on which $\mathcal{B}$ is the densest. For example, when $\lambda = 1$, the size of $\mathcal{B}$ is $50\times\mathbf{12}\times25... \times 25$; when $\lambda = 5$, the size of $\mathcal{B}$ is $50\times\mathbf{12}\times...\times\mathbf{12}\times25$. Obviously, $\rho(\mathcal{B}, 7) > \rho(\mathbf{R}, 7)$ and $\mathcal{B}$ is the hidden-densest block when λ is small. Finally, we labeled the users within $\mathcal{B}$ as "fraud".

Amazon [15]. AmaOffice, AmaBaby, and AmaTools are three collections of reviews about office products, baby-related products, and tool products, respectively, on Amazon. They can be modeled using the relation $\mathbf{R}(user, product, timestamp, X)$. For each entry $t \in \mathbf{R}$, $t = (u, p, t, x)$ indicates a review x that user u reviewed product p at time t. According to the specific cases of fraud discovered by previous studies [12, 38], fraudulent groups usually exhibit suspicious synchronized behavior in social networks. For instance, a large group of users may surprisingly review the same group of products over a short period. Thus, we use a similar method as in [12, 30, 32, 38]. We use a dense block $\mathcal{B}$ to represent the synchronized behavior, where $\mathcal{B}(user, product, timestamp, \mathcal{X})$ has a size of $200 \times 30 \times 1$. In total, we injected four such blocks $\mathcal{B}$ with a mass randomly selected from [1000, 2000]. The users in the injected blocks were labeled as "malicious."

Yelp [25]. The YelpChi, YelpNYU, and YelpZip datasets [21, 25] contain restaurant reviews submitted to Yelp. They can be represented by the relation $\mathbf{R}(user, restaurant, date, X)$, where each entry $t = (u, r, d, x)$ denotes a review x by user u of restaurant r on date d. Note that all three datasets include labels indicating whether or not each review is fake. The detection of malicious reviews or users is studied in [25] using text information. In these datasets, we focus on detecting fraudulent restaurants that purchase fake reviews using the three-dimensional features. Intuitively, the more fake reviews a restaurant has, the more suspicious it is. As some legitimate users have the potential of reviewing fraudulent restaurants, we label a restaurant as "fraudulent" if it has received more than 40 fake reviews.

DARPA [19] was collected by the Cyber Systems and Technology Group in 1998 regarding network attacks in TCP dumps. The data has the form $\mathbf{R}(sourceIP, targetIP, timestamp, X)$. Each entry $t = (IP_1, IP_2, t)$ represents a connection made from IP_1 to IP_2 at time t. The dataset includes labels indicating whether or not each connection is malicious. In practice, the punishment for malicious connections is to block the corresponding IP address. Thus, we compared the detection performance of suspicious IP addresses. We labeled an IP address as suspicious if it was involved in a malicious connection.

AirForce [1] was used for the KDD Cup 1999, and has also been considered in [30, 32]. This dataset includes a wide variety of simulated intrusions in a military network environment. However, it does not contain any specific IP addresses. According to the cardinality of each dimension, we chose the top-2 features and built the relation $\mathbf{R}(src\ bytes, dst\ bytes, connections, X)$, where src bytes denotes the number of data bytes sent from source to destination and dst bytes denotes the number of data bytes sent from destination to source. The target dimension U was set to be *connections*. Note that this dataset includes labels indicating whether or not each connection is malicious.

7.2 Speed and Accuracy of D-Spot

First, we measured the speed and accuracy with which D-Spot detected dense subgraphs in real-world graphs. We compared the

Table 3: Multi-dimensional datasets used in our experiments

	Synthetic	TCP Dumps		Review Data					
		DARPA	AirForce	YelpChi	YelpNYU	YelpZip	AmaOffice	AmaBaby	AmaTools
Entries (Mass)	10K	4.6M	30K	67K	359K	1.14M	53K	160K	134K
Dimensions	7	3	3	3	3	3	3	3	3

performance of D-Spot with that of another dense-subgraph detection algorithm, Fraudar [11], the extension of [6], which maximizes the density metric by greedily deleting nodes **one by one**. We used the three Amazon datasets and applied D-Spot and Fraudar to the same bipartite graph built on the first two dimensions, *users* and *products*, where each edge in the graph represents an entry. We measured the wall-clock time (average over three runs) required to detect the top-4 subgraphs. Figure 2 illustrates the runtime and performance of the two algorithms.

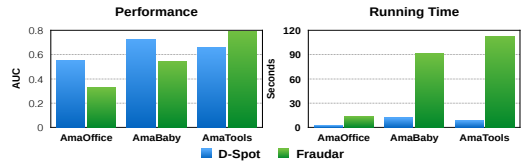

Figure 2: Comparison of D-Spot and Fraudar using the Amazon datasets.

D-Spot provides the best trade-off between speed and accuracy. Specifically, D-Spot is up to 11× faster than Fraudar. This supports our claim in Section 5.2 that the worst-case time complexity of D-Spot ($O(|\mathcal{V}|^2 + |\mathcal{E}|)$) is too pessimistic.

7.3 Effectiveness of ISG+D-Spot

This section illustrates the effectiveness of ISG+D-Spot for detecting fraudulent entities on multi-dimensional tensors. ISG+D-Spot exhibits extraordinary performance compared with the baseline methods (Fraudar is not in the baselines as it only works on the bipartite graph).

Synthetic. Table 4 presents the detection performance of each method for the hidden-densest block. We assume that the injected block $\mathcal{B}$ is the hidden-densest block when $\lambda \leq 3$. In detail, ISG+D-Spot achieves extraordinary performance even when $\lambda = 1$, because each instance of value sharing in $\mathcal{B}$ is accurately captured by ISG and D-Spot, providing a higher accuracy guarantee than the baselines (Theorems 2 and 3). When $\lambda > 3$, the performance of each method improves because the density of $\mathcal{B}$ increases as λ increases.

Amazon. Table 5 presents the results for catching suspicious users by detecting the top-4 dense blocks on the Amazon datasets. ISG+D-Spot detects synchronized behavior accurately. The typical attack scenario involves a mass of fraudulent users creating massive numbers of fake reviews for a comparatively small group of products over a short period. This behavior is represented by the injected blocks. ISG+D-Spot exhibits robust and near-perfect performance. However, the other baselines produce worse performance on the AmaOffice and AmaBaby datasets, even with the multiple supported metrics.

Table 4: Performance (AUC) on the Synthetic datasets

	$\lambda = 1$	$\lambda = 2$	$\lambda = 3$	$\lambda = 4$	$\lambda = 5$

ISG+D-Spot	**0.9875**	**0.9546**	**0.9529**

DARPA. Table 7 lists the accuracy of each method for detecting the source IP and the target IP. ISG+D-Spot assigns each IP address

a specific suspiciousness score. We chose a detected IP with the highest score and found that the IP participated in more than 1M malicious connections. The top ten suspicious IPs were all involved in more than 10k malicious connections. Thus, using ISG+D-Spot would enable us to crack down on these malicious IP addresses in the real world.

Table 7: Performance (AUC) on the DARPA dataset

Dataset	DARPA	
	U = source IP	U = target IP

D-Cube (ari)	**0.9824**	**0.9823**	0.9851
D-Cube (geo)	0.9695	0.9691	**0.9862**
D-Cube (sus)	0.9697	0.9692	0.9737
ISG+D-Spot	**0.9835**	**0.9824**	**0.9877**

7.4 Scalability

As mentioned in Sec.6.1, the ISG **G**s built using real-world tensors are typically sparse, as value sharing should only conspicuously appear in fraudulent entities. We implemented **G** on the three Amazon datasets (details in Figure 3). The edge densities of **G** are quite low (lower than 0.06) across all datasets, which indicates that the worst-case time complexity discussed in Section 6.1 rarely occurs. Figure 3 reports the runtime of ISG+D-Spot on the three Amazon datasets, where the number of edges was varied by subsampling entries in the dataset. In practice, $|\mathbf{E}|$ increases near-linearly with the mass of the dataset. Additionally, because the time complexity of ISG+D-Spot is linear with respect to $|\mathbf{E}|$, ISG+D-Spot exhibits near-linear scaling with the mass of the dataset. Figure 3 demonstrates our conclusion.

	Edge Density
AmaOffice	0.0534
AmaBaby	0.0211
AmaTools	0.0171

Figure 3: ISG+D-Spot runs in near-linear time with respect to the mass of the dataset.

7.5 Feature Prioritization

This section is to demonstrate that ISG+D-Spot is more robust to resist noisy features than existing approaches. ISG automatically weighs each feature and continuously accumulates value sharing by one scan of the tensor, and D-Spot amounts to finds entities with the maximum of value sharing. We conducted the following experiment to demonstrate our conclusion.

Registration is a dataset derived from an e-commerce company, in which each record contains two crucial features, IP subnet and phone prefix, and three noisy features, IP city, phone city, and timestamp. The dataset also includes labels showing whether or not the account is a "zombie" account. Thus, it can be formulated as $\mathbf{R}(accounts, IP, phone, IP\ city, phone\ city, timestamp, X)$. To compare the detection performance of malicious accounts, we applied each method on various **R** by successively appending 1–5 features to $\mathbf{R}(accounts, X)$.

Table 9: Performance (AUC) on the Registration dataset. 'C' represents 'crucial feature' and 'N' represents 'noisy feature'

	1C	2C	2C+1N	2C+2N	2C+3N
M-Zoom (ari)	0.5000	0.5000	0.5031	0.5000	0.5430
M-Zoom (geo)	0.7676	0.8880	**0.8827**	**0.8744**	**0.8439**
M-Zoom (sus)	0.7466	0.8328	0.4009	0.4878	0.4874
M-Biz (ari)	0.5000	0.5000	0.5000	0.5000	0.5004
M-Biz (geo)	**0.7677**	0.8842	0.8827	0.8744	0.8439
M-Biz (sus)	0.7466	0.8328	0.4009	0.4878	0.4874
D-Cube (ari)	0.7073	0.8189	0.8213	0.8295	0.7987
D-Cube (geo)	0.7073	**0.9201**	0.8586	0.8312	0.7324
D-Cube (sus)	0.7522	0.8956	0.7877	0.7642	0.7080
ISG+D-Spot	**0.7699**	**0.9946**	**0.9935**	**0.9917**	**0.9859**

Table 9 gives the variation of each method with regard to the added noisy features (3– 5 dimensions). As each account only possesses one entry, **R** is quite sparse. We found that existing methods usually miss small-scale instances of value sharing because their density is close to the legitimate range on **R**. For example, a 51-member group sharing a single IP subnet was missed by the baseline methods. However, ISG amplifies each instance of value sharing through its information-theoretic and graph features, allowing D-Spot to accurately capture fraudulent entities.

8 CONCLUSIONS AND FUTURE WORK

In this paper, we novelly identified dense-block detection with dense-subgraph mining, by modeling a tensor in ISG. Additionally, we propose a multiple dense-subgraphs detection algorithm that is faster and can be computed in parallel. In future, ISG + D-Spot will be implemented on Apache Spark [39] to support very large tensors.

Link Prediction in Networks with Core-Fringe Data

ABSTRACT

Data collection often involves the partial measurement of a larger system. A common example arises in collecting network data: we often obtain network datasets by recording all of the interactions among a small set of core nodes, so that we end up with a measurement of the network consisting of these core nodes along with a potentially much larger set of fringe nodes that have links to the core. Given the ubiquity of this process for assembling network data, it is crucial to understand the role of such a "core-fringe" structure.

Here we study how the inclusion of fringe nodes affects the standard task of network link prediction. One might initially think the inclusion of any additional data is useful, and hence that it should be beneficial to include all fringe nodes that are available. However, we find that this is not true; in fact, there is substantial variability in the value of the fringe nodes for prediction. Once an algorithm is selected, in some datasets, including any additional data from the fringe can actually hurt prediction performance; in other datasets, including some amount of fringe information is useful before prediction performance saturates or even declines; and in further cases, including the entire fringe leads to the best performance. While such variety might seem surprising, we show that these behaviors are exhibited by simple random graph models.

1 INTRODUCTION

In a wide range of data analysis problems, the underlying data typically comes from partial measurement of a larger system. This is a ubiquitous issue in the study of networks, where the network we are analyzing is almost always embedded in some larger surrounding network [17, 20, 21]. Such considerations apply to systems at all scales. For example, when studying the communication network of an organization, we can potentially gain additional information if we know the structure of employee interactions with people outside the organization as well [32]. A similar issue applies to large-scale systems. If we are analyzing the links within a large online social network, or the call traffic data from a large telecommunications provider, we could benefit from knowing the interactions that members of these systems have with individuals who are not part of the platform, or who do not receive service from the provider.

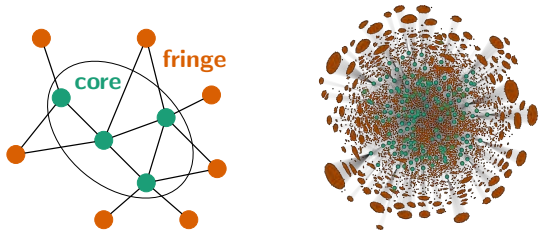

Figure 1: Core-fringe structure. (Left) Illustrative network with labeled core-fringe structure (core nodes in green and fringe nodes in orange). We observe all of the links involving core nodes (in green). Each edge is between two core nodes or between one core and one fringe node. (Right) Core-fringe structure in the Enron email network, which results from data collection—the core nodes in green correspond to the roughly 150 accounts whose emails were released as part of a federal investigation [19]. Here, the number of fringe nodes is orders of magnitude larger than the number of core nodes.

Network data can therefore be viewed as having a *core-fringe* structure (following the terminology of our previous work [6]): we collect data by measuring all of the interactions involving a *core* set of nodes, and in the process we also learn about the core's interaction with a typically larger set of additional nodes—the *fringe*—that does not directly belong to the measured system. Figure 1 illustrates the basic structure schematically and also in a typical real-life scenario: If we collect a dataset by measuring all email communication to and from the executives of a company (the core), then the data will also include links to people outside this set with whom members of the core exchanged email (the fringe).[1] We thus have two kinds of links: links between two members of the core, and links between a member of the core and a member of the fringe. Links between fringe members are not visible, even though we are aware of both fringe nodes through their interactions with the core.

Despite the fundamental role of core-fringe structure in network data and a long history of awareness of this issue in the social sciences [21], there has been little systematic attention paid to its implications in basic network inference tasks. If we are trying to predict network structure on a measured set of core nodes, what is the best way to make use of the fringe? Is it even clear that incorporating the fringe nodes will help? To study these questions, it is important to have a concrete task on the network where notions of performance as a function of available data are precise.

The present work: Core-fringe link prediction. In this paper, we study the role of core-fringe structure through one of the standard network inference problems: *link prediction* [24, 26]. Link

[1] This distinction between core and fringe is fundamentally driven by measurement of the available data; we have measured all interactions involving members of the core, and this brings the fringe indirectly into the data. As such, it is distinct from work on the *core-periphery structure* of networks, which typically refers to settings in which the core and periphery both fully belong to the measured network, and the distinction is in the level of centrality or status that the core has relative to the periphery [7, 16, 31, 37].

prediction is a problem in which the goal is to predict the presence of *unseen* links in a network. Links may be unseen for a variety of reasons, depending on the application—we may have observed the network up to a certain point in time and want to forecast new links, or we may have collected a subset of the links and want to know which additional ones are present.

Abstractly, we will think of the link prediction problem as operating on a graph $G = (V, E)$ whose edges are divided into a set of observed edges and a set of unseen edges. From the network structure on the observed edges, we would like to predict the presence of the unseen edges as accurately as possible. A large range of heuristics have been proposed for this problem, many of them based on the empirical principle that nodes with neighbors in common are generally more likely to be connected by a link [24, 26, 28].

The issue of core-fringe structure shows up starkly in the link prediction problem. Suppose the graph G has nodes that are divided into a core set C and a fringe set F, and our goal is to predict unseen links between pairs of nodes in the core. One option would be to perform this task using only the portion of G induced on the core nodes. But we could also perform the task using larger amounts of G by taking the union of the core nodes with any subset of the fringe, or with all of the fringe. The key question is how much of the fringe we should include if our goal is to maximize performance on the core; existing work provides little guidance about this question.

How much do fringe nodes help in link prediction? We explore this question in a broad collection of network datasets derived from email, telecommunication, and online social networks. For concreteness, our most basic formulation draws on common-neighbor heuristics to answer the following version of the link prediction question: given two pairs of nodes drawn from the core, $\{u, v\}$ and $\{w, z\}$, which pair is more likely to be connected by a link? (In our evaluation framework, we will focus on cases in which exactly one of these pairs is truly connected by a link, thus yielding a setting with a clear correct answer.) To answer this question, we could use information about the common neighbors that $\{u, v\}$ and $\{w, z\}$ have only in the core, or also in any subset of the fringe. How much fringe information should we use, if we want to maximize our probability of getting the correct answer?

It would be natural to suspect that using all available data, i.e., including all of the fringe nodes, would maximize performance. What we find, however, is a wide range of behaviors. In some of our domains—particularly the social-networking data—link prediction performance increases monotonically in the amount of fringe data used, though with diminishing returns as we incorporate the entire fringe. In the other domains, however, we find a number of instances where using an intermediate level of fringe, i.e., a proper subset of the fringe nodes, yields a performance that dominates the option of including all of the fringe or none of it. And there are also cases where prediction is best when we ignore the fringe entirely. Given that proper subsets of the fringe can yield better performance than either extreme, we also consider the process of selecting a subset of the fringe; in particular, we study different natural *orderings* of the fringe nodes and then select a subset by searching over prefixes of these orderings.

To try understanding this diversity of results, we turn to basic random graph models, adapting them to capture the problem of link prediction in the presence of core-fringe structure. We find that simple models are rich enough to display the same diversity of behaviors in performance, where the optimal amount of fringe might be all, some, enough, or none. More specifically, we analyze the signal-to-noise ratio for our basic link prediction primitive in two heavily-studied network models: stochastic block models (SBMs), in which random edges are added with different probabilities between a set of planted clusters [1, 2, 10, 27]; and small-world lattice models, in which nodes are embedded in a lattice, and links between nodes are added with probability decaying as a power of the distance [18, 35]. We prove that there are instances of the SBM with certain linking probabilities in which the signal-to-noise ratio is optimized by including all the fringe, enough of the fringe, or none of the fringe. For small-world lattice models, we find in the most basic formulation that the signal-to-noise ratio is optimized by including an intermediate amount of fringe: essentially, if the core is a bounded geometric region in the lattice, then the optimal strategy for link prediction is to include the fringe in a larger region that extends out from the core; but if we grow this region too far then performance will decline.

The analysis of these models provides us with some qualitative higher-level insight into the role of fringe nodes in link prediction. In particular, the analysis can be roughly summarized as follows: the fringe nodes that are most well-connected to the core are providing valuable predictive signal without significantly increasing the noise; but as we continue including fringe nodes that are less and less well-connected to the core, the signal decreases much faster than the noise, and eventually the further fringe nodes are primarily adding noise in a way that hurts prediction performance.

More broadly, the results here indicate that the question of how to handle core-fringe structure in network prediction problems is a rich subject for investigation, and an important one given how common this structure is in network data collection. An implication of both our empirical and theoretical results is that it can be important for problems such as link prediction to measure performance with varying amounts of additional data, and to accurately evaluate the extent to which this additional data is primarily adding signal or noise to the underlying decision problem.

Finally, software and data associated with this paper are available at https://github.com/arbenson/cflp.

2 EMPIRICAL NETWORK ANALYSIS

We first empirically study how including fringe nodes can affect link prediction on a number of datasets. While we might guess that any additional data we can gather would be useful for prediction, we see that this is not the case. In different datasets, incorporating all, none, some, or enough fringe data leads to the best performance. We then show in Section 3 that this variability is also exhibited in the behavior of simple random graph models.

Evaluating link prediction with core-fringe structure. There are several ways to evaluate link prediction performance [24, 26]. We set up the prediction task in a natural way that is also amenable to theoretical analysis in Section 3. We assume that we have a graph $G = (V, E)$ with a known set of core nodes $C \subseteq V$ and fringe nodes $F = V - C$. The edge set is partitioned into E^{train} and E^{test}, where E^{test} is a subset of the edges that connect two nodes in the core C. The form of E^{test} depends on the dataset, which we describe in

the following sections. In general, our core-fringe link prediction evaluation is based on how well we can predict elements of E^{test} given the graph $G^{\text{train}} = (V, E^{\text{train}})$.

Our atomic prediction task considers two pairs of nodes $\{u, v\}$ and $\{w, z\}$ such that (i) all four nodes are in the core (i.e., $u, v, w, z \in C$); (ii) neither pair is an edge in E^{train}; (iii) the edge (u, v) is a positive sample, meaning that $(u, v) \in E^{\text{test}}$; and (iv) the edge (w, z) is a negative sample, meaning that $(w, z) \notin E^{\text{test}}$. We use an algorithm that takes as input G^{train} and outputs a score function $s(x, y)$ for any pair of nodes $x, y \in C$; the algorithm then predicts that the pair of nodes with the higher score is more likely to be in the test set. Thus, the algorithm makes a correct prediction if $s(u, v) > s(w, z)$. We sample many such 4-tuples of nodes uniformly at random and measure the fraction of correct predictions.

We evaluate two score functions that are common heuristics for link prediction [24]. The first is the *number of common neighbors*:

$$s(x, y) = |N(x) \cap N(y)|, \tag{1}$$

where $N(z)$ is the set of neighbors of node z in the graph. The second is the *Jaccard similarity* of the neighbor sets:

$$s(x, y) = \frac{|N(x) \cap N(y)|}{|N(x) \cup N(y)|}. \tag{2}$$

We choose these score functions for a few reasons. First, they are flexible enough to be feasibly deployed even if only minimal information about the fringe is available; more generally, their robustness has motivated their use as heuristics in practice [14, 15] and throughout the line of research on link prediction [24]. Second, they are amenable to analysis: we can explain some of our results by analyzing the common neighbors heuristic on random graph models, and they are rich enough to expose a complex landscape of behavior. This is sufficient for the present study, but it would be interesting to examine more sophisticated link prediction algorithms in our core-fringe framework as well.

We parameterize the training data by how much fringe information is included. To do this, we construct a nested sequence of sets of vertices, each of which induces a set of training edges. Specifically, the initial set of vertices is the core, and we continue to add fringe nodes to construct a nested sequence of vertices:

$$C = V_0 \subseteq V_1 \subseteq \cdots \subseteq V_D = V. \tag{3}$$

The nested sequence of vertex sets then induces a nested sequence of edges that are the training data for the link prediction algorithm; for a value of d between 0 and D, we write

$$E_d^{\text{train}} = \{(u, v) \in E \mid u, v \in V_d\} \cap E^{\text{train}}. \tag{4}$$

From Eqs. (3) and (4), $E_d^{\text{train}} \subseteq E_{d+1}^{\text{train}}$, and $E_D^{\text{train}} = E^{\text{train}}$. The parameterization of the vertex sets will depend on the dataset, and we examine multiple sequences $\{V_d\}$ to study how different interpretations of the fringe give varying outcomes. Our main point of study is link prediction performance *as a function of* d.

2.1 Email networks

Our first set of experiments analyzes email networks. The core nodes in these datasets are members of some organization, and the fringe nodes are those outside of the organization that communicate with those in the core. We use four email networks; in each, the nodes are email addresses, and the time that an edge formed is given by the timestamp of the first email between two nodes. For simplicity, we consider all graphs to be undirected, even though there is natural directionality in the links. Thus, each dataset is a simple, undirected graph, where each edge has a timestamp and each node is labeled as core or fringe. The four datasets are (i) *email-Enron*: the network in Figure 1, where the core nodes correspond to accounts whose emails were released as part of a federal investigation [6, 19]; (ii) *email-Avocado*: the email network of a now-defunct company, where the core nodes are employees (we removed accounts associated with non-people, such as conference rooms).[2] (iii) *email-Eu*: a network that consists of emails involving members of a European research institution, where the core nodes are the institution's members [23, 36]; and (iv) *email-W3C*: a network from W3C email threads, where core nodes are those addresses with a `w3.org` domain [6, 9]. Table 1 provides basic summary statistics.

Table 1: Summary statistics of email datasets.

Dataset	# core nodes	# fringe nodes	# core-core edges	# core-fringe edges
email-Enron	148	18,444	1,344	41,883
email-Avocado	256	27,988	7,416	50,048
email-Eu	1,218	200,372	16,064	303,793
email-W3C	1,995	18,086	1,777	30,097
email-Enron-1	37	7,511	86	11,862
email-Enron-2	37	6,440	81	10,648
email-Enron-3	37	6,379	80	10,390
email-Enron-4	37	6,587	95	10,987

An entire email network dataset is a graph $G = (V, E)$, where $C \subseteq V$ is a set of core nodes, and each edge $e \in E$ is associated with a timestamp t_e. Here, our test set is derived from the temporal information. Let t^* be the 80th percentile of timestamps on edges between core nodes. Our test set of edges is the final 20% of edges between core nodes that appear in the dataset:

$$E^{\text{test}} = \{(u, v) \in E \mid u, v \in C \text{ and } t_{(u,v)} \geq t^*\}. \tag{5}$$

The training set is then given by edges appearing before t^*, i.e., the edges appearing in the first 80% of time spanned by the data:

$$E^{\text{train}} = \{(u, v) \in E \mid t_{(u,v)} < t^*\}. \tag{6}$$

Fringe ordering. Next, we form the nested sequence of training set edges (Eq. (4)) by sequentially increasing the amount of fringe information (Eq. (3)). Recall that E_d^{train} is simply the set of edges in E^{train} in which both end points are in the vertex set V_d. To build $\{V_d\}$, we start with $V_0 = C$, the core set, and then add the fringe nodes one by one in order of decreasing degree in the graph $G^{\text{train}} = (V, E^{\text{train}})$. By definition, fringe nodes cannot link between themselves, so this ordering is equivalent to adding fringe nodes in order of the number of core nodes to which they connect. For purposes of comparison, we also evaluate this ordering relative to a uniformly random ordering of the fringe nodes. To summarize, given an ordering σ of the fringe nodes F, we create a nested sequence of node sets $V_d = C \cup \{\sigma_1, \ldots, \sigma_d\}$ in two ways: (i) *Most connected*: σ is the ordering of nodes in the fringe F by decreasing

[2] https://catalog.ldc.upenn.edu/LDC2015T03

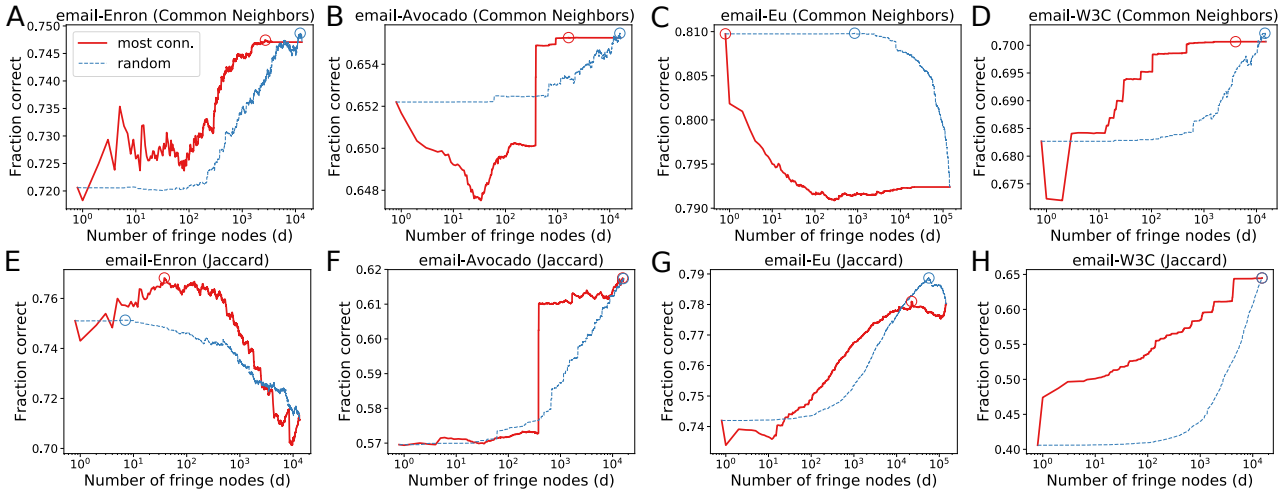

Figure 2: Link prediction performance of the Common Neighbors (top) and Jaccard similarity (bottom) score functions on four email networks as a function of d, the number of fringe nodes included. Two orderings of fringe nodes are considered: one by the most connections to the core (red) and one random (blue). A circle marks the best performance. There is a striking variety in how the fringe affects performance. In some cases, we should ignore the fringe entirely (C); in others, performance increases with the size of the fringe (F, H); and in still others, some intermediate amount of fringe is optimal (E, G).

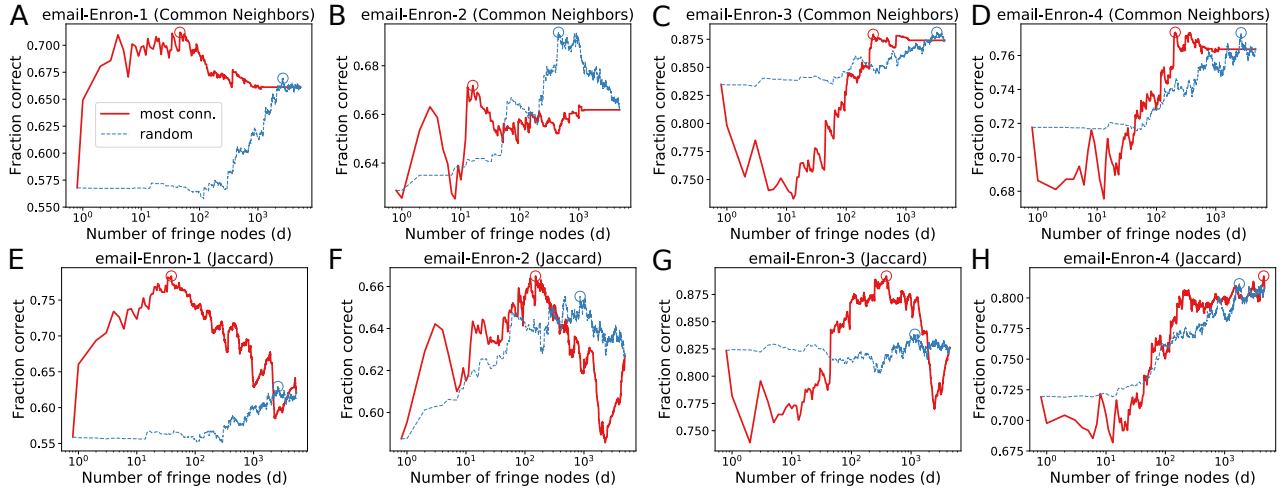

Figure 3: Link prediction performance experiments analogous to those in Figure 2 but on four subsets of email-Enron. In most cases, including some interior amount of fringe nodes—between 10 and a few hundred—yields the optimal performance.

degree in the graph induced by E^{train} (Eq. (6)); and (ii) *Random*: σ is a random ordering of the nodes in F.

Link prediction. We use the *most connected* and *random* ordering to predict links in the test set of edges, as described at the beginning of Section 2. Recall that we needed a set of candidate comparisons between two potential edges (one of which does appear in the test). We guess that the pair of nodes with the larger number of common neighbors or larger Jaccard similarity score will be the set that appears in the test set. We sample $10 \cdot |E^{\text{test}}|$ pairs from E^{test} (allowing for repeats) and combine each of them with two nodes selected uniformly at random that never form an edge. Prediction performance is measured in terms of the fraction of correct guesses as a function of d, the number of fringe nodes included. This entire procedure is repeated 10 times (with 10 different sets of random samples) and the mean accuracy is reported in Figure 2.

The results exhibit a wide variety of behavior. In some cases, performance tends to increase monotonically with the number of fringe nodes (Figures 2F and 2H). In one case, we achieve optimal performance by ignoring the fringe entirely (Figure 2C). In yet another case, some interior amount of fringe is optimal before prediction performance degrades (Figure 2E). In several cases, we see a saturation effect, where performance flattens as we increase more fringe nodes (e.g., Figures 2A and 2D). This is partly a consequence of how we ordered the fringe—nodes included towards the end of the sequence are less connected and thus have relatively less impact on the score functions. In these cases, one practical consequence is

Table 2: Summary statistics of telecommunications datasets. Core nodes are participants in the Reality Mining study.

Dataset	# core nodes	# fringe nodes	# core-core edges	# core-fringe edges
call-Reality	91	8,927	127	10,512
text-Reality	91	1,087	32	1,920

that we could ignore large amounts of the data and get roughly the same performance, which would save computation time. In another case, the first few hundred most connected fringe nodes leads to worse performance, but eventually having enough fringe improves performance (Figure 2B). Finally, there are also cases where the optimal performance over d is better for a random ordering of the fringe than for the most connected ordering (Figures 2D and 2G).

We repeated the same set of experiments on subgraphs of email-Enron by partitioning the core set of nodes C into four groups to induce four different datasets. In each dataset, the other members of the core are removed from the graph entirely (the bottom part of Table 1 lists basic summary statistics). The results in Figure 3 provide further evidence that it is a priori unclear how much fringe information one should include to achieve the best performance. In nearly all cases, the optimal performance when including fringe nodes in order of connectedness is somewhere between 10 and a few hundred nodes, out of a total of several thousand. And we again see that including initial fringe information by connectedness has worse performance than ignoring the fringe entirely, until eventually incorporating enough fringe information provides enough signal to improve prediction performance (Figures 3C and 3D).

2.2 Telecommunications networks

Next, we study telecommunications datasets from cell phone usage amongst individuals participating in the Reality Mining project [12]. This project recorded cell phone activity of students and faculty in the MIT Media Laboratory, including calls and SMS texts between phone numbers. We consider the participants (more, specifically, their phone numbers) as the core nodes in our network. Edges are phone calls or SMS texts between two people, some of which are fringe nodes corresponding to people who were not recruited for the experiment. We process the data in the same way as for email networks—directionality was removed and the edges are accompanied by the earliest timestamp of communication between the two nodes. We study two datasets: (i) *call-Reality*: the network of phone calls [6, 12]; and (ii) *text-Reality*: the network of SMS texts [6, 12]. Table 2 provides some basic summary statistics.

Fringe ordering. The structure of these networks is the same as the email networks—the dataset is a recording of the interactions of a small set of core nodes with a larger set of fringe nodes. We use the same two orderings—most connected to core and random—as we did for the email datasets. Thus, the nested sequence of node sets $\{V_d\}$ is again constructed by adding one node at a time.

Link prediction. Figure 4 shows the link prediction performance on the telecommunications datasets. With the Common Neighbors score function, we again find that the optimal amount of fringe is a small fraction of the entire dataset—around 100 of nearly 9,000 nodes in call-Reality (Figure 4A) and around 10 of over 1,000 nodes in text-Reality (Figure 4B). The performance of the Jaccard similarity

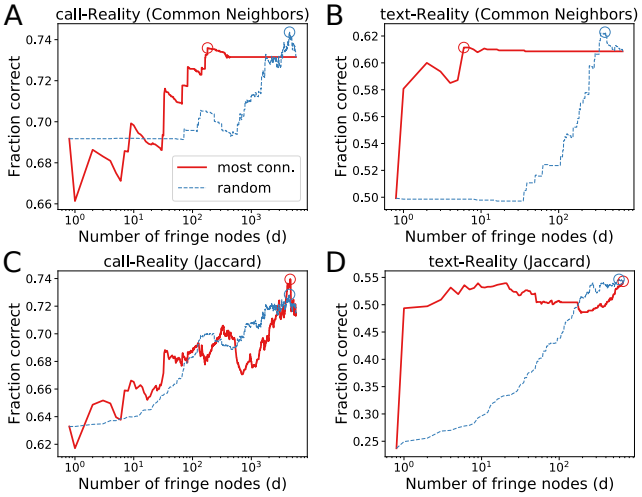

Figure 4: Link prediction performance in the telecommunications datasets as a function of d, the number of fringe nodes used for prediction. Circles mark the largest value. With the Common Neighbors score function, a small number of fringe nodes is optimal for these datasets.

also has an interior optimum for the call-Reality dataset, although the optimum size here is larger—around half of the nodes.

Prediction performance with the fringe nodes ordered by connectedness to the core is in general quite erratic for the call-Reality dataset. This is additional evidence that the fringe nodes can be a noisy source of information. For instance, just including the first fringe node results in a noticeable drop in prediction performance for both the Common Neighbors and Jaccard score functions.

2.3 Online social networks

We now turn to links in an online social network of bloggers from the LiveJournal community [25]. Edges are derived from users listing friends in their profile (here, we consider all links as undirected). Users also list their geographic location, and for the purposes of this study, we have restricted the dataset to users reporting locations in the United States and Puerto Rico. For each user, we have both their territory of residence (one of the 50 U.S. states, Washington D.C., or Puerto Rico; henceforth simply referred to as "state") as well as their county of residence, when applicable.

Table 3: Summary statistics of LiveJournal networks. The sets of core nodes are users in particular states or counties.

Dataset	# core nodes	# fringe nodes	# core-core edges	# core-fringe edges
Wisconsin	16,842	58,965	48,078	87,723
Texas	65,617	155,357	256,174	312,746
New York	82,275	208,516	281,981	477,845
California	152,171	244,605	712,803	722,835
Marathon	223	1,032	390	1,363
Eau Claire	295	1,392	252	1,635
Dane	2,281	15,580	5,192	21,156
Milwaukee	3,743	19,934	10,750	30,955

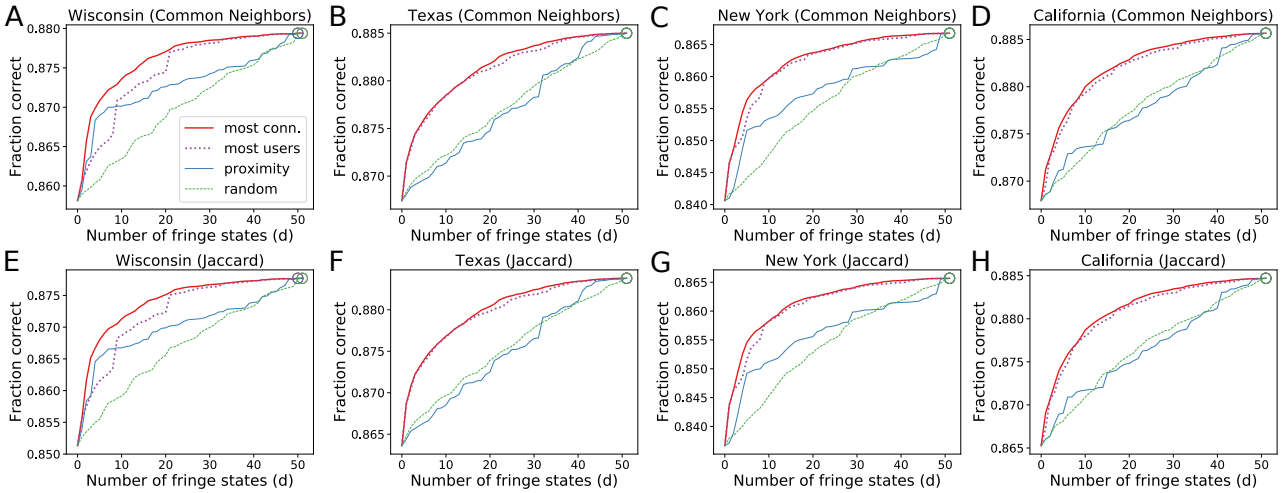

Figure 5: Link prediction performance of the Common Neighbors (top) and Jaccard similarity (bottom) score functions on four LiveJournal datasets where the core consists of users in a state. Performance is measured as a function of d, the number of fringe states included for prediction (for four different orderings of the fringe). The most connected ordering performs the best, monotonically increases with d, and saturates when $d \geq 20$.

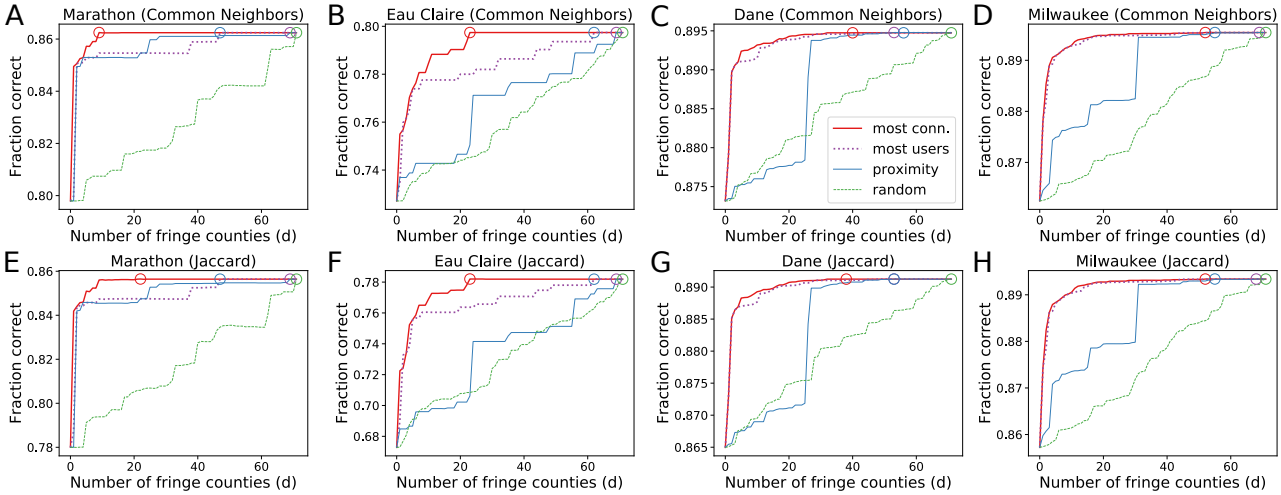

Figure 6: Link prediction analogous to Figure 5 but where the core is a Wisconsin county and the fringe is the rest of the state. Performance is measured as a function of d, the number of fringe counties included for prediction. The most connected ordering performs the best, and performance with this ordering quickly saturates.

We construct core-fringe networks in two ways. First, we form a core from all user residing in a given state S. The core-fringe network then consists of all friendships where at least one node is in state S. We construct four such networks, using the states Wisconsin, Texas, California, and New York. Second, we form a core from users residing in a county and construct a core-fringe network in the same way, but we only consider friendships amongst users in the state containing the county. We construct four such networks, using Marathon, Eau Claire, Dane, and Milwaukee counties (all in Wisconsin). Table 3 lists summary statistics of the datasets.

Unlike the email and telecommunications networks, we do not have timestamps on the edges. We instead construct E^{test} from a random sample of 20% of the edges between core nodes, i.e., from $\{(u, v) \in E \mid u, v \in C\}$, and set $E^{\text{train}} = E - E^{\text{test}}$. Predicting on such held out test sets is used for predicting missing links [8, 13]; here, we use it for link prediction, as is standard practice [26].

Fringe ordering. We again incorporate fringe nodes from a nested sequence of node sets $\{V_d\}$, where $V_d \subseteq V_{d+1}$ and $V_0 = C$, the set of core nodes. The nested sequence of training sets is then $E_d^{\text{train}} = \{(u, v) \in E^{\text{train}} \mid u, v \in V_d\}$. With email and telecommunications, we considered fringe nodes one by one to form the sequence $\{V_d\}$. For LiveJournal, each successive node set instead corresponds to adding all nodes in a state or a county. For the cores constructed from users in a state (Wisconsin, Texas, New York, or California), we form orderings σ of the remaining states in four ways: (i) *Most connected*: σ is the ordering of states by decreasing

number of links to the core state; (ii) *Most users*: σ is the ordering by decreasing number of users; (iii) *Proximity*: σ is the ordering of states by closest proximity to the core state (measured by great-circle distance between geographic centers); and (iv) *Random*: σ is a random ordering of the states.

Let U_S be the users in state S. The sequence of vertex sets is all users in the core and first d states in the ordering σ. Formally, $V_d = C \cup (\cup_{t=1}^{d} U_{\sigma_t})$. For networks whose core are users in a Wisconsin county, we use the same orderings, except we order counties instead of states and the fringe is only counties in Wisconsin.

Link prediction. We measure the mean prediction performance over 10 random trials as a function of the number d of fringe states or counties included in the training data. When states form the core, prediction performance is largely consistent (Figure 5). For both score functions, ordering by number of connections tends to perform the best, with a rapid performance increase from approximately the first 10 states and then saturation with a slow monotonic increase. The prediction by states with the most users performs nearly the same for the three largest states (Texas, New York, and California; Fiugres 5B to 5D). In Wisconsin and New York, ordering by proximity shows a steep rise in performance for the first few states but then levels off (Figures 5A, 5C, 5E and 5G). On the other hand, in California and Texas, ordering by proximity performs roughly as well as a random ordering.

The networks where the cores are users from counties in Wisconsin have similar characteristics to the networks where the cores are users from particular states (Figure 6). The ordering by county with the most connections performs the best. Prediction performance quickly saturates in the two larger counties (Figures 6C and 6D), and the proximity ordering can be good in some cases (Figure 6A).

Summary. Usually, collecting additional data is thought to improve performance in machine learning. Here we have seen that this is not the case in some networks with core-fringe structure. In fact, including additional fringe information can affect link prediction performance in a number of ways. In some cases, it is indeed true that additional fringe always helps, which was largely the case with LiveJournal (Figure 5). In one email network, including any fringe data hurt performance (Figure 2C). And yet in other cases, some intermediate amount of fringe data gave the best performance (Figures 4A and 4B; Figure 3). We also observed saturation in link prediction performance as we increased the fringe size (Figure 6) and that sometimes we need enough fringe before prediction becomes better than incorporating no fringe at all (Figures 2B and 3C). While this landscape is complex, we show in the next section how these behaviors can emerge in simple random graph models.

3 RANDOM GRAPH MODEL ANALYSIS

We now turn to the question of *why* link prediction in core-fringe networks exhibits such a wide variation in performance. To gain insight into this question, we analyze the link prediction problem on basic random graph models that have been adapted to contain core-fringe structure.

Recall how our link prediction problem is evaluated: we are given two pairs $\{u, v\}$ and $\{w, z\}$; our algorithm predicts which of the two candidate edges is the one that appears in the data through a score function; and the values of the score function (and hence the predictions) can change based on the inclusion of fringe nodes. In a random graph model, we can think about using the same score functions for the candidate edges (u, v) and (w, z), but now the score functions and the existence of edges are random variables. As we will show, the signal-to-noise ratio of the difference in score functions is a key statistic to optimize in order to make the most accurate predictions, and this can vary in different ways when including fringe nodes.

The signal-to-noise ratio (SNR). Suppose our data is generated by a random graph model and that the indicator random variables $X, Y \in \{0, 1\}$ correspond to the existence of two candidate edges $\{u, v\}$ and $\{w, z\}$, respectively, where nodes u, v, w, and z are distinct and chosen uniformly at random amongst a set of core nodes. Without loss of generality, we assume that $\Pr[X] > \Pr[Y]$ so that (u, v) is more likely to appear.

We would like our algorithm to predict that the edge $\{u, v\}$ is the one that exists, since this is the more likely edge (by assumption). However, our algorithm does not observe X and Y directly; instead, it sees proxy measurements $(\hat{X}, \hat{Y})$, which are themselves random variables. These proxy measurements correspond to the score function used by the algorithm; in this section, we focus on the number of common neighbors score. Our algorithm will (correctly) predict that edge $\{u, v\}$ is more likely if and only if $\hat{X} > \hat{Y}$.

Furthermore, the proxy measurements are parameterized by the amount of fringe information we have. Following our previous notation, we call these random variables $\hat{X}_d$ and $\hat{Y}_d$. These variables represent the same measurements as $\hat{X}$ and $\hat{Y}$ (such as the number of common neighbors), just on a set of graphs parameterized by the amount of fringe information d.

Our goal is to optimize the amount of fringe to get the most accurate predictions. Formally, if we let $Z_d \triangleq \hat{X}_d - \hat{Y}_d$, this means:

$$\underset{d}{\text{maximize}} \quad \Pr[\hat{X}_d > \hat{Y}_d] \iff \underset{d}{\text{maximize}} \quad \Pr[Z_d > 0].$$

We assume that we have access to $\mathbb{E}[Z_d]$ and $\mathbb{V}[Z_d]$ for all values of d. Our approach will be to maximize the signal-to-noise ratio (SNR) statistic of Z_d, i.e.,

$$\underset{d}{\text{maximize}} \quad \frac{\mathbb{E}[Z_d]}{\sqrt{\mathbb{V}[Z_d]}} \triangleq \text{SNR}[Z_d].$$

We motivate this approach as follows. Absent any additional information beyond the expectation and variance, we must use some concentration inequality. Under the reasonable assumption that $\mathbb{E}[Z_d] > 0$ (which we later show holds in our models), the proper inequality is Cantelli's: $\Pr[Z_d \geq 0] \geq 1 - \frac{\mathbb{V}[Z_d]}{\mathbb{V}[Z_d]+\mathbb{E}[Z_d]^2} = \frac{\text{SNR}[Z_d]^2}{1+\text{SNR}[Z_d]^2}$. Thus, the lower bound on correctly choosing X is monotonically increasing in the SNR of our proxy measurement. Using this probabilistic framework, we can now see how some of the empirical behaviors in Section 2 might arise.

3.1 Stochastic block models

In the stochastic block model, the nodes are partitioned into K *blocks*, and for parameters $P_{i,j}$ (with $1 \leq i, j \leq K$), each node in block i is connected to each node in block j independently with probability $P_{i,j}$. (Since our graphs are undirected, $P_{i,j} = P_{j,i}$.) In our core-fringe model here, $K = 4$, the core corresponds to blocks 1 and 2, and the fringe corresponds to blocks 3 and 4. This model turns out to be flexible enough to demonstrate a wide range of

behaviors observed in Section 2. We use the following notation for block probabilities:

$$P = \begin{bmatrix} p & q & r & s \\ q & p & s & r \\ r & s & 0 & 0 \\ s & r & 0 & 0 \end{bmatrix}. \tag{7}$$

Our assumptions on the probabilities are that $q < p$ and $s \leq r$. We also assume that the first two blocks each contain n_c nodes and that the last two blocks each contain n_f nodes.

We further assume we are given samples of four distinct nodes u, v, w, and z chosen uniformly at random from the core blocks such that u, v, and w are in block 1 and z is in block 2. Following our notation above, let X be the random variable that (u, v) is an edge and Y be the random variable that (w, z) is an edge ($\Pr[X] > \Pr[Y]$ since $p > q$). Our proxy measurements $\hat{X}$ and $\hat{Y}$ are the number of common neighbors of candidate edges $\{u, v\}$ and $\{w, z\}$. Our algorithm will correctly predict that (u, v) is more likely if $\hat{X} > \hat{Y}$.

Our proxy measurements are parameterized by the amount of fringe information that they incorporate. Here, we arbitrarily order the nodes in the two equi-sized fringe blocks and say that the random variable $\hat{X}_d$ is the number of common neighbors between nodes u and v when including the first d nodes in both fringe blocks. Similarly, the random variable $\hat{Y}_d$ is the number of common neighbors of nodes w and z. By independence of the edge probabilities, some straightforward calculations show that

$$\mathbb{E}[\hat{X}_d] = 2(n_c - 1)p^2 + dr^2 + ds^2,\ \mathbb{E}[\hat{Y}_d] = 2(n_c - 1)pq + 2drs$$
$$\mathbb{V}[\hat{X}_d] = 2(n_c - 1)p^2(1 - p^2) + dr^2(1 - r^2) + ds^2(1 - s^2)$$
$$\mathbb{V}[\hat{Y}_d] = 2(n_c - 1)pq(1 - pq) + 2drs(1 - rs).$$

With no fringe information, it is immediate that the SNR is positive, i.e., $\mathrm{SNR}[Z_0] > 0$: $\mathbb{E}[\hat{X}_0 - \hat{Y}_0] = 2(n_c - 1)p[p - q] > 0$ as $p > q$. If the two fringe blocks connect to the two core blocks with equal probability, then the SNR with no fringe is optimal.

Lemma 3.1 (No-fringe optimality). *If $r = s$ in the core-fringe SBM, then $\mathrm{SNR}[Z_d]$ decreases monotonically in d.*

Proof. When $r = s$, by independence of $\hat{X}_d$ and $\hat{Y}_d$,

$$\mathbb{E}[Z_0] = \mathbb{E}[\hat{X}_d - \hat{Y}_d] = 2(n_c - 1)p^2 + dr^2 + ds^2 - 2(n_c - 1)pq - 2drs$$
$$= 2(n_c - 1)p^2 - 2(n_c - 1)pq = \mathbb{E}[\hat{X}_0 - \hat{Y}_0],$$

and $\mathbb{V}[Z_d] = \mathbb{V}[\hat{X}_d] + \mathbb{V}[\hat{Y}_d] > \mathbb{V}[\hat{X}_0] + \mathbb{V}[\hat{Y}_0] = \mathbb{V}[Z_0]$. □

This result is intuitive. If the two fringe blocks connect to the core nodes with equal probability, then the node pairs (u, v) and (w, z) receive additional extra common neighbors according to exactly the same distributions. Thus, these fringe nodes provide noise but no signal. We confirm this result numerically with parameter settings $p = 0.5$, $q = 0.3$, $s = r = 0.2$, and $n_c = 10$ (Figure 7A). Indeed, the SNR monotonically decreases as we include more fringe.

In Section 2, we saw cases where including any additional fringe information always helped. The following lemma shows that we can set parameters in our core-fringe SBM such that including any additional fringe information always increases the SNR.

Lemma 3.2 (All-fringe optimality). *Let $r > 0$, $s = 0$ and $4(n_c - 1)(p^2 - p^4) > 1$ in the core-fringe SBM. Then $\mathrm{SNR}[Z_d]$ monotonically increases in d and $\lim_{d\to\infty} \mathrm{SNR}[Z_d] = \infty$.*

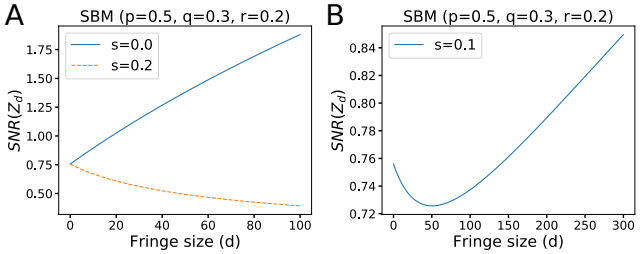

Figure 7: SNR for the difference in the common neighbors in our stochastic block model of core-fringe structure with $n_c = 10$. (A) When the fringe blocks have equal probability of connecting to the two core blocks ($r = s$), the SNR decreases monotonically with fringe size by Lemma 3.1. When fringe blocks only connect to one of the core blocks ($s = 0.0$), the SNR increases monotonically with fringe size Lemma 3.2. (B) For an intermediate parameter setting, including the fringe hurts the SNR until enough fringe is included, at which point the SNR increases monotonically (Lemma 3.3).

Proof. We have that

$$\mathrm{SNR}[Z_d] = \frac{2(n_c-1)p(p-q)+dr^2}{\sqrt{2(n_c-1)(p^2(1-p^2)+pq(1-pq))+dr^2(1-r^2)}}.$$

We can treat this function as continuous in d. Then

$$\lim_{d\to\infty} \mathrm{SNR}[Z_d] = \lim_{d\to\infty} \frac{dr^2}{\sqrt{dr^2(1-r^2)}} = \infty.$$

Similarly, we can compute the derivative with respect to d:

$$\frac{\partial}{\partial d}\mathrm{SNR}[Z_d] = \frac{r^2\sqrt{\mathbb{V}[Z_d]} - \frac{1}{2}r^2(1-r^2)/\sqrt{\mathbb{V}[Z_d]}}{\mathbb{V}[Z_d]}$$

The derivative is positive provided that $r^2\mathbb{V}[Z_d] > \frac{1}{2}r^2(1 - r^2)$, which is true if $\mathbb{V}[Z_0] > \frac{1}{2}$ since $\mathbb{V}[Z_0]$ is monotonically increasing in d. We have that

$$\mathbb{V}[Z_0] = 2(n_c - 1)(p^2(1 - p^2) + pq(1 - pq)) > 2(n_c - 1)(p^2 - p^4).$$

Thus, the result holds provided $4(n_c - 1)(p^2 - p^4) > 1$. □

The result is again intuitive. By setting $s = 0$, the pair of nodes in different blocks (w and z) get no additional common neighbors from the fringe, whereas the pair of nodes in the same block (u and v) get additional common neighbors. This should only help our prediction performance, which is why the SNR monotonically increases. We confirm this result numerically (Figure 7A), where we use the same parameters as the experiment described above. We can also check that the conditions of Lemma 3.2 are met: $n_c = 10$ and $p = 0.5$, so $4(n_c - 1)(p^2 - p^4) = 6.75 > 1$.

The SBM can also exhibit additional behaviors that we observed in Section 2. For example, with the email-Enron-4 dataset, prediction performance initially decreased as we included more fringe and then began to increase (Figures 3D and 3H). The following lemma says that the core-fringe SBM can capture this behavior.

Lemma 3.3 (Enough-fringe optimality). *Let p, q, and r be given. Then there exists a value of s in the core-fringe SBM such that $\mathrm{SNR}[Z_d]$ initially decreases and then increases without bound.*

Proof. To simplify notation, consider the following constants: $\alpha = \mathbb{E}[Z_0] = 2(n_c - 1)(p^2 - pq)$, $\beta = (r - s)^2$, $\gamma = \mathbb{V}[Z_0] = 2(n_c - 1)[p^2(1-p^2)+pq(1-pq)]$, and $\delta = r^2(1-r^2)+s^2(1-s^2)+2rs(1-rs)$.

With this notation, $\text{SNR}[Z_d] = (\alpha + \beta d)/\sqrt{\gamma + \delta d}$. Treating this as a continuous function in d, the derivative is: $\frac{\partial}{\partial d}\text{SNR}[Z_d] = (-\alpha\delta + 2\beta\gamma + \beta\delta d)/(2(\gamma + \delta d)^{3/2})$. For any s, we can choose a sufficiently large D such that the derivative is positive when $d > D$, meaning that $\text{SNR}[Z_d]$ is increasing. Furthermore, $\text{SNR}[Z_d]$ grows as $O(\sqrt{d})$. It is easy to check that the derivative also has at most one root, $d_0 = \alpha/\beta - 2\gamma/\delta$. We claim that d_0 can be made as large as desired. By setting s sufficiently close to r, β approaches 0, while δ is bounded away from 0. The remaining terms are positive constants. Finally, when $d = 0$, the value of the derivative is $(-\alpha\delta + 2\beta\gamma)/(2\gamma^{3/2})$. Again, we can make s sufficiently close to r so that β approaches 0 and the derivative is negative at $d = 0$. Therefore, there exists an s such that its derivative has one root $d_0 \geq 1$, $\text{SNR}[Z_d]$ decreases for small enough d and eventually increases without bound. □

By setting $n_c = 10$, $p = 0.5$, $q = 0.3$, $r = 0.2$, and $s = 0.1$, we see the behavior described by Lemma 3.3—the SNR initially decreases with additional fringe but then increases monotonically (Figure 7B).

By extending the SBM to include a third fringe block, we can also have a case where an intermediate amount of core is optimal. We argue informally as follows. We begin with a setup as in Lemma 3.2, where $s = 0$. Including all of the fringe available in these blocks is optimal. We then add a third fringe block that connects with equal probability to the two core blocks. By the arguments in Lemma 3.1, this only hurts the SNR. Thus, it is optimal to include two of the three fringe blocks, which is an intermediate amount of fringe.

3.2 Small-world lattice models

In the one-dimensional small-world lattice model [18], there is a node for each integer in $\mathbb{Z}$ and a parameter $\alpha \geq 0$. The probability that edge (i, j) exists is

$$\Pr[(i,j) \in E] = \tfrac{1}{|j-i|^\alpha}. \tag{8}$$

We start with a core of size $2c + 1$, centered around 0: $V_0 = C = \{-c, \ldots, c\}$. We then sample two nodes v and w such that

$$u = -c < v < w < c = z \text{ and } 2 \leq v - u < z - w. \tag{9}$$

In our language at the beginning of Section 3, X is still the random variable that edge (u, v) exists and Y is the random variable that edge (w, z) exists. By our assumptions and Eq. (8), we know that $\Pr[X] > \Pr[Y]$. However, we will again assume that we are only given access to the number of common neighbors through the proxy random variables $\hat{X}$ and $\hat{Y}$.

Our parameterization of the proxy measurements are a distance d that we examine beyond the core. Specifically, the nested sequence of vertex sets that incorporate fringe information is given by $V_d = \{-(c + d), \ldots, c + d\}$, and our proxy measurements are

$$\hat{X}_d = |\{s \in V_d \mid (u, s) \text{ and } (v, s) \text{ are edges}\}|$$
$$\hat{Y}_d = |\{s \in V_d \mid (w, s) \text{ and } (z, s) \text{ are edges}\}|.$$

We will analyze the random variable $Z_d = \hat{X}_d - \hat{Y}_d$. We correctly predict that (u, v) is more likely than (w, z) to exist if $Z_d > 0$. As argued above, our goal is to find a d that maximizes $\text{SNR}[Z_d]$.

We focus our analysis on the case of $\alpha = 1$ in Eq. (8). Let A_s be the indicator random variable that node s is a common neighbor of nodes u and v, for $s \in \mathbb{Z}\backslash\{u, v\}$, and let B_s be the indicator random variable that node s is a common neighbor of w and z, for $s \in \mathbb{Z}\backslash\{w, z\}$. Since $u = -c$ and $z = c$, our proxy measurements are

$$\hat{X}_d = \textstyle\sum_{s=-(c+d)}^{-(c+1)} A_s + \sum_{s=-c+1}^{v-1} A_s + \sum_{s=v+1}^{c+d} A_s \tag{10}$$

$$\hat{Y}_d = \textstyle\sum_{s=-(c+d)}^{w-1} B_s + \sum_{s=w+1}^{c-1} B_s + \sum_{s=c+1}^{c+d} B_s \tag{11}$$

Define the independent indicator random variables $I_{s,r}$ and $J_{s,r}$ where $\Pr[I_{s,r} = 1] = 1/(s(s + r))$ and $\Pr[J_{s,r} = 1] = 1/(s(r - s))$. Now we can re-write the expressions for $\hat{X}_d$ and $\hat{Y}_d$ as follows:

$$\hat{X}_d = \textstyle\sum_{s=1}^{d} I_{s,v-u} + \sum_{s=1}^{c+d-v} I_{s,v-u} + \sum_{s=1}^{v-u-1} J_{s,v-u} \tag{12}$$

$$\hat{Y}_d = \textstyle\sum_{s=1}^{d} I_{s,z-w} + \sum_{s=1}^{w-c-d} I_{s,z-w} + \sum_{s=1}^{z-w-1} J_{s,z-w}. \tag{13}$$

The expectations are given by

$$\mathbb{E}[\hat{X}_d] = \textstyle\sum_{s=1}^{d} \frac{1}{s(s+v-u)} + \sum_{s=1}^{c+d-v} \frac{1}{s(s+v-u)} + \sum_{s=1}^{v-u-1} \frac{1}{s(v-u-s)}$$
$$\mathbb{E}[\hat{Y}_d] = \textstyle\sum_{s=1}^{d} \frac{1}{s(s+z-w)} + \sum_{s=1}^{w-c-d} \frac{1}{s(s+z-w)} + \sum_{s=1}^{z-w-1} \frac{1}{s(z-w-s)}.$$

With these expressions, we can now analyze how Z_d behaves as we vary d. The following lemma establishes that Z_d converges to a positive value. Later, we use this to show that the SNR also converges to a positive value.

Lemma 3.4. $\lim_{d\to\infty} \mathbb{E}[Z_d] = Z^* > 0$.

Proof. Let $a = v - u$. Then $\lim_{d\to\infty} \mathbb{E}[\hat{X}_d] = 2\sum_{s=1}^{\infty} \frac{1}{s(s+a)} + \sum_{s=1}^{a-1} \frac{1}{s(a-s)} = 2(\psi(a + 1) + \psi(a) + 2\gamma)/a = 2(2\psi(a) + 1/a + 2\gamma)/a$, where $\psi(\cdot)$ is the digamma function. Similarly, if $b = z - w$, then

$$\lim_{d\to\infty} \mathbb{E}[\hat{Y}_d] = 2(2\psi(b) + 1/b + 2\gamma)/b.$$

Thus, $Z^* = \lim_{d\to\infty} \mathbb{E}[\hat{X}_d] - \mathbb{E}[\hat{Y}_d]$ exists, and $Z^* > 0$ if and only if

$$b(\psi(a) + 1/(2a) + \gamma) - a(\psi(b) + 1/(2b) + \gamma) > 0 \tag{14}$$

Recall that by Eq. (9), $2 \leq a < b$. Numerically, Eq. (14) holds for $(a, b) = (2, 3)$. Since the left-hand-side monotonically increases in b, this inequality holds for $a = 2$.

Now assume $b > a \geq 3$. The Puiseux series expansion of ψ at ∞ gives $\psi(x) + 1/(2x) \in \log(x) \pm \frac{1}{12(x^2-1)}$. Thus, it is sufficient to show that $b(\log(a) - 1/96) + (b - a)\gamma > a(\log(b) + 1/180)$, or that $0.99b\log(a) + \gamma > 1.01a\log(b)$, which holds for $b > a \geq 3$. □

The next theorem shows that the signal-to-noise ratio converges to a positive value. Thus, by measuring enough fringe, our proxy measurements are at least providing the correct direction of information. However, the SNR converges, so at some point, our information saturates.

Theorem 3.5 (SNR saturation). $\lim_{d\to\infty} \text{SNR}[Z_d] = S^* > 0$.

Proof. By Lemma 3.4, $\mathbb{E}[Z_d]$ converges to a positive value. Thus, it is sufficient to show that $\mathbb{V}[Z_d]$ converges. Following Eq. (12),

$$\mathbb{V}[\textstyle\sum_{s=1}^{\infty} I_{s,v-u}] = \sum_{s=1}^{\infty} \mathbb{V}[I_{s,v-u}] = \sum_{s=1}^{\infty} \frac{1}{s(s+v-u)} - \frac{1}{(s(s+v-u))^2}$$

by independence, and converges. □

The random variable $W_{d+1,J} \triangleq Z_{d+J} - Z_d = \sum_{k=d+1}^{k=d+1+J} I_{k,v-u} - I_{k,z-w}$ will be useful for our subsequent analysis. This is the additional measurement available to us if we measured at distance $d + J$ instead of d. The next lemma says that, as we increase d, the expectation of $W_{d,J}$ goes to zero faster than its variance.

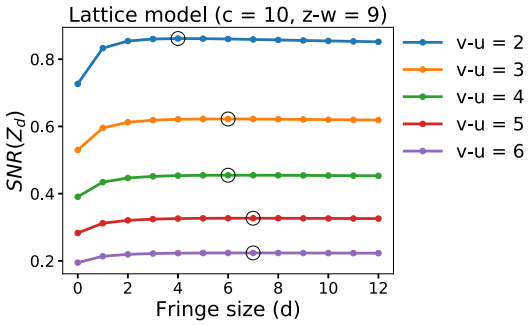

Figure 8: Saturation and interior optima of the SNR the one-dimensional small-world lattice model. Nodes v and w are sampled from $\{u = -c, \ldots, c = z\}$ with $2 \leq v - u < z - w$. The random variable Z_d is the difference in the number of common neighbors of $\{u, v\}$ and $\{w, z\}$ on the node set $\{-(c + d), \ldots, c + d\}$. Since $\text{SNR}[Z_1] > \text{SNR}[Z_0]$, an intermediate amount of fringe produces the optimal SNR (Corollary 3.8); these optima are circled in black. The SNR converges by Theorem 3.5, and we indeed see the consequent saturation.

Lemma 3.6. *For any J, $\lim_{d\to\infty} \mathbb{E}[W_{d,J}]/\mathbb{V}[W_{d,J}] = 0$.*

Proof. Let $a = v - u$ and $b = z - w$. By independence,

$$\mathbb{E}[W_{d,J}] = \sum_{k=d}^{k=d+J} \frac{1}{k(k+a)} - \frac{1}{k(k+b)} = \sum_{k=d}^{k=d+J} \frac{b-a}{k(k+a)(k+b)} = O(\sum_{k=d}^{k=d+J} 1/k^3).$$

For large enough d, $\mathbb{V}[W_{d,J}] = \sum_{k=d}^{k=d+J} \frac{1}{k(k+a)} + \frac{1}{k(k+b)} - \frac{1}{(k(k+b))^2} - \frac{1}{(k(k+a))^2}$, which is $O(\sum_{k=d}^{k=d+J} 1/k^2)$. □

The next theorem now shows that in the one-dimensional lattice model, the signal-to-noise ratio eventually begins to decrease. This means that at some point, the noise overwhelms the signal. Thus, it will never be best to gather as much fringe as possible.

Theorem 3.7. *There exists a D for which $\text{SNR}[Z_D] > \text{SNR}[Z_{D+j}]$ for any $j > 0$.*

Proof. We have that $\text{SNR}[Z_d] > \text{SNR}[Z_{d+j}]$ if and only if

$$\frac{\mathbb{E}[Z_d]}{\sqrt{\mathbb{V}[Z_d]}} > \frac{\mathbb{E}[Z_d + W_{d+1,j}]}{\sqrt{\mathbb{V}[Z_d + W_{d+1,j}]}} \iff \frac{\mathbb{E}[Z_d]^2}{\mathbb{V}[Z_d]} > \frac{2\mathbb{E}[Z_d]\mathbb{E}[W_{d+1,j}] + \mathbb{E}[W_{d+1,j}]^2}{\mathbb{V}[W_{d+1,j}]}.$$

The second inequality above comes from squaring both sides of the first inequality; both terms in the first inequality are positive for large enough d by Lemma 3.4, so we can keep the direction of the inequality. By Theorem 3.5, the left-hand-side of the inequality converges to a positive constant. We claim that the right-hand-side converges to 0.

By Lemma 3.4, $\mathbb{E}[Z_d]$ converges, so it must be bounded by a positive constant constant. Furthermore, since $Z_{d+j} = Z_d + W_{d+1,j}$, we have that $\mathbb{E}[W_{d+1,j}] \to 0$. Combining these results, $2\mathbb{E}[Z_d]\mathbb{E}[W_{d+1,j}] + \mathbb{E}[W_{d+1,j}]^2 = O(\mathbb{E}[W_{d+1,j}])$, and we have that $\mathbb{E}[W_{d+1,j}]/\mathbb{V}[W_{d+1,j}] \to 0$ by Lemma 3.6. □

A consequence of this theorem is that if the SNR initially increases, then an intermediate amount of fringe is optimal. The reason is that the SNR initially increases but at some point begins to decrease monotonically (Theorem 3.7) before converging to a positive value (Theorem 3.5). We formalize this as follows.

Corollary 3.8 (Intermediate-fringe optimality). *If $\text{SNR}[Z_0] < \text{SNR}[Z_1]$, then $d^* = \arg\max_d \text{SNR}[Z_d]$ satisfies $0 < d^* < \infty$.*

Numerically, $\text{SNR}[Z_0] < \text{SNR}[Z_1]$ in several cases (Figure 8). In this experiment, we fix $c = 10$ and $w = 1$ (so $z - w = 9$) and vary the amount of fringe from 0 to 12 nodes on either end of the core. We also vary v so that $v - u \in \{2, 3, 4, 5, 6\}$. We observe two phenomena consistent with our theory. First, by Corollary 3.8, an intermediate amount of fringe information should be optimal; indeed, this is the case. Second, by Theorem 3.5, the SNR converges, indicating that saturation should kick in at some finite fringe size. This is true in our experiments, where saturation occurs after around $d = 8$.

4 DISCUSSION

Link prediction is a cornerstone problem in network science [24, 26], and the models for prediction include those that are mechanistic [5], statistical [8], or implicitly captured by a principled heuristic [3, 4]. The major difference in our work is that we explicitly study the consequences of a common dataset collection process that results in core-fringe structure. Most related to our analysis of random graph models are theoretical justifications of principled heuristics such as the number of common neighbors in latent space models [34] and in general stochastic block models [33].

The core-fringe structure that we study can be interpreted as an extreme case of core-periphery structure in complex networks [7, 16, 31, 37]. In more classical social and economic network analysis, core-periphery structure is a consequence of differential status [11, 22]. In this paper, the structure emerges from data collection mechanisms, which raises new research questions of the kind that we have addressed. However, our results hint that periphery nodes could also be noisy sources of information and possibly warrant omission in standard link prediction. Our fringe measurements can also be viewed as adding noisy training data, which is related to training data augmentation methods [29, 30].

Conventional machine learning wisdom says that more data generally helps make better predictions. We showed that this is far from true in the common problem of network link prediction, where additional data comes from observing how some core set of nodes interacts with the rest of the world, inducing core-fringe structure. Our empirical results show that the inclusion of additional fringe information leads to substantial variability in prediction performance with common link prediction heuristics. We observed cases where fringe information is (i) always harmful, (ii) always beneficial, (iii) beneficial only *up to* a certain amount of collection, and (iv) beneficial only with *enough* collection.

At first glance, this variability seems difficult to characterize. However, we showed that these behaviors arise in some simple graph models—namely, the stochastic block model and the one-dimensional small-world lattice model—by interpreting the benefit of the fringe information as changing the signal-to-noise ratio in our prediction problem. Our datasets are certainly more complex than these models, but our analysis suggests that variability in prediction performance when incorporating fringe data is much more plausible than one might initially suspect. Even when fringe

data is available in network analysis, we must be careful how we incorporate this data into the prediction models we build.

ABSTRACT

Tor hidden services allow offering and accessing various Internet resources while guaranteeing a high degree of provider and user anonymity. So far, most research work on the Tor network aimed at discovering protocol vulnerabilities to de-anonymize users and services. Other work aimed at estimating the number of available hidden services and classifying them. Something that still remains largely unknown is the structure of the graph defined by the network of Tor services. In this paper, we describe the topology of the Tor graph (aggregated at the hidden service level) measuring both global and local properties by means of well-known metrics. We consider three different snapshots obtained by extensively crawling Tor three times over a 5 months time frame. We separately study these three graphs and their shared "stable" core. In doing so, other than assessing the renowned volatility of Tor hidden services, we make it possible to distinguish time dependent and structural aspects of the Tor graph. Our findings show that, among other things, the graph of Tor hidden services presents some of the characteristics of social and surface web graphs, along with a few unique peculiarities, such as a very high percentage of nodes having no outbound links.

1 INTRODUCTION

Research efforts on The Onion Router network (Tor) have recently flourished, focusing on evaluating its security [8], understanding its evolution [24], and discussing its thematic organization [38]. Nevertheless, the limited number of entry points to Tor on the surface Web makes it difficult to fully uncover many of Tor's characteristics. In particular, despite some insights provided over the last years [6, 15, 23, 36], few information are available regards the topology and the volatility of the Tor network. In this study we exploit three sets of crawling data collected over three different time frames to present a thorough analysis of the structural properties of the graph of Tor Hidden Services (HS) that makes it possible to tell apart persistent from variable characteristics.

Similarly to the surface WWW [12], the structure of the Tor HS Web graph can be seen as an indicator of intrinsic characteristics of the Tor network and of latent patterns of interactions among Tor users. Since the work of Watts & Strogats [40] and Barabasi & Albert [5] it has been widely recognized that the in-depth study of the properties of the underlying graph is crucial for determining behavioral and structural aspects of a complex system, and for understanding and possibly explaining the emergence of specific features in real world networks. Our efforts for identifying the distinguishing traits of the topology of the Tor Web can therefore be of great help to shed light on the usage patterns, the dynamics and the vulnerabilities of the Tor network.

The paper also addresses the evolution of the Tor Web graph showing the actual changes that take place in the quality and quantity of available services and in the persistence of their interconnections over time. In particular, we provide a rich set of results and discussions on deltas over time that allow for detailed reasoning on Tor Web connection/topological trends. To the best of our knowledge there are no similar studies on the Tor Web. Our present study, albeit limited as regards its timeframe, therefore provides useful information and hints to foster further research in the area.

The rest of the paper is organized as follows: Section 2 reviews background information and related work; Section 3 describes the methodology used for collecting data, extracting the graphs and studying their properties; Section 4 analyzes the obtained graphs and details on results; Section 5 discusses in depth our findings, in comparison with well-known graph models; finally, Section 6 draws conclusions and suggests directions for future work.

2 BACKGROUND AND RELATED WORK

Past research work on Tor has mainly been devoted to assess its vulnerabilities. However, as a positive side effect, novel data and insights on Tor services and network have been obtained.

Biryukov *et. al.* [8] in 2013 exploited a Tor vulnerability to collect all hidden service descriptors in approximately 2 days using a modest amount of resources. They found out that, while the contents of Tor hidden services is rather varied, the most popular hidden services were related to botnets. It is worth noticing that their approach cannot be reproduced, because they exploited a Tor bug that was fixed in recent versions of the software.

In a previous work [6], we leveraged automated Tor network exploration to the purpose of relating semantic content similarity with Tor topology at the page, host, and service level. The present work largely extends on both data collection and analysis over [6].

Also Ghosh *et. al.* [22] developed an automated tool to explore the Tor network and analyze the contents of onion sites. Their classification framework maps onion site content to a set of categories, and clusters services to categorize onion content. The main difference with respect to our work is that they focus on page content/semantics, and do not consider network topology. Owen *et. al.* [35], by operating 40 relays over a 6 month time frame, reported over hidden services persistence, contents, and popularity. Their aim was classifying services based on their content.

Similarly to our present work, Christin *et. al.* [15] collected crawling data on Tor hidden services over an 8 month lifespan. They evaluated the evolution/persistence of such services over time, and performed a study on the content and topology of the explored network. The main difference with our present work is that the Tor graph we explore is much larger, not being limited to a single marketplace. In addition, we present here a more in depth evaluation of the graph topology. De Domenico *et. al.* [17], used the data collected in [4] to study the topology of the Tor network . They gave a characterization of the topology of the Darknet and proposed a generative model for the Tor network to study its resilience. Their viewpoint is quite different from our own here, as they consider the network at the autonomous system (AS) level.

Very recently Griffith *et. al.* [23] performed a topological analysis of the Tor hidden services graph. They crawled the Tor network using the commercial service *scrapinghub.com*, through the *tor2web* proxy onion link. Interestingly, they reported that more than the 87% of Darkweb sites never link to another site. The main difference with our present work lies in both the extent of the explored network (we collected a much more extensive dataset than that accessible through *tor2web*) and the depth of the analysis of the network itself (we evaluate a larger set of network characteristics).

Differently from the Literature on the Tor network, the topology of the WWW has been the subject of a large number of studies in the past. In this paper we also aim at comparing Tor network characteristics with those of the surface Web, briefly surveyed below.

Among random graph models suitable for the surface Web [28],[10] Kleinberg in particular [26] introduced algorithms for improved Web search and automatic community discovery, thus providing one of the first publicly known portraits of the Web graph. Kleinberg also stressed that traditional random graph models, such as the well-known Erdős-Rényi model [19] do not exhibit many properties of the Web graph. Among other studies on the WWW, Broder *et. al.* [12] discovered the heavy-tailed distribution of node degrees, claiming a power-law distribution, and the presence of large hubs along with a peculiar structure of the graph they called *bow-tie*. Bearing in mind that the adopted crawling technique affects the structure of the results, subsequent studies have somewhat reached different results, [1, 18, 37]. In a recent work Meusel *et. al.* [30] analyzed the structure of the WWW at different levels: pages, hosts and pay-level domain. The last aggregation level can be seen as the Tor service level and we will discuss similarities and differences of their results compared to our findings on the Tor HS graph.

3 METHODOLOGY

In this Section we describe the methodology used for collecting data, building the graphs and studying their properties.

3.1 Data Collection

We aim at characterizing the portion of the Tor Web that can be accessed by using a custom web scraping procedure. Specifically, we assembled a large root set by merging onion urls advertised on well-known Tor wikis and link directories (*e.g.*, "The Hidden Wiki" [1]), or obtained from standard (*e.g.*, Google) and Tor-specific (*e.g.*, Ahmia) search engines. Then, in the 5-month time frame between January 2017 and May 2017, we launched our customized crawler three times and let each execution run for about six weeks. Thus, we obtained three different "snapshots" of the Tor Web, denoted SNP1, SNP2, and SNP3, respectively.

The numbers of our datasets, reported in Table 1, are comparable to – and, as a matter of fact, greater than – similar studies in the Literature [7, 23, 38]. Yet, if we refer to the statistics provided by the Tor Project for the corresponding time window [2], our crawls only reached 25% to 35% of the total number of daily published hidden services. It is not clear to which extent those estimates are inflated by the existence of Tor-specific messaging services in which each user is identified by a unique onion domain [23] and by hidden services that do not host websites. In any case, reaching all active onion urls is not arguably possible with ordinary resources [3] and, to the best of our knowledge, the present study is the widest exploration of the Tor Web performed so far.

To access the Tor network and to collect data from hidden services we evaluated different crawlers. In particular, we evaluated the following alternatives: Apache Nutch [4] [25], Heritrix [5] [31] and BUbiNG [9]. By considering criteria such as performance, configurability and extensibility, we found BUbiNG to be the most appropriate choice for our goals. BUbiNG is a high-performance, scalable, distributed, open-source crawler, written in Java, and developed by the Laboratory for Web Algorithmics (LAW) part of the Computer Science Department of the University of Milan. To allow

Table 1: Outcomes of the three crawling processes.

Crawl	End Date	# records per response type				
		2xx	3xx	4xx	5xx	Total
SNP1	22/02/17	1821842	277813	197128	141205	2437989
SNP2	10/04/17	2339718	471519	262403	324552	3398192
SNP3	22/05/17	765876	393018	105406	67115	1331415

A status code 3xx is related to Web redirection (https://www.w3.org/Protocols/rfc2616/rfc2616-sec10.html). Status codes 4xx and 5xx are error codes.

BUbiNG to operate in the Tor network (instead of the surface Web), we used a HTTP Proxy configured with the SOCKS Proxy provided by Tor. After testing some alternatives we chose privoxy [6]. In particular, we decided not to use polipo [7] that is often used in combination with Tor, because it is no longer maintained and seemed unable to correctly manage the format of some HTTP responses. During the crawling phase we observed that some hidden services check the user-agent of the requester and, if it does not match the last version of the Tor Web browser, they reply with an error. This behavior had to be taken into account when collecting data, to allow the crawler to reach the largest possible portion of hidden services. Another issue that raised during the crawling is the load of the Tor client, *i.e.*, the software used to access Tor. We noticed that under stress (*i.e.*, when too many requests are performed in parallel), the Tor client, quite often, does not respond correctly, *i.e.*, it may mistakenly report that a hidden service is not available, even if the service is actually up and running. The maximum load depends on the specifications of the machine where the software runs, and we assessed it for our configuration during the experimental phase.

3.2 Graph Extraction

For each one of the three snapshots we extracted the associated directed Tor Service Graph (SG) aggregating pages at the service level. To extract the graph we used the Graph Builder module of the toolkit presented in [14]. In the SG, each node represents the set of pages belonging to a hidden service, *i.e.*, a Tor domain identified by a sequence of 16 characters (base32 encoded).[8] In the SG an edge connecting one hidden service to another represents the existence of at least one page of the first service that contains a hypertextual link to any page of the second service. Since we only analyzed onion links, all surface web services and all edges from/to the surface web have been ignored and have not been included in the graphs. We believe including surface web nodes/links would have introduced a bias in the Tor network analysis, due to the large difference in scale between the two underlying graphs. Even just introducing surface border nodes would have affected the analysis and it would not have added relevant information.

[6] https://www.privoxy.org
[7] https://www.irif.fr/ jch/software/polipo/
[8] In October/November 2017 a new generation of hidden services was introduced and supported by the Tor browser. They are identified by character sequences of length 56 instead of the usual 16 (https://blog.torproject.org/tors-fall-harvest-next-generation-onion-services). This change was introduced after our data collection period ended in May 2017.

To further clarify how we built the graphs, let us consider the following example, depicted in Figure 1. We found the hidden service:

`duskgytldkxiuqc6.onion`

to host three pages:

`duskgytldkxiuqc6.onion/comsense.html`;
`duskgytldkxiuqc6.onion/fedpapers/`;
`duskgytldkxiuqc6.onion/fedpapers/federa02.htm`.

To represent these resources we use a single node in the SG.

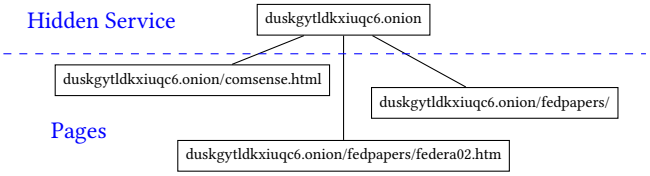

Figure 1: An example of graph construction

Besides the SGs of the three snapshots acquired with our crawls, we considered a fourth graph representing Tor's "stable core". It corresponds to the communal subgraph of SNP1, SNP2 and SNP3 induced by the edges that appear in all the three graphs.

3.3 Graph Analysis

As a first step towards the understanding of Tor dynamics, we compare macroscopic features of the four graphs to assess the persistence of Tor hidden services and of their connections. Next, we characterize the four graphs on both a global and on a local scale. Specifically, for each graph:

- We compute a set of global metrics, including measures of centralization, transitivity and efficiency.
- We extract the in- and out-degree distribution and assess whether these distributions follow a power law.
- We count the number of strongly connected components and characterize the giant strongly connected component (LSCC in the following).
- We consider several centrality measures, draw their distribution and match them with one another.
- We provide and analyze a bow-tie decomposition of the graphs under study.

Based on all gained pieces of information, we infer the general structure of the four graphs, spotting differences and highlighting common aspects that may be assumed to define the topology of Tor hidden services. Additionally, we identify a small set of hidden services that seem to play an especially important role in the graph and, through direct examination, we aimed at explaining why. All symbols and metrics used in the paper are summarized in Table 2.

4 RESULTS

In this Section we report and briefly comment the results of our analysis.

4.1 Services Persistence

As showed by other studies [7, 8, 35], there is a huge variability in the persistence of Tor hidden services. This must be carefully taken

Table 2: Notations and definitions used throughout the present paper.

Symbol	Definition
$G = (V, E)$	Graph with vertex set V and edge set E
N	Number of nodes: $N = \|V\|$
M	Number of edges: $M = \|E\|$
D	Density: $\frac{M}{N(N-1)}$
δ_{in}	Minimum in-degree
Δ_{in}	Maximum in-degree
δ_{out}	Minimum out-degree
Δ_{out}	Maximum out-degree
$\langle \deg \rangle$	Average in/out-degree
ρ	Assortativity: see (26) in [33]
C_{in}	In-degree centralization: $\frac{N*\Delta_{in}-\sum_{v\in V} \deg_{in}(v)}{(N-1)^2}$
C_{out}	Out-degree centralization: $\frac{N*\Delta_{out}-\sum_{v\in V} \deg_{out}(v)}{(N-1)^2}$
C	Global clustering coefficient: $\frac{\#\text{ closed triplets}}{\#\text{ all triplets}}$
T_1	Global transitivity of type 1: $\frac{\#(u,v,w)\text{: } u\to v\wedge v\to w\wedge w\to u}{\#(u,v,w)\text{: } u\to v\wedge v\to w}$
T_2	Global transitivity of type 2: $\frac{\#(u,v,w)\text{: } u\to v\wedge u\to w\wedge (v\to w\vee w\to v)}{\#(u,v,w)\text{: } u\to v\wedge u\to w}$
σ_{vu}	Number of shortest paths from v to u
$\sigma_{vu}(t)$	Number of shortest paths from v to u including t
$dist(v,u)$	Shortest path length from v to u
d	Diameter: $\max_{v\in V} \max_{u\in V} dist(v,u)$
r_{in}	Radius with in-paths: $\min_{v\in V} \max_{u\in V} dist(u,v)$
r_{out}	Radius with out-paths: $\min_{v\in V} \max_{u\in V} dist(v,u)$
$\langle dist \rangle$	Average shortest path length
E_{in}	Global efficiency with in-paths: $\frac{1}{N(N-1)} \sum_{u<v\in V} \frac{1}{d(v,u)}$
E_{out}	Global efficiency with out-paths: $\frac{1}{N(N-1)} \sum_{u<v\in V} \frac{1}{d(u,v)}$
B	Betweenness centrality: $B(v) = \sum_{s\neq v\neq t\in V} \frac{\sigma_{st}(v)}{\sigma_{st}}$
PR	PageRank: see [21]

into consideration in any attempt of characterizing the topology of the Tor Web graph, because by scraping the Tor network we only obtain a snapshot of the hidden services that were active at the time the crawler issued a connection request. More generally, even for the surface Web there is evidence that the crawling process may affect the structure of the extracted graph, leading to incomplete or wrong conclusions [29]. We therefore repeated the entire data collection phase three times over five months in an effort to reduce variance and guarantee the consistency of our results. As a side benefit, we are able to further assess the renowned volatility of Tor hidden services, other than possibly telling apart time dependent from structural features of the Tor web graph.

As a starting point, Figure 2 shows how the total body of accessed hidden services is distributed across the three snapshots. SNP2 clearly emerges as the largest dataset, but this is not surprising if we compare our results with the statistics provided by the Tor Project [9], that show a spike of published hidden services in the second half of March 2017. We note that 10685 hidden services were found by all three crawling runs, suggesting that these services were durably present over the considered five month time frame. This core set represents the 83.3% of services reached during SNP1, the 42.2% of services reached during SNP2 and the 61.2% of services reached during SNP3. We also see that all pairwise intersections are not empty, meaning that during our data harvesting process (at least) 1612 hidden services disappeared, 3066 new hidden services appeared, and most notably, 76 hidden services reappeared after having gone inactive at some point in time. There is also the possibility that some of the hidden services that disappeared in a snapshot were actually active but not reachable by our crawler, for instance due to all paths to those services being temporarily unavailable.

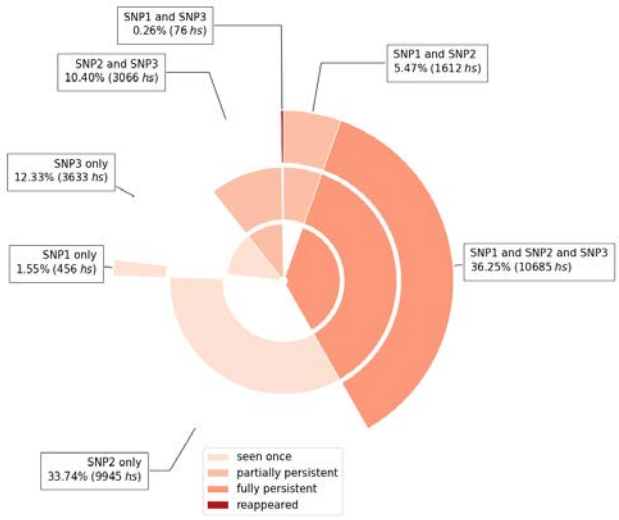

Figure 2: Services persistance over time: inner disc is SNP1, middle disc is SNP2, outer disc is SNP3.

The question now arises of whether hidden services found in two or more snapshots induce the same subgraph in the corresponding snapshots. The answer, summarized in Table 3 by looking at edge density, is no. As a consequence, if we aim at identifying the stable core of our dataset we should not just look at durable hidden services, but we must refer to durable edges. The total amount of durable edges turns out to be 28914, but somewhat surprisingly, one of these edges is isolated from the rest. The common subgraph induced by the set of stable edges consists of two weakly connected components: (i) a giant one, denoted CORE graph in the following, composed of 7669 vertices and 28913 edges, and (ii) a tiny one composed of a single edge connecting the hidden service violet77pvqdmsiy.onion to the hidden service typefacew3ijwkgg.onion.

[9] https://metrics.torproject.org/hidserv-dir-onions-seen.html?start=2017-01-01&end=2017-05-01

Table 3: Density of the subgraphs induced by different nodesets intersections in different graphs.

Nodeset	Density in SNP1	Density in SNP2	Density in SNP3
SNP1 ∩ SNP2	0.000474	0.000461	nd
SNP1 ∩ SNP3	0.000588	nd	0.000507
SNP2 ∩ SNP3	nd	0.000516	0.000435
SNP1 ∩ SNP2 ∩ SNP3	0.000595	0.000584	0.000511

4.2 Global Metrics

The global properties of our four graphs (the three snapshots plus the CORE graph) are summarized in Table 4 and in Table 5. As already mentioned, there is a significant variance in the sizes N and M of the three snapshots, which is however consistent with publicly available aggregated statistics. A common aspect is the lack of a very large hub gathering most of the connections, opposed to the presence of a single vertex that links to, respectively, 44%, 51% and 61% of the whole network. By manual inspection, we found that these onion urls are Tor link directories, not surprisingly. We also checked that the hidden services with greater in- and/or out-degree are generally persistent over the three snapshots, although their rank in the top-degree chart may change. Yet, stability is not a common property of *all* high-degree hidden services, in fact: (i) SNP3 is the only graph including a vertex with in-degree 1464 (which explains the larger C_{in} of that graph), (ii) in the CORE graph the ratios Δ_{in}/N and Δ_{out}/N are comparably smaller with respect to the snapshots, and (iii) in general all parameters strictly related to the presence of hidden services with large in- and/or out-degree (D, Δ_{in}, Δ_{out}, $\langle \deg \rangle$, ρ, C_{in} and C_{out}) appear to be variable over time. The vertex with in-degree 1464 is the hidden service *dhosting4okcs22v.onion* that is a hosting service named `Daniel's Hosting`. Tor users can get a hosting account on the server of the hidden service. The website specifies few rules regarding the contents that can be hosted for the purpose of avoiding illegal or offensive material. The same hidden service contains several sections including a link directory, but each section is registered with a different onion address, *i.e.*, a different hidden service.

Transitivity and clustering coefficients are also variable across time, but in this case the corresponding values for the CORE graph are close to the average of the three snapshots, suggesting that the variance is due to statistical fluctuations in the composition of a network with many volatile nodes. In general the overall frequency of triangles C is substantially in line with the average degree $\langle \deg \rangle$ (as we will better discuss in Section 5), with cycles (T_1) being more frequent than other types of triangles (T_2). The diameter d is stable and logarithmic in N for all graphs, and the ratio of r and d suggests a certain level of symmetry in the graph. The average shortest path length $\langle dist \rangle$ is instead consistently smaller than $\log(N)$, an important factor in determining to what extent the graph resembles a random graph (again, more details will be given in Section 5). Finally, the global efficiencies E_{in} and E_{out}, which should be comparable to $1/\langle dist \rangle$ in uniformly connected networks, are instead diluted by the fact that many pairs of nodes are disconnected (*i.e.*, have no paths connecting each other).

Table 4: Global metrics computed for the services graph of each snapshot

metrics	Graph SNP1	Graph SNP2	Graph SNP3	Graph CORE
$\|V\|$	12829	25308	17460	7669
$\|E\|$	72556	113014	103402	28913
D	0.00044	0.00018	0.00034	0.00049
δ_{in}	1	1	1	0

Table 5: Snapshot Data Details

snp	#scc	LSCC size	out-degree 0	in-degree 1
SNP1	12305	466	90.77%	17.478%
SNP2	24433	820	94.74%	43.15%
SNP3	15029	2371	83.32%	24.43%
CORE	7477	169	95.5%	25.09%

4.3 Degree and Centralities

To deepen our understanding of the structure of the Tor Web graph, we now analyze the distribution of a few metrics that quantify the importance of single vertices in the topology of the network and that can be used to gain an insight into the dynamics and the information flow in the graph. Many measures have been introduced in the last 50 years to understand who occupies critical, or *central*, positions in a network [11]. We chose to focus on the in- and out-degree, the PageRank and the betweenness centrality, which are among the most commonly used to describe real-world graphs because they respond to *semantically* different notions of "vertex centrality". The definition of PageRank and betweenness centrality is reported in Table 2.

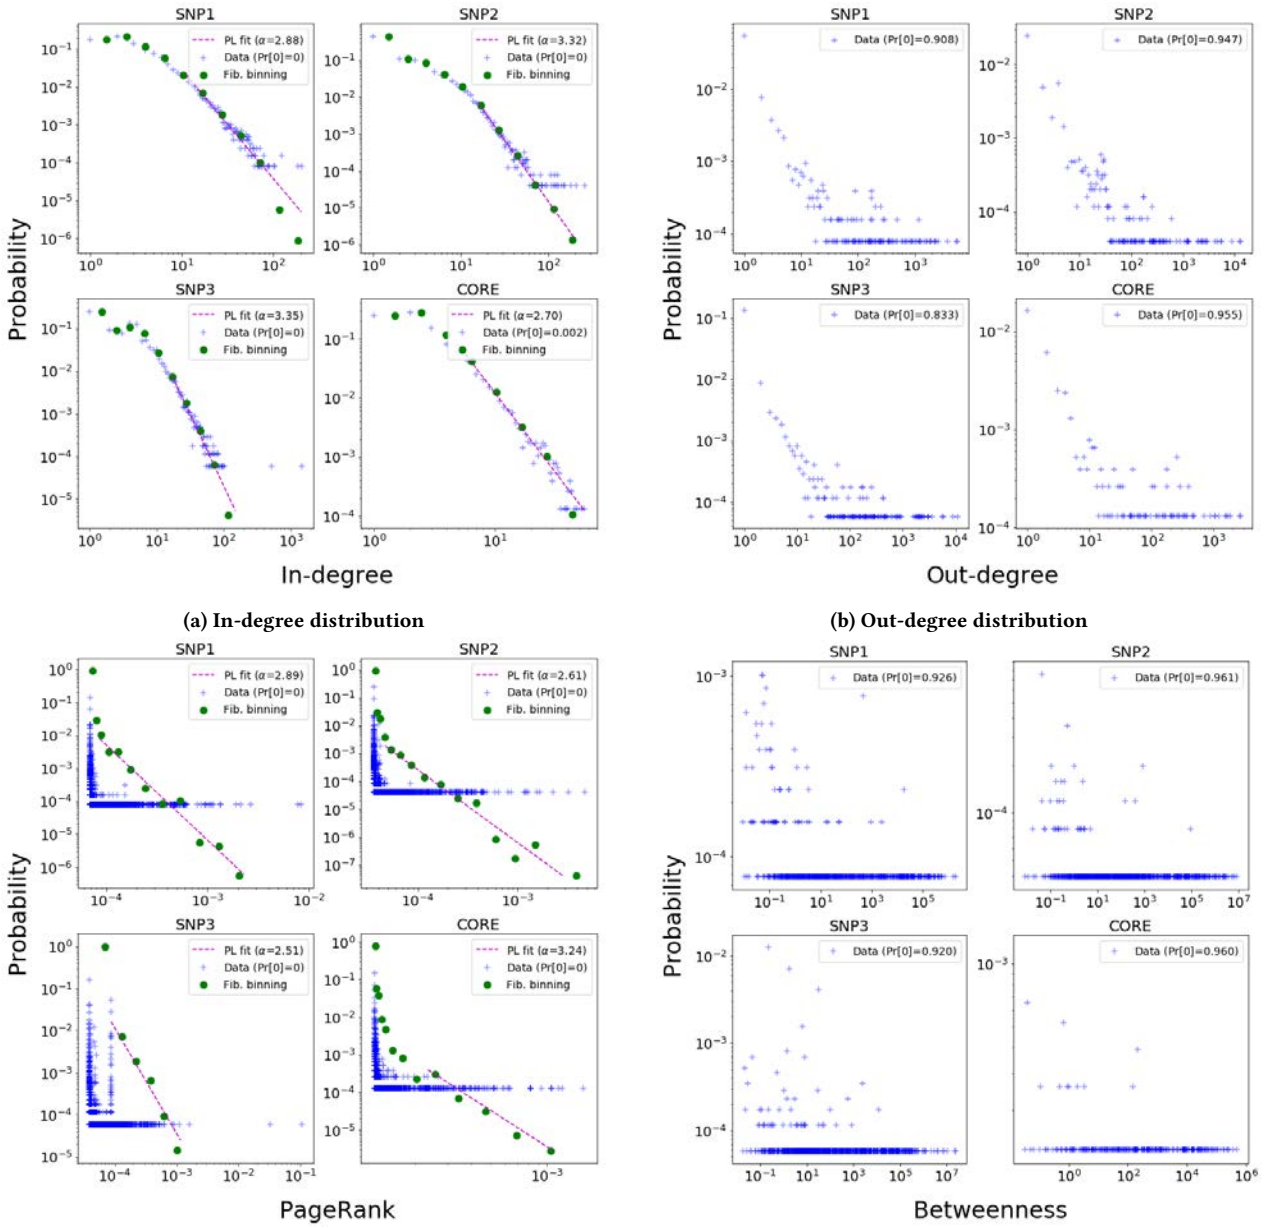
Figures 3a and 3b show the distributions of, respectively, in-degree and out-degree for all four graphs on a log-log scale. Based on Figure 3a, the in-degree distribution seems to follow a power law decay at least for degrees lying in some intermediate range between ~ 10 and ~ 60. This is not surprising: power law degree distributions are typical in social and web networks, as we will better discuss

in Section 5. To confirm this intuition, we fitted a power law to the distribution using the statistical methods developed in [16]. In particular, we relied on the implementation provided by the POWERLAW python package [3]. POWERLAW autonomously finds a lower-bound $k_{\min}$ for degrees to be fitted, and tries to fit the whole tail unless a context-driven upper-bound $k_{\max}$ is explicitly provided by the user. We also used *Fibonacci binning* [39], as done in a previous work about the surface WWW [29], to show how the distribution looks like if a logarithmic binning is used to smoothen the tail. Two aspects of the obtained fit must be underlined: (i) for SNP2 and SNP3 the α exponent is greater than the threshold 3 that is known to control the variance of the distribution, whereas for SNP1 α is close to 2.9 and for the CORE graph it is 2.7; (ii) the $k_{\min}$ returned by POWERLAW is, respectively, 11, 16, 17 and 5, but the vertices with in-degree greater than or equal to this $k_{\min}$ are only 1624 ($\sim$ 12.67%) in SNP1, 1155 ($\sim$ 4.56%) in SNP2 and 964 ($\sim$ 5.52%) in SNP3, whereas they are 1779 ($\sim$ 23.20%) in the CORE graph, which also has a shorter tail. Summing up, the in-degree provides a further element in support of the intuition that the structure of the CORE graph differs significantly from the snapshots.

Figure 3b makes apparent that the out-degree distribution does not follow a power law. Yet, there are at least two remarkable aspects in this distribution. On the one hand, vertices of out-degree 0 weight 83% up to 95%, according to the graph (this number is reported only in the legend since $k = 0$ is cut-off by the log scale). In other words, a vast majority of Tor's hidden services do not link to any other hidden service. On the other hand, the distribution has a long tail, meaning that the large value of Δ_{out} observed in Section 4.2 is not an isolated case, but rather an evidence of a general trend. To better understand how easily the whole graph can be explored from just a few starting points, in Figure 4 we plot the cumulative percentage of the network that is at distance one from the top out-degree vertices. We see that the top-3 and top-6 out-degree hidden services suffice to reach more than 90% of the graph in just one click in SNP3 and SNP2 respectively. In SNP1 we need the top-20 out-degree hidden services to reach the same percentage of the graph, whereas with the top-6 out-degree services we reach 80% of the nodes. This phenomenon is less evident for the CORE graph, albeit 10 hidden services still contain direct links to more than 80% of the network.

Figures 3c and 3d show the distributions of, respectively, the PageRank and the betweenness centrality for all four graphs on a log-log scale. We opted for a log-log scale in order to make these distributions directy comparable with the in- and out-degree, other than with one another. This is especially important for the PageRank because it has been shown that in many real-world networks (*e.g.*, in scale-free networks) the PageRank distribution "mimics" the in-degree distribution, following a power law with very similar exponent [29]. According to the data points plotted in Figure 3c, this may not seem to be the case for the Tor Web: although it has a heavy tail the decay looks much faster than a power law. However, since PageRank is a continuous metrics, a power law decay can only be appreciated graphically when using a suitable binning. We therefore proceeded exactly as for the in-degree by using POWERLAW to fit the distribution and by applying Fibonacci binning to have a more reliable visual perspective. Unfortunately, the apparently good fit plotted in Figure 3c only regards a minimal portion of the graph: it is only valid for 723 vertices ($\sim$ 5.64%) of SNP1, 772 vertices ($\sim$ 3.05%) of SNP2, 298 vertices ($\sim$ 1.71%) of SNP3 and just 113 vertices ($\sim$ 1.47%) of the CORE graph. For what concerns the betweenness centrality, in all four graphs the long tail and the fast decay are accompanied by more than 90% of the vertices having $B(V) = 0$. This is not surprising since, by definition, all vertices having out-degree 0 must have betweennes 0. Figure 3d partially resembles Figure 3b, suggesting that due to the huge percentage of sinks and to the greater imbalance of the out-degree with respect to the in-degree, in the Tor Web the out-degree impacts on the betweenness of a hidden service more that its in-degree. To confirm or deny this intuition, and more generally to assess the level of correlation between different centrality measures, in Figure 5 we plot the pairwise comparison of (normalized) in-degree, out-degree, PageRank and betweenness centrality.

4.4 Bow-Tie Structure



As commonly done to describe Web graphs [12], in Table 6 we provide a bow-tie decomposition of our graphs compared with previous results from the literature. Our findings broadly confirm what emerged in [23], *i.e.*, that the difference between the Tor Web and the WWW is huge and well synthetized by two facts: the LSSC is very small and it lies "on top" of everything else. However, with respect to [23] we implemented a more thorough data collection that brings to the light three novel features of the Tor Web. First, there exists a nonempty set of active hidden services that are completely disconnected from the rest of the graph. Second, the share of the LSCC in the total size of the graph is significantly variable over time, to the point that in SNP3 it is $\sim 4\times$ larger than in the other two snapshots. Finally, the structure of the CORE graph has a few peculiarities: the IN component is non-empty, but instead it is composed of a tiny set of 9 hidden services; the LSCC is even smaller than in the snapshots; the DISCONNECTED component is significanly larger, meaning that in general hyperlinks are more volatile than hidden services.

4.5 Top Hidden Services by Centralities

Considering the pairwise comparison of in-degree, out-degree, PageRank and betweenness of each hidden service shown in Figure 5, we observed that the most interesting services are usually link directories. In SNP1 we find *fhostingesps6bly,*, the service with the top in-degree and PageRank values, that contains an URL redirection[10] to the Hidden Wiki whose current onion address is *zqktlwi4i34kbat3*. The Hidden Wiki is a Tor link directory, probably the most famous. In SNP1 we find also *underdj5ziov3ic7* that is the service with the top betweenness and out-degree values. This service contains a Tor link directory named UnderDir - The Undernet Directory. The last service in SNP1 is *blockchainbdgpzk* that is the service with the second PageRank and in-degree values. This service contains an URL redirection to a surface website of a company named Blockchain Luxembourg S.A.R.L. that offers services related to digital currencies.

In SNP2 we find *tt3j2x4k5ycaa5zt* that is the service with the top PageRank and second in-degree values; it contains a personal

website named Daniel's Home. In the website a section is dedicated to a collection of Tor links. In SNP2 we find also *zlal32teyptf4tvi* that is the top betweenness and second out-degree service. This service is a Tor link directory named Fresh Onions. The last service in SNP2 is *vj5wxqmjaes2bae5* that has the top out-degree value, it contains a Tor link directory.

In SNP3 we find *dhosting4okcs22v* that is the service with top PageRank, betweenness and in-degree values; it contains a hosting service named Daniel's Hosting. This is a section of the website we found in SNP2 named Daniel's Home. It uses a different onion address, but it is actually the same website. The last service in SNP2 is *zlal32teyptf4tvi* that is the service with the top out-degree value containing the Tor link directory named Fresh Onions, that we found in SNP2.

Finally in CORE we find *blockchainbdgpzk* and *underdj5ziov3ic7* that are respectively the services with the top PageRank, second in-degree service and the top betweenness, out-degree values. We already discussed these two onion addresses for SNP1. In CORE we find also *grams7enufi7jmdl* that is the service with the second in-degree value. This service contains a Tor search engine focused on

LSCC is the largest strongly connected component.
IN is the set of nodes $v \in V \setminus$ LSCC such that there is a path from v to LSCC.
OUT is the set of nodes $v \in V \setminus$ LSCC such that there is a path from LSCC to v.
TUBES is the set of nodes $v \in V \setminus$ (LSCC $\cup$ IN $\cup$ OUT) such that there is a path from IN to v as well as a path from v to OUT.
TENDRILS is the set of nodes $v \in V \setminus$ (LSCC $\cup$ IN $\cup$ OUT) such that there is either a path from IN to v or a path from v to OUT, but not both.
DISCONNECTED is the set of all other nodes $v \in V \setminus$ (LSCC $\cup$ IN $\cup$ OUT $\cup$ TUBES $\cup$ TENDRILS).

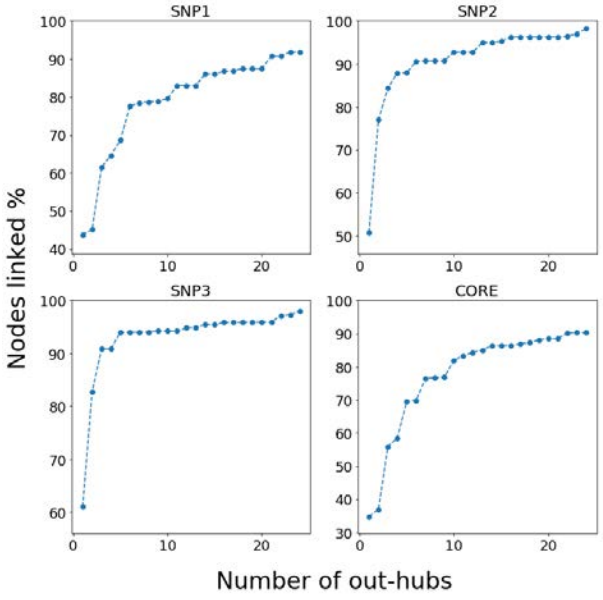

Figure 4: Cumulative percentage of the graph linked by the top out-degree vertices.

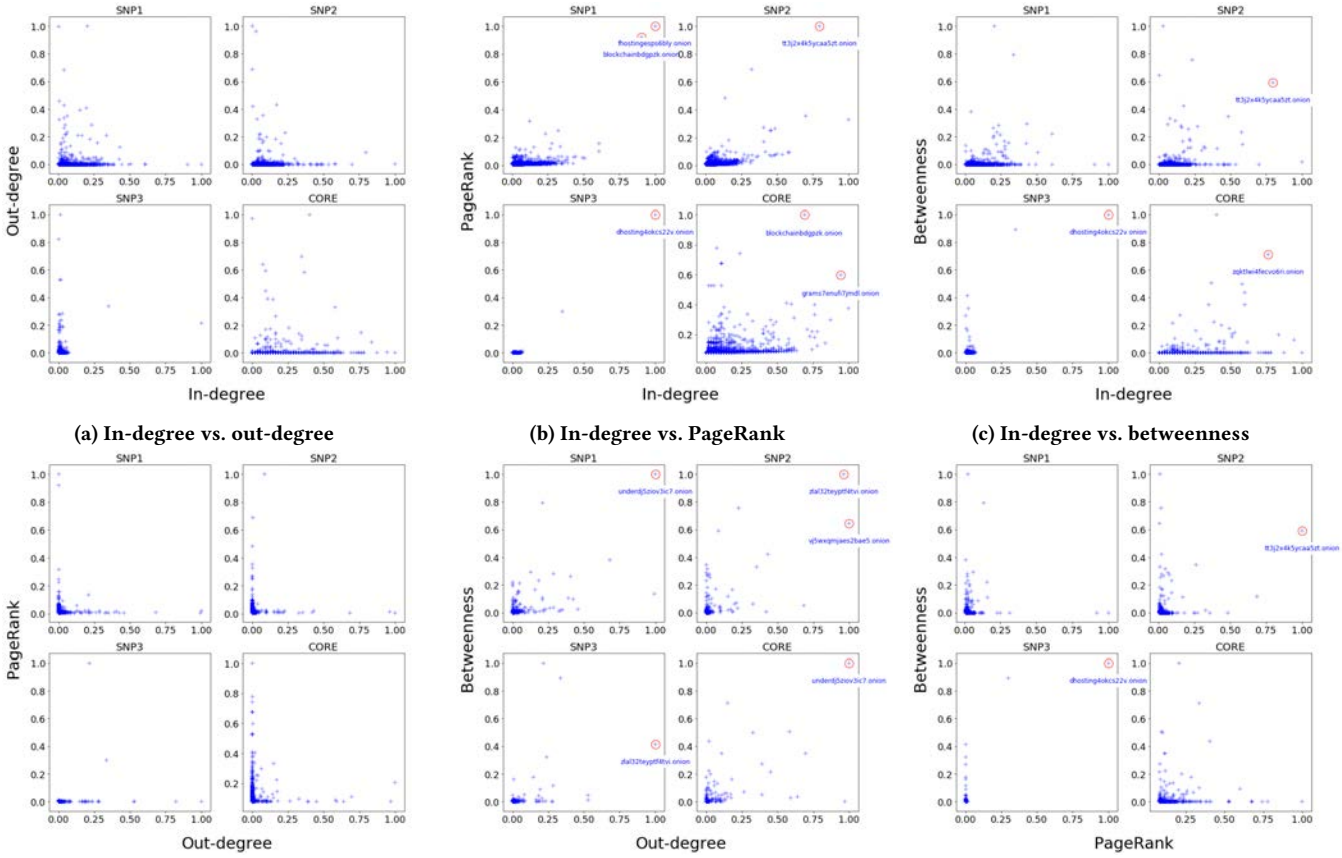
Tor marketplaces. The last service in CORE is *zqktlwi4fecvo6ri* that is the service with the second betweenness value and it contains an URL redirection to the Hidden Wiki.



5 DISCUSSION

In this Section we read and discuss our findings in the light of the body of work on real world complex networks. Aiming at assessing to which extent the Tor Web graph fits the three most-known generative models for random graphs – Erdos-Renyi (ER) [20], Watts-Strogatz (WS) [40], Barabasi-Albert (BA) [5] – we focus on three properties that are especially informative: the average shortest path length (or average distance), the clustering coefficient (or transitivity) and the shape of the degree distribution. Notably, these three characteristics are also known to be discriminatory in many practical settings, such as: for predicting the growth dynamics of a network [2], for controlling the spreading of viruses/rumors [32], or for determining the robustness against random node failures [13].

For what concerns the average distance, the question is whether the Tor graph looks like a *small world* or even an *ultra-small world* network. In small world networks the average distance satisfies $\langle dist \rangle \propto \ln(N)$, whereas in ultra-small networks $\langle dist \rangle \propto \ln\ln(N)$. Although the latter are asymptotic estimates, our numbers suggest that Tor belongs, at least, to the class of small world networks: for all four graphs considered (the three snapshots and the CORE) $\langle dist \rangle$ satisfies $3.5 < \langle dist \rangle < 5$, whereas $2 < \ln\ln(N) < 2.5$ and $8.5 < \ln(N) < 10.5$.

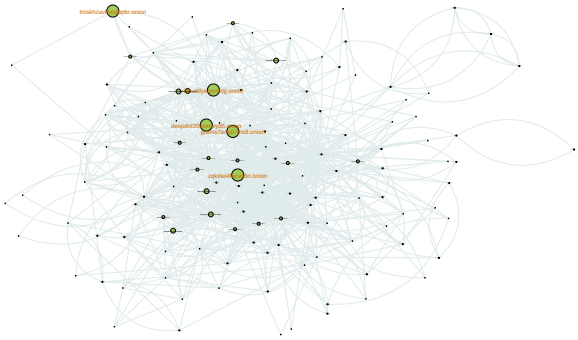
The global clustering coefficient measures the frequency of closed triangles in the graph, thus representing an indicator of the existence of some level of correlation in the adjacency patterns of neighboring vertices. If edges occur independently and uniformly at random, the clustering coefficient C satisfies $C \propto \frac{\langle \deg \rangle}{N}$, where $\langle \deg \rangle$ is the average degree of the network. Again, although the latter is only an asymptotic estimate, our findings speak in favor of the existence of a positive correlation for Tor edges. For directed graphs, other than the global (undirected) clustering coefficient it is possible to consider a few types of directed transitivities: we chose two such metrics, denoted T_1 and T_2 and defined in Table 2. Similarly, the average degree can be computed both ignoring or considering edge directions, and the value reported in Table 4 for $\langle \deg \rangle$ is the average number of in-bound or (equivalently) out-bound edges, thus C should be compared with $\frac{2\langle \deg \rangle}{N}$ in our case. In all four Tor graphs, C is one order of magnitude greater than $\frac{2\langle \deg \rangle}{N}$, and both T_1 and T_2 are one order of magnitude greater than $\frac{\langle \deg \rangle}{N}$.

Finally, when looking at the degree distribution of a network, the first aspect to consider is whether it has a heavy tail, which is symptomatic of the tendency of nodes to connect to "authoritative" hubs. By looking at Figures 3a and 3b it is clear that this is the case for the Tor Web. However, while the in-degree distribution seems to follow a power law for all four graphs, albeit with different

(a) In-degree vs. out-degree **(b) In-degree vs. PageRank** **(c) In-degree vs. betweenness**

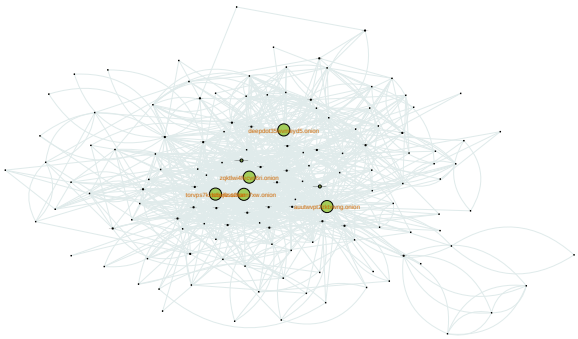
(d) Out-degree vs. PageRank **(e) Out-degree vs. betweenness** **(f) PageRank vs. betweenness**

Figure 5: Pairwise comparison between centrality measures.



exponents, the out-degree shows an even slower decay and an even longer tail.

Our findings make it clear that the Tor Web is not an ER graph. In the ER random graph model with N vertices and with expected degree $\langle \deg \rangle$, the expected average distance satisfies $\langle dist \rangle \propto \ln(N)$, but the expected global clustering coefficient is $C \propto \frac{\langle \deg \rangle}{N}$ and the degree distribution has no heavy tail. The WS model predicts that $\langle dist \rangle \propto \ln(N)$ and that $C \gg \frac{\langle \deg \rangle}{N}$, thus suiting our findings quite well. Yet, the values of C measured in our four graphs are not as large as in other real-world small world networks [5, 32, 40]. Additionally, the WS model alone does not predict the observed power law distribution of the in-degree. The power law degree distribution is the defining property of the BA model. However, the BA model theoretically predicts the existence of two regimes according to whether the power law exponent α satisfies $2 < \alpha < 3$ or $\alpha > 3$. In the former case, the variance of the distribution diverges and the network is ultra-small. In the latter, the variance of the distribution is finite and the network is small. The existence of this threshold is not visible in our findings: SNP1 and CORE have $2 < \alpha < 3$, whereas SNP2 and SNP3 have $\alpha > 3$, but all four graphs have very similar average distance and degree distribution. Although real networks cannot have an infinite variance, if N is large enough, node degrees should span several orders of magnitude if and only if $2 < \alpha < 3$, but this seems not be the case for the out-degree in Tor.



Summing up, Tor shows a blend of different features and a deeper analysis is needed to understand whether any existing generative model matches its characteristics. Among Tor's unique features, we observe that the overall structure is clearly dominated by the presence of a small number of *out-hubs*, which connect both central and peripheral nodes. It is also worth noting that the sizes of the LSCCs are relatively small compared to those reported by other studies on the surface WWW or social networks [5, 27, 32]. It is interesting that the nodes in the LSCC core are persistent in the three snapshots, suggesting that some subnet inside Tor could have specific properties and even a different structure with respect to the whole network.

Many questions that are still open require further analysis. Tor is built with anonymity in mind thus many hidden services are supposedly not interested in having visibility, yet some of its topological features, *e.g.* the radius and diameter, suggest the existence of a peculiar mechanism that leads to the growth of the network. On the practical side, one may be especially interested in understanding how the existence of large *out-hubs* impacts on the topological

properties of the network, and whether topologically similar nodes host analogous contents. To provide a few insights in this regards, we removed from the CORE set the 10 services with maximum out-degree and analyzed the LSCC of the obtained graph, depicted in Figure 6. The most remarkable finding is that, albeit the average shortest path remains almost unchanged, the obtained network has a clustering coefficient more than 20 times larger than that of a random graph of equal size. We also found that *out-hubs* are almost all *hidden directories* and we have some evidence that other centrality measures can be related to the content of the hidden services. In particular, as reported in Table 7, 4 out of the top 5 PageRank services are related to marketplaces, whereas high betweenness seems not equally characteristic of a specific category of services.

(a) Node size proportional to their PageRank.

(b) Node size proportional to their betweenness centrality.

6 CONCLUSIONS

This paper studied three sets of crawling data collected over three different time frames as well as their common "stable" core. It provided a deep characterization of the topology of the Tor services graph, identifying structural and temporal features and further assessing the persistence of hidden services and hyperlinks.

While previous work only focused on the volatility of Tor hidden services, thanks to a graph-oriented perspective we were also able to assess the persistence of Tor hyperlinks. This led to the key finding that edges are more volatile than nodes in the Tor Web graph, as proved by the fact that hidden services shared by two or more snapshots do not induce the same subgraph in these snapshots. Additionally, we observed that the LSCC of the CORE graph is persistent in all three snapshots. Compared with the generally high volatility of the Tor network, this is the first evidence that Tor may be comprised of different layers, each with a precise role in the connectivity patterns of the network, and possibly with different inter- and intra-layer structures.

Table 7: Best 5 nodes with respect to PageRank and betweenness centrality.

We computed several topological metrics on the Tor snapshots and compared them to well-known network models (ER, WS, BA). None of those models appears to be suitable to accurately represent Tor. A small number of *out-hubs* connecting both central and peripheral nodes dominates the structure of the graph, whereas LSCCs are (relatively/due proportions made) smaller than those of the surface Web or social networks. By removing the *out-hubs* with higher degree, the clustering coefficient of the network grows but the average shortest path remains almost constant: this again suggests that additional insights into Tor's dynamics could be obtained by removing and/or isolating specific subnets. Centrality metrics also indicate that there could be some interesting relation among node role/position and content: nodes with higher degree are almost always link directories, whereas we found that four out of five nodes in the top PageRank are related to marketplaces. While these results do not suffice to draw a clear picture, they surely indicate that further research must be carried out [11].

We believe the results presented here will foster a larger discussion on the topic, and will be a useful reference for evaluation and comparison against other real-world graphs.

ABSTRACT

Despite being vast repositories of factual information, cross-domain knowledge graphs, such as Wikidata and the Google Knowledge Graph, only sparsely provide short synoptic descriptions for entities. Such descriptions that briefly identify the most discernible features of an entity provide readers with a near-instantaneous understanding of what kind of entity they are being presented. They can also aid in tasks such as named entity disambiguation, ontological type determination, and answering entity queries. Given the rapidly increasing numbers of entities in knowledge graphs, a fully automated synthesis of succinct textual descriptions from underlying factual information is essential. To this end, we propose a novel fact-to-sequence encoder–decoder model with a suitable copy mechanism to generate concise and precise textual descriptions of entities. In an in-depth evaluation, we demonstrate that our method significantly outperforms state-of-the-art alternatives.

In *Proceedings of the 2019 World Wide Web Conference (WWW '19), May 13–17, 2019, San Francisco, CA, USA.* ACM, New York, NY, USA, 11 pages. https://doi.org/10.1145/3308558.3313656

1 INTRODUCTION

Motivation. A substantial percentage of online search requests involve named entities such as people, locations, businesses, etc. Search engines and digital personal assistants (e.g., Google Assistant, Alexa, Cortana, Siri) alike now extensively draw on *knowledge graphs* as vast databases of entities and their properties.

Most large cross-domain factual knowledge graphs, such as Wikidata [25], the Google Knowledge Graph, YAGO [11], and MENTA [6], include short textual descriptions of entities. These can be provided in response to entity queries (such as *Where is Fogo Island?*), e.g., as an informative direct answer or to enrich a knowledge panel given by a Web search engine such as Google, as shown in Figure 1 for Fogo Island. Such textual descriptions effectively provide for a near-instantaneous human understanding of an entity. They can also be helpful in a number of linguistic tasks, including named entity disambiguation, and can serve as fine-grained ontological types in question answering and reasoning-driven applications.

Despite their eminent importance for information retrieval and other applications, these descriptions are only sparsely available, typically for the more well-known entities, leaving large numbers of entities with no such descriptions. For example, in Wikidata, which is used by Apple's Siri, as many as 7.2 million entities do not have

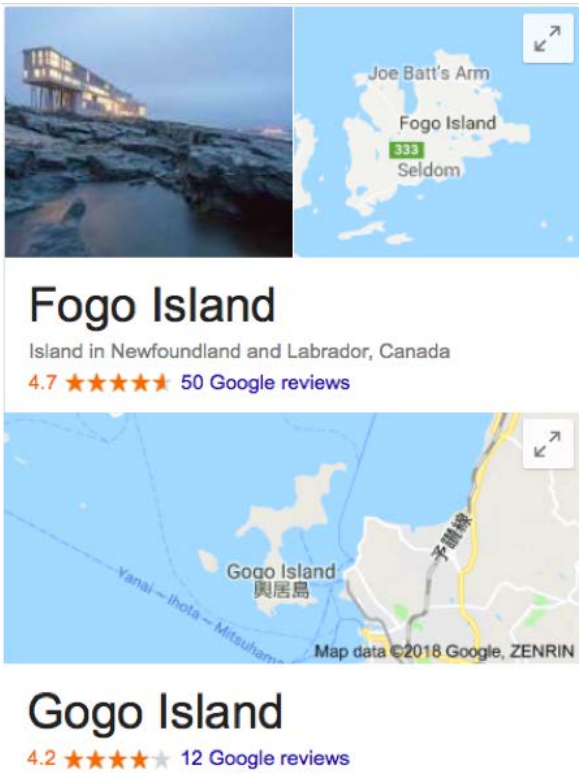

Figure 1: An example of a missing description in Google's Knowledge Graph. Similar to *Fogo Island*, a synoptic description for *Gogo Island* could be *Island in Ehime, Japan.*

any description in any language as of December 2018.[1] Moreover, new entities are added frequently to the existing knowledge graphs. For example, the number of entities in Wikidata almost doubled in the last couple of years.

Given the large number of entities lacking textual descriptions, a promising solution is to fully automatically generate synoptic textual descriptions from the underlying factual data. Ideally, this automatic generation process should be able to synthesize very concise descriptions, retaining only a very small number of particularly discernible pieces of information about an entity. For example, in Wikidata and Google's Knowledge Graph, *occupation* and *nationality* are among the preferred attributes invoked in describing a person (e.g., *Magnus Carlsen* as a *Norwegian chess Grandmaster*). At the same time, however, an *open-domain* solution is needed, in order to cope with the various different kinds of entities users may search for in a knowledge graph, and the various kinds of names that might appear in such descriptions. For instance, for Gogo Island in Figure 1, an appropriate description would perhaps refer to *Ehime, Japan* as the prefecture in which the island is located. Moreover, apart from people and locations, users could likewise also search for paintings, films, or even asteroids. Additionally, the generated descriptions should also be precise, coherent, and non-redundant.

Overview and Contributions. In this paper, we present a novel fact-to-sequence encoder–decoder model that solves this challenging task. Our deep neural model attempts to generate a textual description similar to those created in image and video captioning tasks [17], but instead starts from structured data. Our model is equipped with an explicit copy mechanism to copy fact-specific tokens directly to the output description. Since many names and words in the desired output descriptions are also present in the underlying facts, it is an intuitive design choice to selectively copy words from the facts to the description. The copy mechanism is important, as it is difficult to predict rare or unseen words based on mere statistical co-occurrences of words. In comparison to the state-of-the-art, our model is more than 14x more parameter-efficient and gains 5–8 absolute percentage points across a number of metrics in an empirical evaluation.

This approach is substantially different from previous work on this topic. In contrast to some prior works that focus on generating Wikipedia-style summary descriptions from factual data [1, 14], or textual verbalization of RDF triples [5, 8], our work is focused on synthesizing quickly graspable synoptic textual descriptions from factual knowledge. In most of the cases, these are single-phrase descriptions as compared to multi-sentence Wikipedia-style summaries. Note that we restrict our work only to English description generation, as English is the most prevalent language in which descriptions are available in knowledge graphs. Typically, the first few sentences of Wikipedia articles contain a detailed description of the entity, and one can attempt to generate brief textual descriptions by learning to reproduce the first few sentences based on the remaining article text. However, our goal is to make our method open-domain, i.e., applicable to any type of entity with factual information that may not have a corresponding Wikipedia-like article available. Indeed, Wikidata currently has more than 51 million items, whereas the English Wikipedia has only 5.6 million articles.

[1] https://tools.wmflabs.org/wikidata-todo/stats.php

Our specific contributions in this paper are as follows:

- We introduce a fact-to-sequence encoder–decoder architecture that precisely copies fact-specific words using a two-step pointing and copying mechanism.
- Our model is 14x as parameter-efficient than the state-of-the-art models and 14–20x as parameter-efficient compared to competitive baselines.
- Through extensive evaluation, we show that our method outperforms other baselines with significant improvement, especially with regard to descriptions requiring open-domain name mentions.

2 MODEL

In order to enable concise and precise open-domain entity descriptions, we propose a generative model consisting of a fact-to-sequence encoder–decoder architecture, aided by a pointer network based copy mechanism. Our model comprises a positional fact encoder, a GRU-based sequence decoder, and a copy function to directly transfer factual words to the generated descriptions. Before delving into the details of these key components, however, we first introduce some essential terminologies that we shall use in the following.

2.1 Preliminaries

Property. Each subject entity $s \in \mathcal{E}$ has a number of properties $P \in \mathcal{P}$ associated with it. Each property name is described as a sequence of tokens $P = (w_1^P, w_2^P, ..., w_{|P|}^P)$. Note that these properties are predefined in a schema-based knowledge graph.

Property Value. Each property P of entity s has a corresponding value O_P, which is also a sequence of tokens $O_P = (w_1^o, w_2^o, ..., w_{|O_P|}^o)$. The property values could be another entity $e \in \mathcal{E}$, a date–time value, a string, or a numeric value, etc.

Fact. Each of the property–value pairs is deemed a *fact*. Each subject entity $s \in \mathcal{E}$ has a number of different facts $\mathcal{F} = \{f_1, f_2, \dots f_N\}$ that characterize it.

Description. A short textual description of entity s is a sequence of tokens $\mathcal{D} = (w_1, w_2, \dots, w_n)$. Each word in the description D can be a *factual word*, or a *vocabulary word*.

Factual Words. The factual words for each fact $f \in \mathcal{F}$, denoted as $\mathcal{V}_f$, are the words appearing in the property value. Stop words (e.g., *for, of, in* etc.) are excluded from the factual words vocabulary. Note that the sets of factual words are instance-specific, i.e., $\bigcup_f \mathcal{V}_f$ is different for different entities $s \in \mathcal{E}$.

Vocabulary Words. The vocabulary words, denoted as $\mathcal{V}$, could be a list of frequent words in the English dictionary. For our experiments, we rely on the 1,000 most frequent words appearing in our corpus as vocabulary words. Typically, the words that appear in the property names constitute this vocabulary. This is aligned with the expectation for a schema-based knowledge graph with fixed number of properties. Note that $\mathcal{V}_f \cap \mathcal{V} \neq \emptyset$, which indicates that there could be words in the property value that are also vocabulary words.

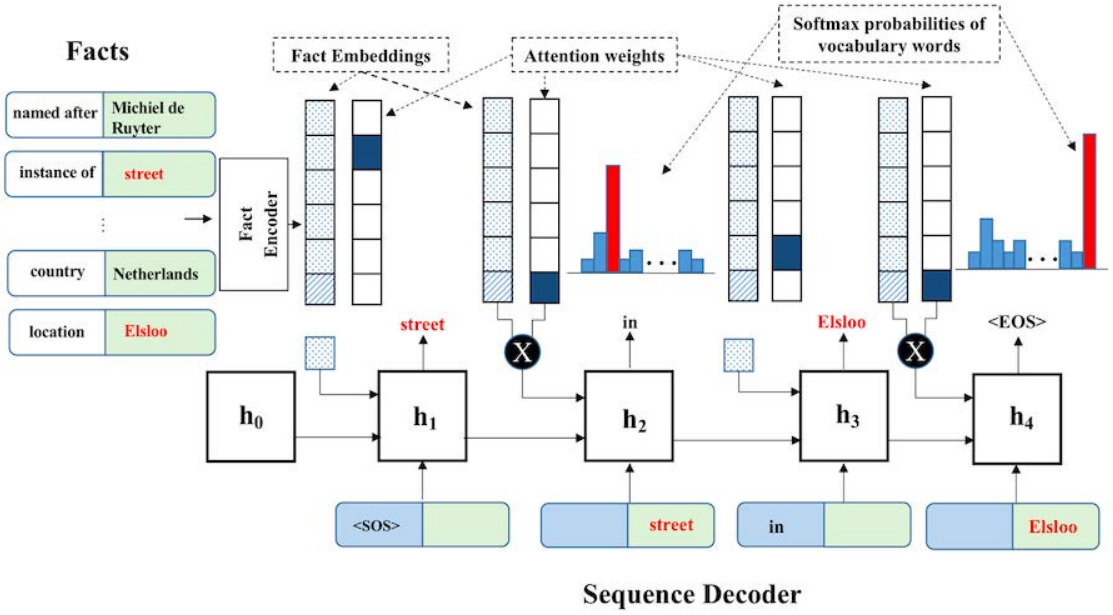

Figure 2: Model architecture. For Wikidata item Q19345316 (*Michiel de Ruyterstraat*), factual words such as *street* and *Elsloo* are directly copied from the underlying facts *(Instance of, street)* and *(location, Elsloo)*, respectively, while the general vocabulary words *in* and *<EOS>* are selected by a softmax classifier.

2.2 Fact Encoder

The fact encoder transforms a set of input facts $\mathcal{F} = \{f_1, f_2, \ldots f_N\}$ into *fact embeddings* – distributed vector representations of facts. For simplicity and efficiency, we use a positional encoding scheme proposed by Sukhbaatar et al. [22] that was also adopted in other architectures [3, 26].

Using the positional encoding scheme, each fact f_i is represented as $\mathbf{f}_i = \sum_j \mathbf{l}_j \odot \mathbf{w}_j^i$, where $\odot$ denotes element-wise multiplication, $\mathbf{l}_j$ is a column vector with the structure $l_{kj} = (1 - \frac{j}{J}) - (k/d)(1 - 2\frac{j}{J})$, with J being the number of words in the fact, and $\mathbf{w}_j^i \in \mathrm{R}^d$ is the word embedding of the j-th word in fact f_i. If the word w_i^j is not a vocabulary word, we replace it with the special token *<UNK>*. This arrangement deals with the rare or unseen words that appear in the factual phrase f_i, which is a concatenation of words in the property name and property value.

We append the fact embeddings with a *mean fact* – a special fact that is responsible for generating vocabulary words. It is derived as the element-wise mean of the fact embeddings, i.e., $\mathbf{f}_{N+1} = \frac{1}{N} \sum \mathbf{f}_i$. We train the model to attend to the mean fact if it has to generate a vocabulary word in the output sequence.

2.3 Output Sequence Decoder

At every time step t, the sequence decoder selects a fact. This selection governs the generation of the next word either from the corresponding factual words, or from the vocabulary words.

2.3.1 Fact Selection. Given the set of fact embeddings $\{\mathbf{f}_1, \mathbf{f}_2, \ldots, \mathbf{f}_{N+1}\}$ as input, the decoder selects a fact at each time step t using an attention mechanism. The attention scores are calculated as a likelihood distribution using the hidden state of the decoder in the previous time step and the fact embeddings. Formally,

$$\mathbf{e}_i = \mathbf{W}_2 \tanh(\mathbf{W}_1[\mathbf{f}_i; \mathbf{h}_{t-1}]) \;\; \forall i \in \{1, N+1\}, \tag{1}$$

$$P(f = f_i \mid \mathbf{f}_i, \mathbf{h}_{t-1}) = \frac{\exp(\mathbf{e}_i)}{\sum_{i' \in \{1, N+1\}} \exp(\mathbf{e}_{i'})}, \tag{2}$$

where $\mathbf{e}_i$ denotes the attention energy of the i-th fact, $[;]$ denotes the concatenation operation, and $\mathbf{W}_1 \in \mathrm{R}^{m \times 2d}$, $\mathbf{W}_2 \in \mathrm{R}^m$ are affine transformations of a 2-layer feed-forward network.

We select the fact with maximum attention score at time step t, denoted as f_t and its corresponding fact embedding $\mathbf{f}_t$ as

$$f_t = \underset{i \in \{1, \ldots, N+1\}}{\arg\max} \; P(f = f_i \mid \mathbf{f}_i, \mathbf{h}_{t-1}) \tag{3}$$

$$\mathbf{f}_t = \mathbf{f}_{f_t} \tag{4}$$

2.3.2 GRU Decoder. We rely on Gated Recurrent Units (GRU), which is a Recurrent Neural Network (RNN) variant, as our preferred decoder. At each time step t, the decoder input is a concatenation of three vectors: the embedding $\mathbf{f}_t$ of a selected fact in the current time step, the embedding $\mathbf{w}_{t-1}$ of the vocabulary word at the previous time step, and a one-hot vector $\mathbf{v}_{t-1}$ corresponding to the position of the copied factual word in the previous time step. Note that since the generated word in the previous time step can either be a vocabulary word or a factual word, either $\mathbf{w}_{t-1}$ or $\mathbf{v}_{t-1}$ is set to a zero vector.

The input representation $\mathbf{x}_t = [\mathbf{f}_t; \mathbf{w}_{t-1}; \mathbf{v}_{t-1}]$ is fed to the GRU decoder to update the states.

$$\mathbf{h}_t = \mathrm{GRU}(\mathbf{x}_t, \mathbf{h}_{t-1}) \tag{5}$$

2.3.3 Generating Vocabulary Words. If the attention mechanism assigns the maximum score to the mean fact f_{N+1}, then the decoder generates a vocabulary word $w_t \in \mathcal{V}$. To generate the vocabulary word, we use the attention-weighted context $\mathbf{c}_t = \sum_i \alpha_i \mathbf{f}_i$ and the GRU output state $\mathbf{h}_t$. A concatenation of these two vectors are fed to a 2-layer feed-forward network with a non-linear ReLU activation applied to the hidden layer. Formally,

$$\mathbf{o}_t = \mathbf{W}_a \text{ReLU}(\mathbf{W}_b[\mathbf{c}_t; \mathbf{h}_t]), \tag{6}$$

where $\mathbf{W}_a$ and $\mathbf{W}_b$ are affine transformations and $\text{ReLU}(\mathbf{x}) = \max(\mathbf{0}, \mathbf{x})$. Finally, a probability distribution over the vocabulary words is obtained by a softmax function and the word with the maximum probability is emitted by the decoder. Formally,

$$P(w \mid \mathbf{c}_t, \mathbf{h}_t) = \text{Softmax}(\mathbf{o}_t) \tag{7}$$

$$w_t = \arg\max_{w \in \mathcal{V}} P(w \mid \mathbf{c}_t, \mathbf{h}_t) \tag{8}$$

2.3.4 Copying Factual Words. The decoder copies factual words directly to the output when the fact selection process selects one of the N facts. To facilitate the copy mechanism, the decoder must select the position index of the factual word within the factual phrase. The position index is predicted by a 2-layer feed-forward network that takes a concatenation of the selected fact embedding $\mathbf{f}_t$ and the output state of the GRU $\mathbf{h}_t$ as input. Then, the position index of the word to copy is determined as follows.

$$\mathbf{r}_t = \mathbf{W}_c \text{ReLU}(\mathbf{W}_d[\mathbf{f}_t; \mathbf{h}_t]) \tag{9}$$

$$P(n \mid \mathbf{f}_t, \mathbf{h}_t) = \text{Softmax}(\mathbf{r}_t) \tag{10}$$

$$n_t = \arg\max_{n \in \{1, \ldots, |\mathcal{V}_{f_t}|\}} P(n \mid \mathbf{f}_t, \mathbf{h}_t) \tag{11}$$

$$w_t = (\mathcal{V}_{f_t})_{n_t} \tag{12}$$

Here, n_t is the position index of the factual word to copy and $\mathcal{V}_{f_t}$ is the sequence of factual words corresponding to fact f_t and $(\mathcal{V}_{f_t})_i$ denotes the i-th item in that sequence.

2.4 Training

Our method requires selective copying of factual words to generate a description. In order to obviate the need for ground truth alignments of output description words with facts for training, we introduce an automated method of annotating each token in the description so as to align it to a matching fact. Specifically, we rely on a greedy string matching algorithm as detailed in Algorithm 1 for this purpose. If a token is not aligned with any of the facts, it is annotated as a vocabulary word. However, if the token is neither present in the vocabulary word set nor in the factual word set, it is assigned the special token <*UNK*> to denote that it is neither a factual word nor a vocabulary word. The symbol NaF in Algorithm 1 indicates that such words are not aligned to any fact. Since in our implementation, we consider the mean fact as a source of vocabulary words, we align these words to the mean fact.

Note that the greedy string matching algorithm used for fact alignment is a heuristic process that can be noisy. If a token in the output description appears in more than one fact, the string matching algorithm greedily aligns the token to the first fact it encounters, even if it is not the most relevant one. However, our manual inspection suggests that in most of the cases the alignment is relevant, justifying our choice of such a greedy approach.

Algorithm 1: Algorithm for fact alignment of description

Data: Input: Set of facts $\mathcal{F}$, Description $\mathcal{D} = (w_1, w_2, \ldots, w_n)$
Result: Ordered sequence of fact aligned description $\tilde{\mathcal{D}}$

```
for t ∈ {1, ..., n} do
    factual_flag ← False
    for f ∈ F do
        if w_t ∈ V_f and factual_flag = False then
            d̃_t ← (w_t, f)
            factual_flag ← True
        end
    end
    if factual_flag = False then
        if w_t ∈ V then
            d̃_t ← (w_t, NaF)
        else
            d̃_t ← (UNK, NaF)
        end
    end
end
D̃ = (d̃_1, d̃_2, ..., d̃_n)
```

Given the input facts $\mathcal{F}$ and the fact-aligned description $\tilde{\mathcal{D}}$, the model maximizes the log-likelihood of the observed words in the description with respect to the model parameters θ,

$$\theta^* = \arg\max_{\theta} \log P(\tilde{\mathcal{D}} \mid \mathcal{F}), \tag{13}$$

which can be further decomposed as

$$\log P(\tilde{\mathcal{D}} \mid \mathcal{F}) = \sum_{t=1}^{|\tilde{\mathcal{D}}|} \log P(w_t \mid w_{1:t-1}, \mathcal{F}). \tag{14}$$

Since the log-likelihood of the word w_t also depends on the underlying fact selection, we can further decompose $P(w_t)$ as

$$P(w_t) = P(w_t \mid f_t, w_{1:t-1})\, P(f_t \mid w_{1:t-1}) \tag{15}$$

Therefore, we train our model end-to-end by optimizing the following objective function:

$$\mathcal{L}(\theta) = -\sum_{t=1}^{|\mathcal{D}|} \log P(w_t \mid f_t, w_{1:t-1}) - \sum_{t=1}^{|\mathcal{D}|} \log P(f_t \mid w_{1:t-1}). \tag{16}$$

Note that the alignment $\tilde{\mathcal{D}}$ of the description $\mathcal{D}$ to the facts $\mathcal{F}$ provides a ground truth fact f_t as each time step t during training.

3 EVALUATION

3.1 Baselines

We compare the performance of our model against a number of competitive baselines, including recent state-of-the-art deep neural methods.

3.1.1 Dynamic Memory-based Generative Model. We use the model proposed by Bhowmik and de Melo [3] as one of our baseline methods, because that model claims to solve essentially the same problem using a dynamic memory-based generative model, achieving state-of-the-art results. The dynamic memory component memorizes

how much information from a particular fact is used by the previous memory state and how much information of a particular fact is invoked in the current context of the output sequence. However, through our experiments and analysis, we show that this approach is unable to obtain precise open-domain descriptions with arbitrary tokens. We use the original implementation[2].

3.1.2 Fact-to-Sequence with Attention. The comparison with this baseline method can be deemed as an ablation study, in which the decoder has no access to the copy mechanism. This baseline resembles the standard sequence-to-sequence with attention mechanism proposed by Bahdanau et al. [2]. However, unlike in their work, the input to this model consists of positionally encoded discrete facts.

Each word in the output sequence is predicted by providing the attention-weighted fact embeddings and the previous hidden state as an input to the GRU decoder. Then, the output of the decoder is concatenated with the attention-weighted fact embeddings and passed through a 2-layer feed-forward network with a ReLU activation. Finally, the output of the MLP is fed to a softmax classifier that outputs a probability distribution for the combined vocabulary of factual and non-factual words $\mathcal{V} \cup \{\bigcup_{s \in \mathcal{E}} \mathcal{V}_f^s\}$. The word with the maximum probability is emitted by the decoder.

Note that Bhowmik and de Melo [3] also implements a "Fact2Seq w. Attention" baseline. However, one key difference is that the baseline considered here has a skip-connection from the attention-weighted fact embeddings, concatenating them with the output of the GRU decoder that is then passed through a 2-layer feed-forward network. The experimental results suggest that our variant with this skip-connection leads to substantially more accurate descriptions.

[2]https://github.com/kingsaint/Open-vocabulary-entity-type-description

3.1.3 Neural Knowledge Language Model (NKLM). We compare against Ahn et al.'s Neural Knowledge Language Model [1], which is able to generate Wikipedia-style multi-sentence summary paragraphs for movie actors. Although the descriptions in our case are much shorter, we adopted their model as a representative baseline for methods yielding multi-sentence summaries, as the tasks are similar in nature. NKLM also adopts a copy mechanism but the decision about whether to copy is made by a binary gating variable that is provided as an additional label by augmenting the dataset during training. By predicting whether the word to generate has an underlying fact or not, the model can generate such words by copying from the selected fact. On the contrary, our model decides to copy whenever a fact other than the mean fact is selected. We implemented and trained their model with the benchmark datasets. Their model also requires an alignment of descriptions to the underlying facts. Additionally, NKLM relies on pre-trained TransE [4] embeddings of objects and relations to obtain the fact embeddings that are provided as inputs to the model.

3.2 Dataset

For our experiments, we rely on two benchmark datasets, each of which consists of 10K entities with at least 5 facts and an English description. The first of these datasets, denoted as *WikiData10K-Imbalanced*, is the one used in Bhowmik & de Melo (2018) [3]. However, since the entities in that dataset were randomly sampled from the Wikidata RDF dump [7], the ontological types of the sampled entities have a long-tail distribution, while an overwhelming 69.17% of entities are instances of *human*. This highly skewed distribution makes the dataset biased towards a particular domain. To decrease the percentage of such entities in the dataset, we created a new dataset, *WikiData10K-OpenDomain*, in which the instances of

WikiFacts10k-OpenDomain		WikiFacts10k-Imbalanced	
Instance of	Pct.	Instance of	Pct.
human	11.45%	human	69.17%
painting	8.73%	painting	2.02%
commune of france	6.41%	commune of france	1.43%
film	6.27%	scientific article	1.36%
scientific article	5.56%	film	1.34%
encyclopedic article	3.30%	encyclopedic article	0.89%
asteroid	2.89%	asteroid	0.62%
taxon	2.58%	taxon	0.57%
album	2.19%	road	0.52%
road	2.02%	album	0.46%

Table 3: Frequency distribution of the top-10 domains in the two datasets.

human are downsampled to 11.45% to accommodate more instances of other ontological types as evinced by the frequency distribution in Table 3. These datasets, both available online[3], are split into training, dev., and test sets in a 80:10:10 ratio.

3.3 Metrics

Following previous work, we use the automatic evaluation metrics BLEU (1 - 4) [19], ROUGE-L [15], METEOR [13], and CIDEr [23] for a quantitative evaluation of the generated descriptions with respect to the ground truth descriptions provided in the benchmark data. These metrics are widely used in the literature for the evaluation of machine translation, text summarization, and image captioning. BLEU is a precision-focused metric, ROUGE-L is a recall-based metric, METEOR uses both precision and recall with more weight on recall than precision, and CIDEr considers TF-IDF-weighted n-gram similarities. Following standard practice, as in the official implementation[4], the raw scores for CIDEr are multiplied by a factor of 10 for better readability, yielding values in $[0, 10]$. For the same reason, following standard practice, the scores for other metrics are multiplied by 100, yielding scores in the range of $[0, 100]$. Note that typically these metrics rely on more than one human-written ground truth output per instance for evaluation. The lack of any alternative descriptions in the benchmark datasets implies that the generated descriptions are each evaluated on a single ground truth description. Additionally, these metrics take a very conservative approach in that they look for overlapping words, word alignment, longest common subsequence etc.

3.4 Experimental Setup

Our model and all other baselines are trained for a maximum 25 epochs. We report the results of the best performing models on the dev set. For NKLM and the dynamic memory-based generative model, we use the default hyper-parameter settings used by the authors. For NKLM, following the authors, we obtain the fact embeddings by concatenating the embeddings of object entity and relation that are obtained by using the TransE embedding model. For our model and the fact-to-sequence with attention baseline, we fix the embedding dimensions of facts and words to 100. The hidden layers of the GRU and the 2-layer feed-forward networks are 100-dimensional. We use Adam as our optimizer with a fixed learning rate of 0.001. We fix the maximum number of facts to 60 including the mean fact. For instances with less that 60 facts, we resort to a suitable masking to obtain the attention scores of the relevant facts. The maximum number of factual words for each fact is limited to 60.

We use the 1,000 most frequent words in the dataset as our default vocabulary. One can also consider using a much larger vocabulary of frequent English words. However, for our experiments we found it unnecessary. Still, because of this restricted vocabulary, our model may occasionally sparsely generate <UNK> tokens, which we remove from the generated description.

The datasets and the PyTorch implementations of all our experiments are available online.[5]

3.5 Results

Tables 1 and 2 provide the evaluation results of our model and the baselines on the WikiFacts10k-Imbalanced and WikiFacts10k-OpenDomain datasets, respectively. Our model outperforms the state-of-the-art dynamic memory-based generative model by more than 8 BLEU-4 points on the imbalanced dataset. We also observe 1 to 7 point gains on the scores across all other metrics. Similar trends are observed for the more challenging WikiFacts10k-OpenDomain dataset, in which our model improves upon the dynamic memory-based generative model by 12.2 points in terms of the BLEU-4 metric. For this dataset, we also observe 5 to 8 point gains across all other metrics. A substantial gain in the BLEU scores indicates that our model can generate longer sequences more accurately than the state-of-the-art model.

Furthermore, we observe that our attention-based fact-to-sequence model also outperforms the dynamic memory-based generative model in most of the metrics across both the datasets. This observation shows that one can do without a dynamic memory module for memorizing fact specific information. It turns out that a GRU-based architecture with an intelligently chosen encoding of the input and an extra skip-connection in the decoder has sufficient memory to retain fact-specific information required to generate words in the output.

The NKLM model by Ahn et al. obtains sub-par results on both datasets, particularly the WikiFacts10k-Imbalanced data, although the original paper focused on descriptions of humans. This shows that their method for generating a short text is unsuitable for our demanding task of generating very concise entity descriptions. Additionally, the pre-trained TransE embeddings required to obtain fact embeddings are not available for previously unseen entities in the test set, thus severely restricting the model's ability to cope with unknown entities.

3.6 Ablation Study

In addition to comparing our method against a number of competitive baselines, we perform a series of ablation studies to evaluate the effect of different components within our model. The results of these experiments are included in Tables 1 and 2.

[3] https://github.com/kingsaint/Wikidata-Descriptions
[4] https://github.com/vrama91/cider
[5] https://github.com/kingsaint/Wikidata-Descriptions

3.6.1 Without Positional Encoder. To understand the effect of the positional encoder, we replace the positional encoder with the average pooling of the constituent word embeddings of the facts to obtain the fact embeddings. The differences between the BLEU scores of our model and this ablated version indicates that the position of the words in the factual phrases indeed plays an important role in encoding a fact that provides a useful signal to the decoder.

3.6.2 Without Mean Fact. To understand the effect of mean fact in our model, we replace the mean fact with a fixed embedding vector of dimension d. The elements of this vector are sampled from a uniform distribution $\mathcal{U}(-\frac{1}{\sqrt{d}}, \frac{1}{\sqrt{d}})$ and do not change during training. The result of this experiment suggests that the role of the mean fact in our model is not of just that of a *sentinel* responsible for generating general vocabulary words. Rather, it encodes some useful semantic information that the model can exploit.

3.6.3 Copy Only. This experiment is an ablation study that we perform to understand how precisely a model can generate descriptions if it only copies factual words. This baseline is a restricted version of our model, in which the model never generates any general vocabulary word. The much inferior performance of this model shows that merely copying factual words to the output does not yield precise descriptions. This further demonstrates the importance of a model that dynamically decides whether to copy words from the input facts or instead emit general vocabulary words.

3.7 Parameter Efficiency

Model	#Parameters
Dynamic memory-based generative model	14,197,741
Fact2Seq w. Attention	14,159,561
Neural Knowledge Language Model (NKLM)	20,569,361
Our Model	979,986

Table 4: Comparison of the number of learnable parameters.

Table 4 shows the number of learnable parameters for our model as well as the baselines. Our model is 14x more parameter-efficient than the competitive baselines. As there are fewer parameters to learn, this drastically improves the average training time of the model as compared to the other baselines. The number of parameters depends on the vocabulary size of the output softmax layer and the input to the word embeddings. Reducing the size of the softmax vocabulary to the most frequent words and making the model copy fact-specific words directly from the input contributes to the parameter efficiency and faster training of the model.

3.8 Importance of Fact Alignment of Descriptions

The alignment of facts to the description teaches the model to choose the right fact for generating a factual word. As shown in Fig. 3, for each word of the generated description, our model precisely selects the relevant underlying fact. The NKLM also shows a similar effect. However, the dynamic memory-based generative model does not always pick the most relevant fact, although it might occasionally generate the right word due to the statistical co-occurrence of the words in the training set.

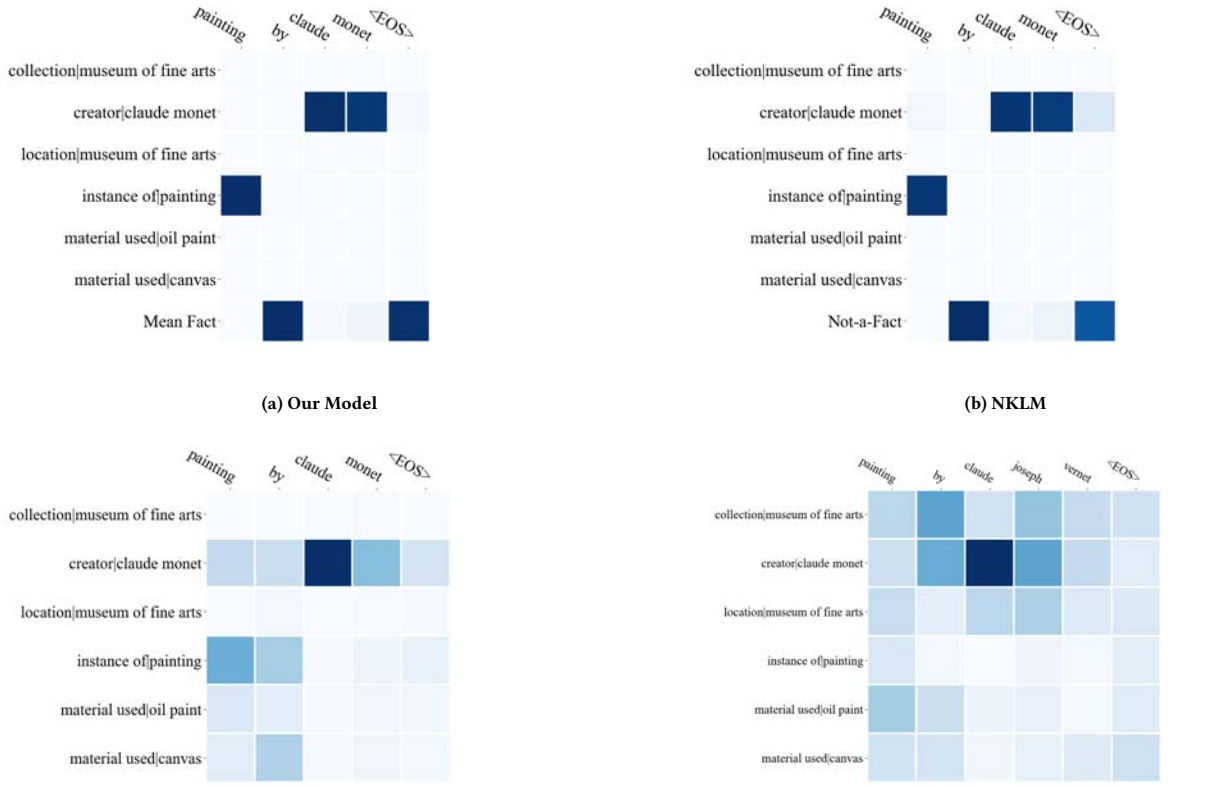
3.9 Significance of the Copy Mechanism

The copy mechanism enables our model to copy fact-specific rare or previously unseen words directly to the output sequence, generating factually correct descriptions. To demonstrate the positive effect of this copy mechanism, we select instances from a subset of 8 ontological types that tend to require explicit copying of factual words. This subset accounts for 19.6% of the test set. Table 6 shows some examples from this subset. We also perform an automatic evaluation on this subset and provide the results in Table 5. Both the models with copy mechanism significantly outperform the baselines lacking any explicit copy mechanism. These results demonstrate that a suitable copy mechanism generates far more precise open-domain descriptions.

4 RELATED WORK

In the following, we review previous research and describe how it differs from the task and approach we consider in this paper.

4.1 Text Generation from Structured Data



Lebret et al. [14] take Wikipedia infobox data as input and train a neural language model that, conditioned on occurrences of words in the input table, generates biographical sentences as output. In a similar vein, Ahn et al. [1] infused factual knowledge into an RNN-based language model to generate Wikipedia-style summary paragraphs of film actors. Similar to ours, their approach also uses a copy mechanism to copy specific words from the input facts to the description. However, these approaches are not directly compatible with our problem setting, which focuses on generating synoptic, rather than detailed multi-sentence descriptions. Additionally, in contrast to our setting, which requires dynamically considering a wide variety of domains and entity types, the previous studies consider just human biographies as a single domain. Our experiments show that our method substantially outperforms the approach by Ahn et al. on our task.

The WebNLG Challenge [8] is another task aiming at generating text from RDF triples. However, it differs quite substantially from the task we study in this paper, as it demands a textual verbalization of every single triple. Our task, in contrast, requires synthesizing a short synoptic description by precisely selecting the most relevant and distinctive facts from the set of all available facts about the entity.

Bhowmik and de Melo (2018) [3] introduced a dynamic memory-based neural architecture that generates type descriptions for Wikidata items. Although the study has similar aims as the present one, the approach proposed there mainly exploits the statistical co-occurrence of words in the target descriptions of the training data. In our experiments, we show that the dynamic memory method is unable to be precise in an open-domain setting, which may require invoking named entities such as *Ehime* for the example in Figure 1.

4.2 Referring Expression Generation

Referring Expression Generation (REG) is a subtask of Natural Language Generation (NLG) that focuses on the creation of noun

Table 7: Examples of generated descriptions for the Wikidata entities with missing descriptions.

phrases that identify specific entities. The task comprises two steps. The *content selection* subtask determines which set of properties distinguish the target entity, and the *linguistic realization* part defines how these properties are translated into natural language. There is a long history of research on generating referring expressions. In one of the recent approaches, Kutlak et al. [12] convert property–value pairs to text using a hand-crafted mapping scheme. However, their method requires specific templates for each domain. Applying template-based methods to open-domain knowledge bases is extremely challenging, as this would require too many different templates for different types of entities. Recently, Ferreira et al. [5] proposed an end-to-end neural approach to REG called NeuralREG. They used a delexicalized WebNLG corpus for the training and evaluation of their model. NeuralREG generates a delexicalized template of the referring expression.

4.3 Neural Text Summarization

Generating descriptions for entities is related to the task of text summarization in that the salience of information needs to be assessed [27]. Similar to abstractive summarization, our task requires the generation of words not seen in the inputs. At the same time, in a similar vein to extractive summarization, our task also requires a selection of words from input facts for copying to the output sequence. The surge of sequence-to-sequence language modeling via LSTMs naturally extends to the task of abstractive summarization by training a model to accept a longer sequence as input and learning to generate a shorter compressed sequence as a summary. To this end, Rush et al. [20] employed this idea to generate a short headline from the first sentence of a text. Recently, Liu et al. [16] presented a model that generates an entire Wikipedia article via a neural decoder component that performs abstractive summarization of multiple source documents. Our work differs from such previous work in that we do not consider a text sequence as input. Rather, our inputs are a series of property–value pairs deemed as facts.

4.4 Pointer Networks and Copy Mechanisms

In order to learn how to solve combinatorial optimization problems that involve output dictionaries of varying sizes, such as the traveling salesman problem, Vinyals et al. [24] proposed a deep neural architecture known as *Pointer Networks*. Such networks rely on an attention mechanism to repeatedly select elements from the input as output. Subsequent works [9, 10, 18] incorporated this idea into hybrid text-based sequence-to-sequence models that occasionally select words from the input and otherwise generate words from a regular output dictionary. This addresses how to cope with rare and unknown words in the desired output sequence, which constitutes one of the key challenges in deploying neural text generation in practice. Since it is not feasible to directly learn from existing examples how to generate all possible vocabulary words that might be needed in the output, oftentimes, it is easier to learn to directly select suitable words from the given input. See et al. [21] investigated the use of such architectures for the task of abstractive text summarization, so as to better cope with long input texts. As mentioned, Ahn et al. [1] rely on a similar copy mechanism to transform facts into summaries.

While our model adopts similar principles, there is a significant difference in our copy mechanism. In the above-mentioned existing works, the pointing and copying is a one-step process, in which a token within a context window is chosen based on simple attention weights. In our model, the pointing and copying is a two-step process. The model first needs to identify a pertinent fact that is salient enough to merit consideration. Then, within the chosen fact, it selects a suitable word for copying. The context window also varies depending on the number of facts and the number of words within a fact. In our experiments, we show that our approach greatly outperforms the model with copy mechanism proposed by Ahn et al.

5 CONCLUSION

Synoptic descriptions of entities provide end-users a near-instantaneous understanding of the identity of an entity. Generating such descriptions requires the selection of the most discernible facts and composing these facts into a coherent sequence. In this paper, we introduced a fact-to-sequence encoder–decoder model with a custom copy mechanism. Through an extensive evaluation, we have shown that our method consistently outperforms several competitive baselines on two benchmark datasets. Additional analysis also shows that our model can precisely choose facts and copy factual words effectively. The success of this novel architecture for generating concise descriptions suggests that it could be adapted for additional applications that may benefit from a repository of structured facts, e.g. dialogue systems and knowledge graph-driven question answering.

ABSTRACT

This paper provides an in-depth and diversified analysis of the Wikidata query logs, recently made publicly available. Although the usage of Wikidata queries has been the object of recent studies, our analysis of the query traffic reveals interesting and unforeseen findings concerning the usage, types of recursion, and the shape classification of complex recursive queries. Wikidata specific features combined with recursion let us identify a significant subset of the entire corpus that can be used by the community for further assessment. We considered and analyzed the queries across many different dimensions, such as the robotic and organic queries, the presence/absence of constants along with the correctly executed and timed out queries. A further investigation that we pursue in this paper is to find, given a query, a number of queries structurally similar to the given query. We provide a thorough characterization of the queries in terms of their expressive power, their topological structure and shape, along with a deeper understanding of the usage of recursion in these logs. We make the code for the analysis available as open source.

1 INTRODUCTION

Wikidata [31] is a free collaborative knowledge base that has been characterized by a gigantic growth in terms of number of edits, number of users and developers, and amount of automated software since its inception in 2012 by the Wikimedia Foundation. The interplay between user and bot activities on Wikidata is for instance an interesting subject to study in order to make sense of the quality of the newly added items produced by the massive numbers of edits in the knowledge base [27]. Contrarily to Wikidata data dumps, which are readily available and allow a flurry of analyses, the activity of both humans and bots on the Wikidata SPARQL endpoints can only be investigated since recently, thanks to the release of large anonymized query logs.[1] These query logs represent a rich swath of information about the robotic and organic query traffic on Wikidata and deserve our attention for further investigation, in particular to understand the structure of complex queries. A preliminary analysis of the Wikidata query logs bootstrapped with a recent paper by Malyshev et al. [20], who first introduced the Wikidata SPARQL service WDQS[2] and pinpointed its technical characteristics and current usage. They also provided a classification of the Wikidata queries into robotic and organic requests that we readily adopt in the present paper and that we recapitulate in Section 9. They made several observations on which we build in this paper, namely that robotic query traffic dominates organic query traffic in terms of volume and query load, and that robotic queries are issued by a single source whereas organic queries are typically multi-source. They also identified a massive presence of recursive queries in these logs, whose prominent fragment consists of queries only containing joins and property paths,[3] also known as conjunctive 2-way regular path queries (C2RPQs) in the literature. These massive logs of recursive queries are the first encountered so far, as opposed to negligible percentages of these queries in previous large-scale logs, including DBpedia queries [9].

C2RPQs are the basic building blocks of graph query languages in the literature of RDF and graph databases. They allow to express navigational patterns on the graph instances by leveraging regular expressions, also known as Property Paths in the SPARQL 1.1 specification [15]. In Wikidata, they are particularly important since they emulate ontological reasoning in SPARQL and also express complex label-constrained reachability queries.

We focus our analysis on these recursive queries in the Wikidata logs and further extend the class of C2RPQs by incorporating the use of Service, Values, Bind, Filter, and Optional. Indeed, Service, Values, and Bind occurred only rarely in other massive logs [9] but are very prominent here. This fragment, which we call C2RPQ+, constitutes more than 85% of the valid queries in the logs.[4] The consideration of this fragment leads us to redesign many tests conducted in [9], among which the triple count and shape analysis, which were based on the less expressive *conjunctive queries*.

Although the distinction between robotic and organic query traffic has been introduced in [20], it has never been used in the

[1] Accompanying the publication by Malyshev et al. [20], the Knowledge-Based Systems Group at TU Dresden released anonymised logs of several hundred million SPARQL queries from the Wikidata SPARQL endpoint [6].
[2] Whose user interface can be found at https://query.wikidata.org/, while the raw SPARQL endpoint is at https://query.wikidata.org/sparql
[3] After removal of subqueries that correspond to Wikidata's labeling service. They also allow the use of Values, which indeed can be done to some extent, see Section 6.
[4] In fact, the 85% only refers to a subfragment that is *suitable for graph shape analysis.*

complex analysis that we carry out in this paper regarding the types of property paths, the computation of triples when property paths are present and the shape analysis of the C2RPQ+ fragment. We also provide a view from rather different angles of these logs by considering them with or without duplicates and by separating the analysis of successfully executed and timeout queries, the latter being analyzed for the first time in our study. We also developed a query similarity search tool capable of identifying from an initial query the set of structurally similar queries by using tree-edit distance. This tool allows to further inspect the logs by having a specific query in mind and in a sense permits to reproduce and reapply the previous complex analysis to the obtained sets for future studies.

We focus in this study on the following research questions: What is the distribution of query sizes? Which qualifiers are popular in queries? How are property paths used and what is their structure? How prominent are conjunctive queries (and variants thereof)? What is the shape and (hyper)treewidth of queries? Given a query, can we find in a subset of the logs the queries that are structurally similar to it? Furthermore, we are also interested in meta-questions, such as: Are there differences between robotic and organic queries? Does a comparison with an earlier study [9] allow us to identify some trends?

As a general remark, our study is significantly more extensive than what we can present in this paper. Our code for the analysis is publicly available [11].

2 DATA SETS

Our corpus consists of all queries in the Wikidata query logs that were recently made publicly available [6]. Precisely, the queries considered in this paper have been downloaded on October 12th, 2018. These logs are anonymized and represent queries that were submitted to the Wikidata SPARQL endpoint from June 12th until September 3rd in 2017. The same queries have been considered in the work of Malyshev et al. [20], as discussed in Section 1. We have partitioned these log files in four disjoint sets: queries for which the HTTP request was successful[5], further partitioned in organic (OrganicOK) and robotic queries (RoboticOK); and timeout queries, further partitioned in organic (OrganicTO) and robotic queries (RoboticTO).

Each query in the downloadable log files has an annotation that indicates if it was classified as a bot or user query by Malyshev et al. [20]. We used the same classification.[6] Sometimes we use OK, (resp., TO) to refer to OrganicOK ∪ RoboticOK (resp., OrganicTO ∪ RoboticTO) for brevity. The TO queries have not been considered in the work of Malyshev et al. [20].

Table 1 describes, for each of the log types, its number of queries (Total #Q), number of valid queries, i.e., queries that parse using Apache Jena 3.7.0 (Valid #Q), and the number of valid queries after removal of duplicates (Unique #Q). For duplicate removal, we considered two queries to be the same if they are the same string after whitespace removal.

[5]HTTP code 200.

[6]Our number of queries in Organic is slightly higher than the number of queries reported on the download page of the query logs. We believe that the Dresden file may be incomplete, since we found organic queries in the "all queries" log files that do not show up in the organic subset in [6].

Table 1: The query logs in our corpus

Source	*Total #Q*	*Valid #Q*	*Unique #Q*
RoboticOK	207,505,296	207,464,954	34,523,883
OrganicOK	661,769	651,385	251,994
RoboticTO	33,616	33,465	3,168
OrganicTO	14,528	14,087	8,729
Robotic	207,538,912	207,498,419	34,527,051
Organic	676,297	665,472	260,723
OK	208,167,065	208,116,339	34,775,877
TO	48,144	47,552	11,897
Total	208,215,209	208,163,891	34,787,774

Table 2: Distribution of Select, Ask, Construct, and Describe

		Valid #Q	*Valid %*	*Unique #Q*	*Unique %*
Select	Robotic	206,006,783	99.28%	34,261,882	99.23%
	Organic	664,323	99.83%	260,114	99.77%
Ask	Robotic	1,127,396	0.54%	73,019	0.21%
	Organic	306	0.05%	132	0.05%
Construct	Robotic	188,088	0.09%	24,587	0.07%
	Organic	516	0.08%	217	0.08%
Describe	Robotic	176,152	0.08%	167,563	0.49%
	Organic	327	0.05%	260	0.10%

Throughout the entire paper, we will use the following notation to discuss data sets. Whenever we report a number or a percentage in the format X (Y), the number X refers to the Valid and the number Y refers to the Unique sets of queries. This notation allows the reader to stay informed throughout the paper about the queries that the endpoint actually receives (Valid) and about those without duplicates in this set (Unique).

Already from Table 1 we can make a number of interesting observations. One simple observation is that the robotic logs contain many more duplicates than the organic logs. Indeed, whereas Organic contains 39.18% unique queries, Robotic only contains 16.64% unique queries. A second observation is that, even though queries do not timeout very often, organic queries time out 100 times more often than robotic queries. The fraction of OrganicTO queries to Organic queries is 2.12% (3.35%), whereas the fraction of RoboticTO to Robotic queries is 0.02% (0.01%). In the set of *unique* timeout queries, a whopping 73.37% are organic.

Data Sets for Analysis. We noticed that almost all Describe queries do not have a body. For this reason, and because Describe queries do not have a well-defined semantics, we solely focus from now on in the paper on the Select, Ask, and Construct queries. This subset of the corpus has 207,987,412 valid queries, 34,619,951 of which are unique. The robotic subset contains 207,322,267 (34,359,488) and the organic subset contains 665,145 (260,463) queries. In all cases, these sets encompass more than 99.5% of the total sets in Table 1, see Table 2.

3 BASIC DEFINITIONS

We assume familiarity with SPARQL, but recall the very basics of the language. The presentation of the following definitions is strongly based on Picalausa and Vansummeren [26] and Bonifati et al. [9]. A *SPARQL query Q* can be seen as a tuple of the form

(*query-type*, *pattern P*, *solution-modifier*).

Here, *query-type* is one of Select, Ask, Construct, and Describe. The *pattern* is the central component of the query, which we will discuss in more detail next, and the *solution-modifier* is for performing aggregation, grouping, sorting, duplicate removal, and returning only a specific window (e.g., the first ten) of the solutions returned by the pattern.

Patterns. By $\mathcal{I}$, $\mathcal{B}$, and $\mathcal{L}$ we denote the sets of *IRIs*, *blank nodes*, and *literals* from SPARQL, respectively. Let $\mathcal{V} = \{?x, ?y, ?z, ?x_1, \ldots\}$ be an infinite set of variables, disjoint from $\mathcal{I}$, $\mathcal{B}$, and $\mathcal{L}$. As in SPARQL, we always prefix variables by a question mark. A *triple pattern* is an element of $(\mathcal{I} \cup \mathcal{B} \cup \mathcal{V}) \times (\mathcal{I} \cup \mathcal{V}) \times (\mathcal{I} \cup \mathcal{B} \cup \mathcal{L} \cup \mathcal{V})$. A *property path* is a regular expression over the alphabet $\mathcal{I}$. A *property path pattern* is an element of $(\mathcal{I} \cup \mathcal{B} \cup \mathcal{V}) \times pp \times (\mathcal{I} \cup \mathcal{B} \cup \mathcal{L} \cup \mathcal{V})$, where pp is a property path. A *SPARQL pattern* P is an expression generated from the following grammar:

$$P ::= \quad t \mid pp \mid Q \mid P_1 \text{ And } P_2 \mid P \text{ Filter } R \mid P_1 \text{ Union } P_2 \mid P_1 \text{ Optional } P_2 \mid \text{Bind } X \text{ AS } v \mid \text{Service } sPR \mid \text{Values } tup\ T$$

Here, t is a triple pattern, pp is a property path pattern, Q is again a SPARQL query, and R is a so-called *SPARQL filter constraint*. SPARQL filter constraints R are built-in conditions which can have a SPARQL query predicate is equalled *SPARQL filter constraint*. SPARQL filter constraints R are built-in conditions which can have unary predicates, (in)equalities between variables, and Boolean combinations thereof. Bind associates a unary expression to a single variable v. Service calls a remote service with name n and sends it a pattern P. Finally, Values binds a tuple tup to values in a given table T. We note that property paths (pp) and subqueries (Q) in the above grammar are new features since SPARQL 1.1. We refer to the SPARQL 1.1 recommendation [16] and the literature [26] for the precise syntax of filter constraints and the semantics of SPARQL queries. We write $vars(P)$ to denote the set of variables occurring in P.

We illustrate by example how parts of our definition correspond to real SPARQL queries. The following query comes from Wikidata ("Locations of archaeological sites", from [32]).

```
SELECT ?label ?coord ?subj
WHERE
{ ?subj wdt:P31/wdt:P279* wd:Q839954 .
  ?subj wdt:P625 ?coord .
  ?subj rdfs:label ?label FILTER(lang(?label)="en") }
```

The query uses the property path `wdt:P31/wdt:P279*`, the literal `wd:Q839954`, and the triple pattern `?subj wdt:P625 ?coord`. It also uses a filter constraint. In SPARQL, the And operator is denoted by a dot (and is sometimes implicit in alternative, even more succinct syntax).

4 QUERY SIZES AND OTHER COUNTING MEASURES

We report in Figure 1 the distribution of length of the queries in terms of the number of their triples. Contrarily to other triple count distributions reported in previous studies, we explicitly focus here on triple counts that include property paths. The reason is that a property path pattern of the form `?x wdt:P31/wdt:P279* ?y` is a shorthand notation for *two* triples and we feel that it should be considered as such. We therefore count property path patterns as follows. Let pp be a property path encoded as a regular expression. We say that the *size* of pp is the number of alphabet symbols in the regular expression. For example, the property path wdt:P279/wdt:P279 has size two. The query illustrated in Section 3 contains two triples of size one and one triple of size two.[7]

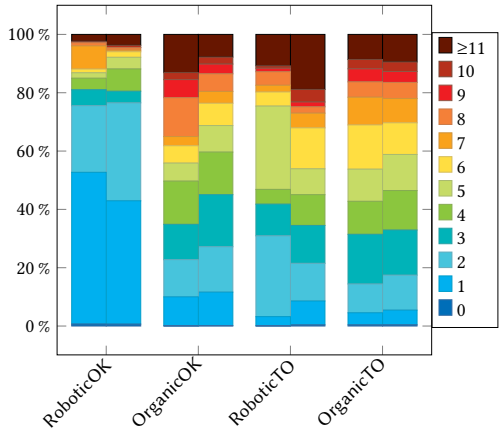

Figure 1: Percentages of queries with corresponding sizes (number of triples plus sizes of property paths) for each dataset – Valid (left) versus Unique (right). The sizes are reported on the right-hand side and range from 0 to ≥ 11.

We analyzed here the triples and property paths inside the Select, Ask, and Construct clauses and explicitly exclude the queries with a Describe clause, as discussed in Section 2. The results for the four data sets can be found in Figure 1. Here, each bar is split in two, where the left side represents the Valid and the right side the Unique version of each data set.

The conclusions of this specific analysis are similar to those made in previous work [7, 20], assessing that user queries are more diverse than robotic ones. Nevertheless, the triple count distributions shown in Figure 1 shows the breakdown in terms of the other dimensions considered in our analysis, encompassing the valid and unique queries and the OK and timeout queries. The timeout queries for instance show a relatively higher complexity in terms of number of triples than the OK ones, and this observation also applies to RoboticTO queries, that are thus quite different from RoboticOK queries. This seems to suggest that timeout queries are queries that failed because of a higher number of triples, which could be interesting to consider in graph query evaluation and optimization studies. The information about the average number of triples confirmed this, since Valid queries have on average 2.58 (2.65) triples, whereas timeout queries have 5.65 (5.94) triples. As a side remark, the highest number of triples that we observed is in the RoboticOK Valid logs and is equal to 67, which was found in 68 queries (in 34 queries in the RoboticOK Valid logs, respectively). The largest size of a property path triple was 19.

Number of Constants and Variables. Counting the number of triples is only one possible measure of the complexity of a query. We enrich this analysis by considering further characteristics of the triples, i.e., whether the triples contain variables or constants. This information is useful for the shape analysis that we conduct in Section 6, in which we show actual differentiations in the obtained shapes by removing or including the constants. We only count the

[7] Notice that the query size computed as described above even with Kleene-star ('*') and transitive closure operators ('+') does not depend on the length of the actual paths in the graph instance when evaluating the query.

queries with these numbers of constants are more abundant than
queries with these numbers of variables.

Usage of Wikidata Properties. We then analyzed the organicOK Unique query logs in order to get a feel of the usage of different Wikidata properties (P856, P31,…) appearing in the queries. The total number of properties found in these logs are 881,490. These are divided into two major namespaces at a top level: `www.wikidata.org` (805,196), and `www.w3.org` (70,829). We report in Figure 2 a sunburst diagram showing the segmentation of the Wikidata properties inside the largest top-level namespace qualifier `www.wikidata.org`. In order to avoid clutter and for ease of presentation in the paper, we have solely annotated the sunburst with the properties whose occurrences are above a given threshold (6,000). More views about the sunburst including the other top-level properties and with complete information about all the number of occurrences, is available via an interactive version of the diagram [29]. Hovering over the various segments of the rings provides the information omitted here in order to avoid clutter in Figure 2.

Subqueries and Projection. Roughly 1% of the queries in the Unique Logs use subqueries. This number goes down to 0.37% for the corresponding subqueries in the Valid logs.

We also ran a test for mining the number of queries that use projection. Projection is a cause of complexity increase of query evaluation for CQ queries, that goes from NP-complete is projection is present to PTIME if projection is absent [5, 18]. Similarly to [9] we use the test for projection in Section 18.2.1 in the SPARQL 1.1 recommendation [15]. Out of the valid queries from Table 2, we found 25,569,947 (12.28%) queries that use projection.[8] Out of the valid Organic queries as reported in Table 2, the amount of queries with projection even rises to 28.85%. These percentages become 18.01% and 28.05% for the unique valid and Organic queries, respectively. In particular, they are much higher than the 13.12% Select/Ask queries found within the Unique query logs of the DBpedia corpus in [9].

[8]This is a lower bound, since our test is sound but incomplete.

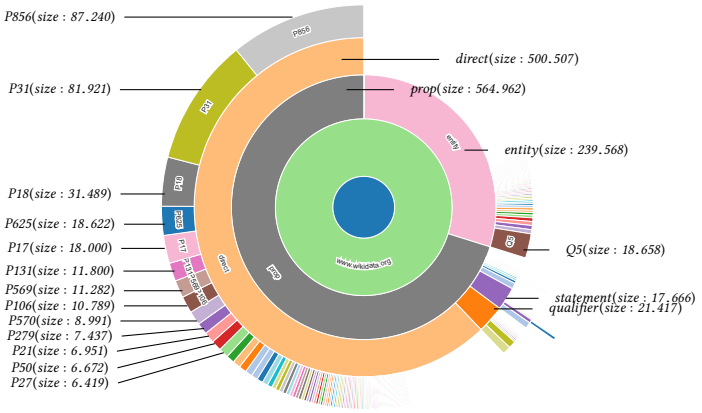

Figure 2: Sunburst distribution of the property qualifiers in Wikidata queries (Unique OrganicOK query logs.). An interactive version is available online at [29].

5 PROPERTY PATH ANALYSIS

Overall, 49,971,258 (13,480,433) queries in our logs use property paths, which amounts to a total of 24.03% (38.94%) of the entire logs. In these queries, we found 165,343 (82,764) property paths in organic queries and 55,168,101 (14,106,489) in robotic ones. (Notice that the same query can contain multiple property paths.) This massive corpus of property paths is the first encountered so far, and significantly (57x) greater than the one found in a large corpus in [9] featuring only 247,404 property paths.

Both organic and robotic property path corpuses are interesting for an analytical study and deserve a deeper inspection in order to classify the occurring path expressions into distinct types. Indeed, when we looked at the *structure* of these path expressions, we found 234 different types of organic expressions, compared to only 64 types of robotic expressions. Such a thorough classification revealed the different characteristics of the organic property paths with respect to the robotic ones, as the former exhibit more variety and heterogeneity than the latter despite their lower occurrences. Here, the *type* of a property path is obtained as follows. We replace each variable or IRI by letters from the alphabet in increasing order. (If a variable or IRI is repeated in the property path, we replace it by the same alphabet letter.) For example, `wdt:P31*/wdt:P279*` is of the type a^*b^* and `wdt:P31/wdt:P31*/wdt:P279*` is of the type aa^*b^*.

Robotic Property Paths. Table 4 contains a summary of the most common types of property paths in robotic queries. The columns with "V" represent results for the *Valid* queries, and the columns with "U" for the *Unique* queries. For succinctness, we aggregated different types together. For example, we aggregated each type with its reverse type. For instance, the row for ab^* also contains the expressions of the form a^*b. Furthermore, we treated $\hat{}a$ ("follow an a-edge in reverse direction") the same as a single label.[9] Finally, we also grouped disjunctions together, denoted by capital letters. In Table 4, a capital letter A denotes a subexpression that matches

[9]The operator $\hat{}$ is used in 0.80% (1.10%) of robotic and 2.03% (3.18%) of organic queries.

Table 4: Structure of property paths for all robotic queries

Expression Type	*AbsoluteV*	*RelativeV*	*AbsoluteU*	*RelativeU*
a^*	27,850,487	50.48%	1,392,865	9.87%
ab^*, a^+	9,417,166	17.07%	2,816,134	19.96%
ab^*c^*	823,153	1.49%	67,502	0.48%

ab^*c	122,286	0.22%	1,680	0.01%
a^*b^*	62,784	0.11%	608	
abc^*	27,287	0.05%	4,083	0.03%
$a?b^*$	15,893	0.03%	11,999	0.09%
A^+	4,674	0.01%	2,043	0.01%
Ab^*	1,562		674	
Other transitive	1,643		161	
$a_1 \cdots a_k$	13,382,005	24.26%	9,368,442	66.41%
A	3,043,725	5.52%	381,434	2.70%
$A?$	31,150	0.06%	296	
$a_1a_2? \cdots a_k?$	25,872	0.05%	5,940	0.04%
$\hat{}a$	21,202	0.04%	471	
$abc?$	7,620	0.01%	8	
Other non-transitive	697		289	
Total	55,168,101	100%	14,106,489	100%

a *disjunction of at least two symbols*. Empirically, an A either denotes an expression of the form $!a$, $(a|!a)$, or a disjunction of the form $(a_1|\cdots|a_k)$ with $k > 1$. We divided Table 4 into *transitive expressions* (top) and *non-transitive expressions* (bottom). Transitive expressions are those that match arbitrarily long paths (i.e., they use the operators * or $^+$). The empty cells represent values that round down to 0.00%.

Interestingly, we see significant differences between the numbers of expressions in the valid and in the unique sets. Whereas the type a^* accounts for 50.48% of the expressions in the valid data set, this drops to 9.87% in the unique set. On the other hand, concatenations of symbols (type $a_1 \cdots a_k$) represent 24.26% in the valid queries, but over 66% in the unique queries. To further understand this phenomenon, we focused on the valid RoboticOK and OrganicOK and computed the most popular 20 queries containing a property path with Kleene-star. The top most popular robotic query with property paths (having 281,096 occurrences) belong to the second most occurring type in Table 4 since it contains a single path expression of the kind `wdt:P31/wdt:P279`*. The query is in fact a *conjunctive regular path query*. [10]

Organic Property Paths. Table 5 contains results on the Organic datasets. Since we had 234 different types of expressions, we needed to aggregate more aggressively to make the results presentable. We grouped the types into 41 different categories, from which we omitted some in the table due to space restrictions. The main difference with Table 4 is that we also allow a capital letter to denote a single symbol. So, A can denote expressions equivalent to a, $(a_1|\cdots|a_k)$, $!a$, or $(!a|a)$. The other difference is that we grouped the types $(ab)^*$ and $a(bc)^*$ together in the type $\sim(ab)^*$. These expressions stand out from the rest, since they are the *only* type of transitive expressions we found that put length constraints on arbitrarily long paths. Indeed, all other transitive expressions allow paths of arbitrary length, once the length exceeds a certain value. This is not the case for $(ab)^*$, since it only allows paths of even length.

[10] By looking at the top most popular organic query (with 1,778 occurrences), we noticed that it belongs to the first most occurring type in Table 5 and exhibits the same single path expression. As a side remark, we can notice that the latter query is fairly more complex and uses Union, Filter, Bind, and Service clauses.

Table 5: Structure of property paths for all organic queries

Expression Type	*AbsoluteV*	*RelativeV*	*AbsoluteU*	*RelativeU*
AB^*	57,913	35.03%	28,034	33.87%
A^*	41,777	25.27%	22,071	26.67%

a^*b^*	3,330	2.01%	849	1.03%
ab^*c^*	2,704	1.64%	1,172	1.42%
$a^*B_1?b_2? \cdots b_k?$	1,789	1.08%	422	0.51%
$ab\|c^*d$	1,514	0.92%	534	0.65%
$a^*\|b^*$	347	0.21%	253	0.31%
$abCD^*$	283	0.17%	219	0.26%
ab^*c	113	0.07%	90	0.11%
$a^*\|B$	102	0.06%	76	0.09%
$\sim(ab)^*$	101	0.06%	82	0.10%
ab^*c^*d	86	0.05%	72	0.09%
$ab^*\|c$	70	0.04%	59	0.07%
$a^*b?c$	56	0.03%	27	0.03%
$a^*b^*c^*$	32	0.02%	28	0.03%
$ab^*\|b^+a^*$	16	0.01%	12	0.01%
ab^+c	13	0.01%	12	0.01%
$ab^*\|cd^*$	13	0.01%	12	0.01%
a^*bc^*	11	0.01%	11	0.01%
Other transitive	22	0.01%	20	0.02%
$A_1a_2 \cdots a_k$	31,032	18.77%	15,754	19.03%
A	13,248	8.01%	7,592	9.17%
$a_1? \cdots a_k?$	1,938	1.17%	1,470	1.78%
$A?$	1,178	0.71%	302	0.36%
$ab_1? \cdots b_k?$	1,117	0.68%	529	0.64%
$ab\|c$	27	0.02%	5	0.01%
Other non-transitive	14	0.01%	13	0.02%
total	165,343	100.00%	82,764	100.00%

Here, the percentages in the unique sets are quite similar to those in the valid sets. The Organic queries generally contain more challenging property paths to evaluate. On average, organic property paths are also larger than robotic ones. They contain 2.07 (2.01) literals on average, whereas robotic property paths only contain 1.49 (1.89) literals on average. There were even expression types which occurred more often in the TO (timeout) logs than in the OK logs, such as $\sim(ab)^*$. This is interesting, because such expressions are known to be complex (NP-complete) to evaluate under simple path semantics [3].

Additional Insights on Wikidata Property Paths. We conclude the section with a discussion of the differences between Tables 4 and 5 and the results of the property path analysis by Bonifati et al. [9]. The remarkable difference between the present study and the former (which was done on a corpus mainly consisting of DBPedia queries) is that here, a much larger fraction of the queries use property paths. This is probably due to the peculiar characteristics of the Wikidata data. Property paths are often used in queries performing class navigation in Wikidata and emulating ontological reasoning. Wikidata has relatively long paths in the data that are labeled with the same label (and that are popular to query, e.g., InstanceOf paths), whereas DBpedia has comparably shorter paths and is more flat.

The remarkable similarity, however, is in the *structure* of the property paths. Martens and Trautner [21] defined the class of *simple transitive expressions*, which are syntactically very restricted, but covered over 99% of the property paths in the corpus of Bonifati et al. [9]. In our corpus, 1.61% (0.48%) of the robotic and 3.83% (2.72%) of the organic property paths are not simple transitive expressions. The most significant reason why property paths fall out of this

Figure 3: Visualization of a query as a graph

fragment is the use of a^*b^* as a subexpression, whereas simple transitive expressions only use one subexpression with Kleene star.

Furthermore, all property paths except 198 (98) are in C_{tract}, which is a broader class introduced by Bagan et al. [3] and which precisely characterizes the set of regular expressions for which the data complexity under simple path semantics is tractable if P ≠ NP.

6 STRUCTURAL ANALYSIS AND RECURSIVE PROPERTIES

Consider the following query, which searches the occupations (P106) of Voltaire (Q9068), and returns the place (P19) and country (P17) of birth.

```
SELECT * WHERE { wd:Q9068 wdt:P19 ?var1 . ?var1 wdt:P17 ?var2
               . wd:Q9068 wdt:P106 ?var3 }
```

This query can be visualized as a graph, see Figure 3. Answering the query essentially boils down to matching this graph in the data and returning answers for each such match.

This query is an example of a *conjunctive query*, i.e., a query that only uses the And operator. For conjunctive queries, there is an extensive body of research that correlates the shape of the graph with the complexity of their evaluation problem (see, e.g., [10, 13, 17, 33]). In particular, *cycles* in the graph play a major role. In general, conjunctive query evaluation is well known to be NP-complete. On an intuitive level, the reason is that, if a conjunctive query has the shape of a k-clique (which is heavily cyclic), deciding if it returns a non-empty result is equivalent to deciding if the data has a k-clique, which is NP-complete. On the other hand, using Yannakakis' algorithm, we can evaluate *acyclic* conjunctive queries in polynomial time [33].

It is known that even a single cycle can have a significant impact on the run-time of queries [9, 16]. Therefore, for queries that behave similar to conjunctive queries, the shape of their graph is important for understanding their complexity. Furthermore, it gives useful insights on the structure of real queries.

In the following, we will define the *graph shape* of several kinds of queries. We focus exclusively on queries that behave similar to conjunctive queries and for which the cyclicity of the graph shape correlates with the complexity of the evaluation. We start by considering conjunctive queries and add other operators one by one.

Bonifati et al. [9] performed a graph shape analysis on the queries in their corpus, but the corpus does not provide much insight for Wikidata, because it only included 308 Wikidata queries. Furthermore, they only considered shapes of conjunctive queries, extended with (safe use of) Filter and Optional.[11] Since only 25.89% (42.48%) of our robotic and 17.89% (21.15%) of our organic queries are eligible for such an analysis, we extended the analysis to incorporate (the safe use of) four extra features: property paths, Bind, Values, and Service. By doing so, we were able to make the analysis applicable to *2 to 3 times more queries in every fragment*, that is, 85.22% (88.39%) of the robotic and 51.50% (65.22%) of the organic queries. Notice that the queries thereby obtained are not merely subsets of the queries that use a given set of keywords. This obviously implies that the shape test is more sophisticated than the keyword test. We explain how we deal with each keyword separately in Sections 6.2–6.4.

[11] By *safe use* we refer to the use of these operators so that the queries still behave similar to conjunctive queries.

6.1 Graph Patterns and Canonical Graphs

In the following we want to define the *graphs* of different types of queries. These graphs will be undirected, that is, $G = (V, E)$ where V is its (finite) set of nodes and E is its set of edges, where an edge e is a set of one or two nodes, i.e., $e \subseteq V$ and $|e| = 1$ or $|e| = 2$.

We need to determine which queries can be adequately represented as graphs. Since graphs are node pairs and SPARQL queries have triple patterns, we need to be careful with the use of variables in the predicate position. In our corpus, 91.68% (96.43%) of the queries only use triple patterns (s, p, o) where p is an IRI, so these queries can be adequately represented as graphs. We also allow $p \in$ Vars if p is not used elsewhere in the query (in this case, p serves as a wildcard, possibly binding to a value that is returned to the output.). We call such patterns *graph patterns*.

The *canonical graph* of a graph pattern P is the graph $G_P = (V_P, E_P)$ with $E_P = \{\{x, y\} \mid (x, \ell, y)$ is a triple pattern in P and $\ell \in \mathcal{I} \cup \mathcal{V}\}$ and $V_P = \{x \mid (x, \ell, y) \in E_P$ or $(y, \ell, x) \in E_P\}$.

6.2 Conjunctive Queries

Conjunctive queries are the basic building blocks of our shape analysis. In the context of SPARQL, we define them as follows.

Definition 6.1. A *conjunctive query (CQ)* is a SPARQL pattern that only uses the triple patterns and the operator And.

In our corpus, 20.88% (33.69%) of the queries are CQs, which is quite low compared to the study of Bonifati et al. [9]. Part of the reason is that Wikidata queries extensively use Service, most commonly for Wikidata's labeling service [7]. In our logs, 8.38% (12.94%) of the queries use Service in some way.

The good news is that 99.97% (99.997%) of the CQs are graph patterns. We call such CQs *eligible* for graph shape analysis. We note that it is also possible to investigate the shape (or cyclicity) of non-eligible CQs, but we need to consider their *hypergraphs*, see Section 7.

The importance of the shape of conjunctive queries becomes clear in the following result, linking the *treewidth (tw)* of the query's graph to the complexity of query evaluation. The precise definition of treewidth is not important for the paper but, intuitively, treewidth measures *how close the graph is to a tree*. For instance, a tree has treewidth 1 and a k-clique (which is very cyclic) has treewidth k. Queries with tw = 1 are also called *acyclic*.

Theorem 6.2 (cfr. [10, 13, 17]). *Let G be a graph and Q an eligible conjunctive query for which the canonical graph has treewith k. Then it can be tested in time $|G|^{O(k)}|Q|^{O(k)}$ if Q returns a non-empty result on G.*

6.3 Adding Filter and Optional

Bonifati et al. [9] investigated the structure of graph patterns that only use the operators And, Optional, and Filter. In our corpus, 27.72% (44.24%) of the queries are in this fragment. Our extension of CQs with Filter and Optional is very similar to the one of Bonifati et al., that is, we focus on *well-designed* patterns (cf. [25]) with *interface width 1* (cf. [4]). Our main difference is that we now allow binary filter constraints to be edges in the graph.

6.4 Adding Recursion, Bind, Service, and Values

Although the previous tests already classify 53,804,198 (14,649,616) queries to be eligible for graph shape analysis, this is still only 25.87% (42.32%) of our queries. We now discuss how property paths (recursion), Bind, Service, and Values can be incorporated to increase the number of suitable queries to 177,022,071 (30,540,864), or 85.11% (88.22%) of the logs.

Property paths are unproblematic. Conjunctive queries extended with property paths closely correspond to the well known *conjunctive two-way regular path queries (C2RPQs)*, which form a basis of navigational query languages for graphs. Indeed, property paths are very closely related to regular path queries and, due to the ˆ-operator, they can navigate edges in both forward and backward direction, which makes them *two-way*. Although there are some semantical differences between two-way regular path queries and property paths [1, 15, 19], these differences are not crucial for the present analysis.

Definition 6.3. A *conjunctive two-way regular path query (C2RPQ)* is a SPARQL pattern that only uses triple patterns, the operator And, and property paths.

Every C2RPQ that is a graph pattern is suitable. The *graph of a C2RPQ* P is obtained from G_P by adding the edges $\{\{x, y\} \mid (x, pp, y)$ is a property path pattern in $P\}$ to E_P (and adding nodes to V_P if necessary).

Adding Filter and Optional to C2RPQs is analogous to adding them to CQs. The resulting classes of queries are referred to as C2RPQ_F and C2RPQ_OF. As such, we obtain that 46.03% (76.44%) of our queries are C2RPQ_OF queries that are suitable for graph shape analysis.

Concerning Bind, we follow a similar approach to Filter. We call a Bind-condition k-ary if it involves k variables. Unary and binary Bind-conditions are considered to be suitable for graph analysis and are materialized as edges in the graph. Higher-arity Bind-conditions are considered in Section 7.

Values-constructs are essentially used to test if a tuple of variables is in a given set. For instance, the subquery

```
VALUES (?book ?title)
{ (:book1 "Robin Hood")
  (:book2 "Little Red Riding Hood") }
```

emposes a binary constraint and is satisfied when the pair of variables (?book, ?title) can be bound to one of the pairs in the body. In the query corpus, it is used almost exclusively for unary conditions, that is, to test if the value of a single variable is in a given set of constants. We therefore also treat Values similar to Filter and Bind. That is, we call a Values block k-ary if there is a k-ary tuple following the Values keyword. Unary and binary Values subqueries are suitable for graph shape analysis and we extend the graph with an edge for each binary Values constraint. Again, higher arity Values conditions are considered in Section 7.

Service is used extensively in Wikidata queries, most commonly for Wikidata's labeling service. For this reason, Bielefeldt et al. [7] ignore the labeling service entirely in their co-occurrence analysis of SPARQL features. Similarly to before, we say that a Service subquery S is k-ary if it contains k variables. All unary or binary Service subqueries are suitable for graph analysis. When we consider the graph of patterns with Service, we add edges of the form $\{x, y\}$ for all binary Service subqueries, in which x and y are the variables. Higher arity Values conditions are considered in Section 7.

By C2RPQ+ we denote the entire fragment that uses And, Optional, Filter, property paths, Bind, Service, and Values and that is suitable for graph analysis. In total, this amounts to 176,679,495 (30,371,003) robotic and 342,576 (169,861) organic queries, which make up 85.22% (88.39%) and 51.50% (65.22%) of the robotic and organic queries, respectively.

6.5 The Set of Shape Analysis Experiments

We have analyzed the graphs of 8 fragments of queries, namely CQ, C2RPQ, CQ_F, C2RPQ_F, CQ_OF, C2RPQ_OF, $\text{CQ}_{\text{OF+}}$, and C2RPQ+. All fragments were analyzed across three dimensions: *robotic* versus *organic*, *Valid* versus *Unique*, and *with constants* versus *without constants*. In the analyses without constants, we removed all nodes in the graphs that originated from IRIs or literals.[12] Furthermore, for all fragments, we analyzed the time-out (TO) queries separately from the others (OK). This results in 64 separate runs of the shape analysis.

We classified the graphs of queries into the following set of shapes, inspired by [9]. A *chain (of length k)* is graph that is isomorphic to the undirected graph with edges $\{x_0, x_1\}, \{x_1, x_2\}, \ldots, \{x_{k-1}, x_k\}$. As an edge case, we allow chains of length zero, i.e., a single node. A *chain set* is a graph in which every connected component is a chain.

A *tree* is a nonempty undirected graph such that, for every pair of nodes x and y, there exists exactly one undirected path from x to y. A *forest* is a nonempty graph in which every connected component is a tree.

A *star* is a tree for which there exists at most one node with more than two neighbors. Hence, every chain is a star.

We also recall the definition of *flowers* from Bonifati et al. A *petal* is a graph consisting of a source node s, target node t, and a set of at least two node-disjoint paths from s to t. (For instance, a cycle is a petal that uses two paths.) A *flower* is a graph consisting of a node x with three types of attachments: chains (the *stamens*), trees that are not chains (the *stems*), and *petals*. Finally, a *bouquet* is a graph in which every connected component is a flower.

[12] We do not have the space to present all these analyses, but we plan to release a full version on ArXiv as soon as the paper is accepted.

Table 6: Cumulative shape analysis of nonempty graph patterns in C2RPQ+ across the valid logs

C2RPQ+ with constants / Valid

6.6 Shape Classification for C2RPQ+

Due to space constraints, we cannot present our complete shape analysis, but we will show and discuss the results on the valid queries in the largest fragment, the C2RPQ+ queries. Furthermore, we give some insights about how the results change for the other fragments. The results for the valid C2RPQ+ queries are in Table 6. We note that some of the queries were empty (0.8% with constants and 2.44% after removing constants); we did not include them.

In Table 6, we see several trends that we also observed in the analysis for the other fragments. First of all, in the shapes that include constants, *stars are quite common*. In the C2RPQ+ queries, 85.17% (87.13%) of the organic and 98.02% (99.30%) of the robotic queries are stars. The number of acyclic queries is even larger: consistently over 99% when constants are absent. As opposed to valid queries, in the timeout logs, the number of cyclic queries significantly increases. For organic CQs, for instance, the number of cyclic queries goes up to about 10%. [13] This number decreases somehow for more complex query fragments, but is still about 7.5% for the unique C2RPQ+ queries (both organic and robotic) and around 3%–4% if constants are removed. Together with the observation from Section 4 that valid queries contain 2.58 triples on average, whereas valid timeout queries have 5.65 triples on average, this suggests that cyclicity and query size play an important role in efficient query evaluation.

The logs strongly confirm a hypothesis that is often stated in theoretical research: the cyclic queries in practical applications are only *mildly cyclic*, i.e., tw $\leq k$ for small values of k. This means that database queries typically do not have large k-cliques encoded in their shape, but remain tree-like. Indeed, the largest treewidth we found in the entire logs was four, for which we found 15 (5) queries.

[13] We omit the exact numbers due to space constraints.

7 HYPERGRAPH ANALYSIS

Hypergraphs generalize graphs in the sense that they allow more than two nodes per edge. As such, the queries that were not suitable for graph shape analysis in Section 6 because they either went beyond *graph patterns* or used Filter, Service, Bind, or Values constraints with arity three or more can be considered here. This amounts to a total of 1,915,550 (1,229,035) $\mathrm{CQ}_{\mathrm{OF+}}$ queries that were not yet analysed in Section 6.

We keep the restriction on well-designed Optional constructs with interface width 1, since for these queries, there still is a correlation between the cyclicity of the hypergraph and complexity of query evaluation [4]. We do not consider queries with property paths in the hypergraph analysis.

A *hypergraph* is a pair $\mathcal{H} = (\mathcal{V}, \mathcal{E})$ where $\mathcal{V}$ is its finite set of nodes and $\mathcal{E} \subseteq 2^{\mathcal{V}}$ is a set of *hyperedges*. The *canonical hypergraph of a SPARQL pattern P* is defined as $\mathcal{E} = \{X \mid$ there is a triple pattern t in P such that X is the set of blank nodes and variables appearing $t\}$ and $\mathcal{V}$ is the union of the nodes in the edges in $\mathcal{E}$.

Using the tool `detkdecomp` [12], we analyzed the hypergraphs of all $\mathrm{CQ}_{\mathrm{OF+}}$ queries for which the Optional constructs are well-designed and have interface width one. Overall, we found 590,005 (273,947) remaining queries with hypertreewidth two. All others new queries had hypertreewidth one.

8 QUERY SIMILARITY SEARCH

Massive query logs are valuable sources of information as long as they are made usable for exploration and analysis. In order to improve the usability of the logs, we designed a query similarity search facility that will be released with our code and whose principles and effectiveness are discussed here. Let us first observe that string similarity search is not suitable for Wikidata logs since they have been modified by an anonymization process prior to their release. Hence, one cannot find a query by simply looking at its exact original string or a sufficiently approximate version of it, by applying string edit distance (SED), for instance. So, how can we enable query similarity search in Wikidata query logs?

Given the differentiations of these logs in terms of the structural features of the underlying queries as explained in Section 6, we opted for using the query structure as a yardstick to compare queries in terms of their similarity. This choice solves several problems when comparing queries: comments, prefixes, and variable names do not affect the structure of a query and can be excluded from the computation of query similarities. Furthermore, the anonymization of the Wikidata logs renames all variable names to names with ascending numbers (?var1, ?var2, etc., see Figure 3). Therefore, if a new variable in the query is placed before other variables, it will shift the names of all subsequent variables in the anonymized version, even though they were unchanged in the original query. This could potentially lead the similarity engine to believe that a large modification took place even though it did not. The anonymisation also removes all prefixes and inlines them, hence the impact of changing a single IRI could become large depending on the length of the IRI in case of adoption of a SED measure.

To enable a structural search on Wikidata queries, we translate the abstract syntax tree (AST) of a query into a tree structure as follows. Recall the definition of a *SPARQL query Q* in Section 3

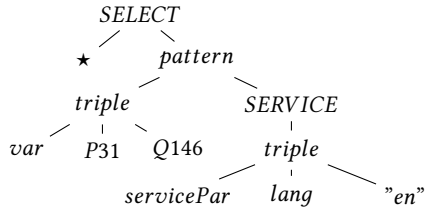

Figure 4: Abstract Syntax Tree of an example query

as a triple (*query-type*, *pattern P*, *solution-modifier*). The *query-type* and the *solution-modifier* of the query respectively become the root and a leaf node in the tree (with a value for the latter), whereas the *pattern P* is a subtree instantiated as a triple t with three leaves ($\langle s, p, o \rangle$), or a property path pattern, or a subtree rooted in And, Filter, Union, Optional, Graph whose respective patterns are also subtrees, or, recursively, the subtree of a query Q.

Figure 4 exemplifies the translation of the following Wikidata query from the logs into the AST.

```
SELECT ?item ?itemLabel WHERE { ?item wdt:P31 wd:Q146.
  SERVICE wikibase:label
   { bd:serviceParam wikibase:language "[AUTO_LANGUAGE],en"}}
```

Notice that in Figure 4, we ignore the actual instantiation of the variable ?item by naming it *var* and we also ignore the variables that are used in the target list of the Select clause for the same reason. We also removed the namespace prefixes. We now measure query similarity by using a tree edit distance (TED) measure. Each node in the above example is given a weight contributing to the TED. In particular, in the above AST for the example query, all nodes have equal weight (= 1 to not introduce bias). Adjustments of the weights are of course possible targeting a specific user requirement. The above example AST tree has thus a total weight of 12, this being the sum of the weight of its nodes. Within the logs, we found a query almost identical to the above example that only changed the object wd:Q146 to wd:Q11538. This renaming a single node in a triple would result in a similarity of 11/12 = 0.92.

Renaming two nodes in a triple would result in a similarity of 0.83. Adding a single triple anywhere, for example, outside the Service clause, would result in a total weight of 16. Such a change amounting to a total weight of 4 would result in a similarity of 12/16 = 0.75. Conversely, this can be seen as as a removal by starting with a tree exhibiting the additional triple and deleting it.

As for the implementation of the TED algorithm, we opted for an available implementation of the APTED algorithm [23, 24], because the implementation was easy to embed into our software, offered the option to use different weights for nodes, and yielded good performance results in our tests.

To calculate the similarity between an initial query Q and a new query Q_2, we take the size of the largest AST and divide it with the calculated TED. We invert this value by subtracting it from 1.0 in order to measure similarity instead of dissimilarity. When collecting matches in a collection of queries (within the same log file), we used a minimum threshold of 0.75. A threshold of 0.5 would mean that two queries are equally similar and dissimilar, so the

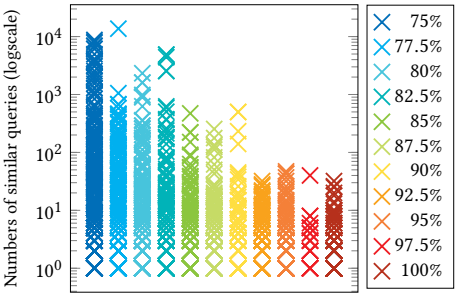

Figure 5: Number of queries that exhibit a similarity degree between 75% and 100%.

step to 0.75 is right in the middle between this and being classified as identical (which corresponds to similarity equal to 1). Based on manually inspecting samples, the threshold of 0.75 already seemed to be rather lenient, and our method based on TED yielded more predictable results for us than another method we experimented with based on SED. For example, a typical Wikidata entity has a string length of about 36. Even if all triples are changing, this can result in almost a 0.9 string similarity for the entire query, because the prefixes of entities are always the same.

In order to measure the structural similarity of Wikidata queries, we focused on the OrganicOK query logs by considering their Unique version only.[14] Since we needed seed queries for which we want to find similar queries, we considered the well known set of online Wikidata examples from [32]. We extracted[15] 356 out of the available 412 queries, which were the ones that could be parsed by Jena. It turns out that matches for most online example queries are found in the Wikidata logs analysed in our paper. Only 28 queries could not be matched, while the rest had at least one match above the threshold of 0.75.

Figure 5 shows in logscale the number of similar queries that we found in the OrganicOK Unique query logs in the order of ascending similarity. We can observe some outliers in several buckets in the scatterplot, showing that these queries have higher number of similar counterparts with respect to their pairs in the same bucket. The entire log could be scanned for the similarity search quite efficiently in less than 20 mins (without any optimization.)

9 RELATED WORK

Several empirical studies of SPARQL query logs have been conducted in the literature investigating statistical features, such as such as occurrences of triple patterns and types of queries [3, 15, 23, 29] along with recent studies on more complex features of the queries, such as structural features and complexity of the queries [10, 27]. However, the analysis of Wikidata queries has been limited in the past due to their unavailability. Bonifati et al. [10] only focused on the online 308 Wikidata queries in their large corpus and, more recently, Malyshev et al. [23] and Bielefeldt et al. [8] were the first to analyze a massive collection of Wikidata queries. Malyshev et al. first introduced the Wikidata SPARQL service WDQS and analyzed basic characteristics of Wikidata queries related to their usage in this service spanning from SPARQL feature prevalence and correlation to annotations and language distributions. They also isolated the robotic and organic queries, on whose classification we rely in this paper (modulo a small correction highlighted in Section 2). This classification considered as organic the queries issued by a browser and robotic the remaining queries. They further corrected the first number by identifying high-volume traffic from a single source (more than 2,000 entries), in which case the queries would be considered as machine-generated. They also identified the C2RPQs fragment, i.e. the largest fragment encountered so far of conjunctive 2-way regular path queries on which we focus in this paper for an in-depth analysis. To the best of our knowledge, the latter is the largest fragment of recursive graph queries available to our community. In this paper, we address the first large-scale structural analysis of this gigantic query collection and articulate it as follows. We provide a structural classification of real-world property paths, on the first large set of property paths relevant for Wikidata, and 57x larger than the set considered mainly for DBpedia in Bonifati et al. [9]. We also investigate the shape of C2RPQs, which could not be possible with the classification for only conjunctive queries (CQs) in Bonifati et al. [9]. The occurrences of property paths in the latter corpus is negligible with respect to the size of the C2RPQ fragment considered in our work (smaller by two orders of magnitude).

10 CONCLUSIONS AND LESSONS LEARNED

We have presented an in-depth analysis of the recently released Wikidata query logs and highlighted the presence of their most prominent query fragment, i.e. C2RPQs. This fragment corresponds to highly complex recursive queries with joins and property paths. Apart from simple counting measures on this fragment, we have focused on tailoring property path analysis and shape analysis to these queries, whereas previous work merely looked at conjunctive queries (CQs) in DBpedia logs [9]. Even though we agree with Bielefeldt et al. [7] on the difficulty of obtaining stable observations from these query logs due to massive presence of robotic traffic, we discovered several similarities, like low hypertreewidth and structure of property paths seem to be relatively consistent between the present study and previous work.

But what about the distinguishing features of these logs compared to previous logs and the findings that were possible on this newly discovered fragment, i.e. C2RPQs? Entirely new observations were made across the distinction in terms of Valid and Unique logs, further segmented into RoboticOK and OrganicOK, the addition of timeout logs never analysed before, which led us to add interesting dimensions to the analysis.

We now revisit the research questions posed at the end of Section 1 and we succinctly report the main findings of our analysis for those questions. About the distributions of sizes, we found out that the RoboticOK queries are less skewed in terms of sizes than the OrganicOK queries and this also applies to OrganicTO and RoboticTO queries, that are also inherently more complex in terms of sizes than the RoboticOK plus OrganicOK queries.

[14] The same analysis can be applied to the other logs but is probably less interesting for the present discussion.

[15] On August 23, 2018. Jena version same as in Section 2.

Next, property paths occur in these logs 57x more than in previously analyzed logs, which made us focus on the most representative query fragment C2RPQs. We noticed that a bigger variety of property path classes again occurs with Organic queries compared to Robotic queries. Still, we see that almost all property paths match paths of *any possible length* once a certain minimum length is exceeded. (Typical such expressions are ab^* or ab^*c.) Expressions that do not satisfy this property, like $(ab)^*$, appear as well, but are less prominent. In fact, the most occurring types of property paths found were similar to those found in an earlier study [9], which may allow us to identify subclasses of expressions that are important in practice. Such a discovery might spur interesting query processing and query optimization questions around C2RPQs, which were not addressed for the much simpler fragments of CQs. For instance, landmarking indexes have been introduced for one of the prominent classes of Robotic queries (A^*) in Valstar et al. [30], but also the other prominent classes need attention when designing indexes for C2RPQs.

In our analysis, we also addressed the question on the prominence of CQs and C2RPQs in these logs compared to other logs, thus bringing to the surface the most occurring recursive fragment of C2RPQs enriched with And, Optional, Filter, Bind, Service and Values (C2RPQ+). We ran a shape classification with and without constants for several fragments ranging between the class of CQs and C2RPQ+ by considering/excluding constants. Here, we see that *star shapes* and *tree-like queries* are very common. The shape analysis with or without constants also led us to identify shifts in the shape classes due to removal of constants that are worth looking at. For instance, if we remove constants from the graph shape of queries in the logs, many (25% organic and 36% robotic) disintegrate to a single node. Constants have been disregarded in the study of C2RPQs, where indexing techniques have mainly considered the labeled paths as key index terms. The combination of indexing techniques looking at constants and labeled paths could thus be a direction to pursue in future studies on indexing structures and index maintenance for these queries [8]. The timeout queries are also interesting because they are on average larger in size and more cyclic than the valid queries.

Concerning treewidth and hypertreewidth, the logs strongly confirm a hypothesis that is often stated in theoretical research: the cyclic queries in practical applications are only *mildly cyclic*. This means that database queries typically do not have large k-cliques encoded in their shape, but remain tree-like. This observation is in line with the data from a previous study [9].

Next, a novel Wikidata-specific query similarity search allows to efficiently navigate the query logs starting from an initial query that the user has at her disposal. This search improves the usability of the Wikidata query logs for both recursive and non-recursive queries and is valuable for identifying subsets of similar queries on which further assessment is possible.

After pre-processing, i.e., computing the Valid and Unique data sets, our entire analysis (except query similarity search, whose performance has been separately measured) takes 12 hours on a 24 core machine with a 2.6 GHz CPU and 128 GB RAM.

We believe that isolating complex query fragments and studying suitable sophisticated metrics is valuable for the community and may lead to further studies and assessment of these logs. We believe that this work can serve as a basis for researchers to find further interesting fragments of queries to study; we report what we see in the logs. However, one should always keep in mind that we are looking at *specific query logs*. It cannot be concluded from this study that a given fragment, operator, or type of query is *not* interesting to study.

What happened? The Spread of Fake News Publisher Content During the 2016 U.S. Presidential Election

Ceren Budak
University of Michigan
Ann Arbor, Michigan
cbudak@umich.edu

ABSTRACT

The spread of content produced by fake news publishers was one of the most discussed characteristics of the 2016 U.S. Presidential Election. Yet, little is known about the prevalence and focus of such content, how its prevalence changed over time, and how this prevalence related to important election dynamics. In this paper, we address these questions using tweets that mention the two presidential candidates sampled at the daily level, the news content mentioned in such tweets, and open-ended responses from nationally representative telephone interviews. The results of our analysis highlight various important lessons for news consumers and journalists. We find that (i.) traditional news producers outperformed fake news producers in aggregate, (ii.) the prevalence of content produced by fake news publishers increased over the course of the campaign–particularly among tweets that mentioned Clinton, and (iii.) changes in such prevalence were closely following changes in net Clinton favorability. Turning to content, we (iv.) identify similarities and differences in agenda setting by fake and traditional news media and show that (v.) information individuals most commonly reported to having read, seen or heard about the candidates was more closely aligned with content produced by fake news outlets than traditional news outlets, in particular for information Republican voters retained about Clinton. We also model fake-ness of retained information as a function of demographics characteristics. Implications for platform owners, news consumers, and journalists are discussed.

1 INTRODUCTION

News production and consumption have always played an important role in our democracy–with noted consequences for political participation [23], voting [21], and charitable giving [13]. This role has been repeatedly reshaped due to the changes in the media technology–from the introduction of cheap newsprint [41] to the growth of online news production and consumption [24]. Each change has led to concerns about the quality of news and its consequences for our democracy. Most recently, the concerns have centered around the shift towards news production and consumption through social media platforms [3, 24]–with a specific focus on the increasing influence of fake news. While the spread of fake news content on social media platforms is not new, the 2016 U.S. Presidential election has highlighted its extent, raised fears that this new paradigm of news consumption is misinforming voters and corroding our democracy [22, 53, 64]. These concerns have garnered significant attention in both media and policy circles, with some journalists even going as far as claiming that results of the 2016 election were a consequence of the spread of fake news [22, 53].

There are a number of factors that likely contributed to the spread of fake news publisher content, such as increasing use of social media platforms that lack a centralized control mechanism for news consumption [29], an overall decreasing trust in mainstream media [25, 62, 69], profitability of fake news production [34], and recognition of otherwise fringe ideas and news by high profile politicians [6, 47]. Understanding to what extent the aforementioned reasons contributed to the spread of fake news content will certainly take a long time. Here, instead of the "why", we focus on the "what"; and examine to what degree individuals shared news from fake news producers as opposed to traditional news outlets during the 2016 U.S. presidential election. Using a rich dataset that includes daily random sample of tweets mentioning the two presidential candidates, the content of external urls shared in those tweets, and nationally representative interviews conducted by Gallup at the daily level, we study the overall prevalence and focus of fake news producers, how the prevalence changed over time, and examine how the production and consumption of such news relate to election campaign dynamics.

By analyzing the overall prevalence of content produced by fake and traditional news outlets and shared on Twitter, we show that:

(1) An overwhelming majority of news content shared on Twitter was produced by *traditional* news outlets.
(2) The prevalence of fake news increased over time.
(3) The increase in prevalence was more drastic in tweets about Hillary Clinton and followed significant campaign moments.
(4) The changes in fake news prevalence followed changes in net Clinton favorability, highlighting a strong correlation

between candidate favorability and fake news production and consumption.

Next, by analyzing the content of the articles, we provide the following contributions:

(1) We identify the similarities and differences between content produced by fake and traditional news outlets using semi-supervised machine learning methods.
(2) We determine that the retained information about Clinton (what likely voters have reported to having *read, seen or heard* about her) was more aligned with fake news agenda compared to traditional news agenda.
(3) We perform statistical modeling of fake-ness of retained information and show that Republican, younger and male interviewees had a higher tendency to report content more closely aligned with fake news publishers. Race and location had no significant effect.

2 RELATED WORK

Social Media and the News. As more news consumption moves to social media platforms [29]—with social media news consumption even providing predictive signals of consumption through all channels [17]—there has been an increasing interest in studying the trustworthiness of content shared through this channel [57, 73].

Recent increase in the volume of misinformation, conspiracy theories, and disinformation and the likely role social media played in this uptick have sparked growing interest in related research [14, 33, 46, 52, 56, 60, 68]. While earlier studies focus on limiting the spread of misinformation as a theoretical optimization problem [14], more recent studies propose data mining and machine learning techniques to identify and limit spread online [56, 60]. Some studies characterize fake news, misinformation, conspiracy theories, and disinformation online [33, 46, 52, 68, 71], while others focus on the types of agents–such as bots—that disseminate such information [1, 7, 20]. Most relatedly, [71] examines rumors that spread on Twitter between 2006 and 2017 and finds that false news spread faster and deeper than true news. Unlike these studies, we focus specifically on the spread of news during 2016 U.S. presidential election.

News Dynamics During 2016 Election. 2016 election has generated increased interest in the study of news dynamics with a particular focus on fake news (e.g. [3, 7, 10, 31, 35, 42, 44, 47, 58]).

Most relatedly, two studies concurrently published with our work investigate the spread of fake news through Twitter [10, 31]. [31] studies the exposure of registered voters on Twitter to fake news content and shows high concentration—only 1% of individuals accounted for 80% of fake news source exposures. They also study engagement with fake news sources as a function of demographics characteristics. [10] studies networks of information flow on Twitter leading up to the 2016 U.S. elections and show that top influencers spreading center and left leaning news influences Clinton supporters. In contrast, the activity of Trump supporters influences the behavior of top fake spreaders.

Other relevant studies include [47] which studies manipulation and disinformation online, provides a survey of various important case studies, and characterizes potential outcomes of such spread. While the main focus is broader than the 2016 election, the authors emphasize the relationship between the mis- and disinformation ecosystem and election campaign dynamics. [3] studies the effect of fake news during the 2016 election. The authors show that social media was an important but not dominant source of election news, and that fake news stories about Hillary Clinton received more attention. They further estimate the fake news exposure of an average American. [7], aiming to determine the role bots played during the 2016 election, examines tweets shared during the campaign season and finds that about one-fifth of the entire conversation was produced by bots. [64]—focusing on the most commonly shared urls on Facebook—shows that (i.) hyper-partisan news articles attracted more attention than mainstream news articles on Facebook during the 2016 election, (ii.) hyper-partisan and fake news sites had a strong ideological bias against Hillary Clinton. Also relatedly, [42] studies the peer-production of content related to the two presidential candidates on Wikipedia; [58] provides a new method to estimate media bias; and [35] presents a new dataset for examining misinformation on social media.

Our study complements these investigations by bringing together data sources from social media, news media, and Gallup interviews. Unlike related work, we study the focus and the changes in dynamics of fake news prevalence and relate these to important election dynamics. Furthermore, we present the first study that analyzes the relationship between the favorability of the candidates and the production and consumption of news—with a particular focus on content produced by fake news.

3 DEFINING FAKE AND TRADITIONAL NEWS

Identifying the credibility and quality of news content is a challenging task. A recent publication by leading scholars studying misinformation advocates for classification at the outlet level [45]. The authors advocate for "... focusing on the original sources—the publishers—rather than individual stories, because we view the defining element of fake news to be the intent and processes of the publisher. A focus on publishers also allows us to avoid the morass of trying to evaluate the accuracy of every single news story". This paper follows this guideline and defines fake and traditional news at the producer (web domain) level.

Fake News Publishers. In this study, we rely on the fake news classification provided by [4]. The set of fake news producers published by [4] are gathered from 5 distinct lists: (i) a research project by Grinberg et al. [30] (490 publishers); (ii) PolitiFact's article titled "PolitiFact's guide to fake news websites and what they peddle" [27] (325 publishers); (iii) the list provided in the three articles published by BuzzFeed on fake news [63, 65, 66] (223 sites); (iv) a research project by Guess et al. [32] (92 publishers); and (v) FactCheck's article titled "Websites that post fake and satirical stories" [59]. [27, 59, 63, 65, 66] are published by organizations that apply journalistic standards in evaluating the validity of news articles. [30, 32] use a combination of these resources as well as lists published by [12, 75] with some further verification from Snopes.com.

There are a number of of fake news producer lists available online (e.g. [27, 30, 32, 59, 63, 65, 66] as described briefly above). We rely on the classification provided by [4] for two main reasons. First, this list provides the widest coverage. Second, the authors provide the most detailed robustness checks of their list compared to other

efforts (e.g. [75]). A key concern here is the potential selection bias in the list of fake news sites gathered. The authors perform two robustness checks. First, they focus on sites that are identified as fake news sites by at least two or three lists instead of one. Second, they consider lists of sites assembled from any four out of the five original lists. They show that the general trends of fake news coverage is consistent across these definitions.

Traditional news. We use Alexa [2] to identify traditional news domains. Alexa provides commercial web traffic analytics using a large panel of Internet users and their web-browsing patterns. This site also provides a rich ontology of the web [1]. Using the Alexa ontology, we identify the set of websites listed under the news category. There are in total 5,497 domains listed under this category including national, regional as well as international news sources. We remove the set of web domains listed by [4] and classify the rest of the sites as traditional news sources. Note that the news categorization provided by Alexa has also been used in past work to identify news outlets (e.g. [3, 58]).

We note that future work is needed to measure and improve the accuracy and coverage of the aforementioned lists of traditional and fake news outlets. Furthermore, such lists need to be maintained in a dynamic fashion to account for changes in the news media space.

4 DATA

Social and News Media. The social media dataset used in this study is described in detail in [54]. Data are collected through Sysomos MAP[2]. This service allows gathering of tweets sampled uniformly at random on a daily level. The dataset covers the time period between May 23, 2014 and January 1, 2017. For each day within that time period, we use (i.) 5,000 tweets that were uniformly randomly sampled from all tweets that included the keyword *Trump*, and (ii.) 5,000 tweets that are similarly sampled from all tweets that mention *Clinton* [54]. The resulting dataset includes approximately 4.8 million tweets about Donald Trump and, similarly, approximately 4.8 million tweets about Hillary Clinton. Given that our goal is to analyze news content, we then remove tweets that do not include an external url. The dataset after filtering tweets without urls includes: (i.) 3,072,251 shares of 1,529,251 unique shortened urls by 600,915 unique Twitter users, and (ii.) 4,689,087 shares of 2,025,203 unique shortened urls by 602,613 unique Twitter users for Trump and Clinton.

Given the set of tweets that include a shortened url (of the form: http://t.co/xxxxxxxxxx), we next use automated scripts to identify the url redirect and extract the content of the webpage. We remove urls internal to Twitter since such urls correspond to quoted retweets as opposed to external news content. The resulting dataset includes approximately 1.7 million unique urls. For each share (i.e. tweet including a valid url), we record the following data: i.) the shortened url, ii.) the original url, iii.) domain name (e.g. wsj.com), iv.) title of the document, v.) text body of the document, vi.) the date of the tweet, vii.) Twitter id of the user sharing the url, and (viii.) a binary categorization that indicates whether this tweet is in our Clinton or Trump sample. When we limit our data to domains that are included in the fake and traditional news domains lists (detailed below), there are approximately 270K unique articles that were shared in approximately 564K tweets about Trump (in tweets that mention Trump), and approximately 350K unique articles about Clinton that were shared in 1.1M Clinton tweets.

Gallup Data. In order to characterize the election dynamics as perceived by the U.S. population, we also use responses to two open-ended questions fielded as part of the Gallup Daily survey. Respondents were asked, "What have you recently read, seen, or heard about [CANDIDATE]?" for both Donald Trump and Hillary Clinton (asked in random order). To the best of their ability, telephone interviewers recorded individuals' responses verbatim. Gallup asked these questions to a random sample of 500 adults (ages 18 and higher, living in all 50 U.S. states and the District of Columbia, approximately 60% cellphone and 40% landline) each day between July 11 and November 7, 2016. The margin of sampling error at the weekly level is ±2 percentage points at the 95% confidence level. For each interview response, the dataset also includes the gender, age, location, and ideological leaning of the respondent. We refer the reader to [9] for additional details about the survey.

5 OVERALL PREVALENCE OF FAKE NEWS PRODUCER CONTENT

A number of investigative efforts suggest wide spread of fake and hyper-partisan news consumption during the 2016 election. For instance, a *Buzzfeed News* study [64] showed that *top* hyper-partisan news articles attracted more attention (measured in terms of total number of shares, reactions, and comments) than *top* mainstream news articles on Facebook by examining top Facebook stories of the election season. Here, we extend this knowledge in three important ways: First, we examine the aggregate popularity (measured in terms of number of shares) of all content shared by traditional and fake news publishers, as opposed to focusing on the top few most commonly shared articles. Second, given that our dataset is balanced over time due to random tweet sampling at the daily level, our results are not dominated by few articles that were in the public eye for a short amount of time. Third, in this study we use data from Twitter, which has important differences in dynamics of information sharing compared to Facebook[3]. As a result, we extend the understanding of the prevalence of fake news in 2016 Presidential election cycle to a new social media platform.

We find that traditional news articles were shared by 2.8 users on average while this number was 2.88 for articles published by fake news outlets–the small difference observed is not statistically significant ($p \approx 0.08$). Similarly, a traditional news article was shared on 4.7 days on average while this number is 5.5 for articles published by fake news producers ($p < 0.001$ for the difference in means). The distributions are highly skewed ($\approx$ 14 standard deviation for the number of shares and $\approx$ 33 for the number of days). Median of the distributions are the same (1 for both number of shares and number of days). These measures point to comparable popularity *per article* produced by fake and traditional news publishers[4]. Yet, because the

[1] Since our data collection, Alexa has stopped sharing the ontology.
[2] http://sysomos.com/products/overview/sysomos-map

[3] Since the writing of this study, two other studies ([10, 31]) also examined Twitter content, albeit through different data collection mechanisms. We find similar qualitative findings in fake news prevalence despite different data collection choices.
[4] Note. however, that our data only include articles with *at least one* share.

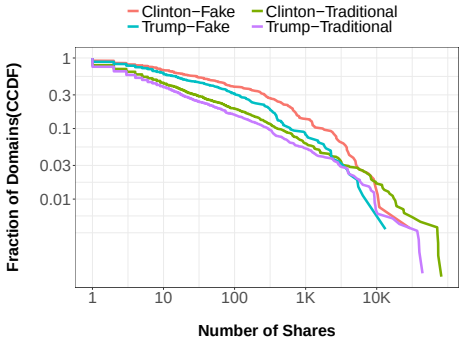

Figure 1: Popularity of Fake and Traditional News Domains for Clinton and Trump Related Tweets.

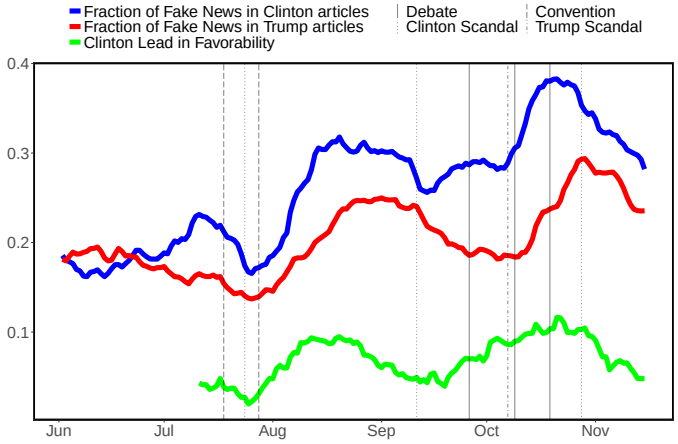

Figure 2: Fraction of article shares that are from fake news producers and Clinton net favorability over time. The error bars give standard errors.

volume of traditional news production was higher, collectively traditional news accounted for significantly more shares–the number of users sharing traditional news content outnumbered those that share content produced by fake news outlets roughly one to four.

We further investigate how this popularity is concentrated across different publishers and present the results of our findings in Figure 1. The x-axis denotes the popularity of a given domain (separately among tweets mentioning Trump and Clinton) and the y-axis denotes the fraction of domains of the corresponding type (e.g. a fake news domain in Clinton tweets is given by the red curve) with at least that much popularity. Here popularity is defined as the number of tweets that included a url from the corresponding domain. This figure shows that there are a larger fraction of fake news publishers that were able to garner *reasonable* attention compared to traditional news sites. For instance, 68% and 61% of fake news publishers had popularity strictly less than 100 for Trump and Clinton respectively. These numbers are 84% and 81% for traditional news publishers. In contrast, traditional news coverage dominance was mostly driven by a small number of big outlets that drove most of the traffic. For instance, there are no fake news publishers that single-handedly garnered more than 30K shares in our dataset while there are a number of traditional news sites (e.g. New York Times, Fox News). This highlights important differences in production and consumption of fake and traditional news publishers—popularity was more concentrated in the head for traditional news compared to fake news.

6 CHANGES IN FAKE NEWS PRODUCTION AND CONSUMPTION

Here we investigate the relationship between fake news production/consumption and the favorability of the two candidates. Our goal is to determine whether the prevalence of content produced by fake news outlets was correlated with campaign dynamics–following a pattern similar to the relative favorability of candidates and changes to this measure. The favorability of Hillary Clinton on a given day i, denoted by $Fav_{Clinton,i}$, is computed using the Gallup interview dataset as:

$$Fav_{Clinton,i} = \frac{\sum_{r \in R_i} I_{r,Clinton} * w_r}{\sum_{r \in R_i} w_r} \quad (1)$$

where R_i is the set of respondents on day i, $I_{r,Clinton}$ is an indicator that is equal to 1 if respondent r is favorable towards Hillary Clinton, and w_r is the weight used for post-stratification to correctly estimate sentiment across the United States.[5] A similar method is used to identify Donald Trump favorability ($Fav_{Trump,i}$) at the daily level. Next, Clinton lead in favorability on day i is computed as $Fav_{\Delta Clinton,i} = Fav_{Clinton,i} - Fav_{Trump,i}$.

We next compute the fake news ratio on a daily level. First, we define 4 sets of tweets for each day i: $T_{Clinton,i}$, $T_{Trump,i}$, $F_{Clinton,i}$, and $F_{Trump,i}$ that correspond to the set of tweets that include (i) link to a traditional publisher and the word "Clinton", (ii) link to a traditional publisher and "Trump", (iii) link to a fake news publisher and "Clinton", and (iv) link to a fake news publisher and "Trump". Next, fake news content fraction for Clinton and Trump tweets are measured as $f_{Clinton,i} = \frac{|F_{Clinton,i}|}{|F_{Clinton,i}|+|T_{Clinton,i}|}$ and $f_{Trump,i} = \frac{|F_{Trump,i}|}{|F_{Trump,i}|+|T_{Trump,i}|}$ respectively.

The prevalence of fake news content ($f_{Clinton,i}$ and $f_{Trump,i}$) and net Clinton favorability ($Fav_{\Delta Clinton,i}$) over time are provided in Figure 2. The blue curve in Figure 2 denotes the prominence of articles produced by fake news producers in tweets about Clinton. Since $f_{Clinton,i}$ can fluctuate from day-to-day, we smooth out the curve by using and plotting a moving average of 15 days centered at i. The red curve gives a similar measure for the fraction of fake news content in Trump tweets ($f_{Trump,i}$). The green curve denotes the net Clinton favorability over time ($Fav_{\Delta Clinton,i}$). This time series is smoothed out to give the 15-day running average for consistency.

Figure 2 provides a number of important insights. First, tweets about Clinton had a higher fraction of shares from fake news publishers compared to tweets about Trump. Past work shows that ideological bias is commonly exercised by criticizing the other side as opposed to championing for the preferred party [15]. Therefore,

[5]The computation of the weight are described here: https://www.gallup.com/185462/gallup-daily-work.aspx.

our finding suggests that fake news domains were commonly publishing negative content about Hillary Clinton. This finding is also in agreement with [64] that claims that fake news content commonly had an anti-Hillary Clinton bias. We further substantiated this conjecture by performing tone analysis of content published by fake and traditional news producers that are shared in Clinton tweets using Lexicoder [74].[6]

Figure 2 also shows an increasing popularity of fake news producers over time—more so for Clinton tweets but also for Trump tweets. While the average fraction of fake news content is about 20% before the conventions, it lies at $\approx 30\%$ after the nominations and reaches $\approx 40\%$ right before the election. For both time series, we observe two peaks. The first upward trending starts after the conventions and the second starts after the second presidential debate. Fake news content popularity is ultimately a function of both production and consumption. This trend can be due to an increase in production of fake news content for ideological reasons to drive public opinion or due to consumption that is a result of changes in public opinion, or a combination of the two.

Finally, and most intriguingly, net Clinton favorability (blue curve) and the prevalence of fake news content (red and green curves) are highly correlated (pearson correlation of 0.8). Intrigued by this correlation, we next perform cross-correlation analysis [70] to investigate whether changes in net Clinton favorability *lead* or *lag* changes in fake news content ratio. CCF or cross correlation function is defined as the set of correlations between the two time series s^1_{t+l} and s^2_t for lags $l = 0, \pm 1, \pm 2, \ldots$. A negative value for l represents a correlation between the s^1-series at a time *before* t and the s^2-series at time t. If, for example, the lag $l = -3$, then the cross correlation value would give the correlation between s^1_{t+3} and s^2_t.

The results of the cross-correlation analysis reveals that the highest correlation of 0.85 is observed for $l = 4$, indicating that fake news production/consumption changes *lag* changes in net Clinton favorability. We caution the reader that this analysis is only correlational. While the results suggest a strong relationship between production of fake news content and changes in candidate favorability, this should not be taken as evidence for the *effect* of fake news in the outcome of the 2016 election. If anything, our results suggest that fake news production and consumption responded to changes in the 2016 election campaigns as opposed to affecting them. We further caution that the causal mechanism is unknown. These observed patterns can be due to production (with outlets producing more damaging content for Hillary Clinton to combat improvements in her favorability numbers) or due to consumption, or rather a combination of the two. It is also entirely possible for both candidate favorability patterns and the fake news production and consumption to be responding to a third signal—with the fake news response being delayed longer. Future research is needed to identify the causal story—our analysis highlights the importance of carrying out such analysis.

[6]Lexicoder is a Java-based, multi-platform software for automated content analysis of text. Lexicoder provides two dictionaries—negative and positive words—designed to capture the sentiment of political texts. This method has been used by various studies to examine tone in news coverage [28, 67]. Using the dictionaries, we identify the set of positive and negative words in each article in our dataset and measure the net positivity as #positive - #negative words. Next, we measure the average net positivity of articles shared from fake and traditional news outlets separately. Our findings indeed show that articles published by fake news outlets and shared in tweets mentioning Clinton are on average more negative compared to articles published by traditional news outlets. The average tone is -1.3 and 2.2 respectively for fake and traditional news content.

7 FAKE AND TRADITIONAL NEWS TOPICS

Here our goal is to determine the similarities and differences between fake and traditional news coverage leading up to the 2016 election through topic modeling.

The topics covered by traditional and fake news media and shared by Twitter users are inferred through the methodology proposed by [11]. This methodology involves four high level steps: 1) identifying candidate topics and topic-words through vanilla LDA [8] where the number of topics is chosen through topic coherence scores [51], 2) remapping topics and topic words to a smaller subset of coherent topics and associated seed words through expert manual labeling, 3) employing guided LDA [38] using these seed word lists, and 4) collapsing topics that share the same human readable category into a single topic and removing topics without coherence (using top words per topic). This approach produces 19 distinct topics. Each article is then assigned to a single topic according to the maximum probability of its topic distribution. These article-topic pairs are next evaluated manually through Amazon Mechanical Turk. The results reveal that 15 out of the 19 topics to have high accuracy ($F1 \geq 0.75$). Table 1 provides a summary of the 15 coherent topics identified by [11]. We refer the reader to [11] for more details about the methodology.

Having identified the topic of each article in our sample and filtered out articles that do not map to one of the 15 coherent topics, we next examine the similarities and differences between the agenda setting functions of fake and traditional news outlets. In Figure 3(a), we summarize the frequency of each topic separately for fake and traditional news outlets among the set of articles that map to one of the 15 topics. The topics are ordered as a function of the difference in coverage by fake and traditional news outlets. For instance, the top-most topic—*election*—accounts for approximately 48% of traditional news shares while it only accounts for 24% of fake news shares. The difference of 24% signifies to what degree this topic was more central to traditional news production and

(a) Topic Coverage

(b) Candidate Focus

Figure 3: Topical Analysis of Traditional and Fake News Media Shared on Twitter. The topics are ordered from most uniquely associated with traditional news (top) to most uniquely associated with fake news producers (bottom)

consumption compared to fake news production and consumption. In contrast, the bottom-most topic—*emails*—accounts for 31% of fake news shares while it accounts for 16% of traditional news shares. The difference of −15% indicates to what degree emails was a central theme of the fake news coverage and attention.

A number of important patterns emerge here. First, we see that election-related—or in other words horse-race—topic was most significantly overly represented in traditional news coverage. This finding is in line with established research that highlights the significance of the horse-race in news coverage [37] leading up to elections. Here, we show that fake news production diverges from traditional news in this context. Other topics more unique to traditional news outlets include policy focused topics such as the economy, women, and the environment. In comparison, topics that relate to Clinton scandals (emails, sex scandals—commonly about Bill Clinton—, the Benghazi scandal, candidate health issues) were most distinctly covered in articles published by fake news outlets and shared on Twitter. These findings highlight important differences in agenda setting and coverage by these two types of sources.

Despite these clear differences, important similarities emerge when one focuses on the coverage in absolute numbers. For instance, even though emails was a more important topic for fake news outlets compared to traditional news, this topic still made up a significant fraction (16%) of traditional news shares—making emails a more important topic for traditional news than the economy or other policy issues. We further emphasize that no Trump related scandal was common enough to be identified as a coherent topic. Overall, we find that traditional news coverage was extremely light on policy and the focus on a single scandal was disproportionately applied to Clinton. This finding is in line with related work [55] which suggests that traditional new outlets failed to inform the electorate properly leading up to the 2016 U.S. presidential election.

Next, we also investigate whether the coverage of topics were more particularly focused on Clinton or Trump and how that pattern differed across topics. To measure the Clinton focus of a given topic, we compute the fraction of times articles on that topic were shared in Clinton tweets (as opposed to Trump tweets)—separately for fake and traditional news outlets. The results are presented in Figure 3(b). The topics are ordered in the same order as Figure 3(a) for ease of viewing. The x-axis denotes the Clinton focus of the given topic. For instance, the first row shows that approximately 48% of shares of fake news sources on the election were mentioning Clinton, while approximately 54% of shares of traditional news sources on the same topic mentioned Clinton.

Topics with $x > 0.5$ for both fake and traditional news media are consistently Clinton scandals (emails, sex scandals—commonly about Bill Clinton—, Benghazi, candidate health problems, Clinton Wall Street speech scandal). Furthermore, when a topic can relate to scandals of either candidate (e.g. health problems and sex scandals[7]), the coverage of fake news producers focused significantly more on Clinton compared to Trump. The opposite is observed for policy coverage—fake news coverage had a stronger Trump emphasis when covering topics such as abortion and the economy. This suggests that the fake news outlets had a higher tendency to cover Trump policy positions, conditional on covering a given policy topic. These findings further support the claim that fake news production was consistently pro-Trump and anti-Clinton.

8 FAKE NEWS EXPOSURE

Did the information Gallup interview respondents retain about the two candidates better align with traditional or fake news coverage? To answer this question, we compute a measure of fake-ness—the

[7]Both Hillary Clinton and Trump had health issues leading up to the election. Similarly, sex scandals could be referring to Donald Trump or Bill Clinton.

degree to which the given word is unique to fake news coverage—for each unique word uttered by respondents when asked about what they have seen, heard, or read about Clinton (and separately for Trump). Next, we aggregate this information across all interviews to (i.) examine the fake-ness of popular phrases uttered in interviews by individuals with different party alignments, and (ii.) to build a mixed-effects model to characterize fake-ness of interview responses as a function of the attributes of the interviewee (e.g. party, gender, age).

Measuring word fake-ness. We adopt the log-odds-ratio technique with informative Dirichlet priors [48] to compute the fake-ness measure for each word for each candidate. This method has the advantage of de-emphasizing fluctuation of rare words by leveraging the prior information obtained from the background corpus, and has been shown to outperform other methods such as PMI and TF-IDF [40, 48, 50].

Using the log-odds-ratio with informed Dirichlet priors, the usage difference for word w among two corpora is computed as:

$$\delta_w^{(i-j)} = \log \frac{y_w^i + \alpha_w}{n^i + \alpha_0 - y_w^i - \alpha_w} - \log \frac{y_w^j + \alpha_w}{n^j + \alpha_0 - y_w^j - \alpha_w} \quad (2)$$

where n^i (resp. n^j) is the size of corpus i (resp. j), y_w^i (resp. y_w^j) is the word count of w in corpus i (resp. j), α_0 is the size of the background corpus, and α_w is the word count of w in the background corpus. The variance of this measure is:

$$\sigma^2(\delta_w^{(i-j)}) \approx \frac{1}{(y_w^i + \alpha_w)} + \frac{1}{(y_w^j + \alpha_w)} \quad (3)$$

and the Z-score is:

$$Z = \frac{\delta_w^{(i-j)}}{\sqrt{\sigma^2(\delta_w^{(i-j)})}} \quad (4)$$

We measure the fake-ness of a word w (through its Z-score) separately for Clinton and Trump. We do this since the usage of the same phrase when uttered for the two candidates has divergent implications.[8] Here we describe the process to compute fake-ness scores for each unique lemmatized word $w \in W_{int,Clinton}$ uttered when interviewees were asked what they heard, read or saw about Clinton: We first create three documents that correspond to corpus i, j, and background corpus described above. Corpus i (fake news corpus) includes all $w \in W_{int,Clinton}$ weighted by the number of times w is observed in the body of an article shared in a Clinton tweet in our dataset[9]. Similarly, corpus j (traditional news corpus) includes all $w \in W_{int,Clinton}$ weighted by the number of times w is observed in the body of an article produced by traditional news outlets and shared on Twitter with a Clinton mention. The background corpus is the concatenation of the two documents i and j. Next, we apply equations (2-4) to compute the fake-ness scores of each word when uttered for Clinton. We refer to this measure as $f(w_{Clinton,fake})$. The same method is applied next to compute the fake-ness of each word for Trump ($f(w_{Trump,fake})$).

This method assigns a value of 68.2 for the word *email* when used for Hillary Clinton—meaning that the word is more frequently observed in fake news articles and is therefore associated with positive *fake-ness*. The word *debat* ("debate" lemmatized), on the other hand is more frequently observed in traditional news articles and has a *fake-ness* measure of -48.5. Table 2 provides an ordered list of the top-20 fake words (words with the highest Z-score) and the list of the top-20 traditional news words (words with the lowest Z-score) for Trump and Clinton. This table highlights the effectiveness of this methodology. For instance, words relating to Clinton scandals (e.g. Huma, Wikileaks, corrupt) have high fake-ness measures (in line with [64]).

Table 2: Words that are most unique to fake vs. traditional articles for Trump and Clinton tweets.

News Outlet	Candidate	Most unique words
Fake	Trump	advertis, video, islam, continu, pleas, twitter, liber, obama, media, illeg, america, leav, establish, advanc, cruz, share, lie, support, christian, alien
Traditional	Trump	voter, campaign, republican, compani, casino, percent, photo, former, citi, iowa, advis, univers, hotel, tower, regist, month, busi, presidenti, chariti, build
Fake	Clinton	video, foundat, lawsuit, document, twitter, corrupt, huma, wikileak, lie, die, file, sex, court, death, report, email, content, forget, advertis, healthi
Traditional	Clinton	sander, percent, voter, campaign, democrat, photo, iowa, candid, republican, presidenti, primari, support, hampshir, senat, nomin, debat, poll, race, biden, gop

Fake-ness of popular interview phrases. Next, we compute the fake-ness of top-k words[10] uttered in Gallup surveys by a set of respondents R for each candidate c as follows:

$$f_{c,k,R}^G = \frac{\sum_{w \in G_{c,k,R}} f(w_{c,fake}) * n_{c,w}}{\sum_{w \in G_{c,k}} n_{c,w}} \quad (5)$$

where $G_{c,k}$ are the set of top-k words uttered by respondents R for candidate c in the Gallup interviews and $n_{c,w}$ is the number of times word w occurred in responses from R for candidate c. In other words, when computing the fake-ness of top-k words uttered by a group of respondents R, we weigh the estimate by how frequently each word is uttered by this group. For instance, email occurs 2.5 times more frequently than *debate* when considering all respondents. Therefore, "email" will account 2.5 times more heavily compared to "debate". Next, we inspect $f_{c,k,R}^G$ for both candidates separately for (i.) all respondents, (ii.) only Democrats, and (iii.) only Republicans, with k ranging between 1 and 100. As a result, we are able to compare and contrast the alignment between fake news coverage and information retained by different groups. The result of this analysis is summarized in Figure 4. The first panel in Figure 4 characterizes the fake-ness of responses from the three groups

[8] Consider for instance, the word "foundation". This word, when uttered for Clinton, is likely to refer to the Clinton foundation and the relevant scandals that were damaging for her [39]. The same phrase when uttered about Trump is likely to refer to the Trump foundation and the scandals that were damaging to him [26].

[9] If a word w is seen three times in a fake news article that is shared 10 times and twice in another article that is shared 20 times, w will be repeated $3 * 10 + 2 * 20 = 70$ times in corpus i.

[10] Stop words are removed for this analysis.

when asked about what they had read, seen or heard about Hillary Clinton recently. The solid, dotted, and dashed lines correspond to all respondents, Democrats, and Republicans respectively. The second panel presents the same information for the responses about Donald Trump.

A number of observations are worth noting from Figure 4. First, the top-100 words the interviewees uttered about Hillary Clinton consistently resemble fake news coverage more than traditional news coverage (with y-values greater than 0). Second, there is a clear divide between the Republican and Democrat interviewees. Popular Republican leaning interviewee response words are consistently in line with fake news coverage while the popular words used by Democrat leaning interviewees are more in line with traditional news coverage. It is important to note that our findings are purely correlational. While suggestive, one cannot conclude that the fake news producers and content shared by them *resulted in* the topics individuals remember. Indeed, the result we observe can very well be due to fake news domains focusing more on topics that were more memorable (discriminately for the Republican leaning voters). Indeed, *email* provides a good example here. While this word had a positive fake-ness, i.e. more central to fake news coverage, an interviewee could very well have heard about it from traditional news. While we cannot establish causality using this observational data without a more careful causal inference framework, the alignment between the fake news agenda and retained information extracted from Gallup interviews is worthy of further exploration.

The results presented for Donald Trump (second panel) are rather distinct from what we observed for Hillary Clinton. The most frequent words for all interviews were more in line with traditional news coverage compared to the first panel. The fake-ness becomes positive only beyond the most popular topics and compared to Hillary Clinton analysis, the magnitude is small. In addition, the difference between the Republican and Democrat leaning interviewees is much smaller—even hard to detect—and the directionality of the results is largely consistent between these two groups. What explains the relatively low degree to which survey responses align with fake news content about Donald Trump? One conjecture is as follows: Past research claims that fake and hyper-partisan sites were predominantly pro- Donald Trump and anti- Hillary Clinton [64]. Our findings suggest that they showed their ideological leaning not by writing positive articles about Donald Trump but by writing critical articles about Hillary Clinton. Such behavior could lead to a lack of alignment in this topic

Measuring fake-ness of interview responses as a function of demographic characteristics. Figure 4 demonstrates that party affiliation had a strong correlation with the fake-ness of the content interviewees remembered about each candidate. We investigate to what extend party affiliation and other demographic characteristics such as gender, age, race, and geographic area matters through statistical analysis.

To that end, we first measure the fake-ness of an interview response—or rather the fake-ness of the words uttered in it—as a function of the demographic characteristics of the interviewee

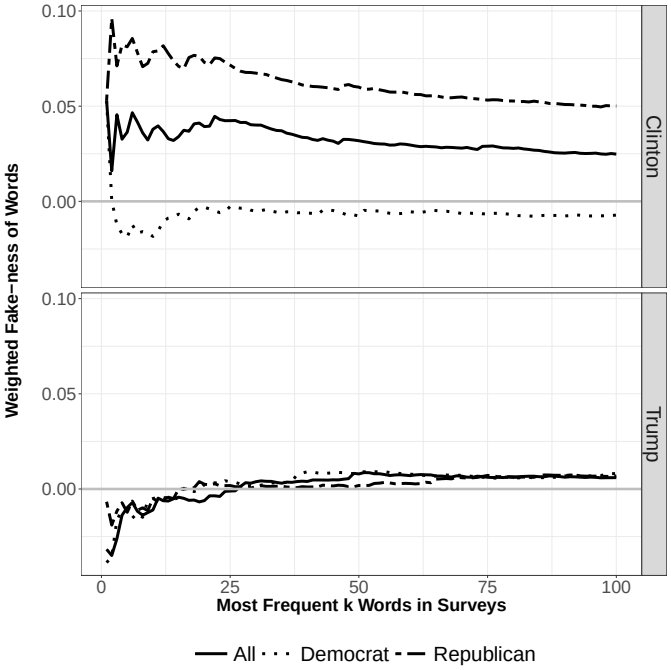

Figure 4: Fake-ness of the top-100 words uttered about Hillary Clinton and Donald Trump in interviews with respondents with party affiliations

and temporal patterns. In particular, we fit the following random-intercept multi-level regression model:

$$f_{i,j} = \beta_0 + \beta_1 party_i + \beta_2 age_i + gender_i + \beta_3 race_i + \beta_4 location_i + \beta_5 months_i + \alpha_i + \epsilon_{i,j} \quad (6)$$

$$\epsilon_{i,j} \sim N(0, \sigma_e^2) \quad (7)$$

$$\alpha_i \sim N(0, \sigma_u^2) \quad (8)$$

where $f_{i,j}$ is the fake-ness of the j−th word uttered by interviewee i, $party_i$ gives the party of interviewee i (Democrat, Independent, or Republican), age_i denotes the age (categorical scale, interview responses coded as 18-29, 30-49, 50-64, or 65+.), $gender_i$ denotes the gender of interviewee i, $race_i$ gives the race (Asian, Hispanic, Non-Hispanic White, and Non-Hispanic Black [11]), $location_i$ denotes the region where the interviewee resides (Southeast, New England, East Central/Great Lakes, Middle Atlantic, West Central, Rocky Mountain, Pacific or Southwest) and $months_i$ denotes the timing of the interview as the time between the interview and the election. This model allows grouping of all words uttered in the same response as opposed to treating them like independent measurements. We fit $f_{i,j}$ separately for response about Clinton and Trump to identify demographic and temporal characteristics that determine how aligned retained information for each candidate was with fake news coverage. Furthermore, since our fake-ness measurement of words that are more commonly observed in the news dataset is less noisy, we perform weighted generalized linear regression where each datapoint ($f_{i,j}$) is weighted by the frequency

[11] A fifth category of "Other" is filtered out.

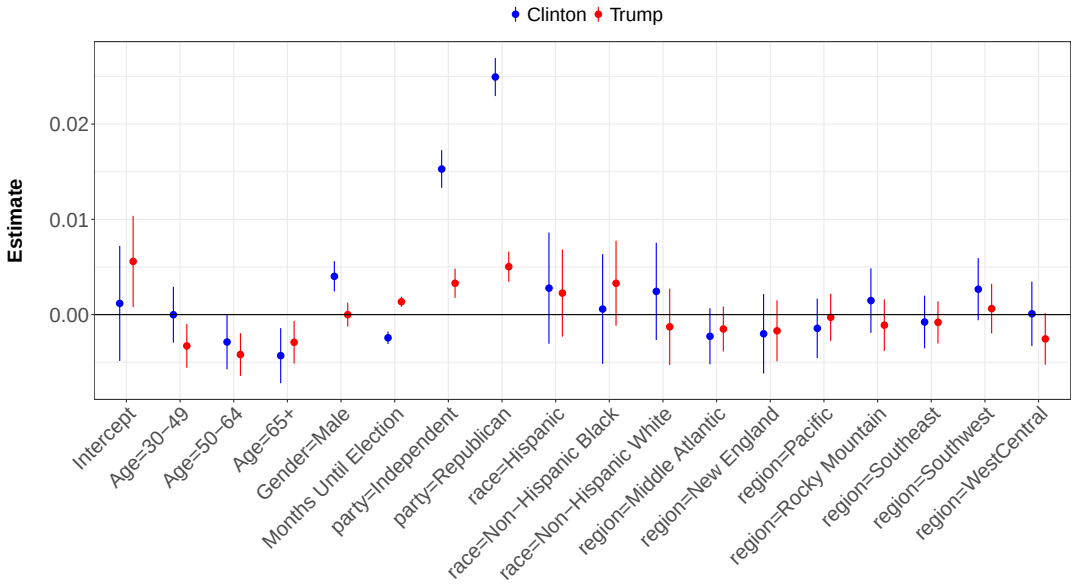

Figure 5: Coefficient estimates from linear mixed-effect models for fake-ness of recalled information about Clinton and Trump shared in interview responses as a function of interviewee characteristics. Base class for gender is female; race is Asian; region is East Central/Great Lakes. Data points are colored to according to the candidate the interviewee was listing retained information about. Each data point gives the coefficient estimate. Error bars mark standard errors of the estimates.

with which we observe the given word in our news sample (across fake and real news combined, in log-scale).

The estimated coefficients are provided in Figure 5. Statistically significant effect sizes are identified for age, gender, party, and timing. The effect directions are largely consistent across the Trump and Clinton responses. However, the effect sizes are significantly larger for Clinton responses. The exception to the consistency between the models is observed for timing patterns. The fake-ness of interview responses increases over time for retained information about Clinton while it decreases for Trump. This difference in temporal patterns can readily be explained by the *increasing* emphasis fake news producers placed on Clinton—observed through various analysis presented earlier in the paper (e.g. Figure 2). Focusing on effects with consistent direction and divergent effect sizes, we see that the Republicans (and to a lesser extent, Independents), younger and male interviewees had a higher tendency to remember information better aligned with fake news publishers. The effects were larger for Clinton. Geographical area and race are not statistically significant. The patterns observed for age are consistent with [3] that claims that fake news commonly spread on social media and older voters were less likely to be exposed to such content. Increased tendency of male respondents to share words with positive fake-ness measures are in line with recent research that showed significant gender effects in views of the two candidates. This highlights the importance of future research to better understand what characteristics are predictive of consuming and retaining information more aligned with fake news publishers.

9 LIMITATIONS

It is worthwhile to note a number of shortcomings of the analysis provided here. First, identifying fake, hyper-partisan, and otherwise fake news at the domain (as opposed to article) level, while supported by related work [45], has certain shortcomings. First, domains classified as fake at times might publish reliable news. Second, even mainstream news sites exhibit ideological bias and at times can disseminate misinformation. Future work that increases the accuracy of fake news classification—both at the article and domain levels—will be crucial for forming a richer understanding. This open problem is something that platforms are increasingly facing. The perfect solution is yet to be identified. This is evidenced in how platforms such as Facebook are alternating between publisher [19] and article [18] level solutions.

Second, content analysis performed in this paper is at the word level. Future studies that employ other content analysis methods and provide a rich qualitative analysis of open-ended Gallup responses can provide further insights about the alignment between fake news coverage and retained information about the candidates. Third, much of our analysis is based on Twitter. While Twitter is one of the popular social media sites used for sharing and consuming the news, it certainly is not the only one [29] and its population is not representative of the U.S. population. Furthermore, we can only examine articles shared at least once in our Twitter sample. Consequently, we cannot disentangle the effects of fake news production and consumption. Future work that examines *all* articles published by these producers can help us determine the effects of consumption and production separately.

Most notably, the analyses presented in this paper are purely correlational. Our findings unearth interesting patterns—such as the relationship between favorability of candidates and fake news consumption or the alignment between the information retained by voters and the content of fake news articles. However, such patterns are only suggestive. Finally, we do not consider the effects of fake news on readers' voting or other relevant attitudes. For instance, our study cannot help determine whether the spread of fake news determined the outcome of the 2016 U.S. Presidential election.

10 DISCUSSION AND IMPLICATIONS

Given the growing pace with which fake news spreads and the societal implications of such spread, it is crucial to examine fake news publisher content and understand its appeal. Motivated by this challenge, here we study the overall prevalence and focus of fake news content leading up to the 2016 U.S. Presidential election and examine how fake news production and consumption related to election campaign dynamics using a rich dataset that includes daily sample of random tweets mentioning the two presidential candidates, content of external urls shared in those tweets and nationally representative interviews conducted by Gallup at the daily level. Consequently, this paper extends our understanding fake news production and consumption and highlights various implications for platform owners and journalists.

First, despite initial fears raised by investigative journalism [64], we observe that fake news producer prevalence was limited compared to traditional news producers. Despite this positive finding, however, the prevalence of fake news producers was far from negligible. This highlights the importance of technology and design mechanisms that filter out unreliable content or provide means for the consumers to easily inspect the quality of a piece of information. Platform owners are already taking notice. For instance, Facebook has [19] announced in early 2018 that they plan to begin prioritizing "trustworthy" media outlets in users' feeds. Yet, this is a serious technological challenge that requires further research. Indeed, a few months later, Facebook announced that they started labeling content at the article (or video/photo) level [18].

Second, we show that the prevalence of fake news content quickly increased over the course of the campaign. This highlights the importance of tracking mechanisms that keep platform owners in the know early enough for the platform to respond to such challenges. Encouragingly, companies are beginning to reach out to academia to help them define important metrics to keep track of for combatting misinformation [36]. Our study highlights the importance of keeping track of prevalence of fake news content in a continuous manner.

Third, we present the first study to examine the relationship between the favorability of presidential candidates and the production and consumption of fake and traditional news. We show that the patterns in prevalence of fake news and favorability of the candidates are consistent. Indeed, we observe that increases in production and consumption of fake news *follows* increase in relative favorability of Clinton. This contribution highlights the importance of studying these two phenomena in conjunction. Yet, one must be cautious here. Our findings do not determine a *causal* relationship between these two trends.

Fourth, through semi-supervised machine learning techniques, we identify similarities and differences in agenda setting and coverage by fake and traditional news outlets. To the best of our knowledge, this is the first study to examines the similarities and differences between the agenda setting functions of fake and traditional news media leading up to the 2016 U.S. Presidential election. Some of our findings here suggest a failing by traditional news outlets, as evidenced by the similarity between the popular topics for fake and traditional news domains. Through the inspection of traditional news content, we observed that these outlets had a rather weak focus on policy and covered scandals of the two candidates unevenly. The behavior of traditional news outlets might be partially explained through the pressure of competing with fake news domains. Regardless, this brings about questions that journalists need to tackle to provide richer and more useful information to voters in the future. Our findings highlight the potential of tools that reveal to journalists similarities and differences between their coverage and the coverage of fake publishers.

Finally, we also showed that information voters retained about Clinton—especially by Republican voters—were more in line with fake news content than traditional news. Our study also highlights the relationship between demographic characteristics and fake-ness of the information people remembered about presidential candidates. The heterogeneity of vulnerability of different demographic groups will be important to keep in mind while building solutions to combat misinformation. This perhaps highlights the importance of diversity of social connections. Individuals with a diverse ego-network can be exposed to more diverse information and being exposed to diverse information can help one question the reliability of fake content. However, challenges still exist given the confirmation bias tendency. In fact, research is inconclusive. Diversity seems to play a positive role under some circumstances [16] while being negative in others [5]–highlighting the importance of context in which people are exposed to diverse ideas.

Where do we go from here? If fake news corrodes our democracy, what can and should be done about it? Social media platforms, while initially skeptical about their role [43], have taken steps to identify fake news content and warn their consumers [49, 61], mostly relying on independent organizations for fact checking. A similar step has been taken by search companies that provide news aggregation tools [72]. These are undoubtedly important steps towards a more robust news ecosystem. We believe further research on identifying and combating such problematic content is vital to the health of our democracy. We need to build the tools of strategy for traditional news organizations to stay relevant and compete with this growing industry and tools of literacy for news consumers to distinguish credible news content from unreliable ones.

ABSTRACT

Incorporating knowledge graph (KG) into recommender system is promising in improving the recommendation accuracy and explainability. However, existing methods largely assume that a KG is complete and simply transfer the "knowledge" in KG at the shallow level of entity raw data or embeddings. This may lead to suboptimal performance, since a practical KG can hardly be complete, and it is common that a KG has missing facts, relations, and entities. Thus, we argue that it is crucial to consider the incomplete nature of KG when incorporating it into recommender system.

In this paper, we jointly learn the model of recommendation and knowledge graph completion. Distinct from previous KG-based recommendation methods, we transfer the **relation** information in KG, so as to understand the reasons that a user likes an item. As an example, if a user has watched several movies *directed by* (relation) the *same person* (entity), we can infer that the director relation plays a critical role when the user makes the decision, thus help to understand the user's preference at a finer granularity.

Technically, we contribute a new translation-based recommendation model, which specially accounts for various preferences in translating a user to an item, and then jointly train it with a KG completion model by combining several transfer schemes. Extensive experiments on two benchmark datasets show that our method outperforms state-of-the-art KG-based recommendation methods. Further analysis verifies the positive effect of joint training on both tasks of recommendation and KG completion, and the advantage of our model in understanding user preference. We publish our project at https://github.com/TaoMiner/joint-kg-recommender.

1 INTRODUCTION

Knowledge Graph (KG) is a heterogeneous structure that stores the world's knowledge in the form of machine-readable graphs, where nodes denote entities, and edges denote the relations between entities. Since proposed, KG has attracted much attention in many fields, ranging from recommendation [40], dialogue system [18, 21], to information extraction [3]. Focusing on recommendation, the structural knowledge has shown great potential in providing rich information about the items, offers a promising solution to improving the accuracy and explainability of recommender systems.

Nevertheless, existing KGs (e.g., DBPedia [20]) are far from complete, which limits the benefits of the transferred knowledge. As illustrated in Figure 1, the red dashed line between *Robert Zemeckis* and *Death Becomes Her* indicates a missing relation *isDirectorOf*. Assuming that the user has chosen movies *Back to The Future I & II* and *Forrest Gump*, by using the KG, we can attribute the reason of user's choices to the director *Robert Zemeckis*. In this case, although we have accurately captured the user's preference on movies, we may still fail to recommend *Death Becomes Her* (which is also of interest to the user), due to the missing relation in the KG (cf. the red dashed line). As such, we believe that it is critical to consider the incomplete nature of KG when using it for recommendation, and more interestingly, can the completion of KG benefit from the improved modeling of user-item interactions?

In this paper, we propose to unify the two tasks of recommendation and KG completion in a joint model for mutually enhancements. The basic idea is twofold: 1) utilizing the facts in KG as auxiliary data to augment the modeling of user-item interaction, and 2) completing the missing facts in KG based on the enhanced user-item modeling. For example, we are able to understand the user's preference on director via the related entities and relations; meanwhile we can predict that *Robert Zemeckis* is the director of *Death Becomes Her*, if there exist some users who like the movie also have a preference of other movies directed by *Robert Zemeckis*.

Although many prior efforts have leveraged KG in recommender systems [16, 29, 30, 44, 48, 50], there are few works that jointly

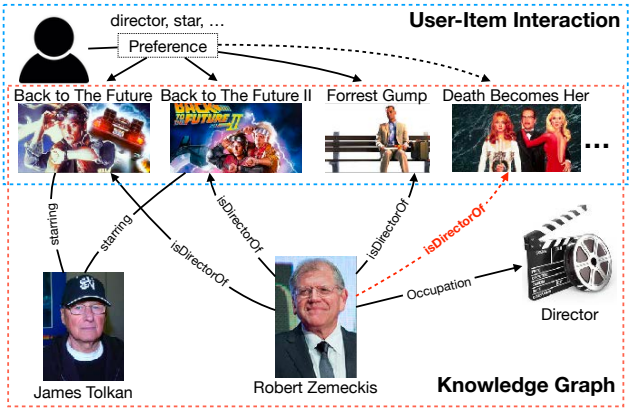

Figure 1: An illustrative example on the necessity of considering the missing relations in KG for recommendation.

model the two tasks of knowledge graph learning and recommendation. CoFM [31] is the most similar work that aligns the two latent vector spaces in each task together by regularizing or sharing entity and item embeddings if they refer to the same thing. However, it ignores the important role of entity relations in user-item modeling, and fails to offer interpretation ability.

In this work, we propose a **T**ranslation-based **U**ser **P**reference model (TUP) to integrate with KG learning seamlessly. The key idea is that there exists multiple (implicit) relations between users and items, which reveal the preferences (i.e., reasons) of users on consuming items. An example of the "preference" is the director information in Figure 1 that drives the user to watch the movies *Back to Future I & II* and *Forest Gump*. While we can pre-define the number of preferences and train TUP from user-item interaction data, the preferences are expressed as latent vectors that are opaque to deeper understanding. To endow the preferences with explicit semantics, we align them with the relations in KG, capturing the intuition that the type of item attributes plays a crucial role in user decision-making process. Technically speaking, we transfer the relation embeddings as well as entity embeddings learned from KG to TUP, simultaneously training the KG completion and recommendation tasks. We term the method as **K**nowledge-enhanced TUP (KTUP) that jointly learns the representations of users, items, entities, and relations. The main contributions are summarized:

- We propose a new translation-based model, which exploits the implicit preference representations to capture the relations between users and items.
- We emphasize the importance of jointly modeling item recommendation and KG completion to couple the preference representations with the knowledge-aware relations, thus empowering the model with explainability.
- We perform extensive experiments on two datasets for top-N recommendation and KG completion tasks, which verify the rationality of joint learning. Experimental results demonstrate the effectiveness and explainability of our model.

2 RELATED WORK

Our proposed methods involve two tasks: item recommendation and KG completion. In this section, we first introduce related work for each task, before discussing their relations.

2.1 Item Recommendation

In the early stage of item recommendation, researchers focus on recommending similar users or items to a target user using history interactions alone, such as collaborative filtering (CF) [35], factorization machines [33], matrix factorization techniques [19], BPRMF [34], and their extensions [46]. The key challenge here lies in extracting features of users and items to compute their similarity, namely **similarity-based methods**.

With the surge of neural network (NN) models, a host of methods extend **similarity-based methods with NN** and present a more effective mechanism in automatically extracting latent features of users and items for recommendation [7, 12–14]. However, they still suffer from the data sparsity issue and cold-start problem. **Content-based methods** deal with the issues by introducing various side information, such as the contextual reviews [9, 25], relational data [10, 36] and knowledge graphs [6]. Another advantage of additional contents is the improved explainable ability to understand why an item is being recommended out of others. This has been found to be important for the effectiveness, efficiency, persuasiveness, and user satisfaction of recommender systems [8, 39, 49].

Among the side information, knowledge graphs (e.g., DBPedia [20]) show great potentials on recommendations due to its well-defined structures and adequant resources. This type of methods mostly transfer structural knowledge of entities from KG to user-item interaction modeling based on the given mapping between entities and items. We roughly classify them into two groups: the methods augmenting the data of user-item pairs with KG triplets, and the methods combining item and entity embeddings learned from different sources. In the first group, Piao and Breslin [29] extracted lightweight features drived from KG (i.e. property-object, subject-property) for factorization machines. Zhang et al. [48] constructed a unified graph by adding a *buy* relation between users and items, then applied transE [2] to model relational data. On the other hand, the methods in the second group usually improve the quality of item embeddings using entity embeddings if they refer to the same thing [16, 44]. Piao and Breslin [30] summerized the recommendation results using different entity embeddings (i.e. node2vec, doc2vec and transE), and found that node2vec improves the most. CoFM [31] first takes into account the refinements of entity embeddings from user-item modeling as another transfering task. However, the above methods heavily rely on the alignments between items and entities. Zhou et al. [50] introduced entity concepts in KG to deal with the sparisity issue of the alignments, but still fail to consider the importance of entity relations in transfering knowledge from KG.

Another line of work is **translation-based recommendation**, inspired by KG representation learning. It assumes that the selection of items satisfies translational relations in the latent vector space, where the relations are either regarded as related to users in sequential recommendation [11], or modeled implicitly via Memory-based Attention [37]. We thus improve this type of method by considering the N-to-N issue[1] in modeling user preferences as translational relations, which shall be further enhanced by transfering knowledge of entities and their relations from KG.

[1]N-to-N issue here means that one user may like multiple items, and also, several users may like a single item, which will be detailed in Section 4.2.

2.2 KG Completion

External knowledge has been found to be effective in many tasks of natural language processing, such as the question answering [47], which accelerates the popularity of KGs. Although there are a host of methods for finding entities [4, 5] and their relations from texts [22], existing KGs are far from complete. Recent studies for KG completion show a great enthusiasm for learning low-dimensional represention of entities and relations while perserving structural knowledge of the graph. We roughly categorize such representation learning methods into two groups: translational distance models and semantic matching models.

TransE [2] first proposed the core idea of translational distance models that the relationship between two entities corresponds to a translation in their vector space. Although it is simple and effective, it is sometimes confusing because some relations can translate one entity to various entities, namely the 1-to-N problem. Similarly, there are other N-to-1 and N-to-N problems. To address these problems, a host of methods extended TransE by introducing additional hyperplanes [42], vector spaces [23], textual information [41] and relational path [22].

The second group measures the plausibility of facts by matching semantic representations of entities and relations through similarity-based scoring functions. RESCAL [27] represents each relation as a matrix to capture the compositional semantics between entities, and utilizes a bilinear function as similarity metrics. To simplify the learning of relation matrices, DistMult [43] restricts them to be diagonal, HolE [26] defines a circular correlation [32] to compress relation matrices as vectors, and ComplEx [38] introduces complex-value for asymmetric relations. Instead of modeling the compositional relation, another line of methods directly introduce NNs for matching. SME [1] learns relation specific layers for head entity and tail entity, respectively, and then feeds them into the final matching layer (e.g., dot production), while NAM [24] conducts the semantic matching with a deep architecture.

2.3 Relationship between Two Tasks

Items usually correspond to entities in many fields, such as books, movies and musics, making it possible to transfer knowledge between fields. These information involving in two tasks are complementary, revealing the connectivity among items or between users and items. In terms of models, the two tasks both aim to rank candidates given a query (i.e., an entity or a user) as well as their implict or explict relatedness. For example, KG completion aims to find correct movies (e.g., *Death Becomes Her*) for the person *Robert Zemeckis* given the explicit relation *isDirectorOf*, while item recommendation aims at recommending movies for a target user satisfying some implicit preference. Therefore, we are able to fill in the gap between item recommendation and KG completion via a joint model, to systematically investigate how the two tasks impact each other.

3 PRELIMINARY

Before introducing our proposed methods, let's first formally define the two tasks as well as TransH [42] as the component for KG completion in our model.

3.1 Tasks and Notations

Item Recommendation : Given a list of user-item interactions $\mathcal{Y} = \{(u, i)\}$, we use implicit feedback as the protocol so that each pair (u, i) implies the user $u \in \mathcal{U}$ consumes the item $i \in \mathcal{I}$. The goal is to recommend top-N items for a target user.

KG Completion : A **Knowledge Graph** $\mathcal{KG}$ is a directed graph composed of *subject-property-object* triple facts. Each triplet denotes that there is a relationship r from head entity e_h to tail entity e_t, formally defined by (e_h, e_t, r), where $e_h, e_t \in \mathcal{E}$ are entities and $r \in \mathcal{R}$ are relations. Due to the incompleteness nature of KGs, KG completion is to predict the missing entity e_h or e_t for a triplet (e_h, e_t, r), which can also be regarded as recommending top-N entities for a target (e_t, r) or (e_h, r).

TUP denotes the model for item recommendation. It takes a list of user-item pairs $\mathcal{Y}$ as input, and outputs a relevance score $g(u, i; p)$ indicating the likelihood that u likes i, given the preference $p \in \mathcal{P}$, where the number of the preference set $\mathcal{P}$ is predefined. For each user-item pair, we induce a preference, serving as a similar role with the relation for two entities. To deal with the N-to-N issue, we introduce preference hyperplanes, and assign each preference with two vectors: $\mathbf{w}_p$ for the projection to a hyperplane, $\mathbf{p}$ for the translation between users and items.

KTUP is a multi-task architecture. Given $\mathcal{KG}$, $\mathcal{Y}$, and a set of item-entity alignments $\mathcal{A} = \{(i, e)|i \in \mathcal{I}, e \in \mathcal{E}\}$, where each (i, e) means that i can be mapped to an entity e in the given KG. KTUP is able to output not only $g(u, i; p)$, but also a score $f(e_h, e_t, r)$ indicating how possible the fact is true, based on the jointly learned embeddings of users $\mathbf{u}$, items $\mathbf{i}$, preferences $\mathbf{p}, \mathbf{w}_p$, entities $\mathbf{e}$ and relations $\mathbf{r}, \mathbf{w}_r$.

Example 3.1. As shown in Figure 1, given a user, the interacted movies (e.g., *Back to The Future I & II* and *Forrest Gump*), and the related triplets, KTUP is able to (1) figure out the user preference of the *isDirectorOf* relation on movies, (2) recommend the movie *Death Becomes Her* based on the induced preference, and (3) predict the missing head or tail entity for the triplet (*Death Becomes Her-isDirectorOf-Robert Zemeckis*). The above three goals shall be achieved by considering not only the structural knowledge in KG but also the user-item interactions.

Next, we will briefly describe transH as the module of KG completion in our joint model.

3.2 TransH for KG Completion

Learning distributional representations of KG provides an effective and efficient way of manipulating entities while perserving their structural knowledge. TransE [2] is a widely used method due to its simplicity and remarkable effectiveness, inspiring many research fileds [45]. Its basic idea is to learn embeddings for entities and relations, satisfying $\mathbf{e}_h + \mathbf{r} \approx \mathbf{e}_t$ if there is a triplet (e_h, e_t, r) in KG. However, a single relation type may correspond to multiple head entities or tail entities, leading to serious 1-to-N, N-to-1 and N-to-N issues [42].

Therefore, TransH [42] learns different representations for an entity conditioned on different relations. It assumes that each relation owns a hyperplane, and the translation between head entity and

tail entity is valid only if they are projected to the same hyperplane. It defines an energy score function for a triplet as follows:

$$f(e_h, e_t, r) = \| \mathbf{e}_h^{\perp} + \mathbf{r} - \mathbf{e}_t^{\perp} \| \tag{1}$$

where a lower score of $f(e_h, e_t, r)$ indicates that the triplet is possbily true, otherwise no. $\mathbf{e}_h^{\perp}$ and $\mathbf{e}_t^{\perp}$ are projected entity vectors:

$$\mathbf{e}_h^{\perp} = \mathbf{e}_h - \mathbf{w}_r^{\mathrm{T}} \mathbf{e}_h \mathbf{w}_r \tag{2}$$

$$\mathbf{e}_t^{\perp} = \mathbf{e}_t - \mathbf{w}_r^{\mathrm{T}} \mathbf{e}_t \mathbf{w}_r \tag{3}$$

where $\mathbf{w}_r$ and $\mathbf{r}$ are two learned vectors of relation r, $\mathbf{w}_r$ denotes the projection vector of the corresponding hyperplane, and $\mathbf{r}$ is the translation vector. $\| \cdot \|$ denotes the L1-norm distance function used in the presented paper.

Finally, the training of TransH encourages the discrimination between valid triplets and incorrect ones using margin-based ranking loss:

$$\mathcal{L}_k = \sum_{(e_h, e_t, r) \in \mathcal{KG}} \sum_{(e'_h, e'_t, r') \in \mathcal{KG}^-} [f(e_h, e_t, r) + \gamma - f(e'_h, e'_t, r')]_+ \tag{4}$$

where $[\cdot]_+ \triangleq \max(0, \cdot)$, $\mathcal{KG}^-$ contains incorrect triplets constructed by replacing head entity or tail entity in a valid triplet randomly, and γ controls the margin between positive and negative triplets.

4 TUP FOR ITEM RECOMMENDATION

Inspired by the above translation assumption between two entities in KG, we propose TUP to explictly models user preferences and regards them as translational relationships between users and items. Given a set of user-item interactions $\mathcal{Y}$, it automatically induces a preference for a user-items pair, and learns the embeddings of preference $\mathbf{p}$, user $\mathbf{u}$ and item $\mathbf{i}$, satisfying $\mathbf{u} + \mathbf{p} \approx \mathbf{i}$.

Considering the implicity and variety of user preferences, we design two main components in TUP: Preference Induction and Hyperplane-based Translation.

4.1 Preference Induction

Given a user-item pair (u, i), this component is to induce a preference from a set of latent factors $\mathcal{P}$. These factors are shared by all users, and each $p \in \mathcal{P}$ denotes a different preference, which aims at capturing the commonality among users as global features complementary to user embeddings that focus on a single user locally. Similar with topic models, the number $P = |\mathcal{P}|$ is a hyperparameter, and we cannot nominate the exact meaning of each preference. With the help of KG, the number of preferences can be automatically set and each preference is assigned with explanations (Section 5).

We design two strategies for preference induction: a hard approach that selects one out of the P preferences, and a soft way that combines all preferences with attentions.

4.1.1 Hard Strategy. The intuition behind our hard strategy is that only a single preference takes effect when a user makes a decision over items. We use Straight-Through (ST) Gumbel SoftMax [17] for discretely sampling the preference given a user-item pair, which utilizes reparameterization trick for backpropagation, making it possible to calculate the continuous gradients of model parameters during the end-to-end training.

ST Gumbel SoftMax approximately samples one-hot vectors from a multi-classification distribution. Assuming that the probability of belonging to class p in a P-way classification distribution is defined as log softmax:

$$\phi(p) = \frac{\exp(\log(\pi_p))}{\sum_{j=1}^{P} \exp(\log(\pi_j))} \tag{5}$$

where π_p is the unnormalized output of a score function. Then, we sample a one-hot vector $\mathbf{z} = [z_1, \cdots, z_P] \in \mathbb{R}^P$ from the above distribution as follows:

$$z_p = \begin{cases} 1, & p = \arg\max_j(\log(\pi_j) + g_j) \\ 0, & \text{otherwise} \end{cases} \tag{6}$$

where $g = -\log(-\log(u))$ is the Gumbel noise and u is generated by a certain noise distribution (e.g., $u \sim \mathcal{N}(0, 1)$). The noise term increases the stochastic of arg max function and makes the process become equivalent to drawing a sample accroding to a continuous probability distribution $\mathbf{y} = [y_1, \cdots, y_p, \cdots, y_P]$:

$$y_p = \frac{\exp((\log(\pi_p) + g_p)/\tau)}{\sum_{j=1}^{P} \exp((\log(\pi_j) + g_j)/\tau)} \tag{7}$$

This is called Gumbel-Softmax distribution, where τ is a temperature parameter. The related proofs can be found in the original papers.

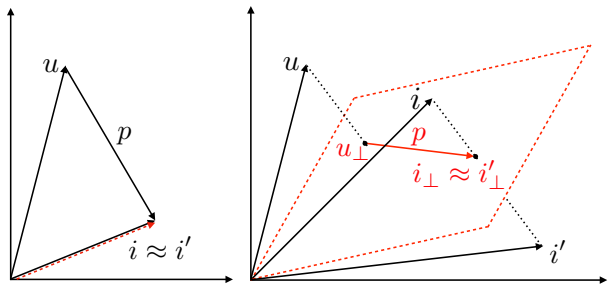
Straight-Through (ST) gumbel-Softmax takes different paths in the forward and backward propagation, so as to maintain sparsity yet support stochastic gredient descent (SGD). In the forward pass, it discretizes the continuous probability distribution for a one-hot vector as mentioned above. And in the backward pass, it simply follows the continuous $\mathbf{y}$, thus the error signal is still able to be backpropagated.

In the hard strategy, we define the score function for π_p as the similarity between the user-item pair and preference:

$$\phi(u, i, p) = \text{Similarity}(\mathbf{u} + \mathbf{i}, \mathbf{p}) \tag{8}$$

We use dot product as similarity function.

4.1.2 Soft Strategy. Actually, a user might like an item according to various factors, which have no distinct boundary. Instead of selecting the most prominent preference, the soft strategy is to combine multiple preferences via the attention mechanism:



$$\mathbf{p} = \sum_{p' \in \mathcal{P}} \alpha_{p'} \mathbf{p}' \tag{9}$$

where $\alpha_{p'}$ is the attention weight of preference p', and defined as proportional to the similarity score:

$$\alpha_{p'} \propto \phi(u, i, p') \tag{10}$$

4.2 Hyperplane-based Translation

Inspired by TransH, we introduce the hyperplane to deal with the variety of preferences. That is, different users may share the same preference to different items (i.e., N-to-N issue), which is pretty common in practice. Obviously, it is confusing for the TransE-like

(a) TransE (b) TransH

Figure 2: Illustration of the two translation schemes for item recommendation

transition: the embeddings of items are close as long as a user who likes both of them are due to the some preference (Figure 2(a)), leading to an incorrect conclusion that a user consuming one shall consume the other, no matter what the user's preference is.

Such limitations are alleviated by introducing perference hyperplanes as illustrated in Figure 2(b): i and i' have different representations, and are similar only when they are projected to a specific hyperplane. We thus define the hyperplane-based translation function as follows:

$$g(u, i; p) = \| \mathbf{u}^{\perp} + \mathbf{p} - \mathbf{i}^{\perp} \| \tag{11}$$

where $\mathbf{u}^{\perp}$ and $\mathbf{i}^{\perp}$ are projected vectors of the user and the item, and are obtained through the induced preference p that plays a similar role as relations in TransH:

$$\mathbf{u}^{\perp} = \mathbf{u} - \mathbf{w}_p^{\mathrm{T}} \mathbf{u} \mathbf{w}_p \tag{12}$$

$$\mathbf{i}^{\perp} = \mathbf{i} - \mathbf{w}_p^{\mathrm{T}} \mathbf{i} \mathbf{w}_p \tag{13}$$

where $\mathbf{w}_p$ is the projection vector that is obtained along with the induction process of preferences p: either to pick up the corresponding one using the hard strategy, or through attentive addition of all projection vectors based on the induced attention weights in the soft strategy:

$$\mathbf{w}_p = \sum_{p' \in \mathcal{P}} \alpha_{p'} \mathbf{w}_{p'} \tag{14}$$

We encourage the translation distances of the interacted items to be smaller than random ones for each user through BPR Loss function:

$$\mathcal{L}_p = \sum_{(u,i) \in \mathcal{Y}} \sum_{(u,i') \in \mathcal{Y}'} -\log \sigma[g(u, i'; p') - g(u, i; p)] \tag{15}$$

where $\mathcal{Y}'$ contains negative interactions by randomly corrupting an interacted item to a non-interacted one for each user.

Tranditional methods (e.g., BPRMF [34]) recommend items for a user by computing a scalar score based on user and item embeddings, which indicates to which extent the user prefers to the item. Instead, we model preferences as vectors in order to (1) capture the commonality among users as global latent features, compared with user embeddings which only concerns with the local features of the user alone, and (2) reflect richer semantics for explainable ability.

5 JOINT LEARNING VIA KTUP FOR TWO TASKS

KTUP extends the translation-based recommendation model, TUP, by incorporating KG knowledge of entities as well as relations. Intuitively, the auxiliary knowledge supplements the connectivity among items as constraints to model user-item pairs. On the other hand, the understanding of users' preferences to items shall reveal their commonality related to some relation types and entities, which may be missing in the given KG.

5.1 KTUP

Figure 3 presents the overall framework of KTUP. On the left side is the inputs: user-item interactions, knowledge graph and the alignments between items and entities. At the top-right corner is TUP for item recommendation, while TransH for knowledge graph completion is at the bottom-right corner. KTUP jointly learns the two tasks by enhancing the embeddings of items and preferences with that of entities and relations. We define the knowledge enhanced TUP translation function as follows:

$$g(u, i; p) = \| \mathbf{u}^{\perp} + \hat{\mathbf{p}} - \hat{\mathbf{i}}^{\perp} \| \tag{16}$$

where $\hat{\mathbf{i}}^{\perp}$ is the projected vector for the enhanced item embedding $\hat{\mathbf{i}}$ by the corresponding entity embedding $\mathbf{e}$:

$$\hat{\mathbf{i}}^{\perp} = \hat{\mathbf{i}} - \hat{\mathbf{w}}_p^{\mathrm{T}} \hat{\mathbf{i}} \hat{\mathbf{w}}_p \tag{17}$$

$$\hat{\mathbf{i}} = \mathbf{i} + \mathbf{e}, \ (i, e) \in \mathcal{A} \tag{18}$$

And $\hat{\mathbf{p}}$ and $\hat{\mathbf{w}}_p$ are the translation vector and the projection vector enhanced by those of the corresponding relation embedding according a predefined one-to-one mapping $\mathcal{R} \to \mathcal{P}$. We obtain these two vectors as follows:

$$\hat{\mathbf{p}} = \mathbf{p} + \mathbf{r} \tag{19}$$

$$\hat{\mathbf{w}}_p = \mathbf{w}_p + \mathbf{w}_r \tag{20}$$

Thus, for entities and items, the enhanced item embeddings contain the relational knowledge among items that is complementary to user-item interactions, and improves item recommendation, since the entity embedding $\mathbf{e}$ perserves the structural knowledge in KG. Meanwhile, the entity embedding $\mathbf{e}$ shall be fine tuned by the additional connectivity through users and items during back-propagation. Note that we don't use the combined embeddings for both tasks, because it makes the embeddings of items the same as corresponding entities in two tasks, which actually degrades our model to share embeddings between items and entities.

For relations and preferences, the usage of relations not only offers explicit interpretation of explainability, but also further combines the two tasks more sufficiently at model level. On one hand, through the one-to-one mapping, the meaning of each preference is revealed by the relation label. For instance, the relation *isDirectorOf* reveals a preference to director, or *starring* for a preference to movie stars. On the other hand, many items have no aligned entities due

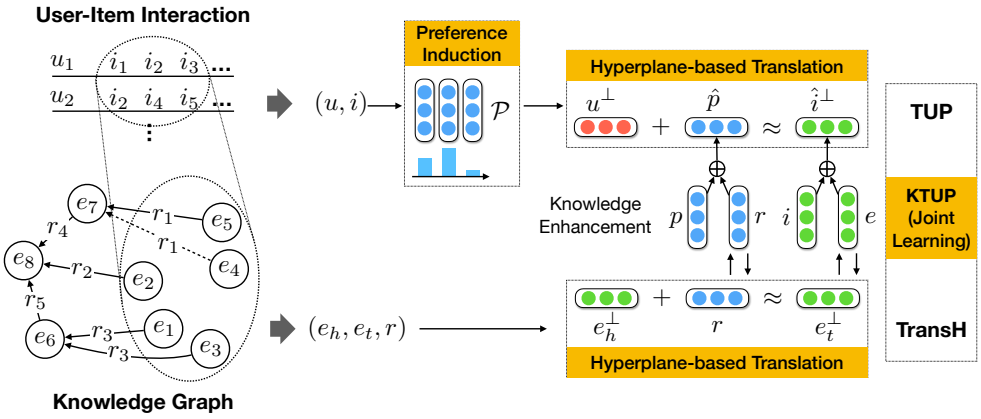


Figure 3: Framwork of KTUP. At the top is TUP for item recommendation including two components: preference induction and hyperplane-based translation. KTUP jointly learns TUP and TransH to enhance the item and preference modeling by transfering knowledge of entities as well as relations.

to the incompleteness of KG, which limits the mutual impacts to the alignments between entities and items in the models that only transfer knowledge of entities. Considering that each user-item pair has a preference and so does the relations between two entities, KTUP optimizes all users, items and entities more thoroughly.

5.2 Training

We train KTUP using the overall objective function as follows:

$$\mathcal{L} = \lambda \mathcal{L}_p + (1 - \lambda)\mathcal{L}_k \tag{21}$$

where λ is a hyperparameter to balance the two tasks.

5.3 Relationship to SOTA Models

In this section, we give a discussion on the relationship between KTUP and the other state-of-the-art KG-based recommendation methods to facilite a deep understanding between two tasks in Section 6. We choose three typical models that transfer knowledge of entities at data level (CFKG [48]), at embedding level (CKE [44]) and in both directions (CoFM [31]). We summerize the main differences and similarities from the following aspects:

Implicity of User Preference CKE and CoFM can be regarded as extentions of collaborative filtering. This type of methods consider the preferences from users to items implicitly and rely on their embeddings to compute a score (i.e., dot product) indicating in which degree the user likes the item. CFKG and KTUP model the preferences explictly and learn the vectoral representations instead of scalars to capture more comprehensive semantics.

Variety of User Preference CFKG defines the only *buy* preference between users and items, which obviously suffers from the serious N-to-N issue and fails to deal with it through the TransE-like scoring function. TKUP distinguishes different user perferences and introduces hyperplanes for each preference as well as each relation to learn the various representations of items and entities.

Transfered Knowledge from KG CKE and CoFM only focus on transfering knowledge of entities. CFKG also transfers relations in the way of data integration through a unifed graph. Except for entities and items, KTUP combines the embeddings of relations and preferences according to the predefined one-to-one mapping, which brings another byproduct of the explainable ability to recommendation mechanism.

6 EXPERIMENTS

In this section, we conduct quantitative experiments on separate tasks of item recommendation and KG completion. For each task, we use two datasets in different domains and give further evaluations on the influence of data sparsity as well as the N-to-N issue. We then investigate the mutual impacts between the two tasks during joint training. Finally, we highlight real examples for qualitative analysis to give an intuitive impression of explainability. We publish our project at https://github.com/TaoMiner/joint-kg-recommender.

6.1 Datasets

Following CoFM [31], we use two publicly available datasets in the movie and book domains: MovieLens-1m [28] and DBbook2014 [2]. Both datasets consist of users and their ratings on movies or books, which are then refined for LODRecSys [15, 28, 29] by mapping items into DBPedia entities if there is a mapping available. Following most item recommendation work that models implicit feedback [40], we treat existing ratings as positive interactions, and generate negative ones by randomly corrupting items.

To collect the related facts from DBPedia, we only consider those triplets that are directly related to the entities with mapped items, no matter which role (i.e. subject or object) the entity serves as. We then preprocess the two datasets by: filtering out low frequency users and items (i.e., lower than 10 in MovieLens and 5 in DBbook), filtering out infrequent entities (i.e., lower than 10 in both datasets), cutting off unrelated relations and merging similar relations manually.

Table 1 shows the statistics of MovieLens-1m and DBbook2014 datasets[3]. After preprocessing, there are 6,040 users and 3,230 items

[2] http://2014.eswc-conferences.org/important-dates/call-RecSys.html

[3] Because we cannot find the released triplets for the two datasets, we collect them as our KG as mentioned above, which leads to a little difference with those papers using the same datasets (e.g., CoFM [31]).

Table 1: Statistics of MovieLens-1m and DBbook2014

		MovieLens-1m	DBbook2014
User-Item Interactions	# Users	6,040	5,576
	# Items	3,240	2,680
	# Ratings	998,539	65,961
	# Avg. ratings	165	12
	Sparsity	94.9%	99.6%
KG	# Entity	14,708	13,882
	# Relation	20	13
	# Triple	434,189	334,511
Multi-Tasks	# Item-Entity Alignments	2,934	2,534
	Coverage	90.6%	94.6%

with 998,539 ratings in Movielens-1m, the average number of ratings per user is 165 and the sparisity rate is 94.9%. The data sparisity issue is more severe in DBbook2014. It consists of 5,576 users and 2,680 items with 65,961 ratings, where the average number of ratings per user is 12 and the sparisity rate reaches up to 99.6%. The triplets used in the two datasets are at the same scale, where the subgraph for MovieLens-1m composes of 434,189 triplets with 14,708 entities and 20 relations, while the subgraph of DBbook has 334,511 triplets with 13,882 entities and 13 relations. Note that the alignments between items and entities for transfering are fewer in MovieLens-1m than that in DBbook2014.

6.2 Baselines

For item recommendation, we compare our proposed models with the following state-of-the-art baselines involving typical similarity-based methods and KG-based methods.

- Typical similarity-based methods: we choose the widely used collaborative filtering models, **FM** [33] and **BPRMF** [34], because they are the foundations of other baselines and also achieve the state-of-the-art performance on many benchmark datasets.
- **CFKG** [48] that integrates the data of two sources and applies TransE on a unifed graph including users, items, entities and relations;
- **CKE** [44] that combines various item embeddings from different sources including TransR on KG;
- **CoFM** [31] that jointly trains FM and TransE by sharing parameters or regularization of aligned items and entities. We mark the two schemes as CoFM (share) and CoFM (reg), respectively.

For KG completion, we choose the typical methods **TransE** [2], **TransH** [42] and **TransR** [23] that are widely used in this field. Also, we evaluate the above KG-based methods even if they have not been done so in the original papers to investigate the impacts of different transfer schemes.

For fair comparison, we carefully reimplement them in our released codes because they did not report the results on the same datasets and we cannot find their released codes. Note that we remove the components of side information modeling like reviews and visual information, since they are not available in the datasets and are out of the scope of this paper.

6.3 Training Details

We construct training set, validation set and test set by randomly spliting the dataset with the ratio of $7:1:2$. For item recommendation, we split the items for each user and ensure at least one item exist in the test set.

For hyperparameters, we apply a grid search on BPRMF and TransE to find the best settings for each task, and use them for all of the other models since they share the basic learning ideas[4]. The learning rate is searched in $\{0.0005, 0.005, 0.001, 0.05, 0.01\}$, the coefficient of L_2 regularization is in $\{10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}, 0\}$, and the optimization methods include Adaptive Moment Estimation (Adam), Adagrad and SGD. Finally, we set the learning rate as 0.005 and 0.001 for item recommendation and KG completion, respectively, L_2 coefficient is set to 10^{-5} and 0, and the optimization methods is set to Adagrad and Adam. Particularly, for the models involving two tasks, we have tried both sets of parameters, and pick up the latter set of parameters due to its superior performance.

Other hypermeters are empirically set as follows: the batch size is 256, the embedding size is 100 and we perform early stopping strategy on the validation sets.

We predefine the number of preferences in TUP as 20 and 13 for MovieLens-1m and DBbook2014, respectively, which are set according to the relations of the collected triplets. For the models involving two tasks (i.e., CFKG, CKE, CoFM and KTUP), we set the joint hyperparameter λ as 0.5 and 0.7 on the two datasets after searching in $\{0.7, 0.5, 0.3\}$, so as to balance their impacts, and use the pretrained embeddings of the basic model (i.e., BPRMF and TransE).

The main goal in this paper is to investigate the mutual impacts on each task during jointly training, rather than achieving best performance by tuning parameters. Thus, our proposed models as well as baseline methods are trained once for each dataset and evaluate for both tasks of item recommendation and KG completion.

6.4 Item Recommendation

In this section, we evaluate our models as well as the baseline methods on the task of item recommendation. Given a user, we take all items in test sets as candidates and rank them according to the scores computed based on the embeddings of users and items. Thus, the N items ranked at top are the recommended items.

6.4.1 Metrics. We use five evaluation metrics that have been widely used in previous work:

- Precision@N: It is the fraction of the items recommended that are relevant to the user. We compute the mean of all users as the final precision.
- Recall@N: It is the proportion of items relevant to the user that have been successfully recommended. We compute the mean of all users as the final recall.
- F1 score@N: It is the harmonic mean of precision at rank N and recall at rank N.

[4]We have tested other parameters for baselines and find performance drop.

Table 2: Overall performance on Item Recommendation

	MovieLens-1m (@10, %)					DBbook2014 (@10, %)				
	Precision	**Recall**	**F1**	**Hit**	**NDCG**	**Precision**	**Recall**	**F1**	**Hit**	**NDCG**
FM	29.28	11.92	13.81	81.06	59.48	3.44	21.55	5.75	30.15	20.10
BPRMF	30.81	12.95	14.84	83.18	61.02	3.56	22.46	5.96	31.26	21.01
CFKG	29.45	12.49	14.23	82.24	58.97	3.17	19.69	5.30	28.09	19.87
CKE	38.67	16.65	18.94	88.36	67.05	3.92	23.41	6.51	33.18	**27.78**
CoFM (share)	32.08	13.02	15.12	83.30	58.69	3.41	20.78	5.67	29.84	20.92
CoFM (reg)	31.74	12.74	14.87	82.67	58.66	3.32	20.54	5.54	28.96	20.53
TUP (hard)	37.29	17.07	18.98	**89.60**	67.40	3.40	21.11	5.67	29.56	20.19
TUP (soft)	37.00	16.79	18.76	89.47	67.02	3.62	22.81	6.06	31.42	21.54
KTUP (hard)	40.87	17.24	19.79	88.97	69.65	4.04	24.48	6.71	34.49	27.38
KTUP (soft)	**41.03**	**17.25**	**19.82**	89.03	**69.92**	**4.05**	**24.51**	**6.73**	**34.61**	27.62

- Hit ratio@N: It is 1 if any gold items are recommended within the top N items, otherwise 0. We compute the mean of all users as the final hit ratio score.
- nDCG@N: Normalized Discounted Cumulative Gain (nDCG) is a standard measure of ranking quality, considering the graded relevance among positive and negative items within the top N of the ranking list.

6.4.2 Overall Results. Table 2 shows the overall performance of our proposed models as well as the baseline methods, where *hard* and *soft* denote the two preference induction strategies in Section 4.1. We can observe that:

- Our proposed methods perform the best compared with the baseline methods on the two datasets. Particularly, TUP performs competitively to other KG-based models, while it doesn't require any additional information. This is because TUP automatically infers the knowledge of preferences from the user-item interactions, and performs much better especially when the amount of interaction data is sufficient, like MovieLens-1m. By incorporating KG, KTUP further presents more promising improvements on DBbook than MovieLens (i.e., 11.06% v.s. 4.43% gains in F1), which implies that the knowledge is more helpful for sparse data.
- The hard strategy performs better than the soft strategy only when it is used for TUP on MovieLens-1m, which implies that to induce a deterministic user perference requires sufficient data, and the soft strategy is more robust.
- CFKG and CoFM perform slightly better than the typical models (i.e., FM and BPRMF) on MovieLens-1m, but perform worse on the sparse dataset of DBbook2014. One possible reason is that they both transfer entities by forcing their embeddings to be similar with the aligned items, leading to the loss of knowledge that has been perserved in the embeddings, and the loss becomes more serious when there is insufficient training data.
- CKE achieves pretty good performance on the two datasets mainly because it combines the embeddings of items and entities that perserve the information from both sources, instead of aligning them with similar positions in the latent space.
- All models preform much better on MovieLens-1m than on DBbook2014 due to the relatively sufficient training data and an easier test (a higher value even using random initializations). Interestingly, the improvement by utilizing KG is larger on dense dataset of MovieLens than that on the sparse dataset of DBbook. This goes against our intuitions that the more sparse the dataset is, the more potentials it shall have in absorbing richer knowledge. Thus, we further split the test set according to different sparisity levels of training data, and investigate the impacts from KG on each subset in the next section.

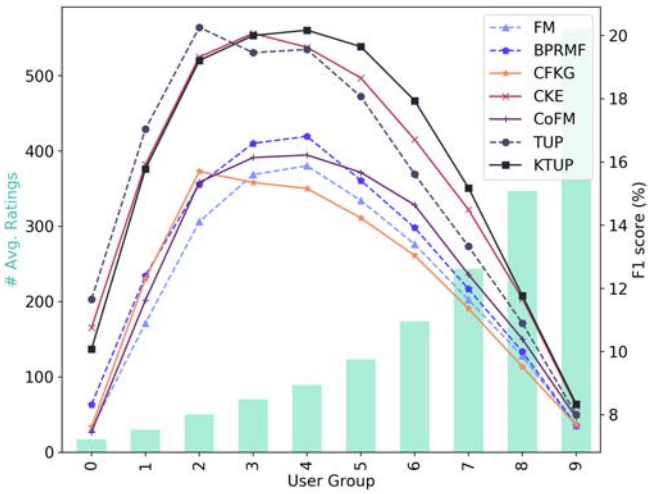

Figure 4: Influence of Different Sparsity on MovieLens-1m. The x-axis shows 10 user groups splited according to interaction number, the left y-axis corresponds to the bars indicating the number of interactions in each user group, and the right y-axis denotes F1-score of curves.

6.4.3 Influence of Training Data Sparsity. To investigate the influence of data sparsity on knowledge transfer, we split the test set of MovieLens-1m into 10 subsets according to the rating number of each user for training; meanwhile we also try to balance the number of users as well as ratings in each subset. The detailed results of F1 score are shown in Figure 4. Green bars represent the average

Table 3: Performance on MovieLens by Relation Category

Task	Prediction Head (Hits@10, %)				Prediction Tail (Hits@10, %)			
Relation Category	**1-to-1**	**1-to-N**	**N-to-1**	**N-to-N**	**1-to-1**	**1-to-N**	**N-to-1**	**N-to-N**
TransE	59.62	56.76	64.55	24.56	**65.38**	62.16	78.52	46.25
TransH	61.54	48.65	65.73	25.51	57.69	78.38	75.62	46.73
TransR	17.31	29.73	32.88	18.50	17.31	43.24	53.12	38.88
CFKG	59.62	51.35	63.31	20.30	57.69	70.27	78.56	41.22
CKE	19.23	21.62	24.16	14.81	7.69	24.32	37.83	34.82
CoFM (share)	65.38	59.46	66.13	24.42	61.54	72.97	**81.05**	45.99
CoFM (reg)	69.23	**70.27**	66.09	24.30	48.08	**86.49**	80.72	45.79
KTUP (hard)	67.31	59.46	66.42	25.67	57.69	81.08	79.22	47.24
KTUP (soft)	**75.00**	56.76	**67.16**	**26.09**	63.46	81.08	78.34	**47.65**

rating number per user ranging from 17 to 563[5]. We denote the models without KG knowledge as dashed lines, and other models as solid lines.

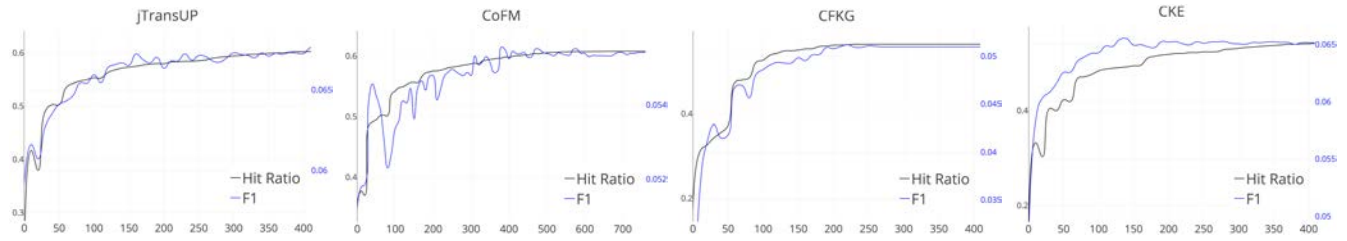
We can see that (1) KG-based methods (i.e., CKE and KTUP) outperform the other models the most when the average number of ratings per user ranges from 100 to 200. (2) The gap between the two types of models is getting closer as the amount of the training data decreases, and the improvements become similar with that on DBbook when their training data is at the similar sparisity level. (3) Meanwhile, the gap almost disappears when the average ratings are 563 (the left most bar), which implies that the impacts of KG become negligible if there if sufficient training data. Note that the performance of all models are getting worse when the average ratings are larger than 89. The possible reason is the user likes so many items that the preferences are too general to capture. (4) TUP outperforms KTUP when user preferences are relative simple to model (i.e., #rating<50), showing the effectiveness and necessity to fully utilize user-item interactions for preference modeling.

Table 4: Overall performance on KG Completion

	MovieLens-1m		DBbook2014	
	Hit@10 (%)	**Mean Rank**	**Hit@10 (%)**	**Mean Rank**
TransE	46.95	537	60.71	531
TransH	47.63	537	60.06	556
TransR	38.93	609	56.33	563
CFKG	41.56	523	58.83	547
CKE	34.37	585	54.66	593
CoFM (share)	46.62	515	57.01	529
CoFM (reg)	46.51	**506**	60.81	521
KTUP (hard)	48.39	525	60.53	501
KTUP (soft)	**48.90**	527	**60.75**	**499**

6.5 Knowledge Graph Completion

In this section, we evaluate on the task of KG completion. It is to predict the missing entity e_h or e_t for a given triplet (e_h, e_t, r). For each missing entity, we take all entities as candidates and rank them according to the scores computed based on entity and relation embeddings.



[5]Note that the sparisity of DBBook2014 can be concluded into the 0th user group in MovieLens-1m, in which we observe similar results.

6.5.1 Metrics. We use two evaluation metrics that have been widely used in previous work [42]:

- Hit ratio@N: It is 1 if the miss entity are ranked within the top N candidates, otherwise 0. We compute the mean of all triplets as the final hit ratio score.
- Mean Rank : It is the averaged rank of the missing entities, the smaller the better.

6.5.2 Overall Results. Table 4 shows the overall performance. We can see that KTUP almost outperforms all the other models on both datasets except the mean rank value on MovieLens-1m. We argure this metric is less important since it is easily reduced by an obstinate triple with a low rank [41]. Compared with TransH, it achieves a larger improvement on Hit Ratio for MovieLens-1m as compared to that for DBbook2014 (2.67% v.s. 1.15%), because Movielens-1m contains more connectivities between users and items that are helpful for modeling structural knowledge between entities. We also observe that CFKG, CKE and CoFM show a performance drop as compared to their basic KG components: TransE and TransR. One reason may be that these methods force the embeddings of aligned entities to satisfy the other task of item recommendation, while the aligned entities are only a small portion (i.e. 19.95% and 18.25% on the two datasets), which actually degrades the learning for KG completion. Another reason is that the N-to-N issues of user preferences have negative impacts on the representation learning of entities and relations, especially for the *buy* relation in CFKG. CKE takes this issue into account but TransR contains a lot of trainable parameters and does not work well on such a small training set.

6.5.3 Capability to Handle N-to-N Relations. Table 3 shows the separate evaluation results on each relation category. Following [2], we divide relations into four types: 1-to-1, 1-to-N, N-to-1 and N-to-N. We can see that (1) TransR and its related models (i.e., CKE) perform the worst which is consistent with the above overall performance. (2) KTUP achieves the best performance on N-to-N issues, and also performs competitively with TransE and CoFM on 1-to-1, 1-to-N and N-to-1 problems, which indicates the capability of our methods in hanling complex relations and improves both tasks. (3) CFKG presents a lower value on N-to-N relations than TransE, which implies that the unifed graph may have introduced more confusing relational semantics. (4) CoFM performs competitively in KG completion task while worse in item recommendation, becuase their knowledge transfering schemes lead to unstable joint training.

(a) KTUP ($\rho = 0.97$) (b) CoFM ($\rho = 0.81$) (c) CFKG ($\rho = 0.97$) (d) CKE ($\rho = 0.94$)

Figure 5: Correlation of Training Curves between Two Tasks on DBbook2014, which is denoted by the Pearson's correlation coefficient ρ. The x-axis is training epoch, the left y-axis corresponds to KG completion via hit ratio, and the right y-axis is for item recommendation through F1. (Note that we scale the values of both F1 and Hit Ratio to the same magnitude.)

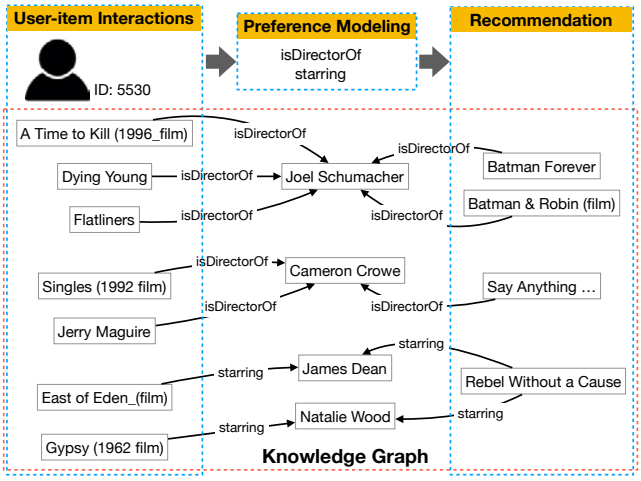


Figure 6: Real Example from MovieLens-1m

That is, it is difficult to control the positive impacts of knowledge transfer on which task, and different parameters for separately training CoFM on each task is required, which is also concluded in the original paper [31].

6.6 Mutual Benefits of Two Tasks

Although the evalutions on separate tasks have been conducted, it is still unclear how different transfer schemes take effect. We thus investigate the correlations between the training curves of two tasks. Intuitively, a strong correlation implies a more complete transfer learning, and a better utilization of the complementary information from each other. Because KG completion has no F1 measures, so we present its hit ratio corresponds to left y-axis, and item recommendation through F1 is presented on right y-axis.

As shown in Figure 5, we can see that KTUP and CFKG present the strongest correlations between their curves, that is, the increase and decrease of one curve shall be reflected on the other curve simultaneously. This implies that the transfer of relations plays an important role in training the two tasks together. However, CFKG does not perform well on both tasks (as shown in Table 2 and Table 4) mainly because of 2 reasons. First, it cannot deal with complex relations; second, it only increase the connectivity in the unified graph through the integration of relations and preferences, which are actually not transitional. Instead, KTUP combines the embeddings of relations and preferences that perserve two types of structural knowledge, and meanwhile introduces hyperplanes for the N-to-N issue. The curves of CoFM and CKE are obviously not correlated strongly due to the small portion of transfered entities. Concretely, CoFM forces the embeddings of aligned entities and items to be similar which may result in unstable training. CKE focuses on unidirectional enhancements by combining their embeddings, and thus performs well in item recommendation but worse in KG completion.

6.7 Case Study

In this section, we present an example of Movielens-1m to give an intuitive impression of our explainability. On the left is a user who has interacted with 7 movies. KTUP first induces user preferences to these movies, and finds that what the user is concerned is the relations of *isDirectorOf* and *starring* (the preferences having highest attention in Section 4.1). Thus, it searches the nearest items according to Equation 16 based on the induced preferences. We present the recommended four movies on the right side. In particular, *Batman Forever* and *Batman & Robin (film)* are recommended because the user shows preference with their director *Joel Schumacher*. Similarly, the preference to director also helps to induce the movie *Say Anything ...* directed by *Cameron Crowe*. Besides, the user also has preferences on *starring*, such as *James Dean* in *East of Eden (film)* and *Natalie Wood* in *Gypsy (1962 film)*; together, the system suggests another movie *Rebel Without a Cause*.

7 CONCLUSION

In this paper, we proposed a novel translation-based recommender model, TUP, and extended it to integrate KG completion seamlessly, namely KTUP. TUP is capable of modeling various implicit relations between users and items which reveal the preferences of users on consuming items. KTUP further enhances the model explainability via aligned relations and perferences, and improves the preformances of both tasks via joint learning.

In future, we are interested in inducing more complex user preferences over multi-hop entity relations and introducing KG reasoning (e.g., rule mining) techniques for unseen user preferences to deal with the cold start problem.

ABSTRACT

Enriching the content of news articles with auxiliary resources is a technique often employed by online news services to keep articles up-to-date and thereby increase users' engagement. We address the task of enriching news articles with related search queries, which are extracted from a search engine's query log. Clicking on a recommended query invokes a search session that allows the user to further explore content related to the article. We present a three-phase retrieval framework for query recommendation that incorporates various article-dependent and article-independent relevance signals. Evaluation based on an offline experiment, performed using annotations by professional editors, and a large-scale online experiment, conducted with real users, demonstrates the merits of our approach. In addition, a comprehensive analysis of our online experiment reveals interesting characteristics of the type of queries users tend to click and the nature of their interaction with the resultant search engine results page.

1 INTRODUCTION

Enriching news articles with auxiliary content that is extracted from rich and diverse sources is a popular trend used by Web news services to improve user engagement. Content enrichment solutions provide an opportunity to bring relevant knowledge, meaning, and added value to the content consumed. One such approach exposes the user to additional related news articles [30]. Other popular forms are based on user-generated content (UGC), where users are empowered to comment on an article, or to reply to others' comments, generating lively discussion threads [31]. Relevant tweets and blog posts can further enrich an article's content [20], providing complementary and sometimes controversial points of view.

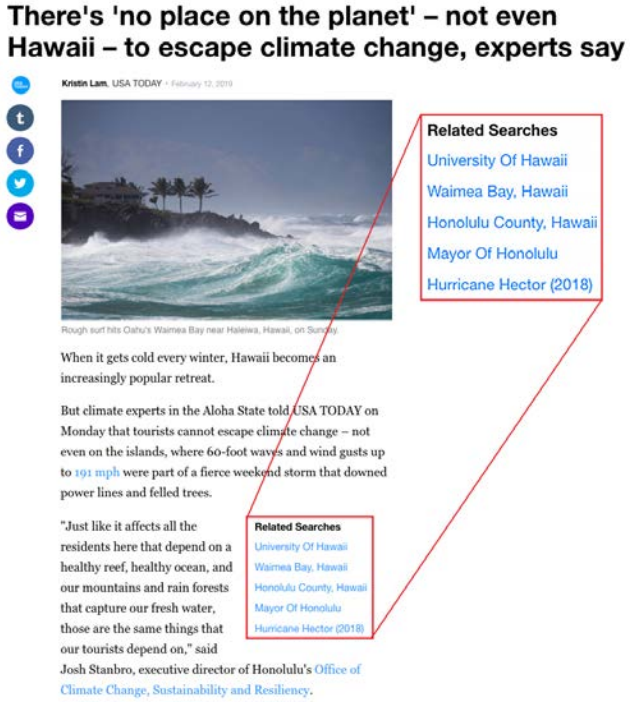

Figure 1: Example of recommended search queries.

These auxiliary sources provide a dynamic and continuously updated content stream, focused on the article's topic. This keeps the article relevant and fresh, thereby deepening users' engagement with the news service.

In this work we address the task of enriching news articles with related search queries that are extracted from a search engine's query log [5]. A search session is invoked when a user clicks on one of the recommended queries, and the subsequent search engine results page (SERP) exposes the user to supplementary content. An example is shown in Figure 1.

There are several requirements that we consider important for the recommended queries to satisfy. First and foremost, the queries should be related to the article's content. We consider the following two notions of query relatedness. The queries might focus on one of the topics covered in the article, allowing the user to further explore that specific topic. Such queries can potentially help users discover different angles of a story. Alternatively, recommended

queries could expose new and interesting aspects related to the topic, which are not explicitly covered in the article [5]. Given that our task is to enrich news articles, only very fresh and emerging queries are considered relevant. Freshness, our second key requirement, is especially important when dealing with breaking news articles that discuss trending stories [11]. Privacy is another important requirement. Because the recommended queries are extracted from a query log, they must respect the privacy of the users who issued them, without exposing any personal or sensitive information [18]. In addition, queries should respect the article's tone and sentiment. For example, it would be inappropriate to recommend queries related to travel deals to Hawaii for an article dealing with a plane crash in Hawaii. Similarly, a query about buying sneakers for boys is an inappropriate recommendation for an article describing a police search for a missing boy. Like any other UGC, queries extracted from the log might be offensive or malformed [13, 34, 35]. We should avoid presenting such queries to users. Finally, although this is not our main focus, we can prioritize queries that can contribute to the overall monetization of the system while also improving user engagement.

We propose a three-phase retrieval approach to address the task. In the first phase, an initial query list is retrieved in response to the article using a limited set of features. In the second phase, a rich set of features are used to re-rank the list retrieved in the previous phase. The weights of the features are learned using a learning-to-rank approach [23]. We consider both article-dependent features, such as the textual and semantic similarity between the query and the article's title, as well as article-independent features, such as the query length and the number of distinct users who submitted the query. In the third phase, two types of filters are employed. One of the filters is used to improve the quality of the recommendations by removing semantically unrelated queries. The other filter is used to diversify the list of recommended queries by removing similar queries that express the same information need.

We conducted an offline evaluation using a dataset manually created by professional editors, as well as a large-scale online experiment with real users. The results of the two experiments demonstrate the merits of the proposed three-phase retrieval approach. A deeper analysis of our results reveals interesting insights regarding the characteristics of the queries users tend to click as well as the nature of the users' interaction with the resultant SERP . For example, we found that users are more likely to click on longer queries that are expressed as questions. In addition, we found that users who clicked on recommended queries are more likely to explore images and videos, and are less likely to click on organic results ("blue links").

2 RELATED WORK

News articles are often augmented with related social media content, including tweets and blogs [8], encyclopedic knowledge [25], and related search queries [5]. In what follows we cover some of the works most relevant to ours.

Mihalcea et al. [25] introduced the use of Wikipedia as a resource to automatically enrich a text with links to encyclopedic knowledge. Given an input text, important concepts are identified and automatically linked to the corresponding Wikipedia pages. Cheng et al. [9] showed that user queries are often triggered by previously consumed content. The query in such scenarios might be better served by a search engine that uses the originating page as contextual information. The authors used multiple features in a learning-to-rank approach for query recommendation. Some of the features are based on the textual similarity between the query and the page. Others are extracted from a page-query bipartite graph that was constructed using historical query logs. The main limitation of this approach is that it is more effective for popular pages that were visited many times by many different users, making it inherently inapplicable for fresh content such as news articles. Kong et al. [19] explored the reasons users initiate a search. The authors conducted an in-depth analysis using a large-scale query log, studying the relations between previously consumed content and the triggered queries. A feature-based approach is proposed to predict which queries a user is likely to issue after visiting a particular page. The features are computed based on the textual match between the query and the visited page, the user's search history, and the entities appearing on the page.

Bordino et al. [5] addressed a task similar to ours. An article was represented using a set of Wikipedia entities that were extracted from it. A random walk on an entity-query graph, which is based on a long-history query log, was used to identify additional related entities and queries. In a following work, Bordino et al. [6] studied the question of what makes a result serendipitous, i.e., encourages users to explore further. For this purpose, the content of an entity graph was further enriched with metadata about the sentiment, writing quality, and topical category of the text surrounding an entity. The authors investigated whether entities that encompass more emotion provide better results. Their findings show that such entities are not enough to draw the user's attention, suggesting a more complex relationship between topics and entities in serendipitous search. While the entity-query graph provides a very appealing framework for content enrichment with related queries, it does not suit our news-article enrichment task, since only very fresh and emerging queries related to the article are considered relevant in our case. Indeed, our experiments show that queries with decreasing popularity are less suitable for recommendation in our case. On the other hand, recommending serendipitous queries for content enrichment might be very appealing in our setting. We leave this direction for future work.

Another related direction is automatic question generation from some form of input [14, 29]. Such techniques focus primarily on generating questions that can be answered by the given text, while our focus is on queries that enhance and elaborate the article's content. We note, however, that such generation techniques, modified for content enhancement, might be a suitable complementary approach that deserves further investigation. Synthetic query generation is another complementary approach [22]. Queries in the work by Lee et al. were generated from text passages selected by the user rather than identified in a query log. No emphasis was put on freshness.

3 RETRIEVAL FRAMEWORK

Given an article r and a corpus of queries Q, our goal is to produce a highly precise ranking of queries that fulfill several requirements.

The queries should: be relevant to the article, address recent events, disclose nothing about the user who issued them, respect the tone of the article, be non-offensive, and be possibly monetizable. To this end, we take a three-phase retrieval approach. In the first phase, an initial query list Q_{init} is retrieved in response to the article using a limited set of features. In the second phase, a rich set of features is used for re-ranking the n most highly ranked queries in Q_{init}. Additional refining filters are applied in the third phase and the top-k ($k < n$) recommendations are presented to the user. We now present further details for the three retrieval phases. Details regarding the creation of the query corpus are provided in Section 4.1.1.

3.1 First Phase: Initial Ranking

We represent each query $q \in Q$ using the query's raw text (q_T), a concatenation of the search result titles previously retrieved in different searches in which the same query was issued (q_R), and the entities identified in the query's text (q_E). Similarly, an article r is represented using its title (r_T); body (r_B); summary (r_S), which contains a subset of the top-θ terms selected from the article's body according to their TF.IDF values; and the set of entities identified in the article's title and body (r_E). Additional details about the entity-linking tools used are provided in Section 4.

The initial query retrieval is based on the similarity between the different texts representing the article and query, as well as a set F of article-independent query-quality measures:

$$Score_{\text{Init}}(q, r) \stackrel{def}{=} \sum_{X \in \{T,R\}; Y \in \{T,S\}} \lambda_{XY} Sim(q_X, r_Y) + \lambda_E Sim(q_E, r_E) + \sum_{f \in F} \lambda_f f(q); \quad (1)$$

$Sim(\cdot,\cdot)$ is an inter-text similarity measure described below; λ_{XY}, λ_E and λ_f are free parameters; $f(q)$ is the score assigned to q by a quality measure f. Inspired by the state-of-the-art performance of the Sequential Dependence approach in the Markov Random Field model [24], to compute the similarity between texts x and y, we use

$$Sim(x, y) \stackrel{def}{=} \lambda_T Sim_{\text{T}}(x, y) + \lambda_U Sim_{\text{U}}(x, y), \quad (2)$$

where $Sim_{\text{T}}(x, y)$ and $Sim_{\text{U}}(x, y)$ are the similarity values, computed using BM25 [28], between terms and unordered term-pairs (within a 5-term window), respectively, in x and y; λ_T and λ_U are free parameters.

We use four measures $f \in F$ to quantify different article-independent properties of the query. Popular queries that were issued by many users might be more interesting. Hence, we count the number of distinct users who issued the query during the last three weeks (**DistinctUsers**). We also examine the interaction of users with the SERP retrieved in response to the query: rich interaction with the SERP is a potential indicator of how attractive and informative it is, and hence of the high query quality. We compute the average number of cards[1] [32] on the page (**Cards**), the average number of clicked URLs after the query was issued (**ClicksPerUser**), and the clickthrough rate (CTR) of ads presented on the SERP (**AdsCTR**). Additional measures are integrated via our learning-to-rank approach in the second retrieval phase, as detailed in the next section.

[1]Cards are results presented directly on the SERP to spare a user an additional click [32].

Table 1: Features used in the learning-to-rank algorithm.

	Feature	Description
Article Dependent	EntitySim	$Sim(q_E, r_E)$
	TitleSim	$Sim(q_X, r_T)$ for $X \in \{T, R\}$
	SummarySim	$Sim(q_X, r_S)$ for $X \in \{T, R\}$
	BodySim	$Sim(q_X, r_B)$ for $X \in \{T, R\}$
	Overlap	Jaccard similarity between q_T and r_T
	W2V	Semantic similarity using word2vec
	ESA	Semantic similarity over Wikipedia concepts
Article Independent	QueryLength	Number of query terms
	AvgIDF , MaxIDF	Average and maximum IDF of query terms
	DistinctUsers	Number of distinct users that submitted the query
	RPM	Revenue per mille (thousand query submissions)
	AdsCTR	Clickthrough rate of ads presented on the SERP retrieved for the query
	ClicksPerUser	Number of clicked URLs divided by the number of users that issued the query
	DistinctClicked	Distinct number of clicked URLs
	DecDistinctUsers	Decaying sum of the number of users that submitted the query during the last three weeks
	AvgUsers , StdvUsers	Average and standard deviation of the number of users that submitted the query during the last three weeks
	AvgUserHistory	Average number of users who issued the query in a specific time period during the last three weeks

3.2 Second Phase: Learning to Rank

We re-rank Q_{init}, the initial query list retrieved in the first phase, to improve its quality. The re-ranking model was trained using a learning-to-rank (**LTR**) approach [23], details of which are provided in Section 4.1.4. Each pair of an article and query is represented as a feature vector. As in Equation 1, we consider two types of features: article dependent and article independent. The features[2] are listed in Table 1.

3.2.1 *Article-Dependent Features.*

Textual Similarities. We use several textual similarity estimates between the different texts representing the article and query. One group of features, which we also used in the initial retrieval phase, includes the BM25 similarity between the entities identified in the article and query (**EntitySim**). We use two entity-linking tools to identify entities in texts (see Section 4 for details). Hence, considering all possible combinations of the entity sets extracted by the two tools, we get four features. Another group of features includes the similarities between the query and the article's title (**TitleSim**), body (**BodySim**), and summary (**SummarySim**), where the query is represented using either its raw text or by a concatenation of its result titles. While a single similarity estimate (BM25) was

[2]We applied Z-score normalization over feature values, which we found to be more effective than applying Min-Max normalization or not normalizing at all.

used to instantiate Equation 2 in the first retrieval phase, here we use three estimates: TF.IDF , BM25 [28], and LM [21] (language models with Jelinek-Mercer smoothing). We get 18 features: 3 similarity estimates (TF.IDF , BM25 , and LM) × 3 texts representing the article (r_T, r_S, and r_B) × 2 texts representing the query (q_T and q_R). In addition, we compute the Jaccard similarity between the query's raw text and the article's title (**Overlap**), where texts are represented by stemmed unigrams after stopword removal.

Semantic Similarities. We use two semantic similarity measures to address the potential vocabulary mismatch between the query and article, which cannot be captured by the textual similarity measures defined above. The first is based on Explicit Semantic Analysis (**ESA**) [12], in which the query's text (q_T) and the article's title (r_T) are embedded into a Wikipedia concept space. Specifically, each text is represented as a weight vector over all Wikipedia concepts (roughly 6M concepts), where the weight of a concept is the similarity value (computed using BM25) between the text and the concept's Wikipedia page. The second measure is based on a word2vec (**W2V**) representation [26]. We train a W2V model using Wikipedia, and represent each text using the centroid of its terms' W2V vectors. We use cosine similarity to compare the query and corresponding article representations for both ESA and W2V . While ESA captures semantic relatedness through a comparison over a concept space, W2V captures the same notion through a comparison of the context of the two texts. Using more complicated entity embedding techniques is an interesting future direction we intend to explore [4].

3.2.2 Article-Independent Features. As already noted, we use multiple article-independent measures to quantify different properties of the query. The first group of measures are computed based on the query's text: query length (**QueryLength**), and average (**AvgIDF**) and maximum (**MaxIDF**) IDF of the query terms. We assume that longer queries with higher IDF values are more interesting. The DistinctUsers measure, which was also used in the first retrieval phase, quantifies query popularity. In addition, high-revenue queries might be favored not only to increase the system's revenue, but also because they are likely to be popular. Hence, we also consider the revenue per thousand query submissions on resultant SERP s (**RPM**). To capture the informativeness and attractiveness of the resultant SERP , we compute several features based on the interaction of users with the SERP: the CTR on Ads (AdsCTR), the average number of clicks performed per user (ClicksPerUser), and the distinct number of clicked URLs (**DistinctClicked**). Finally, we use several features to quantify the trendiness of a query. Queries that were issued only a few times in the past but became popular lately might be more interesting than those whose popularity has been decreasing over time. Hence, we examine the submission history of the query per hour and compute the average (**AvgUsers**) and standard deviation (**StdvUsers**) of the number of distinct users who submitted the query during a one-hour sliding time window over the past three weeks. We also compute a weighted sum of the number of users who submitted the query, where the value in each hour is multiplied by a decaying factor (**DecDistinctUsers**). We experimented with several decaying factors and ended with the following three: Light (0.996), Moderate (0.993), and Heavy (0.986). These provided different decay patterns in user interests for a large portion of the queries. The higher the decaying factor, the lower the difference between weights assigned to different hours. For example, the weight associated with the number of distinct users who issued the query (a day, a week, two weeks) ago will be (0.908, 0.510, 0.260), (0.845, 0.307, 0.094), and (0.713, 0.094, 0.009), for the Light , Moderate , and Heavy decaying factors, respectively. In addition, we divide the three-week hourly submission history into five equal time periods and compute the average number of distinct users who submitted the query in each period (**AvgUserHistory**), resulting in five features.

3.3 Third Phase: Query Filtering

We apply two types of filters on the query ranking produced in the second phase. The first is used to further improve the quality of the recommended queries. The filter is based on the ESA and W2V representations of the query's text and article's title. We filter out queries for which the cosine similarity between their ESA or W2V representation and the corresponding representation of the article is below a given threshold, τ_{ESA} or τ_{W2V}, respectively.

The second filter is used to diversify the list of queries presented to the user by eliminating highly similar queries that express the same information need. To this end, we scan the query ranking from top to bottom. If the similarity between the next query in the ranking and all the preceding queries is below a given threshold τ_{JAC}, the query is considered novel and is added to the final result list; otherwise, it is ignored and the next query in the list is examined. The similarity between queries is measured using Jaccard, where each query is represented via the union of its unigrams and bigrams.

4 EVALUATION

4.1 Experimental Setting

4.1.1 Query Extraction and Indexing. To guarantee that all the articles will be associated with the latest queries, we update the queries dataset (and index) on a regular basis. This is especially important for breaking news articles, where relevant queries start to appear very quickly after the event occurs. New queries that hit the log of the Yahoo commercial Web search engine are identified every four hours and added to the dataset. To ensure that private information about the users who issued these queries will not be revealed, we only consider queries that were searched at least 10 times (by different users) in a day and at least twice during the last 4 hours. Additionally, we filter out offensive and adult queries using blacklists manually curated by in-house professional editors. Finally, we filter out non-Latin queries and queries longer than 10 terms.

For each instance of a query submission, we collect the query's raw text, the top-10 results ("blue links") presented on the SERP and clicks on these results, the displayed ads and the clicks on these ads, and the cards (direct answers) presented on the SERP . We then combine the queries based on their raw text (after lower-casing, but before stemming) over a history of three weeks. Hence, each entry in our query dataset contains a unique query with its top-100 aggregated search result titles scored by their frequency, the number of distinct users who submitted the query, the clickthrough rate for ads, revenue per 1000 submissions (RPM), and the submission history per hour during the last 3 weeks. The 3-week restriction

Table 2: Examples of article titles and queries labeled relevant ('+') and non-relevant ('−') by the editors.

3 Colors You Should Always Wear in a Job Interview
+ What to Say in an Interview
− Wear TV 3

ensures that only relatively fresh queries will be served. Our query dataset, on average, contains approximately 500K queries.

4.1.2 Offline Evaluation. Since our query dataset is constantly updated, we fixed a dataset of 411,646 queries collected on April 25, 2017, and randomly sampled a set of 3082 news articles published on this date on Yahoo News. By varying the free-parameter values in Equation 1, we collected a large set of queries to be judged by in-house professional editors. The results were pooled together and up to 30 queries were selected per article, based on their aggregated score across the different free-parameter variations. Binary relevance labels were assigned by the editors; each query was annotated by one editor. The editors were instructed to label queries that satisfied all the requirements discussed in Section 1 as relevant. Table 2 lists a few examples of queries labeled relevant and non-relevant by the editors. We randomly sampled 250 articles for testing. Two thirds of the remaining articles were used to train the learning-to-rank model and one third to set parameter values.

We are mostly focused on high precision. Hence, to estimate the effectiveness of our approach, we used the precision of the top-3 (p@3) and top-5 (p@5) results, the mean average precision of the top-5 results (MAP), and the mean reciprocal rank of the top-5 results (MRR). In addition to the above-mentioned metrics, we also study in Section 4.2.2 the effectiveness of our approach in terms of the overall expected system revenue. Statistically significant differences in performance were determined using the two-tailed paired t-test at a 95% confidence level.

4.1.3 Online Evaluation. In addition to the offline evaluation performed using the dataset described above, we also conducted an online experiment involving two parts. Our goal in the first part was to collect data for training a learning-to-rank model using explicit user feedback rather than editorial judgments. During a period of 40 days (December 22, 2017 until January 30, 2018) our recommended queries were presented to all Yahoo News users. The users were from the United States and used only desktop devices. The initial ranking (first retrieval phase) and the filters (third retrieval phase) were applied with the free-parameter values learned using our offline dataset. The learning-to-rank approach was not employed in this part of the experiment. After applying the two filters, the retrieval score assigned to queries in the first phase was linearly interpolated with the query's RPM value using a free parameter ρ; we set $\rho = 0.3$ following an analysis performed using the offline dataset, as shown in Section 4.2. This linear interpolation allowed us to control the balance between query relevance and system revenue.

The collected feedback was used to train two learning-to-rank models so as to overcome the bias incurred in users' clicking decisions.[3] (Additional analysis about the position bias is provided in Section 4.2.8.) The first, henceforth **Skip** , was learned using an approach similar to "Click > Skip Above" [17]. Specifically, the training data consisted of all the searches (approximately 35K) in which a "skip" occurred: a user clicked on a query in rank $i > 1$, and skipped (did not click on) the queries ranked above it. All the queries ranked above rank i, and the unclicked queries ranked below it, were considered non-relevant. The query in rank i and all the clicked queries ranked below it were considered relevant. The second model, **Balanced** , was trained using the data collected to train the Skip model as well as searches in which the highest ranked query was clicked. For these searches, all the clicked queries were considered relevant, while the non-clicked were deemed non-relevant. We note that the number of searches in which a user clicked on the highest ranked query was much higher than those in which a skip occurred. Hence, we randomly subsampled the data to get a balanced training set.

In the second part of the experiment, we studied the effectiveness of our approach via A/B testing [15]. We simultaneously launched five buckets each of which served 5% of Yahoo News traffic; users were randomly split between buckets. This experiment lasted 10 days. One of the buckets corresponded to the model used in the first part of the experiment (**Control**). Two additional buckets corresponded to the two models described above. Finally, as was the case in the first part of our experiment, we also linearly interpolated the retrieval score of a query with its RPM value ($\rho = 0.3$), which resulted in two additional buckets: **Skip+RPM** and **Balanced+RPM** .

Since our main focus is on improving user engagement, we use the clickthrough rate on the recommended queries (CTR) to estimate the effectiveness of our approach. In addition, since any click on one of the recommended queries initiates a standard search, we also report the total system revenue per thousand sessions that were initiated by such queries (Revenue) and the query reformulation rate (Reformulation) on the SERP . Low reformulation rate presumably implies that the user was satisfied with the results without having to refine the query, attesting to the effectiveness of the recommended query. We report the improvement in percentages with respect to the Control model.

4.1.4 Additional Implementation Details. We used Apache Lucene[4] for experiments. We applied porter stemming and removed stopwords using Lucene's English stopword list. We used an online variant of RankSVM with a linear kernel [16] to train the re-ranking model. The algorithm uses pairwise training examples and iteratively updates the model via the AROW update step [10]. The hyper-parameters were set to optimize p@5 over the validation set. To identify entities in a text, we applied two in-house entity-linking tools. Each entity was represented using a Wikipedia entity ID

[3] Two thirds of the data was used to train the learning-to-rank models and one third to set parameter values.

Table 3: Offline results. 'i' and 'l' mark statistically significant differences with Init and Init+LTR+ESA+W2V , respectively. The best result in a column is underlined.

	p@3	p@5	MAP	MRR
Init	44.3_{l}	44.6_{l}	58.0_{l}	62.3_{l}
Init+ESA	57.5^{i}_{l}	55.1^{i}	73.0^{i}_{l}	76.9^{i}_{l}
Init+W2V	55.9^{i}_{l}	52.4^{i}_{l}	71.2^{i}_{l}	73.8^{i}_{l}
Init+ESA+W2V	60.3^{i}	$\underline{57.0}^{i}$	76.2^{i}_{l}	78.3^{i}_{l}
Init+LTR	54.4^{i}_{l}	45.8_{l}	71.5^{i}_{l}	74.8^{i}_{l}
Init+LTR+ESA	61.9^{i}	52.4^{i}_{l}	77.4^{i}	80.3^{i}
Init+LTR+W2V	59.1^{i}_{l}	51.4^{i}_{l}	76.9^{i}_{l}	79.6^{i}_{l}
Init+LTR+ESA+W2V	$\underline{62.5}^{i}$	55.8^{i}	$\underline{78.6}^{i}$	$\underline{80.8}^{i}$

along with a score reflecting the confidence of the tool. To compute $Sim(q_E, r_E)$, the IDF of each entity was scaled using the confidence score assigned to it by the entity-linking tool [27].

We mapped the article-independent feature values into a five-dimensional binary feature vector by dividing the feature's range into equal-sized bins. The value in a bin equals one if the feature's value falls in that bin's interval. This binary transformation resulted in better performance compared to using the raw feature values. We applied a logarithmic transformation to the AdsCTR , ClicksPerUser and DistinctClicked features since the ranges of these features were rather large; binary transformation was not applied in this case.

Free-Parameter Values. As mentioned above, free-parameter values were set using a validation set in the online and offline experiments. The number of queries initially retrieved using Equation 1 per article was $n = 25$; $k = 5$ queries were presented to users. The number of terms used to create the article's summary was $\theta = 10$. In Equation 1, we set $\lambda_{TT} = \lambda_{TS} = 10$, $\lambda_{RT} = \lambda_{RS} = 3.5$, $\lambda_E = 2.5$ and $\lambda_f = 0.25$. In Equation 2, we set $\lambda_T = 0.8$ and $\lambda_U = 0.2$. The article's summary (r_S) and the entities identified in the query (q_E) and article (r_E) are unordered sets of tokens, hence when computing the similarity with these texts we set $\lambda_T = 1$ and $\lambda_U = 0$. The free parameters of BM25 ($k1$ and b) and the Jelinek-Mercer smoothing parameter were set to standard values: 1.2, 0.75 and 0.1, respectively. We used W2V 's Continuous Bag-of-Words (CBOW) model. The dimension of the vectors and the window size were set to 300 and 5, respectively; all other parameters were set to default values. In the ESA and W2V filters, we set $\tau_{ESA} = 0.15$ and $\tau_{W2V} = 0.6$. To filter out similar queries, we set $\tau_{JAC} = 0.66$.

4.2 Experimental Results

4.2.1 Offline Results. The results of our offline evaluation are presented in Table 3. We study the effectiveness of the query rankings produced in the first (Init), second (Init+LTR), and third (Init+LTR+ESA+W2V) retrieval phases. We also examine the contribution of the LTR approach and the semantic filters (ESA and W2V) when integrated in different stages of our framework. Note that the similar-queries filter, presented in Section 3.3, was applied to all query rankings. We can see that re-ranking the query list retrieved in the first phase using our LTR model yields statistically significant performance improvements over the initial ranking (Init+LTR vs. Init). Applying the semantic filters (either after the first retrieval phase or after the second phase) substantially improves the performance in both cases. The ESA filter is somewhat more effective than W2V ; however, integrating the two filters leads to further improvements compared to using each alone. Interestingly, Init+ESA+W2V outperforms Init+LTR , further attesting to the clear merits of applying the semantic filters. The best results are almost always attained for Init+LTR+ESA+W2V when considering all three retrieval phases; Init+LTR+ESA+W2V is outperformed only by Init+ESA+W2V for p@5 , but the difference is not statistically significant.

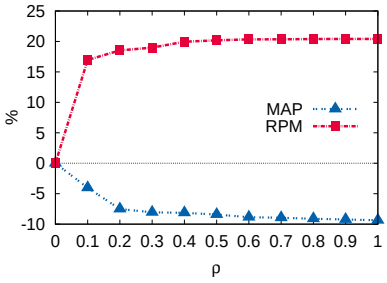

Figure 2: The effect of ρ on MAP and average RPM of the top-five results when interpolating the retrieval score of a query with its RPM value. We report the relative improvement with respect to using the original model Init+LTR+ESA+W2V ($\rho = 0$).

4.2.2 Relevance versus Revenue. After a user clicks on a recommended query, she is taken to a regular SERP where a variety of ads and sponsored links may appear next to organic search results. Such commercial sources of information can increase the overall revenue of the system. Similar to past work on sponsored search [36], we study the tradeoff between recommending queries that are intended to increase user engagement and those aimed at maximizing system revenue. To facilitate the promotion of high-revenue queries, we linearly interpolated the final retrieval score of a query after the third retrieval phase with its RPM value using a free parameter ρ. Figure 2 presents the effect of ρ on MAP and average RPM of the top-five results; the percentages indicate the improvement with respect to using only the original score, i.e., employing the Init+LTR+ESA+W2V model. As ρ increases and more weight is given to the query's RPM value, MAP decreases and the system's expected revenue (RPM) increases. The steepest drop in performance is observed for $\rho \leq 0.3$. For $\rho > 0.3$, MAP continues to drop at a much slower pace.

In Table 4 we show examples of queries recommended by our algorithm for $\rho = 0$, where no weight was given to the query's RPM value, and for $\rho = 0.3$, where a moderate weight was assigned.[5] We see that the queries recommended for $\rho = 0.3$ have a stronger commercial intent. These queries include keywords that users are more likely to use before making a purchase. Conversely, the queries recommended for $\rho = 0$ have a stronger news intent and tend to be more informative. For example, based on a random sample of 280 articles, we found that the terms "sale", "tickets" and "buy" were

[5]We note that in both example articles, the queries recommended for $\rho > 0.3$ were identical to those recommended for $\rho = 0.3$, but they were not necessarily ranked in the same order.

Table 4: Examples of article titles and the top-three recommended queries for different values of ρ. The higher the value of ρ, the more weight is given to the query's RPM value.

	iPhone 9 and X Plus? New iPhone Rumours, Release Dates and Everything We Know
$\rho = 0$	1. iPhone 11 Release Date 2. iPhone Store Near Me 3. iPhone Battery Drains Fast
$\rho = 0.3$	1. Can iPhones Get Viruses 2. iPhone 8 Plus Price 3. Used iPhones for Sale
	Sacred Riana's Weird 'America's Got Talent' Magic Act
$\rho = 0$	1. America Got Talent 2018 2. Courtney America Got Talent 3. America Got Talent Judges
$\rho = 0.3$	1. America Got Talent Tickets 2. NBC America Got Talent 3. America Got Talent 2018

more popular for $\rho = 0.3$. These terms appeared in 6.1%, 5.4% and 4.6% of the recommended queries, respectively, for $\rho = 0.3$ vs. 1.8%, 0% and 1.4% for $\rho = 0$. In contrast, the terms "news", "today" and "twitter" were more popular for $\rho = 0$: they appeared in 9.3%, 5.7% and 2.1% of the queries for $\rho = 0$ vs. 5%, 2.1% and 0% for $\rho = 0.3$.

4.2.3 Online Results. The results of the online evaluation are presented in Table 5. We inspect three metrics quantifying different aspects of our approach: CTR , the user's engagement; Revenue , the system's revenue; and Reformulation , a proxy for the user's dissatisfaction with the search results. Supporting our offline results, we observe substantial improvements in CTR when applying the LTR model in all four buckets; the highest improvement is attained for the Balanced model. Examining Revenue , we see a decrease in revenue for both the Skip and Skip+RPM models, even though the latter explicitly incorporates RPM into the retrieval process. Comparing Balanced with Balanced+RPM , we observe a trend similar to the one we saw in our offline experiment: the CTR is higher for the Balanced model, which uses RPM as a feature in the learning-to-rank model, whereas Revenue is higher for Balanced+RPM , which also explicitly interpolates the RPM value of a query with its retrieval score. The best performance is attained by the Balanced model, which had the highest CTR , second highest Revenue , and lowest Reformulation . Table 6 lists a few examples of queries recommended by this model.

Figure 3 illustrates the change in CTR during the 10-day experiment. As was the case thus far, we report the relative improvement in CTR with respect to the Control model. We first observe that among the 4 considered models, Balanced was the most stable throughout the experiment, especially during the last 6 days. We also see that Balanced is the only model for which the change in CTR was always positive. In contrast, for the other three models, the CTR decreased compared to the Control model at least once during the experiment. These findings, along with the results presented in Table 5, attest to the effectiveness of the Balanced model.

Table 5: Online results. The relative improvement (in percentages) over the Control model. The best result in a row is underlined.

	Skip	Balanced	Skip+RPM	Balanced+RPM
CTR	18.3	<u>22.6</u>	6.5	16.1
Revenue	−23.6	17.4	−23.5	<u>22.4</u>
Reformulation	14.4	<u>−13.5</u>	−7.0	0.6

TitleSim	ClicksPerUser	W2V	AdsCTR
Overlap	DecDistinctUsers	AvgUserHistory	ESA
SummarySim	StdvUsers	AvgIDF	

4.2.4 Feature Analysis. We next analyze the contribution of the features and feature groups used in the learning-to-rank approach employed in the second retrieval phase. To this end, we arrange the features in descending order of their weights in learning-to-rank model and assign each feature with a score that is the reciprocal of its rank. For example, the scores of the top-three features are 1, $\frac{1}{2}$ and $\frac{1}{3}$, respectively. These feature scores are then averaged over groups of features as follows. For each of the article-independent features, excluding AdsCTR , ClicksPerUser , and DistinctClicked , we average the scores of their corresponding five binary features (refer back to Section 4.1.4). In addition, for DecDistinctUsers , the scores are also averaged over the three decaying factors and for AvgUserHistory over the five time periods. For the article-dependent features, TitleSim , SummarySim , and BodySim , we average the scores over the three similarity measures (BM25 , TF.IDF and LM)

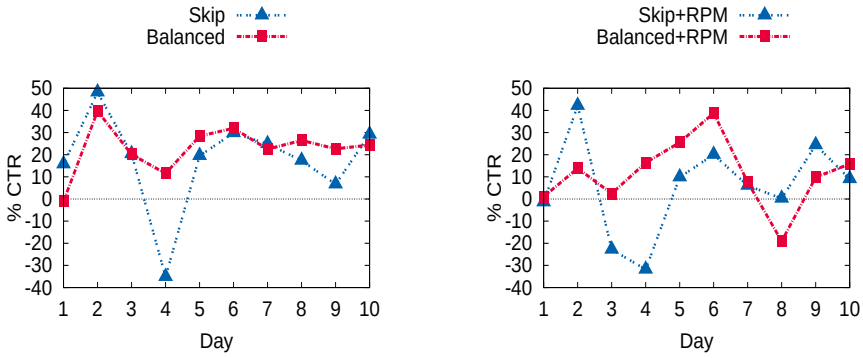

Figure 3: Relative improvement in CTR over time.

and the two texts representing the query (q_T and q_R). Finally, for EntitySim , we average the scores over the four features corresponding to the different combinations of the entity-linking tools.

Table 7 presents the features in descending order of importance for the Balanced model, which is the best performing model among the four we examined. We see that among the top-five features, four (TitleSim , SummarySim , BodySim and Overlap) are estimates of the textual similarity between the article and query, which attests to the importance of the textual similarity features in our task. The semantic similarity features (ESA and W2V), on the other hand, are ranked much lower. This may be because these features are also used to filter out queries in the third retrieval phase, resulting in some redundancy. RPM is the most important article-independent feature, which might explain the lift in Revenue we observed in Table 5 for the Balanced model. AdsCTR is among the least important features. Because this feature was also used in the first retrieval phase, it might be somewhat redundant in the second phase. The AvgUsers , DecDistinctUsers , and StdvUsers features, which quantify the trendiness of the query, are among the top-10, supporting our postulation about the importance of presenting users with very fresh and popular queries. Finally, inspecting the textual similarity features, we found that among the 3 similarity estimates, BM25 , LM , and TF.IDF , BM25 is the most important while LM is the least important. In addition, we found that features measuring the similarity with the query's text (q_T) are less important than those considering the concatenation of the result titles retrieved in response to the query (q_R).

4.2.5 Query Characteristics. To get a better sense of the type of queries users tend to click, we examined the characteristics of all the queries recommended by the five models tested in the second part of our online experiment. We distinguish between clicked and non-clicked queries, where the values extracted per each clicked (non-clicked) query are scaled by the number of times the query was presented and clicked (non-clicked). We performed a similar analysis for queries recommended by each of our five models separately. Here, we scaled the values attained per query by the number of times the query was presented to the users in the corresponding bucket. We consider the following five attributes: (i) Questions : percentage of queries formulated as questions[6]; (ii) Length1 : query length in words; (iii) Length2 : query length excluding stopwords of all queries except those that begin with a question word (iv) SW1 : percentage of stopwords in a stopword list that appear in the query [3]; and, (v) SW2 : percentage of terms in the query that are stopwords[7] [3].

Table 8: Characteristics of queries. Questions : percentage of queries starting with a question word. Length1 : query length in words. Length2 : query length excluding stopwords and queries starting with a question word. SW1 and SW2 : stopword-based measures [3].

	Questions	Length1	Length2	SW1	SW2
Clicked	5.37	4.39	4.00	1.08	6.55
Not Clicked	4.95	3.87	3.56	0.81	5.53
Control	3.47	3.35	3.12	0.60	4.18
Skip	5.93	4.10	3.77	0.89	5.84
Balanced	4.65	3.95	3.64	0.85	5.77
Skip+RPM	6.00	3.97	3.64	0.88	6.06
Balanced+RPM	4.65	3.93	3.62	0.83	5.73

Table 8 presents the results. Comparing clicked versus non-clicked queries, we see that users click on longer queries, which are more likely to contain stopwords and start with a question word. This implies that users prefer queries expressed in a natural language as opposed to those solely containing important keywords, e.g., "how old is prince harry" vs. "prince harry age". The queries recommended by the Control model, for which the lowest CTR was attained, are shorter than those recommended by the other models and are the least likely to contain stopwords or start with a question word. The queries recommended by Skip are longer than those recommended by Balanced , and are more likely to start with a question word. Nevertheless, Balanced outperformed Skip in terms of CTR , indicating that these attributes are important but insufficient in determining query relevance.

[6] We consider queries that start with one of the following question words: who, where, why, when, how, what, which, whose, whom, is, are, do, does, did, was, were, has, have, will and can.
[7] We use Lucene's English stopword list.

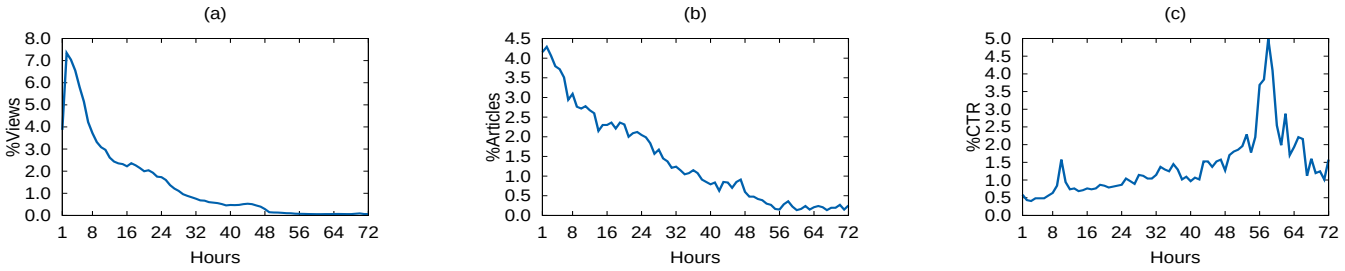

Figure 4: The change in (a) the percentage of article views, (b) the percentage of articles with at least five clicks on recommended queries, and (c) the CTR on the queries as a function of the number of hours that passed since an articles was first viewed.

Table 9: Distribution of clicks on organic results and the various verticals shown on the SERP .

	Balanced	SameQuery	AfterNewsURL	AfterNewsOther
Organic	10.82	36.72	38.60	54.84
News	32.28	22.96	19.45	5.11
Entities	5.63	3.79	7.00	2.96
Images	25.25	10.01	17.26	7.57
Videos	13.92	6.02	8.37	3.69
Ads	10.89	8.11	6.64	20.02
Other	1.21	12.39	2.68	5.81

4.2.6 Recommended versus Native Queries. In Section 4.2.3 we studied the interaction of users with the SERP presented after a recommended query was clicked in terms of Revenue and Reformulation . In what follows, we compare users' interactions with the SERP once they open it either by clicking on a recommended query or by issuing a native query themselves. We extracted all the searches initiated by queries that were recommended by the Balanced model. This was done during a non-consecutive two-day time period in which the model served all Yahoo News users. (These users were from the United States working on desktop devices.) We compared these searches with those invoked by native user queries. Specifically, we consider searches in which the user issued a query, not necessarily after reading a news article; this query was also clicked by users presented with queries recommended by the Balanced model (SameQuery). In addition, we consider searches initiated by a user query that was issued within the first five minutes after the user read a news article, where no other actions were performed in between. We distinguish between searches in which at least one (AfterNewsURL) or none (AfterNewsOther) of the query terms appeared in the originating article's URL; the former queries are more likely to be related to the news article. We excluded searches that were initiated by 40 different navigational queries, such as "facebook", "youtube", and "google". Since we recommend fresh queries that were added to our dataset recently (e.g., the day before), for the native searches we inspected not only the two days mentioned above, but also the searches that took place a day before, i.e., we inspected four days in total.

In Table 9 we present the click distribution on different result types (verticals) that are shown on the page [2], including Organic (organic "blue links" results), News (news articles), Entities (mostly presenting information about persons and locations [7]), Images , Videos and Ads . We can see that among the four types of searches we inspected, users arriving to a search page after clicking on a recommended query are more likely to examine additional news articles that are potentially related to the previously read article. These users are also more likely to click on images and videos. This might suggest that recommended queries elicit users to seek auxiliary visual information to further deepen their knowledge and satisfy their curiosity. Similar to Kong et al. [19], we see that users are more likely to seek information about various entities after reading a news article (see Balanced and AfterNewsURL vs. SameQuery and AfterNewsOther).

Although the SameQuery searches were invoked by queries that were also recommended by the Balanced model, they are quite different. For example, in the SameQuery searches, users are more inclined to click on organic results. This is also the case for the AfterNewsURL and AfterNewsOther searches, which are invoked following an interaction with a news article. We also see that the Ads vertical receives the highest percentage of clicks in the AfterNewsOther searches. Presumably queries leading to these searches are less likely to be related to the originating news article and are therefore more likely to have some commercial intent.

4.2.7 Article Freshness. As already noted, time plays a key role when dealing with news, especially breaking news, articles. In this work, we have taken a number of steps to promote fresh and emerging queries. First, the query index was updated on a regular basis. Second, only queries that were issued in the past three weeks were kept in the index. Third, several features that quantify the trendiness of queries were used in the learning-to-rank model (i.e., AvgUsers , StdvUsers , DecDistinctUsers and AvgUserHistory).

While the emphasis so far was on query freshness, in what follows we focus on article freshness. In Figure 4 we examine various aspects of the change in the users' behavior when interacting with news articles, and our recommended queries in particular, as a function of the time that has passed from the moment an article was first viewed. This analysis is based on logs collected during the second part of the online experiment. Here, we do not distinguish between the different buckets. At any given time, we only consider articles with at least five clicks on the recommended queries. All

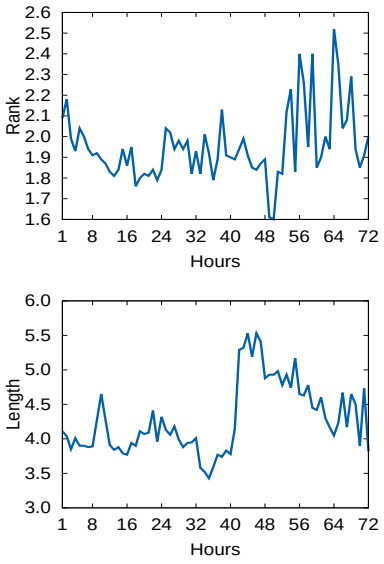

Figure 5: The change in the average click rank and average query length as a function of the number of hours that passed since an articles was first viewed.

the numbers are sum-normalized with respect to the total attained during the three-day time period

We start by studying the percentage of views an article received in an hour over the course of the three days. We observe a sharp decline in the number of views. For example, we found that on average an article reaches 50.1% of its views during the first ten hours and 81.2% during the first day. This finding demonstrates the relatively short lifespan of news articles and the fast pace of news consumption. We next examine the percentage of articles with at least five clicks on the recommended queries in an hour. Here again we observe a sharp decline, which testifies to the need for a fast algorithm that can produce recommendations immediately after the article is published. Inspecting the CTR (sum normalized over the three-day time period), we see that users start clicking on recommendations from the very first moment the article is viewed, i.e., already in the first hour. We observe a steady lift in CTR during the first two days, and a rather sharp increase during the third day. We postulate that the few articles that still get clicks during the third day discuss compelling and ongoing events, in which case users are more inclined to explore further. Indeed, we found that the CTR of articles with clicks in the first day only was 3.4 times lower than that of articles with clicks in all three days.

In Figure 5 we examine the properties of the clicked queries as a function of article freshness. We notice that the average rank of the clicked queries is rather stable in the first two days (average: 1.91; standard deviation: 0.09) and is slightly higher during the third day (average: 2.03; standard deviation: 0.24). A similar observation can be made about query length that increases during the third day. We attribute these changes to the somewhat different nature of the articles that are still being read during the third day and the users' desire for additional related content for such articles.

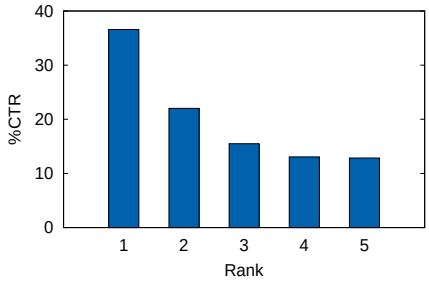

Figure 6: Sum-normalized CTR across the top-five ranks.

For example, we found that the average query length was 3.8 for articles that received clicks during the first day only, and 4.3 for those that received clicks during the entire three-day time period. Integrating the article's freshness into the query recommendation algorithm is an interesting future research direction.

4.2.8 Position Bias. To learn feature weights using user feedback in the second retrieval phase, we experimented with two different training sets so as to overcome the bias incurred in users' clicking decisions [17]. In what follows, we study the severity of the position (trust) bias wherein users tend to click on highly ranked items even if they are less relevant than those ranked lower. In Figure 6 we show the CTR across the five ranks in which queries were recommended during a two-week time period to all Yahoo News users. During this time the top-five queries recommended by the Balanced model were randomly shuffled across ranks. As expected, a rather sharp position bias can be observed: the higher the query is presented, the more likely it is to receive clicks. This finding, along with the differences in performance observed earlier between the Skip and Balanced models, attest to the importance of correctly interpreting user clicks. Testing additional approaches is left for future work [1, 33].

5 CONCLUSIONS AND FUTURE WORK

Content enrichment lets users access information they may not be aware of, such as related articles or relevant facts or events, thereby serving to increase engagement. We addressed the task of enriching news-articles by recommending related search queries that are extracted from a search engine's query log. The three-phase approach we proposed for generating the recommendations is based on a learning-to-rank model that uses various article-dependent and article-independent features. Our approach also integrates several highly effective semantic query filters. Empirical evaluation performed using an offline dataset created by professional editors and a large-scale online experiment with real users attested to the effectiveness of our approach. A deeper analysis of the results revealed interesting characteristics of the types of queries users tend to click and the unique behavior of users after clicking on such queries. For future work we intend to study the effectiveness of our approach when applied to other domains. For example, focusing on specific categories, such as sports, finance or scientific articles with a unique jargon (e.g., Jets, Dolphins and Giants are sport team names). We also plan to study the influence of the user interface on user engagement, considering the position of the recommendations

within the article, the number of recommendations per article and the possible differences between desktop and mobile devices.

Revisiting Opinion Dynamics with Varying Susceptibility to Persuasion via Non-Convex Local Search

ABSTRACT

We revisit the opinion susceptibility problem that was proposed by Abebe et al. [1], in which agents influence one another's opinions through an iterative process. Each agent has some fixed innate opinion. In each step, the opinion of an agent is updated to some convex combination between its innate opinion and the weighted average of its neighbors' opinions in the previous step. The resistance of an agent measures the importance it places on its innate opinion in the above convex combination. Under non-trivial conditions, this iterative process converges to some equilibrium opinion vector. For the unbudgeted variant of the problem, the goal is to select the resistance of each agent (from some given range) such that the sum of the equilibrium opinions is minimized.

Contrary to the claim in the aforementioned KDD 2018 paper, the objective function is in general non-convex. Hence, formulating the problem as a convex program might have potential correctness issues. We instead analyze the structure of the objective function, and show that any local optimum is also a global optimum, which is somehow surprising as the objective function might not be convex. Furthermore, we combine the iterative process and the local search paradigm to design very efficient algorithms that can solve the unbudgeted variant of the problem optimally on large-scale graphs containing millions of nodes.

1 INTRODUCTION

We revisit the opinion susceptibility problem that was proposed by Abebe et al. [1], in which agents in a network influence one another's opinions through an iterative process. In this model, the opinion of an agent at each step is a function of its *innate* opinion and its neighbors' opinions in the previous step. The susceptibility of an agent i to persuasion is measured by a resistance parameter $\alpha_i \in (0, 1)$, where a larger value of α_i means that agent i places more importance on its innate opinion. Under very mild conditions (such as every $\alpha_i > 0$), the iterative process converges to a unique equilibrium opinion vector.

As remarked in [1], opinion interference in social networks have wide applications in product marketing and political campaigns. While most previous works [6, 11, 16] investigated models on changing the opinions directly, [1] is the first work that considered modifying the susceptibility of individual agents. Using a number in $[0, 1]$ to represent an agent's opinion, they considered the problem of modifying the agents' resistances such that the sum of the equilibrium opinions is minimized (or equivalently maximized by applying the transformation $x \mapsto 1 - x$ on each opinion).

Abebe et al. [1] pointed out several works in social psychology that have investigated people's susceptibility to persuasion, including studies on how peer pressure can make adolescents exhibit risky and antisocial behavior [2, 5, 7], and on the role of susceptibility in politics [19]. Factors such as self-esteem, locus of control, awareness of specific issues, as well as exposure to people in the same network can contribute to an individual's susceptibility to persuasion. As a result, by affecting these factors or introducing persuasive cues [15], one can make an individual more or less susceptible to persuasion, i.e., the resistance parameter can be lowered or increased.

Observe that the problem is trivial if the resistance of each agent can be picked from the closed interval $[0, 1]$. For minimizing the equilibrium opinions, it suffices to make the agent with the minimum innate opinion the most resistant (setting its resistance to 1) and everyone else totally compliant (setting its resistance to 0). The problem is non-trivial if the resistance α_i of each agent i can take value from some interval $[l_i, u_i]$, where $0 < l_i < u_i < 1$. Under this restriction, Abebe et al. [1] showed that it suffices to consider extreme points in the resistance vector space, i.e., for each agent i, one can pick $\alpha_i \in \{l_i, u_i\}$. Moreover, they attempt to model the problem using a convex program. However, contrary to their claim, we have discovered that the objective function is in general neither convex nor concave (see Figure 1 in Section 2). Hence, there could be potential correctness issues with their approach. Furthermore, a general convex program is quite expensive to solve, and indeed, the experiments in [1] were performed on networks with less than 1000 nodes, most likely because their approach is non-scalable to large networks.

This work resolves both the correctness and scalability issues in [1]. We give a thorough analysis of the problem structure to design a provably correct local search framework, and further exploit the properties of the iterative process to implement our algorithms that are efficient enough to run on networks with millions of nodes.

Our Contributions. We study the structure of the opinion susceptibility problem [1] in detail, and also make algorithmic contributions, which we describe as follows.

- *Analysis of problem structure.* Contrary to the claim in [1], we discover that the objective function is in general neither convex nor concave. However, we have also recovered (in Corollary 3.4) that for each agent, it is sufficient to set its resistance to either the lower or the upper bound, i.e., we can search for an optimal resistance vector from the set of extreme points of its feasible region.
  We analyze the mathematical structure of the problem in Section 3. Perhaps the most important technical insight in this paper is that we show (in Lemma 3.9) that if the current vector solution is not optimal, then there exists a coordinate that can be flipped such that the objective will be strictly improved. This shows that an optimal vector can be found by a simple local search algorithm.
- *Local search with irrevocable updates.* In general, local search could still take exponential time to find an optimal solution, for instance, the simplex algorithm for linear programming. For minimizing the sum of equilibrium opinions, we show (in Lemma 4.1) that starting from the upper bound resistance vector, then the local search algorithm will flip each coordinate at most once, which implies that an optimal vector can be found in polynomial time.
- *Efficient Local Search on Large-Scale Graphs.* Typically, in local search, the objective function needs to be evaluated at the current solution in each step. However, since the objective function involves matrix inverse, its evaluation will be too expensive when the dimension of the matrix is in the order of millions. Instead, we use the iterative process of the opinion dynamics model itself to approximate the equilibrium vector. We have developed several update strategies for local search. For *conservative* or *opportunistic* updates, one always makes sure that the error of the estimated equilibrium vector is small enough before any coordinate of the resistance vector is flipped. For *optimistic* update, one might flip a coordinate of the resistance vector even before the estimated equilibrium vector is accurate enough. However, this might introduce mistakes which need to be corrected later. Nevertheless, experiments show that mistakes are rarely made by the optimistic update strategy. In any case, for all three update strategies, an optimal vector will be returned when the local search terminates.
  Our approaches are scalable and can run on networks with millions of nodes. We report the experimental results in Section 5. In particular, using multiple number of threads, the optimistic update strategy can solve the problem optimally on networks with up to around 65 million nodes.

1.1 Related Works

The most related work is the KDD 2018 paper [1] by Abebe et al., who gave a history of the problem and other related works, to which the reader can refer. Here we just give a brief summary.

History of Model. As mentioned in [1], the opinion dynamics model is inspired by the works of DeGroot [4] and Friedkin and Johnsen [8]. DeGroot considered the special case where all resistance α_i's equal 0, and the opinion vector update rule reduces to $z^{(t)} := Pz^{(t-1)} \in \mathbb{R}^V$, for some row stochastic matrix P. This model is well understood through the theory of Markov chains, which typically uses the transpose of P in the update rule: $z^{(t)} := P^{\mathsf{T}}z^{(t-1)} \in \mathbb{R}^V$. The iterative process considered in this paper is exactly the model in [8], which also investigated the conditions under which the process converges to a unique equilibrium vector.

Budgeted Variant. We have so far discussed only the *unbudgeted* variant of the opinion optimization problem, where the resistance of every agent can be modified. The *budgeted* variant of the problem has also been considered in [1], where some initial resistance vector $\alpha \in (0,1)^V$ and some budget $k \in \mathbb{Z}$ are given, and the algorithm is allowed to change at most k coordinates of α. It is shown that the budgeted variant is NP-hard [1]. An obvious approach is to use some greedy paradigm to pick k coordinates to modify one by one, where the next coordinate is picked to have the largest improvement in the objective function. However, no theoretical guarantee was given for budgeted variant in [1]. Since our analysis of the unbudgeted variant is already quite involved, this paper will focus on the unbudgeted case. We will leave the analysis of the greedy algorithm for the budgeted variant as future work, which we briefly discuss in the conclusion section.

Non-Convex Optimization. In general, optimizing a non-convex function under non-convex constraints is NP-hard. However, in many cases, one can exploit the structure of the objective function or constraints to devise polynomial-time algorithms; see the survey by Jain and Kar [13] on non-convex optimization algorithms encountered in machine learning. Indeed, variants of the gradient descent have been investigated to escape saddle points by Jin et al. [14], who also gave examples of problems where all local optima are also global optima; some examples are tensor decomposition [9], dictionary learning [22], phase retrieval [21], matrix sensing [3, 20] and matrix completion [10]. However, all these problems involve some quadratic loss functions, whose structures are totally different from our objective functions which involve matrix inverse.

Hartman [12] considered the special case that the objective function is the difference of two convex functions. Strekalovsky devised a local search method to optimize such objective functions. Even though the objective functions in our problem are somewhere convex and somewhere concave (see Figure 1), it is not immediately clear if they can be expressed as differences of convex functions.

2 PRELIMINARIES

We revisit the opinion susceptibility problem that was proposed by Abebe et al. [1], which we rephrase using more general parameters. In an opinion dynamics model, there is a set V of agents, whose innate opinions are given by a vector $s \in [0,1]^V$. The interaction between agents are captured by a row stochastic matrix $P \in [0,1]^{V \times V}$, i.e., each entry of P is non-negative and every row sums to 1. In

the rest of this paper, we always call P the interaction matrix. The susceptibility of the agents is measured by the resistance vector $\alpha \in (0,1)^V$, where a higher α_i value means that agent i is more resistant.

As mentioned in [1], the opinion vector of agents evolves in discrete time according to the equation $z^{(t+1)} := As + (I - A)Pz^{(t)}$, where $A = \text{Diag}(\alpha)$ is the diagonal matrix with $A_{ii} = \alpha_i$ and I is the identity matrix. Equating $z^{(t)}$ with $z^{(t+1)}$, one can see that the equilibrium opinion vector is given by $z = [I - (I - A)P]^{-1}As$, which exists under non-trivial conditions such as every $\alpha_i > 0$. The objective is to choose a resistance vector α to minimize the sum of equilibrium opinions $\langle \mathbf{1}, z \rangle = \mathbf{1}^T z$. Observe that one can also consider maximizing the sum of equilibrium opinions; however, since the techniques are essentially the same, we will focus on the minimization variant of the problem.

Definition 2.1 (Opinion Susceptibility Problem). Given a set V of agents with innate opinions $s \in [0,1]^V$ and interaction matrix $P \in [0,1]^{V \times V}$, suppose for each $i \in V$, its resistance is restricted to some interval $\mathcal{I}_i := [l_i, u_i] \subseteq [0,1]$ where we assume that $0 < l_i < u_i < 1$.

The objective is to choose $\alpha \in \mathcal{I}_V := \times_{i \in V} \mathcal{I}_i \subseteq [0,1]^V$ such that the following objective function is minimized:

$$f(\alpha) := \mathbf{1}^T [I - (I - A)P]^{-1} As,$$

where $A = \text{Diag}(\alpha)$ is the diagonal matrix with $A_{ii} = \alpha_i$. Observe that the assumption $\alpha > 0$ ensures that the above inverse exists.

Unbudgeted vs Budgeted Variants. In Definition 2.1, we are allowed to modify the resistance of any agent, and this is known as the unbudgeted variant. However, in [1], the budgeted variant is also considered: given some initial resistance vector and a budget k, the resistance of at most k agents can be changed. In this paper, we focus on efficient algorithms that optimally solve the unbudgeted variant.

Technical Assumption. To simplify our proofs, we assume that the interaction matrix P corresponds to an irreducible random walk. Irreducibility is satisfied if P arises from a connected graph.

Non-convex Objective. Contrary to the claim in [1], the objective f in Definition 2.1 is in general not a convex function of α. In fact, the following example shows that it might be neither convex nor concave. Consider three vertices $V = \{1, 2, 3\}$, where the innate vector s and the interaction matrix P are given by: $s = \begin{bmatrix} 1 \\ 0.5 \\ 0 \end{bmatrix}$ and $P = \begin{bmatrix} 0 & 0.5 & 0.5 \\ 0.5 & 0 & 0.5 \\ 0.5 & 0.5 & 0 \end{bmatrix}$.

Suppose we fix $\alpha_2 = \alpha_3 = 0.1$ and consider the objective as a function of α_1 as $g(\alpha_1) = \mathbf{1}^T [I - (I - A)P]^{-1} As$, where $A = \text{Diag}(\alpha_1, \alpha_2, \alpha_3)$. Then, the plot of g in Figure 1 (a) shows that it is not convex. Moreover, suppose this time we fix $\alpha_1 = \alpha_2 = 0.1$ and consider the objective as a function of α_3 as $h(\alpha_3) = \mathbf{1}^T [I - (I - A)P]^{-1} As$. Then, the plot of h in Figure 1 (b) shows that it is not concave.

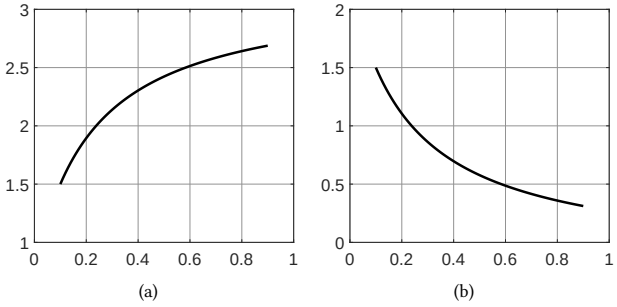

Figure 1: Cross-Sections of Objective Function

3 STRUCTURAL PROPERTIES OF OBJECTIVE FUNCTION

In this section, we investigate the properties of the objective function f in Definition 2.1; we assume that the interaction matrix P and the innate opinion vector s are fixed, and f is a function on the resistance vector α. Contrary to the claim in [1], the objective function is in general not convex. Fortunately, we can still exploit some properties of the function. As we shall see, even when the function is not convex, every local optimum (which will be defined formally) is a global optimum. This enables us to use variants of the local search method to solve the problem optimally.

3.1 Marginal Monotonicity

As in [1], we show that when one chooses the resistance α_i for each agent $i \in V$, it suffices to consider the extreme points $\{l_i, u_i\}$. Our approach explicitly analyzes the partial derivative $\frac{\partial f(\alpha)}{\partial \alpha_i}$ which plays a major role in the local search algorithm that we later develop.

Intuition: Guidance by Current Equilibrium Vector. Observe that given the innate opinion vector s and irreducible interaction matrix P, for some resistance vector $\alpha \in (0,1)^V$, the equilibrium opinion vector is given by $z(\alpha) = [I - (I - A)P]^{-1}As$, where $A = \text{Diag}(\alpha)$. For some $i \in V$, if the innate opinion s_i is larger than its equilibrium $z_i(\alpha)$, this suggests that by being more stubborn, agent i should be able to increase its equilibrium opinion. In other words, one would expect $\frac{\partial z_i(\alpha)}{\partial \alpha_i}$ and $s_i - z_i(\alpha)$ to have the same sign. However, what is surprising is that in Lemma 3.2, we shall see that even for any $j \in V$, $\frac{\partial z_j(\alpha)}{\partial \alpha_i}$ and $s_i - z_i(\alpha)$ have the same sign.

Notation. For any $\alpha \in \mathbb{R}^V$ and $K \subseteq V$, let $\alpha_{-K} \in \mathbb{R}^V$ denote the vector such that $\alpha_{-K}(i) = \alpha(i)$ if $i \notin K$, and $\alpha_{-K}(i) = 0$ if $i \in K$, i.e., the coordinates K of α are replaced with 0. Similarly, given $\alpha \in \mathbb{R}^V$, we denote $A_{-K} = \text{Diag}(\alpha_{-K})$.

In Definition 2.1, observe that the inverse $[I - (I - A)P]^{-1}$ is involved in the objective function $f(\alpha)$, where $A = \text{Diag}(\alpha)$. Since we wish to analyze the effect on $f(\alpha)$ of changing only a subset of coordinates in α, the next lemma will be used for simplifying matrix arithmetic involving the computation of inverses. Its proof is deferred to Section 6.

Lemma 3.1 (Inverse Arithmetic). *Given $K \subsetneq V$ and $\alpha \in (0,1)^V$, let $A := \text{Diag}(\alpha)$ and recall that P is the irreducible interaction matrix. Then, the inverse $M = [I - (I - A_{-K})P]^{-1}$ exists, and every entry*

of M is positive. Moreover, for each $k \in V$, define $a_k = 0$ if $k \in K$, otherwise $a_k = \alpha_k$. Then, we have:

(1) $(PM)_{kk} = \frac{M_{kk}-1}{1-a_k} > 0$;

(2) $(PM)_{kj} = \frac{M_{kj}}{1-a_k} > 0$, *for each $j \neq k$.*

Lemma 3.2 (Sign of Partial Derivative). *In the Opinion Susceptibility Problem in Definition 2.1, given the innate opinion vector s and irreducible interaction matrix P, recall that $z(\alpha) := [I-(I-A)P]^{-1}As$, where $A = \mathrm{Diag}(\alpha)$. Then, for any $\alpha \in (0,1)^V$ and any $i, k \in V$, the two values $\frac{\partial z_k(\alpha)}{\partial \alpha_i}$ and $s_i - z_i(\alpha)$ have exactly the same sign in $\{-, 0, +\}$.*

In particular, this implies that $\frac{\partial f(\alpha)}{\partial \alpha_i} = \sum_{k\in V} \frac{\partial z_k(\alpha)}{\partial \alpha_i}$ also has the same sign as $s_i - z_i(\alpha)$.

Proof. By the definition of the inverse of a matrix B, we have $BB^{-1} = I$. The partial derivative with respect to a variable t is: $\frac{\partial B}{\partial t}B^{-1} + B\frac{\partial B^{-1}}{\partial t} = 0$. Hence, we have $\frac{\partial B^{-1}}{\partial t} = -B^{-1}\frac{\partial B}{\partial t}B^{-1}$. Applying the above result with $B = I - (I - A)P$ and $t = \alpha_i$ and denoting $M = [I - (I - A)P]^{-1}$, we get $\frac{\partial M}{\partial \alpha_i} = -M\mathbf{e}_i\mathbf{e}_i^T PM$. Considering $z(\alpha) = MAs$, we have $\frac{\partial z(\alpha)}{\partial \alpha_i} = \frac{\partial M}{\partial \alpha_i}As + M\mathbf{e}_i\mathbf{e}_i^T s$. Replacing $\frac{\partial M}{\partial \alpha_i}$, we obtain for any $i, k \in V$:

$$\frac{\partial z_k(\alpha)}{\partial \alpha_i} = -\mathbf{e}_k^T M\mathbf{e}_i\mathbf{e}_i^T PMAs + \mathbf{e}_k^T M\mathbf{e}_i\mathbf{e}_i^T s = M_{ki}\cdot[s_i - \mathbf{e}_i^T Pz(\alpha)].$$

By Lemma 3.1 with $K = \emptyset$, we know that every entry of M is positive. Thus, the sign of $\frac{\partial z_k(\alpha)}{\partial \alpha_i}$ is the same as that of the scalar $s_i - \mathbf{e}_i^T Pz(\alpha)$.

Recalling $M = [I - (I - A)P]^{-1}$, we have $[I - (I - A)P]M = I \Rightarrow (I - A)PM = M - I \Rightarrow PM = (I - A)^{-1}(M - I)$ where $(I - A)^{-1}$ exists since $\alpha_j < 1$ for each $j \in V$.

Next, since $z(\alpha) = MAs$, we have:

$$Pz(\alpha) = PMAs = (I - A)^{-1}(M - I)As = (I - A)^{-1}[z(\alpha) - As].$$

Finally, replacing $Pz(\alpha)$, we have

$$\begin{aligned} s_i - \mathbf{e}_i^T Pz(\alpha) =& s_i - \mathbf{e}_i^T (I - A)^{-1}[z(\alpha) - As] \\ =& s_i - \frac{1}{1-\alpha_i}[z_i(\alpha) - \alpha_i s_i] \\ =& \frac{1}{1-\alpha_i}[s_i - z_i(\alpha)]. \end{aligned}$$

Since $1-\alpha_i > 0$, it follows that $\frac{\partial z_k(\alpha)}{\partial \alpha_i}$ and $s_i - z_i(\alpha)$ have exactly the same sign in $\{-, 0, +\}$, as required. □

The next lemma shows that the sign of the partial derivatives with respect to coordinate i is actually independent of the current value α_i. Its proof is deferred to Section 6.

Lemma 3.3 (Sign of Partial Derivative Independent of Coordinate Value). *Referring to Lemma 3.2. For any $\alpha \in (0,1)^V$ and any $i \in V$, denote $M = [I - (I - A_{-\{i\}})P]^{-1}$. Then, $\frac{\partial f(\alpha)}{\partial \alpha_i}$ has the same sign in $\{-, 0, +\}$ as $s_i - \sum_{j\neq i} M_{ij}\alpha_j s_j$, which is independent of α_i.*

Corollary 3.4 (Extreme Points are Sufficient). *In Definition 2.1, for any $i \in V$, fixing the resistance values of all other agents except i, the objective $f(\alpha)$ is a monotone function in α_i. This implies that to minimize f, it suffices to consider the extreme points $\alpha_i \in \{l_i, u_i\}$, for each $i \in V$.*

3.2 Local vs Global Optimum

As shown in Corollary 3.4, it suffices to choose the resistance vector α from the extreme points in Definition 2.1. Lemma 3.2 readily gives a method to decide, given a current choice of α, whether the objective f can be decreased by changing the resistance of some agent. In Lemma 3.9, we show that if α is not a global minimum, then such an agent must exist. As we shall see, this implies that a local search method can find a global minimum.

Given α and $\alpha' \in \mathbb{R}^V$, denote $\Delta(\alpha, \alpha') := \{i \in V : \alpha_i \neq \alpha'_i\}$ as the set of coordinates at which the vectors differ.

Definition 3.5 (Local Minimizer). Given an objective function $f : \mathcal{I}_V \to \mathbb{R}$, a vector $\alpha \in \mathcal{I}_V$ is a local minimizer of f, if for all $\alpha' \in \mathcal{I}_V$ such that $\Delta(\alpha, \alpha') = 1$, $f(\alpha) \leq f(\alpha')$.

Notation. When we wish to consider the effect of changing the resistance of only 2 agents $i \neq k \in V$, we write $f(\alpha) = f(\alpha_i, \alpha_k)$, assuming that $\alpha_{-\{i,k\}}$ is fixed.

Lemmas 3.6 and 3.7 give some technical results involving changing the resistance of two agents. Their proofs are deferred to Section 6.

Lemma 3.6. *For any $i, k \in V$ such that $i \neq k$, let $M = [I - (I - A_{-\{i\}})P]^{-1}$ and $R = [I - (I - A_{-\{i,k\}})P]^{-1}$. Then for any $j \in V$, we have*

(1) $M_{jk} = \frac{R_{jk}}{1+\alpha_k R_{kk} - \alpha_k}$,

(2) $M_{jh} = R_{jh} - \frac{\alpha_k R_{jk} R_{kh}}{1+\alpha_k R_{kk} - \alpha_k}$, *for $h \neq k$.*

In particular, the quantity in Lemma 3.3 can be rewritten as follows:

$$s_i - \sum_{j\neq i} M_{ij}\alpha_j s_j = s_i - \sum_{j\neq i,k} R_{ij}\alpha_j s_j - \frac{\alpha_k R_{ik}}{1 + \alpha_k R_{kk} - \alpha_k}(s_k - \sum_{j\neq i,k} R_{kj}\alpha_j s_j).$$

Lemma 3.7 (Diagonal Entry). *Suppose $\alpha \in (0,1)^V$, recall that $A_{-\{i,k\}} := \mathrm{Diag}(\alpha_{-\{i,k\}})$, and P corresponds to an irreducible interaction matrix. For any $i, k \in V$ such that $i \neq k$, let $R = [I - (I - A_{-\{i,k\}})P]^{-1}$, then $R_{ii} = \max_{j\in V} R_{ji}$. Moreover, $R_{ii} = R_{ki}$ if and only if $P_{kk} + P_{ki} = 1$.*

The following lemma gives the key insight for why local search works. Intuitively, it shows that there does not exist any discrete "saddle point". Even though its proof is technical, we still include it here because of its importance.

Lemma 3.8 (Switching Lemma). *Recall that f is defined in Definition 2.1 with an irreducible interaction matrix P, and assume $|V| \geq 3$. Suppose $\alpha, \beta \in (0,1)^V$ such that $\Delta(\alpha, \beta) = \{i, k\}$ for some $i \neq k$. Moreover, suppose further that*

$$\min\{f(\alpha_i, \alpha_k), f(\beta_i, \beta_k)\} < \min\{f(\alpha_i, \beta_k), f(\beta_i, \alpha_k)\}.$$

Then, we have

$$\max\{f(\alpha_i, \alpha_k), f(\beta_i, \beta_k)\} > \min\{f(\alpha_i, \beta_k), f(\beta_i, \alpha_k)\}.$$

Proof. We prove the lemma by contradiction. Suppose

$$\max\{f(\alpha_i, \alpha_k), f(\beta_i, \beta_k)\} \leq \min\{f(\alpha_i, \beta_k), f(\beta_i, \alpha_k)\}.$$

Without loss of generality, suppose further that $f(\alpha_i, \alpha_k) \geq f(\beta_i, \beta_k)$. Then, we have

$$f(\alpha_i, \alpha_k) \leq \begin{cases} f(\beta_i, \alpha_k) \\ f(\alpha_i, \beta_k) \end{cases} \quad \text{and } f(\beta_i, \beta_k) < \begin{cases} f(\beta_i, \alpha_k) \\ f(\alpha_i, \beta_k). \end{cases}$$

We remark that it is important to distinguish between the strict and non-strict inequality. We use the notation f_i' to denote the partial derivative with respect to coordinate i.

From $f(\alpha_i, \alpha_k) \leq f(\beta_i, \alpha_k)$ and the fact that f is marginally monotone (Lemma 3.3) and $f_i'(x, \alpha_k)$ has the same sign in $\{-, 0, +\}$ for $x \in (0, 1)$, we have

$$f_i'(_, \alpha_k) \cdot (\alpha_i - \beta_i) \leq 0. \tag{1}$$

On the other hand, from the strict inequality $f(\beta_i, \beta_k) < f(\beta_i, \alpha_k)$, we know the partial derivative $f_k'(\beta_i, y)$ must have the same non-zero sign in $\{-, +\}$, again from Lemma 3.3. Therefore, we have:

$$f_k'(\beta_i, _) \cdot (\alpha_k - \beta_k) > 0. \tag{2}$$

Similarly, $f(\alpha_i, \alpha_k) \leq f(\alpha_i, \beta_k)$ and $f(\beta_i, \beta_k) < f(\alpha_i, \beta_k)$ give the following:

$$f_k'(\alpha_i, _) \cdot (\alpha_k - \beta_k) \leq 0, \tag{3}$$

$$f_i'(_, \beta_k) \cdot (\alpha_i - \beta_i) > 0. \tag{4}$$

Next, using Lemma 3.3 and R as defined in Lemma 3.6, the above inequalities (1) to (4) become:

$$[s_i - \sum_{j \neq i,k} R_{ij}\alpha_j s_j - \frac{\alpha_k R_{ik}}{1 + \alpha_k R_{kk} - \alpha_k}(s_k - \sum_{j \neq i,k} R_{kj}\alpha_j s_j)](\alpha_i - \beta_i) \leq 0,$$

$$[s_k - \sum_{j \neq i,k} R_{kj}\beta_j s_j - \frac{\beta_i R_{ki}}{1 + \beta_i R_{ii} - \beta_i}(s_i - \sum_{j \neq i,k} R_{ij}\beta_j s_j)](\alpha_k - \beta_k) > 0,$$

$$[s_k - \sum_{j \neq i,k} R_{kj}\alpha_j s_j - \frac{\alpha_i R_{ki}}{1 + \alpha_i R_{ii} - \alpha_i}(s_i - \sum_{j \neq i,k} R_{ij}\alpha_j s_j)](\alpha_k - \beta_k) \leq 0,$$

$$[s_i - \sum_{j \neq i,k} R_{ij}\beta_j s_j - \frac{\beta_k R_{ik}}{1 + \beta_k R_{kk} - \beta_k}(s_k - \sum_{j \neq i,k} R_{kj}\beta_j s_j)](\alpha_i - \beta_i) > 0.$$

Recall that $\alpha_j = \beta_j$ for $j \neq i, k$. Hence, we denote:

$$c_i := s_i - \sum_{j \neq i,k} R_{ij}\alpha_j s_j = s_i - \sum_{j \neq i,k} R_{ij}\beta_j s_j,$$

$$c_k := s_k - \sum_{j \neq i,k} R_{kj}\alpha_j s_j = s_k - \sum_{j \neq i,k} R_{kj}\beta_j s_j,$$

$$g_i(x) := \frac{xR_{ki}}{1 + xR_{ii} - x} \text{ and } g_k(x) := \frac{xR_{ik}}{1 + xR_{kk} - x}.$$

Then, we have

$$[c_i - g_k(\alpha_k)c_k](\alpha_i - \beta_i) \leq 0, \tag{5}$$

$$[c_k - g_i(\beta_i)c_i](\alpha_k - \beta_k) > 0, \tag{6}$$

$$[c_k - g_i(\alpha_i)c_i](\alpha_k - \beta_k) \leq 0, \tag{7}$$

$$[c_i - g_k(\beta_k)c_k](\alpha_i - \beta_i) > 0. \tag{8}$$

Observe that $c_i \neq 0$, otherwise (6) and (7) contradict each other. Similarly, $c_k \neq 0$, otherwise (5) and (8) contradict each other. We next argue that $c_i c_k > 0$.

From (5) and (8) we have

$$[c_i - g_k(\alpha_k)c_k][c_i - g_k(\beta_k)c_k] \leq 0. \tag{9}$$

If $c_i c_k < 0$, then the above expression will be positive, because $g_k(\cdot) \geq 0$ (we shall see that later). Hence, we conclude that c_i and c_k have the same sign.

From (6) and (7) we have

$$[c_k - g_i(\beta_i)c_i][c_k - g_i(\alpha_i)c_i] \leq 0. \tag{10}$$

Rearranging (9) and (10), we have:

$$[\frac{c_i}{c_k} - g_k(\alpha_k)][\frac{c_i}{c_k} - g_k(\beta_k)] \leq 0,$$

and

$$[\frac{c_k}{c_i} - g_i(\beta_i)][\frac{c_k}{c_i} - g_i(\alpha_i)] \leq 0.$$

Note that every entry of R is positive by Lemma 3.1 and we can easily prove $g_i(\cdot)$ and $g_k(\cdot)$ are both strictly increasing functions in $[0, 1]$. Since $\alpha, \beta \in (0, 1)^V$, the above two inequalities imply that

$$0 = g_k(0) < g_k(\min\{\alpha_k, \beta_k\}) \leq \frac{c_i}{c_k},$$

$$\frac{c_i}{c_k} \leq g_k(\max\{\alpha_k, \beta_k\}) < g_k(1) = \frac{R_{ik}}{R_{kk}} \leq 1,$$

and

$$0 = g_i(0) < g_i(\min\{\alpha_i, \beta_i\}) \leq \frac{c_k}{c_i},$$

$$\frac{c_k}{c_i} \leq g_i(\max\{\alpha_i, \beta_i\}) < g_i(1) = \frac{R_{ki}}{R_{ii}} \leq 1,$$

where $\frac{R_{ik}}{R_{kk}} \leq 1$ and $\frac{R_{ki}}{R_{ii}} \leq 1$ are from Lemma 3.7.

Notice that we get $0 < \frac{c_i}{c_k} < 1$ and $0 < \frac{c_k}{c_i} < 1$, which is a contradiction. Hence, the proof is completed. □

Lemma 3.9 (Descending Coordinate). *Let f be the function as defined in Definition 2.1. Suppose $\alpha, \beta \in (0, 1)^V$ such that $f(\alpha) > f(\beta)$. Then, there exists some $i \in \Delta(\alpha, \beta)$ and $\gamma \in (0, 1)^V$ such that $\Delta(\alpha, \gamma) = \{i\}$, $\Delta(\gamma, \beta) = \Delta(\alpha, \beta) \setminus \{i\}$, and $f(\alpha) > f(\gamma)$.*

In other words, by switching one coordinate (corresponding to i) of α to that of β, the objective function f decreases strictly.

Proof. We prove the lemma by induction on $|\Delta(\alpha, \beta)|$. The base case $|\Delta(\alpha, \beta)| = 1$ is trivial.

We consider the inductive step with $|\Delta(\alpha, \beta)| = q$, for some $q \geq 2$. Given a list S of coordinates from $\Delta(\alpha, \beta)$, we use $\alpha_{[S]}$ to denote the resulting vector obtained from switching coordinates S of α to those of β.

For contradiction's sake, we assume that for all $j \in \Delta(\alpha, \beta)$, $f(\alpha_{[j]}) \geq f(\alpha)$; moreover, we pick $i \in \Delta(\alpha, \beta)$ such that $f(\alpha_{[i]})$ is minimized.

Observe that $f(\alpha_{[i]}) \geq f(\alpha) > f(\beta)$ and $|\Delta(\alpha_{[i]}, \beta)| = q - 1$. Therefore, by the induction hypothesis, there exists some $k \in \Delta(\alpha_{[i]}, \beta)$ such that $f(\alpha_{[i]}) > f(\alpha_{[i,k]})$.

Next, starting from α, we shall fix all coordinates in V except i and k, and we write the objective $f(x, y)$ as a function on only these two coordinates.

Observe that we have already assumed that

$$f(\alpha_i, \alpha_k) \leq \min\{f(\beta_i, \alpha_k), f(\alpha_i, \beta_k)\}. \tag{11}$$

Moreover, from above, we have $f(\alpha_{[i]}) > f(\alpha_{[i,k]})$, which translates to $f(\beta_i, \alpha_k) > f(\beta_i, \beta_k)$. Observe that we must have $f(\alpha_i, \beta_k) \leq f(\beta_i, \beta_k)$; otherwise, we have $f(\beta_i, \beta_k) < \min\{f(\beta_i, \alpha_k), f(\alpha_i, \beta_k)\}$, which, together with (11), will contradict Lemma 3.8.

Therefore, we have $f(\alpha_{[k]}) = f(\alpha_i, \beta_k) \le f(\beta_i, \beta_k) < f(\beta_i, \alpha_k) = f(\alpha_{[i]})$, which contradicts the choice of $i \in \Delta(\alpha, \beta)$ to minimize $f(\alpha_{[i]})$. This completes the inductive step and also the proof of the lemma. □

Corollary 3.10. *For the function f in Definition 2.1 every local minimizer is a global minimizer.*

Proof. Suppose that α is a local minimizer, but there is some β with $f(\alpha) > f(\beta)$. Then, Lemma 3.9 implies there is some γ with $|\Delta(\alpha, \gamma)| = 1$ such that $f(\alpha) > f(\gamma)$, contradicting that α is a local minimizer. □

4 EFFICIENT LOCAL SEARCH

In Section 3, we conclude in Corollary 3.4 that it suffices to consider the extreme points of the search space of resistance vectors. Moreover, Corollary 3.10 states that every local minimizer is a global minimizer. Since we know how to compute the sign of the partial derivative with respect to each coordinate using Lemma 3.2, we can design a simple local search algorithm to find a global minimizer.

However, it is possible that $O(2^n)$ extreme points are encountered before a global minimizer is reached. Fortunately, in this section, we will explore further properties of the objective function, and design a local search algorithm that encounters at most $O(n)$ extreme points before finding a global minimizer.

4.1 Irrevocable Updates

Local Search Strategy. We shall start with the upper bound resistance vector, i.e., for each $i \in V$, $\alpha_i = u_i$. This induces the corresponding equilibrium opinion vector $z(\alpha)$. According to Lemma 3.2, if there is some agent i such that $\alpha_i = u_i$ and $s_i - z_i(\alpha) > 0$, then we should flip α_i to the lower bound l_i. The following lemma shows that each α_i will be flipped at most once. Essentially, we show that we will never encounter the situation that there is some agent k such that $\alpha_k = l_k$ and $s_k - z_k(\alpha) < 0$, in which case we would have to switch α_k back to u_k.

Lemma 4.1 (Each Coordinate Flipped at Most Once). *Starting from the upper bound resistance vector, the above local search strategy flips each α_i at most once.*

Proof. We first show that for each agent $k \in V$, the quantity $s_k - z_k(\alpha)$ cannot decrease when α is modified according to the local search strategy. According to the strategy, α is modified because there is some agent i such that $\alpha_i = u_i$ and $s_i - z_i(\alpha) > 0$. By Lemma 3.2, $\frac{\partial z_k}{\partial \alpha_i} > 0$ for each $k \in V$. Hence, after α_i is switched from u_i to l_i, $z_k(\alpha)$ decreases, and the quantity $s_k - z_k(\alpha)$ increases.

Observe that if a coordinate α_k is ever flipped from u_k to l_k, this means that at that moment, we must have $s_k - z_k(\alpha) > 0$, which, as we have just shown, will stay positive after α is subsequently updated. □

4.2 Approximating the Equilibrium Vector

Observe that in our local search algorithm, we need to compute the equilibrium opinion vector $z(\alpha) = [I - (I - A)P)]^{-1}As$ for the current resistance vector α, where $A = \mathrm{Diag}(\alpha)$. However, computing matrix inverse is an expensive operation. Instead, we approximate $z(\alpha)$ using the recurrence $z^{(0)} \in [0,1]^V$ and $z^{(t+1)} := As + (I - A)Pz^{(t)}$. The following lemma gives an upper bound on the additive error for each coordinate.

Lemma 4.2 (Approximation Error). *Suppose for some $\epsilon > 0$, for all $i \in V$, $\alpha_i \ge \epsilon$. Then, for every $t \ge 0$, $\|z(\alpha) - z^{(t)}\|_\infty \le \frac{(1-\epsilon)^t}{\epsilon}$.*

Proof. Using the Neumann series $[I - (I - A)P)]^{-1} = \sum_{j=0}^{\infty}[(I - A)P]^j$, we have $z(\alpha) - z^{(t)} = \sum_{j=t}^{\infty}[(I - A)P]^j As - [(I - A)P]^t z^{(0)}$.

We next prove, by induction, that for any $x \in [0,1]^V$, $\|[(I - A)P]^j x\|_\infty \le (1 - \epsilon)^j$, for all $j \ge 0$. The base case $j = 0$ is trivial because every coordinate of x is between 0 and 1. For the inductive step, assume that for some $j \ge 0$, every coordinate of $y = [(I - A)P]^j x$ has magnitude at most $(1 - \epsilon)^i$. Since P is a row stochastic matrix, it follows that $\|Py\|_\infty \le (1 - \epsilon)^j$; finally, since $\alpha_i \ge \epsilon$ for all $i \in V$, we have $\|(I - A)Py\|_\infty \le (1 - \epsilon)^{j+1}$, completing the induction proof.

Finally, observing that both $\sum_{j=t}^{\infty}[(I - A)P]^j As$ and $[(I - A)P]^t z^{(0)}$ have non-negative coordinates, we have

$$\|z(\alpha) - z^{(t)}\|_\infty \le \max\{\|\sum_{j=t}^{\infty}[(I - A)P]^j As\|, \|[(I - A)P]^t z^{(0)}\|\}$$
$$\le \sum_{j=t}^{\infty}(1 - \epsilon)^j = \frac{(1 - \epsilon)^t}{\epsilon}$$

as required. □

4.3 Local Search Algorithm

Based on Lemmas 4.1 and 4.2, we give a local search framework in Algorithm 1. Observe that in line 1, we perturb the innate opinions s slightly to ensure that for each resistance vector α encountered, no coordinate of s and $z(\alpha)$ would coincide.

The **while** loop in line 4 combines local search to update α and estimation of the equilibrium vector $z(\alpha)$. Here are two general update strategies, which are both captured by the non-deterministic step in line 7:

- **Conservative Update.** The opinion vector z is iteratively updated in line 5 until all coordinates of z and s are sufficiently far apart. Then, for every coordinate α_i such that $\alpha_i = u_i$ and $z_i < s_i$, we flip α_i to the lower bound l_i.
  After we update α, we reset t to 0, and continue to iteratively update z. Whenever we update α and set t to 0, we say that a new *phase* begins; we use the convention that the initial phase is known as phase 0.
- **Opportunistic Update.** Instead of waiting for the approximation error of every coordinate of z to be small enough, we can update some coordinates α_i, if $\alpha_i = u_i$ and $z_i \le s_i - \mathrm{err}(t)$ is small enough. However, there is some tradeoff between waiting for the errors of all coordinates to be small enough and updating coordinates of α that are ready sooner. In Section 5, we will evaluate empirically different update strategies.

Optimistic Update. In both conservative and opportunistic updates, a coordinate α_i is flipped only when we know for sure that the current estimate z_i has small enough error with respect to the equilibrium $z_i(\alpha)$; hence, no mistake in flipping any α_i is ever made.

Algorithm 1: Local Search Framework

Input: Innate opinions $s \in [0,1]^V$; interaction matrix P; for each agent $i \in V$, upper u_i and lower l_i bounds for resistance.
Output: Optimal resistance vector $\alpha \in \times_{i \in V}\{l_i, u_i\}$.

1 *(Technical step.)* Randomly perturb each coordinate of s slightly.
2 Initially, for each agent i, set $\alpha_i \leftarrow u_i$ to its upper bound; denote $\epsilon_\alpha := \min_{i \in V} \alpha_i$.
3 Pick arbitrary $z \in [0,1]^V$, and set $t \leftarrow 0$; denote $\mathrm{err}(t) := \frac{(1-\epsilon_\alpha)^t}{\epsilon_\alpha}$.
4 **while** $\exists i \in V : |s_i - z_i| \le \mathrm{err}(t) \vee (z_i < s_i \wedge \alpha_i = u_i)$ **do**
5 $z \leftarrow As + (I - A)Pz$, where $A = \mathrm{Diag}(\alpha)$
6 $t \leftarrow t + 1$
7 *(Non-deterministic step.)* Pick arbitrary $L \subseteq V$ (that can be empty) such that for each $i \in L$, $z_i \le s_i - \mathrm{err}(t)$ and $\alpha_i = u_i$.
8 **if** $L \neq \emptyset$ **then**
9 **for** *each* $i \in L$ **do**
10 Set $\alpha_i \leftarrow l_i$ to its lower bound (and update ϵ_α).
11 $t \leftarrow 0$
12 **return** *Resistance vector* α.

Algorithm 2: Optimistic Local Search

Input: Innate opinions $s \in [0,1]^V$; interaction matrix P; for each agent $i \in V$, upper u_i and lower l_i bounds for resistance.
Output: Optimal resistance vector $\alpha \in \times_{i \in V}\{l_i, u_i\}$.

1 *(Technical step.)* Randomly perturb each coordinate of s slightly.
2 Initially, for each agent i, set $\alpha_i \leftarrow u_i$ to its upper bound; denote $\epsilon_\alpha := \min_{i \in V} \alpha_i$.
3 Pick $z = (1, 1, \ldots, 1)$, and set $t \leftarrow 0$; denote $\mathrm{err}(t) := \frac{(1-\epsilon_\alpha)^t}{\epsilon_\alpha}$.
4 **while** $\exists i \in V : |s_i - z_i| \le \mathrm{err}(t)$ **do**
5 $z \leftarrow As + (I - A)Pz$, where $A = \mathrm{Diag}(\alpha)$
6 $t \leftarrow t + 1$
7 *(Optimistic Candidates.)* Set $L \leftarrow \{i \in V : z_i \le s_i \wedge \alpha_i = u_i\}$.
8 *(Rare Mistakes.)* Set $J \leftarrow \{i \in V : z_i > s_i \wedge \alpha_i = l_i\}$.
9 **if** $L \cup J \neq \emptyset$ **then**
10 **for** *each* $i \in L$ **do**
11 Set $\alpha_i \leftarrow l_i$ to its lower bound (and update ϵ_α).
12 **for** *each* $i \in J$ **do**
13 Set $\alpha_i \leftarrow u_i$ to its upper bound (and update ϵ_α).
14 $t \leftarrow 0$
15 **return** *Resistance vector* α.

However, our insight is that as the algorithm proceeds, the general trend is for every z_i to decrease.

The first intuition is that if we start with some $z^{(0)}$ such that every coordinate of $z^{(0)}$ is at least its equilibrium coordinate of $z(\alpha)$, then $z^{(t)}$ should converge to $z(\alpha)$ from above. The second observation is that every time we flip some α_i, this will not increase any coordinate of the equilibrium vector $z(\alpha)$, thereby preserving the condition that the current estimate $z^{(t)} \ge z(\alpha)$. Hence, without worrying about the accuracy of the current estimate z, we will simply flip coordinate α_i to l_i when z_i drops below s_i. However, it is possible that we might need to flip α_i back to u_i, if z_i increases in the next iteration and becomes larger than s_i again. We shall see in Section 5 that this scenario is extremely rare. Specifically, in line 8 of Algorithm 2, the set J is (almost) always empty.

5 EXPERIMENTS

Experimental setup. Our experiments run on a server with 2.1 GHz Intel Xeon Gold 6152 CPU and 64GB of main memory. The server is limited to activate at most 24 threads by the administrator. The real network topologies we use in our experiment are shown in Table 1; we interpret each network as an undirected graph. The number n of nodes in the dataset networks ranges from about 1 million to 65 million; in each network, the number m of edges is around $2n$ to $30n$.

Input Generation. For each dataset, we utilize the network topology and generate the input parameters as follows. The innate opinion s_i of each agent i is independently generated uniformly at random from $[0,1]$. For each edge $\{i,j\}$ in the network, we independently pick w_{ij} uniformly at random from $[0,1]$; otherwise, we set $w_{ij} = 0$. For $(i,j) \in V \times V$, we normalize $P_{ij} := \frac{w_{ij}}{\sum_{k \in V} w_{ik}}$. From Lemma 4.2, one can see that approximating the equilibrium opinions is more difficult when the resistance is low. However, since we still want to demonstrate that the resistance for each agent can have varied lower and upper bounds, we set the lower bound l_i of each agent i independently such that with probability 0.99, l_i equals 0.001, and with probability 0.01, it is picked uniformly at random from $[0.001, 0.1]$. Similarly, each upper bound u_i is independently selected such that with probability 0.99, it equals to 0.999, and with probability 0.01, it is chosen uniformly at random from $[0.9, 0.999]$.

5.1 Update Strategies Comparison

We compare the following three update strategies described in Section 4: conservative, opportunistic and optimistic. For the three smaller networks (com-Youtube, com-LiveJournal, LiveJournal), we apply all three update strategies. For the largest network (com-Friendster), we only report the performance of the optimistic update strategy, as the other two update strategies are not efficient enough for such a large dataset.

Experimental Setup. For fair comparison among the update strategies, we always initialize $z = (1, 1, \ldots, 1)$. To compare their performances, we plot a curve for each strategy. The curves have a common x-axis, which corresponds to the number of times that the vector z has been updated so far, i.e., the number of times line 5 (in both Algorithms 1 and 2) has been executed. Since line 5 is the most time-consuming part of the algorithms, it will be a suitable common reference. We use the term *iteration* to refer to each time z is updated. For each update strategy, we explain what is plotted for the y-axis.

- **Conservative Strategy.** We run Algorithm 1 such that in line 7, L is non-empty only if for all $i \in V$, $|s_i - z_i| > \mathrm{err}(t)$, in which case, we pick L to be the collection of all i's such that $\alpha_i = u_i$ and $z_i \le s_i - \mathrm{err}(t)$.
  For the y-axis, we plot the ratio of agents i for which currently $\alpha_i = l_i$, or we know definitely that α_i should be switched to l_i, i.e., currently $\alpha_i = u_i$ and $z_i \le s_i - \mathrm{err}(t)$.
  In Algorithm 1, the iterations (referring to each time z is updated) are grouped into *phases*, where a non-empty L in an iteration marks the end of a phase. Observe that at the end of a phase, for all $i \in L$, α_i is set to l_i and t is reset to 0.

Table 1: Datasets Information

Name	Number n of Nodes	Number m of Edges	Description	Source
com-Youtube	1,134,890	2,987,624	Youtube online social network	[18]
com-LiveJournal	3,997,962	34,681,189	LiveJournal online social network	[18]
LiveJournal	10,690,276	112,307,385	LiveJournal user and group membership network	[17]
com-Friendster	65,608,366	1,806,067,135	Friendster online social network	[18]

Hence, in the next iteration, no coordinate α_i is certain to be switched. Hence, the curve has a step-like shape, where each plateau occurs after the end of each phase.

Observer that initially $\epsilon_\alpha = \min_i u_i \geq 0.9$. Hence, it takes very few number of iterations to satisfy $\forall i \in V : |s_i - z_i| > \text{err}(t)$; we call this the phase 0. At the end of the phase 0, we set some $\alpha_i = l_i$ and ϵ_α decreases significantly. Hence, subsequent phases have many more iterations.

Observe that we can stop the iterative process, when for all $i \in V$, $|s_i - z_i| > \text{err}(t)$, but there is no $i \in V$ such that $z_i < s_i$ and $\alpha_i = u_i$. This marks the end of the curve.

In each phase, we pick L of line 7 as the collection of all i's such that $z_i \leq s_i - \text{err}(t)$ only when $\forall i \in V : |s_i - z_i| > \text{err}(t)$ (otherwise, we pick $L = \emptyset$). Then, we set $\alpha_i = l_i$ for each $i \in L$ and $t = 0$. We call such a phase a *conservative phase*.

- **Opportunistic Strategy.** We run Algorithm 1 similarly as before. Phase 0 is the same as the conservative strategy; we call a phase *conservative*, if it follows the conservative update strategy.

  Starting from phase 1, we can perform it in an opportunistic manner as follows. Recall that at the beginning of a phase, t has just been reset to 0. At the t-th iteration of that phase, we use $L(t)$ to denote the collection of i's such that $z_i \leq s_i - \text{err}(t)$. For every 1000 iterations, we compute an estimate $\text{slope}(k) := \frac{|L(1000k)| - |L(1000(k-1))|}{1000}$ of the slope; we keep track k_m of the maximum slope computed so far. After some iteration, if the estimated slope drops below some factor (we use 0.1 in our experiments) of k_m, then we end this phase. Intuitively, each additional iteration flips only a small number of coordinates α_i, and hence, one would like to end this phase. We call such a phase *opportunistic*.

  Since typically the total number of phases is around 8, we run phase 1 to 6 opportunistically, after which we run the remaining phases conservatively to make sure that all coordinates α_i that need to be changed will be flipped.

  As in the conservative update strategy, for the y-axis, we plot the ratio of coordinates α_i that currently $\alpha_i = l_i$, or we know for sure should be switched to l_i, i.e. $\alpha_i = u_i$ and $z_i \leq s_i - \text{err}(t)$.
- **Optimistic Strategy.** We implement Algorithm 2, where in each iteration after z is updated, a coordinate α_i is (re)set to l_i if $z_i < s_i$, and (re)set to u_i if $z_i > s_i$. For the y-axis, we plot the ratio of coordinates that currently take their lower bounds. The curve ends when enough iterations are performed after some coordinate of α is last updated, in order to ensure that the estimate z is close enough to the equilibrium vector according to Lemma 4.2.

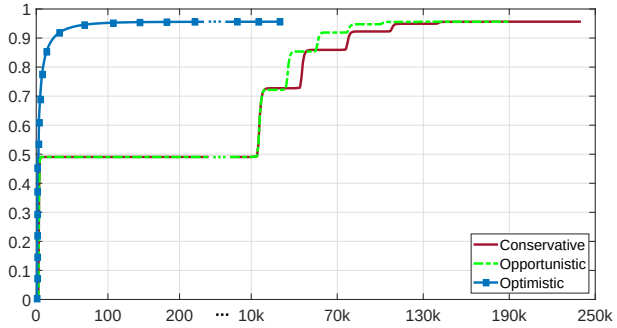

Figure 2: Update Strategies Comparison on com-Youtube.

Experiment Results. Each of Figures 2, 3 and 4 shows the plots for the three strategies in the corresponding network (com-Youtube, com-LiveJournal or LiveJournal). Figure 5 shows the plot of the optimistic strategy in the com-Friendster network, where the other two strategies are not efficient enough for such a large network. As expected, the opportunistic strategy is slightly better than the conservative strategy. From the positions of the plateaus, we can see that the initial opportunistic phases end sooner than their conservative counterparts. Hence, overall the opportunistic strategy performs slightly better than the conservative strategy; in increasing sizes of the three tested networks, the numbers of iterations taken by the opportunistic strategy are 79.2%, 77.9% and 71.5%, respectively, of those taken by the conservative strategy.

On the other hand, the optimistic strategy can achieve the optimal resistance vector with much fewer number of iterations than the other two strategies. In increasing sizes of the three smaller networks, the numbers of iterations taken by the optimistic strategy are only 12.8%, 13.4% and 12.4%, respectively, of those taken by the conservative strategy. Moreover, the optimistic strategy makes very few mistakes; in increasing sizes of the four networks, the numbers of times coordinates are flipped from lower bounds back to upper bounds are 1, 0, 13 and 168, which are negligible for networks with millions of nodes.

5.2 Running Time with Multiple Threads

We compare the actual running time using different number of threads for the optimistic strategy on only the three smaller networks, since the largest network takes too long using only one thread. Using all 24 available threads, running the optimistic strategy on the com-Friendster network already takes around 50 hours.

The three bar graphs in Figure 6 show the running time (measured in minutes) for running the optimistic strategy with different

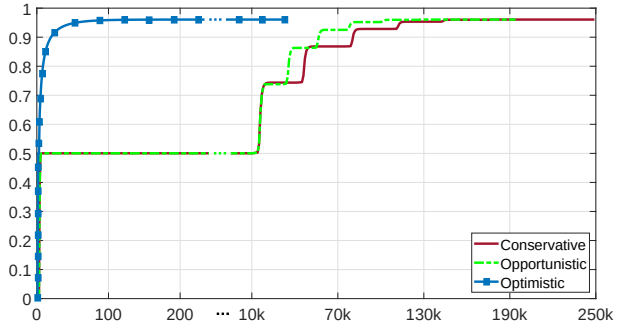

Figure 3: Update Strategies Comparison on com-LiveJournal.

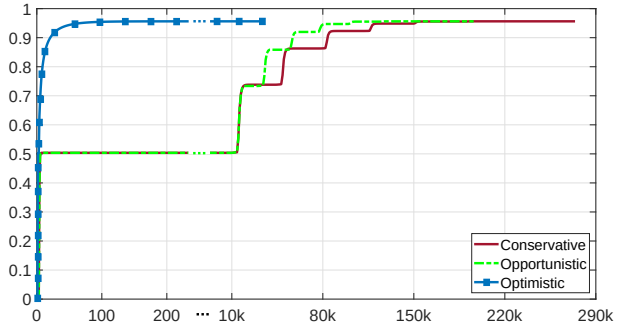

Figure 4: Update Strategies Comparison on LiveJournal.

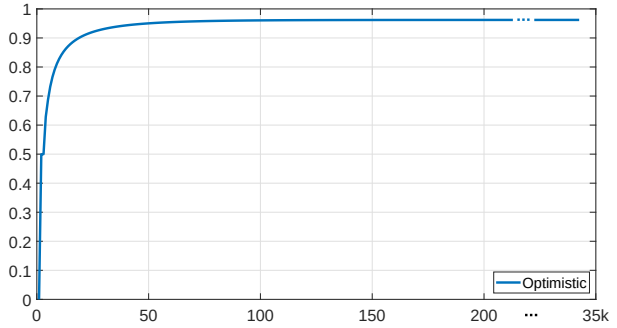

Figure 5: Optimistic Strategy on com-Friendster.

number of threads on the com-Youtube, com-LiveJournal and LiveJournal networks. Since updating z (line 5 of Algorithm 2) is the most time-consuming part of the algorithm, the fact that it is readily parallelizable supports the empirical results that using multiple threads can greatly reduce the running time, where the effect is more prominent for larger networks.

6 TECHNICAL PROOFS

Lemma 6.1. *(Lemma 3.1 restated) Given $K \subsetneq V$ and $\alpha \in (0,1)^V$, let $A := \mathrm{Diag}(\alpha)$ and recall that P is the irreducible interaction matrix. Then, the inverse $M = [I - (I - A_{-K})P]^{-1}$ exists, and every entry*

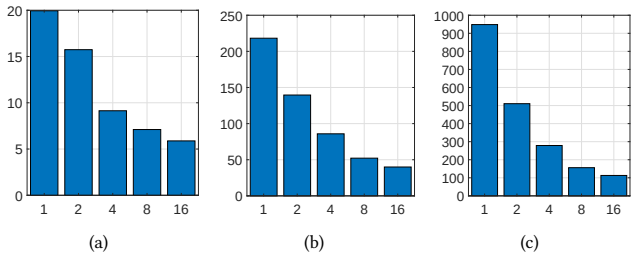

Figure 6: Running Time with Different Number of Threads on com-Youtube, com-LiveJournal and LiveJournal

of M is positive. Moreover, for each $k \in V$, define $a_k = 0$ if $k \in K$, otherwise $a_k = \alpha_k$. Then, we have:

(1) $(PM)_{kk} = \frac{M_{kk}-1}{1-a_k} > 0$;

(2) $(PM)_{kj} = \frac{M_{kj}}{1-a_k} > 0$, *for each $j \neq k$.*

Proof. Observe that P corresponds to an irreducible random walk. Hence, $(I - A_{-K})P$ represents a diluted random walk, where at the beginning of each step, the measure at nodes $i \notin K$ will suffer a factor of $1 - \alpha_i \in (0,1)$. The irreducibility of the random walk P means that every state is reachable from any state. Hence, starting from any measure vector, eventually the measure at every node will tend to 0. This means that $(I - A_{-K})P$ has eigenvalues with magnitude strictly less than 1. Therefore, we can consider the following Neumann series of a matrix:

$$M = [I - (I - A_{-K})P]^{-1} = I + \sum_{k=1}^{\infty} [(I - A_{-K})P]^k,$$

which implies that the inverse M exists, and every entry of M is positive; in particular, for every $k \in V$, $M_{kk} > 1$.

By the definition of M, we have $[I - (I - A_{-K})P]M = I$. We fix some $k \in V$. By considering the (k,k)-the entry, i.e., the dot product between the k-th row of $[I - (I - A_{-K})P]$ and the k-th column of M, we have

$$M_{kk} - \sum_{i \in V} (1 - a_k) P_{ki} M_{ik} = 1$$

where $a_k = 0$ if $k \in K$, otherwise $a_k = \alpha_k < 1$. Hence, we have $(PM)_{kk} = \sum_{i \in V} P_{ki} M_{ik} = \frac{M_{kk}-1}{1-a_k}$.

Similarly, for $j \neq k$, by considering the dot product between the k-th row of $[I - (I - A_{-K})P]$ and the j-th column of M, we have

$$M_{kj} - \sum_{i \in V} (1 - a_k) P_{ki} M_{ij} = 0.$$

Hence, we have for $j \neq k$,

$$(PM)_{kj} = \sum_{i \in V} P_{ki} M_{ij} = \frac{M_{kj}}{1 - a_k},$$

as required. □

Lemma 6.2. *(Lemma 3.3 restated) Referring to Lemma 3.2. For any $\alpha \in (0,1)^V$ and any $i \in V$, denote $M = [I - (I - A_{-\{i\}})P]^{-1}$. Then, $\frac{\partial f(\alpha)}{\partial \alpha_i}$ has the same sign in $\{-, 0, +\}$ as $s_i - \sum_{j \neq i} M_{ij} \alpha_j s_j$, which is independent of α_i.*

Proof. Using the Sherman-Morrison formula, we consider

$$\begin{aligned}X :=&[I-(I-A)P]^{-1}=[I-(I-A_{-\{i\}}-\alpha_i\mathbf{e}_i\mathbf{e}_i^T)P]^{-1}\\ =&[I-(I-A_{-\{i\}})P+\alpha_i\mathbf{e}_i\mathbf{e}_i^TP]^{-1}\\ =&M-\frac{\alpha_i}{1+\alpha_i\mathbf{e}_i^TPM\mathbf{e}_i}M\mathbf{e}_i\mathbf{e}_i^TPM.\end{aligned}$$

Observe that $\mathbf{e}_i^TPM\mathbf{e}_i=(PM)_{ii}$ and $(M\mathbf{e}_i\mathbf{e}_i^TPM)_{ij}=M_{ii}(PM)_{ij}$ for each $j\in V$. Then, by Lemma 3.1 with $K=\{i\}$, we have

$$\begin{aligned}X_{ii}=&M_{ii}-\frac{\alpha_iM_{ii}(PM)_{ii}}{1+\alpha_i(PM)_{ii}}=M_{ii}-\frac{\alpha_iM_{ii}(M_{ii}-1)}{1+\alpha_i(M_{ii}-1)}\\ =&\frac{(1-\alpha_i+\alpha_iM_{ii}-\alpha_iM_{ii}+\alpha_i)M_{ii}}{1-\alpha_i+\alpha_iM_{ii}}=\frac{M_{ii}}{1-\alpha_i+\alpha_iM_{ii}};\end{aligned}$$

and for $j\neq i$,

$$\begin{aligned}X_{ij}=&M_{ij}-\frac{\alpha_iM_{ii}(PM)_{ij}}{1+\alpha_i(PM)_{ii}}=M_{ij}-\frac{\alpha_iM_{ii}M_{ij}}{1+\alpha_i(M_{ii}-1)}\\ =&\frac{(1-\alpha_i+\alpha_iM_{ii}-\alpha_iM_{ii})M_{ij}}{1-\alpha_i+\alpha_iM_{ii}}=\frac{(1-\alpha_i)M_{ij}}{1-\alpha_i+\alpha_iM_{ii}}.\end{aligned}$$

By Lemma 3.2, we know $\frac{\partial f(\alpha)}{\partial\alpha_i}$ and $s_i-z_i(\alpha)$ have the same sign in $\{-,0,+\}$. Recall that $z(\alpha)=[I-(I-A)P]^{-1}As=XAs$. Applying the above results, we have

$$\begin{aligned}s_i-z_i(\alpha)=&s_i-\sum_{j\in V}X_{ij}\alpha_js_j\\ =&s_i-\frac{M_{ii}\alpha_is_i}{1-\alpha_i+\alpha_iM_{ii}}-\sum_{j\neq i}\frac{(1-\alpha_i)M_{ij}\alpha_js_j}{1-\alpha_i+\alpha_iM_{ii}}\\ =&\frac{s_i(1-\alpha_i+\alpha_iM_{ii})-M_{ii}\alpha_is_i-(1-\alpha_i)\sum_{j\neq i}M_{ij}\alpha_js_j}{1-\alpha_i+\alpha_iM_{ii}}\\ =&\frac{(1-\alpha_i)(s_i-\sum_{j\neq i}M_{ij}\alpha_js_j)}{1-\alpha_i+\alpha_iM_{ii}}.\end{aligned}$$

Since $\alpha_i\in(0,1)$, we conclude that $\frac{1-\alpha_i}{1-\alpha_i+\alpha_iM_{ii}}>0$. Thus $\frac{\partial f(\alpha)}{\partial\alpha_i}$, $s_i-z_i(\alpha)$ and $s_i-\sum_{j\neq i}M_{ij}\alpha_js_j$ have the same sign. □

Lemma 6.3. *(Lemma 3.6 restated) For any $i,k\in V$ such that $i\neq k$, let $M=[I-(I-A_{-\{i\}})P]^{-1}$ and $R=[I-(I-A_{-\{i,k\}})P]^{-1}$. Then for any $j\in V$, we have*

(1) $M_{jk}=\frac{R_{jk}}{1+\alpha_kR_{kk}-\alpha_k}$,

(2) $M_{jh}=R_{jh}-\frac{\alpha_kR_{jk}R_{kh}}{1+\alpha_kR_{kk}-\alpha_k}$, *for each $h\neq k$.*

In particular, the quantity in Lemma 3.3 can be rewritten as follows:

$$s_i-\sum_{j\neq i}M_{ij}\alpha_js_j=s_i-\sum_{j\neq i,k}R_{ij}\alpha_js_j-\frac{\alpha_kR_{ik}}{1+\alpha_kR_{kk}-\alpha_k}(s_k-\sum_{j\neq i,k}R_{kj}\alpha_js_j).$$

Proof. Using the Sherman-Morrison formula, we have

$$\begin{aligned}M&=[I-(I-A_{-\{i,k\}})P+\alpha_k\mathbf{e}_k\mathbf{e}_k^TP]^{-1}\\ &=R-\frac{\alpha_k}{1+\alpha_k\mathbf{e}_k^TPR\mathbf{e}_k}R\mathbf{e}_k\mathbf{e}_k^TPR\end{aligned}$$

We can compute that $\mathbf{e}_k^TPR\mathbf{e}_k=(PR)_{kk}$ and $(R\mathbf{e}_k\mathbf{e}_k^TPR)_{jh}=R_{jk}(PR)_{kh}$ for $j,h\in V$. Then we have

$$M_{jh}=R_{jh}-\frac{\alpha_kR_{jk}(PR)_{kh}}{1+\alpha_k(PR)_{kk}}.$$

By Lemma 3.1, we obtain

$$M_{jh}=R_{jh}-\frac{\alpha_kR_{jk}R_{kh}}{1+\alpha_kR_{kk}-\alpha_k}\text{ for }j,h\in V\text{ and }h\neq k,$$

and

$$M_{jk}=R_{jk}-\frac{\alpha_kR_{jk}(R_{kk}-1)}{1+\alpha_kR_{kk}-\alpha_k}=\frac{R_{jk}}{1+\alpha_kR_{kk}-\alpha_k}\text{ for }j\in V.$$

as required. □

Lemma 6.4. *(Lemma 3.7 restated) Suppose $\alpha\in(0,1)^V$, recall that $A_{-\{i,k\}}:=\mathrm{Diag}(\alpha_{-\{i,k\}})$, and P corresponds to an irreducible interaction matrix. For any $i,k\in V$ such that $i\neq k$, let $R=[I-(I-A_{-\{i,k\}})P]^{-1}$, then $R_{ii}=\max_{j\in V}R_{ji}$. Moreover, $R_{ii}=R_{ki}$ if and only if $P_{kk}+P_{ki}=1$.*

Proof. We have $[I-(I-A_{-\{i,k\}})P]R=I$. By considering the dot product between each row of $[I-(I-A_{-\{i,k\}})P]$ and column i of R, we have

$$R_{ii}-\sum_{h\in V}P_{ih}R_{hi}=1,R_{ki}-\sum_{h\in V}P_{kh}R_{hi}=0,$$

$$\text{and }R_{ji}-\sum_{h\in V}(1-\alpha_j)P_{jh}R_{hi}=0,\text{ for }j\neq i,k.$$

After rearranging, we have

$$R_{ii}=1+\sum_{h\in V}P_{ih}R_{hi},R_{ki}=\sum_{h\in V}P_{kh}R_{hi},$$

$$\text{and }R_{ji}=(1-\alpha_j)\sum_{h\in V}P_{jh}R_{hi},\text{ for }j\neq i,k.$$

Now it suffices to show that for $j\neq i,k$, the above R_{ji} cannot be the maximum among them, and $R_{ki}\leq R_{ii}$.

First, we show that R_{ji} cannot be the maximum. Since $\sum_{h\in V}P_{jh}=1$ and $\alpha_j\in(0,1)$, we have

$$R_{ji}=(1-\alpha_j)\sum_{h\in V}P_{jh}R_{hi}\leq(1-\alpha_j)\max_{h\in V}R_{hi}<\max_{h\in V}R_{hi}.$$

Thus, R_{ji} cannot be the maximum.

Next, we show that $R_{ki}\leq R_{ii}$ by contradiction. Suppose $R_{ki}>R_{ii}$, then R_{ki} is the unique maximum in the i-th column of R. Since $\sum_{h\in V}P_{kh}=1$ and $R_{ki}=\sum_{h\in V}P_{kh}R_{hi}$, it must be the case that $P_{kk}=1$. This means P corresponds to a random walk with absorbing state k, which contradicts that P is irreducible. Therefore, we have $R_{ki}\leq R_{ii}$, and hence $R_{ii}=\max_{h\in V}R_{hi}$.

Observe that we already know $R_{ji}<R_{ii}$ for $j\neq i,k$, and $R_{ki}=\sum_{h\in V}P_{kh}R_{hi}$. Hence, $R_{ki}=R_{ii}$ implies that $P_{kk}+P_{ki}=1$.

Conversely, $P_{kk}+P_{ki}=1$ implies that $R_{ki}=P_{kk}R_{ki}+P_{ki}R_{ii}$. As argued above, we must have $P_{kk}\neq1$, which implies $R_{ki}=R_{ii}$. □

7 CONCLUSION AND FUTURE WORK

We have given a solid theoretical analysis of the unbudgeted variant of the opinion susceptibility problem, and designed scalable local search algorithms that can solve the problem optimally on graphs with millions of nodes.

We believe that our techniques will lead to insights for the analysis of the budgeted variant of the problem. We leave the task of providing theoretical guarantees for greedy algorithms on the budgeted variant as future work.

Trajectories of Blocked Community Members: Redemption, Recidivism and Departure

ABSTRACT

Community norm violations can impair constructive communication and collaboration online. As a defense mechanism, community moderators often address such transgressions by temporarily blocking the perpetrator. Such actions, however, come with the cost of potentially alienating community members. Given this tradeoff, it is essential to understand to what extent, and in which situations, this common moderation practice is effective in reinforcing community rules.

In this work, we introduce a computational framework for studying the future behavior of blocked users on Wikipedia. After their block expires, they can take several distinct paths: they can reform and adhere to the rules, but they can also recidivate, or straight-out abandon the community. We reveal that these trajectories are tied to factors rooted both in the characteristics of the blocked individual and in whether they perceived the block to be fair and justified. Based on these insights, we formulate a series of prediction tasks aiming to determine which of these paths a user is likely to take after being blocked for their first offense, and demonstrate the feasibility of these new tasks. Overall, this work builds towards a more nuanced approach to moderation by highlighting the tradeoffs that are in play.

1 INTRODUCTION

The health of online communities is often threatened by individuals that violate their norms and rules [24]. Communities have limited defense mechanisms against such offenses, ranging from the deletion of problematic comments [4], to temporarily blocking the perpetrators, to outright excluding them [22]. Such actions, however, come at the cost of potentially alienating valuable community members and raise issues of freedom of speech, fairness and bias [22, 25, 45]. Considering their potential negative impacts, it is important to understand to what extent, and in which situations, these moderation mechanisms are effective at enforcing community norms.

In this work we take a first step towards answering these questions by focusing on *temporary blocks* in the Wikipedia community of editors. Unlike other moderation actions, these have the explicitly stated purpose of "deterring any future possible repetitions of inappropriate conduct" by the perpetrators, while reintegrating them in the community (thus the temporary nature of the block). However, following their initial block, nearly half of first-time offenders either recidivate—18% of established members violate the rules again within 6 months of the block—or straight-out abandon the community—30% of established members depart within 6 months (a third of which depart during the block). This discrepancy between the stated goal and the empirical outcomes of temporary blocks motivates an investigation into the factors that determine the likely trajectory a community member will take after their block expires: redemption, recidivism or departure.

We ground our investigation in offline theories of deterrence and defiance [46], which point to at least three broad classes of factors determining future compliance: those pertaining to the characteristics of the perpetrator [48], those pertaining to the actual severity of the punishment [16, 27] and those pertaining to whether the perpetrator perceives their treatment as fair [40]. While relying on these theories to guide our selection of factors and potential confounds to consider in our analysis, we refrain from drawing any direct parallels between offline and online rule-enforcement strategies given their distinct nature and goals.

Individual characteristics. Behavior of community members and their adherence to community norms has been shown to vary according to their level of involvement with the community [6, 10, 18, 42]. We find that individuals that exhibit a high level of community involvement (e.g., have interacted with more users over a longer period of time) are less likely to abandon the community during a temporary

https://doi.org/10.1145/3308558.3313638

block. On the other hand, these individuals are also more likely to recidivate soon after the block. This suggests that users with high community involvement are more immune to the effects of blocks, both undesired (departure) and desired (reforming).

Block duration. Existing literature on offline rule compliance varies in their accounts of how the nature of the punishment determines the likelihood of recidivism [49]. The traditional (institutional) perspective is that the severity of the punishment is the main factor determining compliance [16, 27]. A contrasting (normative) perspective, however, argues that perhaps a more important factor is whether the perpetrator regards the punishment as being fair and justified [32, 48]. In the context of the Wikipedia community, we find that even though longer—and thus more severe—blocks come at the cost of higher departure rates, they do not appear to have any effect on recidivism.

Perceived fairness. To capture whether an individual perceives their initial block as fair, we leverage a mechanism specific to online moderation: block appeals. Blocked individuals can contest a block by opening a discussion with Wikipedia moderators during the block. In turn, moderators have the option to lift the block early—i.e., to *unblock* the individual—as a result of these discussions. This process provides us with a glimpse into a blocked individual's perception of fairness: we can analyze their language as well as the outcome of the appeal.

Using this methodology, we find that users who perceive the block to be unfair have an increased rate of recidivism, while those that acknowledge their wrongdoing and apologize have a decreased rate. Furthermore, even though the block duration itself does not appear to affect recidivism, the post-hoc reduction of this duration by a moderator drastically diminishes recidivism rates, perhaps by improving the user's perception of the moderation system as being fair and reasonable. Combined, these results suggest that the effectiveness of temporary blocks is not so much dependent on their actual severity, but rather on the blocked user's perception of how appropriate the block is.

To summarize, in this work we:

- investigate the effectiveness of temporary blocks by considering possible trajectories an individual can take after their block expires;
- reveal factors that are indicative of these future trajectories, reflecting both the engagement patterns of the blocked individual, as well their perception of the fairness of the block;
- analyze the relative importance of each of these factors by using them in a series of forecasting tasks aiming to determine which path a user is likely to take after their first block.

More broadly, we propose a computational framework for analyzing the outcomes of a common moderation practice in online communities. In doing so, we expose the underlying tradeoffs and provide the means to further explore factors that mediate them.

2 BLOCKS ON WIKIPEDIA

While Wikipedia is primarily known as an online encyclopedia, it also plays host to a vibrant community of editors who continually write new articles and improve existing ones. To support this community, Wikipedia has a feature known as *talk pages*: special pages on which editors can discuss a particular article or Wikipedia policy, or simply unwind with casual conversation. Every Wikipedia article has an associated talk page, on which editors can discuss proposed edits to the article. Similarly, every registered user has an associated *user talk page*, where other editors can engage directly with the respective user on issues pertaining to their general behavior. This is where the social functions of the community surface: editors discuss inappropriate behavior and norm violations, ask for support, offer advice or encourage each other. In this work we use the complete conversational history between English Wikipedia editors on both article and user talk pages. With over 90 million conversations between 4 million users on 24 million talk pages, this is one of the largest collections of public conversations [20].

Like many online communities, Wikipedia has a moderation system aimed at imposing community rules. What makes Wikipedia particularly suitable for our proposed investigation is that its rules apply uniformly to the entire community and moderation is entirely transparent to the public [13]. This is unlike other large communities, such as Reddit, where rules can vary drastically between sub-communities and where aspects of the moderation remain private [4].

Blocking mechanism. Wikipedia moderators (formally referred to as administrators, though we will continue to use the term "moderator" as we are focused on their role in maintaining community norms) are elected from among community members through public elections [1, 30]. Among other privileges, moderators have the ability to block users from making any edits or comments. They can either block a user indefinitely, in cases of accounts that are clearly used for bad-faith purposes, or temporarily if they see the user as a potentially valuable member of the community that has momentarily gone awry. In fact, the stated purpose of temporary blocks is "to deter any future possible repetitions of inappropriate conduct", thus keeping the door open for reintegration after the expirations of the blocks.[1] Our focus in this work is on temporary blocks (henceforth simply called blocks), and their effectiveness in reforming blocked users.

[1] https://en.wikipedia.org/wiki/Wikipedia:Blocking_policy

Total number of blocks	104,245
Number of blocked users	72,332
Number of blocking moderators	1,706
Users with block reason in disruption subset	21,043
Users with first block in disruption subset	18,909
Users remaining after minimum activity filters	6,026

Table 1: Statistics of the blocked users dataset.

When temporarily blocking an individual, moderators are required to notify the user by posting a message on their user talk page. This notification includes the reason for the block and its duration. The duration of the block is at the discretion of the moderator, and can vary greatly—the standard deviation of block durations is 194 days. However, this high variance is largely the result of a small set of extreme outliers, and in practice most blocks are very brief—the median duration is 1 day.

For the duration of the block, the targeted user may not contribute to Wikipedia articles or make any comments on talk pages, with the sole exception of their own user talk page, where they are allowed to discuss the block.

Block reason. When moderators block a user, they must cite a reason that reflects one of the community rules. Wikipedia groups these reasons under two broad categories: *protection* and *disruption*. The former concerns behaviors that may put Wikipedia editors or Wikipedia itself at risk, such as making legal threats, releasing personal information or violating copyright law. The latter concerns the health of the community—or, as Wikipedia phrases it, maintaining a "civil, collegial atmosphere". We identify a subset of four such disruption block types relating to breaches of community norms (rather than to legal concerns specific to Wikipedia): personal attacks and incivility, harassment, edit warring, and disruptive editing. These reflect norms that can be broken even by established and valuable members of the community, unlike spam or vandalism which most often come from illegitimate, disruption-only accounts.

Blocked users dataset. We extract information about the nature of the blocks from the *block log*, a centralized and public record of all blocks that have ever happened on Wikipedia containing over 136,000 actions (including both blocks and manual block modifications) at time of collection. We automatically extract from this log the block's duration,[2] its type, its date,[3] and the involved users (blocking moderator and blocked individual). We seek to focus our analysis on actual members of the community as opposed to disruption-only accounts, because such accounts are made in bad faith and hence have no reason to reform once caught [15]. To this end, we discard accounts whose first block was not one of the four disruption block types previously described, and impose a minimum activity before the first block: at least one month and eight comments. Finally, we join the resulting block meta-data with the conversational record. Details of the resulting dataset are summarized in Table 1. We make this processed dataset publicly available[4] to encourage the study of moderation in a community where all activity is by design fully transparent and public.[5]

3 TRAJECTORIES AFTER THE BLOCK

After their block expires, a user can take several distinct trajectories: they can reform and adhere to the rules, but they can also recidivate, or straight-out abandon the community. Here we formally define these (un)desired outcomes and reveal their relative prevalence.

Throughout, we focus on the very *first* block a user receives, thus discarding any potential lingering effects of previous blocks and putting all users in our dataset on equal ground at the time of investigation. We consider a maximum future horizon of 6 months, and thus are constrained to discard users whose initial block takes place less than 6 months before the end of our dataset (June 2018) since for these we cannot know what the future holds. This is a common solution for limited horizon in longitudinal studies [10].

Departure. Wikipedia and other collaborative communities have traditionally struggled to retain their members [17]. Thus, the risk of alienating users needs to be taken into consideration when evaluating the efficacy of moderation. This is particularly true for temporary blocks, which by their very nature aim at re-integrating the targeted user into the community rather than discouraging them to contribute again (for which a moderator would use a permanent block).

We consider a user to *depart* from the community at the time of their last comment on community talk pages; we use this instead of their last edit on an article as the indicator of quitting because we are specifically interested in their engagement with the community. We impose the same 6 month maximum future horizon as we did when considering recidivism. Out of all 6,026 blocked users selected for this study (Section 2), 30% depart in the 6 months following their first block, and 10% depart *during* the block itself.

To illustrate the connection between departure rates and the block itself, Figure 1 compares the probability of a user

[2]We merge consecutive blocks and account for post-hoc reduction in block duration.

[3]In our analysis we discard blocks happening in the first five years of the community, allowing for Wikipedia community norms to stabilize [13, 17].

[4]As part of ConvoKit (convokit.cornell.edu)

[5]All editors are expressly informed, during all edits, that "Work submitted to Wikipedia can be edited, used, and redistributed—by anyone", where "work" is defined as content on any Wikipedia page, talk pages included. See https://en.wikipedia.org/wiki/Wikipedia:Ownership_of_content.

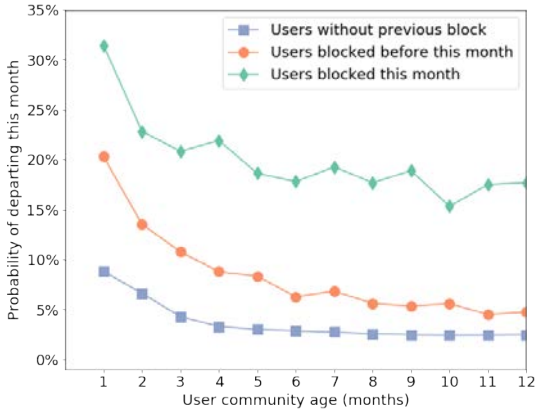

Figure 1: Probability of a user quitting at a given community age (in months), given that they were never blocked before (blue squares), blocked anytime prior to that month (orange circles) or blocked in that same month (green diamonds). The trends continue beyond the 12 months illustrated here.

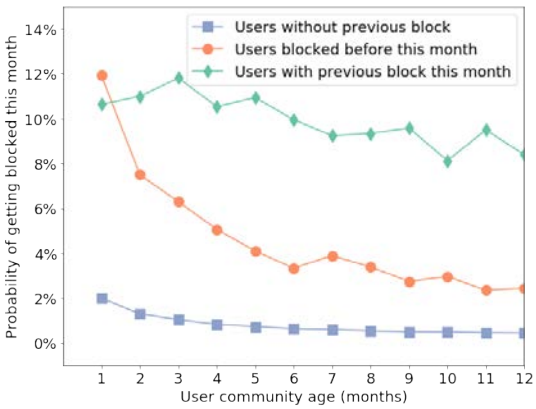

Figure 2: Probability of a user getting blocked at a given community age (in months), given that they were never blocked before (blue squares), previously blocked anytime prior to that month (orange circles) or previously blocked in that same month (green diamonds).

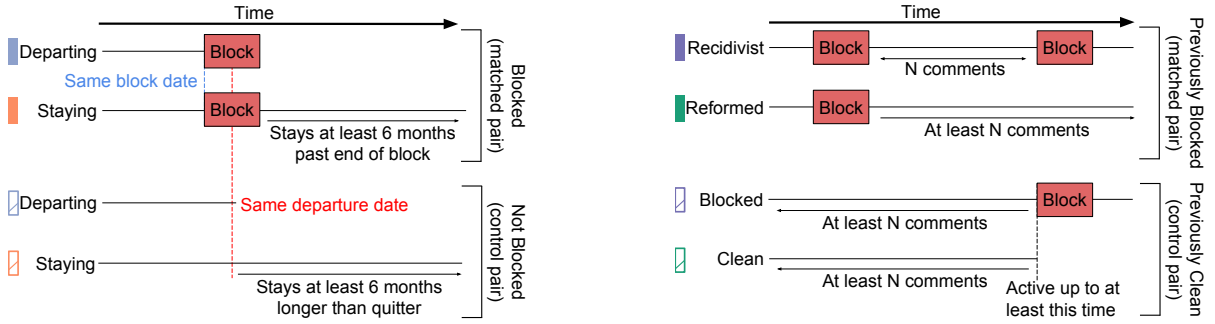
abandoning the community at different stages in their community life (i.e., time since their first activity), conditioning on whether (and when) they were blocked before. We first note that departure is not independent from blocking events (compare blue squares with orange circles): users are much more likely to depart if they were blocked before, especially in the first months of their life in the community. But even controlling for the fact that a user was previously blocked (compare orange circles with green diamonds), they are much more likely to depart during the month of their block. This strong recency effect shows that blocking and departure are events that are also temporally connected.

Recidivism. A previously-blocked user *recidivates* if they are blocked again for any other breach of community rules, and *reforms* if they never get blocked again. There is a wide variance in how long it takes recidivst users to re-offend. While some get blocked again within a week, others remain "clean" for years before re-offending. Only 47.7% of blocked users in our dataset have no (blocked) offenses after their first block. Among the users who do have a second known offense, the median time to reoffense is 32 days.



To study recidivism at different temporal scales, we consider two categories of users: *long-term recidivists* are those who re-offend within the next 6 months after their initial block, and *short-term recidivists* are the subset who re-offend within the first week after their first offense. Out of all blocked users selected for this study, 38.5% breach the norms again in the 6 months following their initial block; and 15.4% recidivate in just one week after the initial block.

To put recidivism rates into perspective and differentiate the phenomenon from general rule violations, Figure 2 compares the probability of a user getting (re)blocked at different stages in their community life, conditioned on whether (and when) they were already blocked or not. Perhaps unsurprisingly, individual block events are not independent: the probability of being blocked is much higher for individuals who were already blocked before than for those that were not, even after controlling for community age (compare blue squares with orange circles). We also observe a dramatic decrease in probability of recidivism during the first year of a user's community age. Importantly, this effect is specific to recidivism, rather than just reflecting a tendency to get blocked in general—the probability of getting blocked for the first time (blue squares) stays relatively flat over time. Finally, as in the case of departure, we also observe a recency effect (compare green diamonds with orange circles), showing that consecutive blocks are temporally related events.

Having established a relation between blocks and departure or recidivism, we now move towards a more thorough analysis of the factors that are in play. We will explore two broad classes of factors inspired by theories of deterrence and defiance [46]. The first class of factors concerns the characteristics of the perpetrator (Section 4): some types of individuals might simply be more likely to (re)offend or depart. The second class of factors concerns the actual context of the block: its actual severity and how the perpetrator perceives it (Section 5).

4 USER CHARACTERISTICS

We have already seen that community age is an important factor mediating the likelihood of departure and (re)offense: overall, newcomers are more likely than experienced users to follow one of these undesired paths after being temporarily blocked. Here we explore how these outcomes relate to

(a) Departure matching and control

(b) Recidivism matching and control

Figure 3: We matched comparable blocked users with opposite outcomes: (a) departs or not during the first block; (b) offends or not after the first block. For each matched pair, we also select a control pair of users (with the same opposite outcomes) who were not blocked.

other user characteristics, focusing on factors indicating a member's level and type of engagement in the community.

We consider two broad types of features: how active the user is and how broad their social connections are in the community. To foreshadow our findings, we find that individuals that are more active in the community are overall more immune to blocks: they are both less likely to depart during a block, but also less likely to reform. However, the way an individual spreads their activity is also informative: if their activity is directed at a broader set of users they are more likely to either depart or reform.

Activity level. We consider both the number of comments a user contributes to other users' talkpages (contributed activity), as well as the number of comments they receive from other users on their own talkpage (received activity) before the block. To disentangle a user's activity from their community age, we normalize these measures by the number of days between the user's first recorded activity in the community and the time of the block.

Activity spread. An active individual can either engage a broad audience, or instead concentrate on a narrow set of individuals. We capture the *received activity spread* of an individual by counting the number of unique users who wrote comments on their talk page before the block, then normalizing it by the total number of such comments. A higher value of this ratio indicates brief interactions with a relatively large number of peers, while conversely, a smaller ratio indicates extended interactions with a relatively small group of peers. Analogously, we define *contributed activity spread* as the ratio between the number of other users' talk pages to which an individual contributed comments and the number of such comments they contributed.

Departure. To make meaningful comparisons between users who depart *during* their first block and those who don't, hence eliminating trivial confounds, we use a matching technique inspired by causal inference methods [43]. As illustrated in Figure 3a (top), we pair each departing user with a user whose first block took place on the same date (within 1% tolerance) but who stayed active for at least 6 more months (our maximum future horizon). This procedure results in 1,156 paired departing and staying users.

As a secondary question, we also want to understand whether any differences we observe are specific to blocked individuals, or generally characterize community departure. To this end, for each matched pair of blocked departing-staying individuals, we construct a control pair of departing-staying individuals that were not blocked. This control pair consists of a non-blocked departing individual with the same departure date (within tolerance) as the blocked departing individual, and a staying individual who remained active at least 6 months past that date. This process is also illustrated in Figure 3a (bottom).

Figure 4 summarizes how our engagement factors relate to departure during the block (solid bars). Departed users receive and contribute less daily activity in their life before the block than non-departed users. The activity they do receive comes from a broader set of users, potentially signaling they are not integrated into a tight social group.[6] This is however not true for the spread of the activity they contribute, which is similar between departing and staying users.

We note that these relations between activity and departure are specific to blocked individuals (compare hashed bars in Figure 4). Departing users in our matched pairs do not have significantly different activity levels or activity spreads than their staying counterparts. This finding reinforces the

[6]These trends continue to hold, and remain significant, if we consider only the top half of active users in our comparison, thus separating them from the previously described trends in raw activity counts.

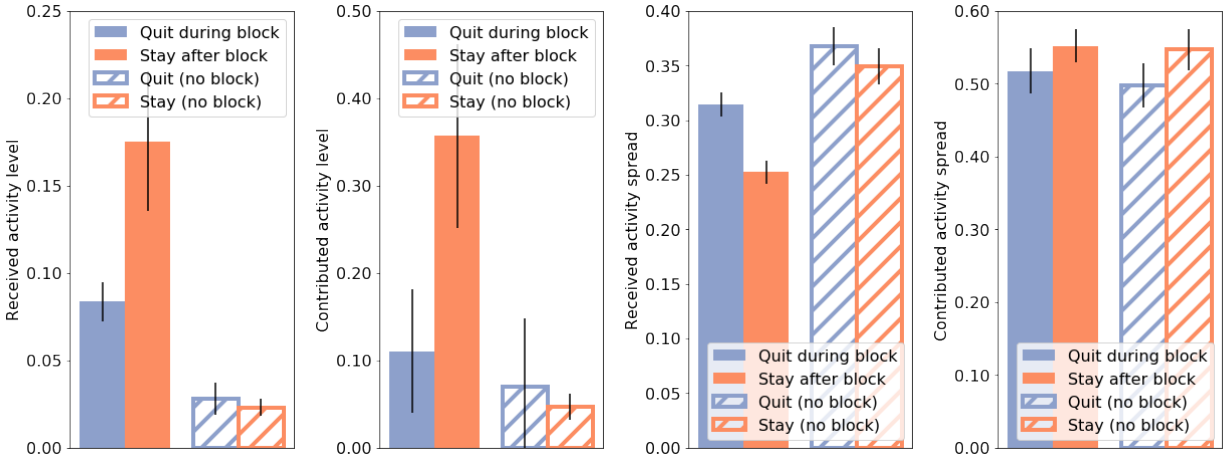


Figure 4: Difference between the community engagement patterns of departing and staying users. From left to right: receiving activity level, contributed activity level, receiving activity spread, contributed activity spread. Solid bars compare blocked departing and staying users; hashed bars compare non-blocked departing and staying users. Throughout errorbars indicate 95% binomial proportion confidence intervals.

notion that departure during a block is a distinct phenomenon from departure in general.

Recidivism. Having shown that activity level and activity spread are indicative of departure, we now explore whether they might also signal recidivism. As before, we use matching to eliminate trivial confounds. In this setting, the primary concern is that higher activity might trivially result in higher likelihood of recidivism merely because users with more activity tend to write more comments, which means they have more things they could be blocked for, probabilistically speaking. We therefore match each recidivist user by counting the number of actions (new comments, comment edits, or comment deletions) they performed between consecutive blocks, and choosing a reformed user who made at least that many actions in their lifetime after their first (and only) block; this is visualized in Figure 3b (top). This ensures that both users had at least as many opportunities to be blocked, so any differences that remain must result from the quality, not quantity, of their actions. This pairing results in 1,332 paired short-term recidivists and reformed users and 3,278 paired long-term recidivists and reformed users.

As in the departure analysis, we also find a set of control pairs to help us understand whether any differences we observe are specific to recidivism, or apply generally to norm violations. Each control pair contains a first-time offender and a user who is completely clean up to the time of the first-time offender's block. Selection is done on number of actions, just like the pairing of the experimental group. This procedure is visualized in Figure 3b (bottom).

Figure 5 summarizes how our engagement factors relate to recidivism and to blocking in general. For space considerations, we only present results for long-term recidivism; short term recidivism shows the same trends and statistical significance levels. Recidivist users receive and contribute more daily comments, but the received activity comes from a narrower set of users (solid bars). Taken together, these indicate that recidivist users' interaction patterns have more depth than breadth; they engage with a smaller set of users but each engagement is more prolonged. This may signal the presence of sustained back-and-forth with a restricted circle of editors. These engagement patterns echo general blocking patterns (hashed bars): unsurprisingly, the type of individuals that are likely to get blocked in general are also more likely to recidivate (although this was not the case for departure). In the following sections we will complement this general observation by exploring factors that relate to the context of the first block, and thus are specific to recidivism.

Predicting future trajectory. To estimate the relative predictive power of these user characteristics factors and compare them with natural baselines we formulate three new *future* prediction tasks: one for departure, one for long-term recidivism, and one for short-term recidivism. Each task is run on the respective paired sets of users previously described, resulting in a balanced prediction task.

For transparency, we train a simple SVM classifier with our activity features as input, employing both the normalized and unnormalized versions of the activity level features. In each prediction task, hyperparameters for the SVM are selected through iteration over different combinations on a held-out

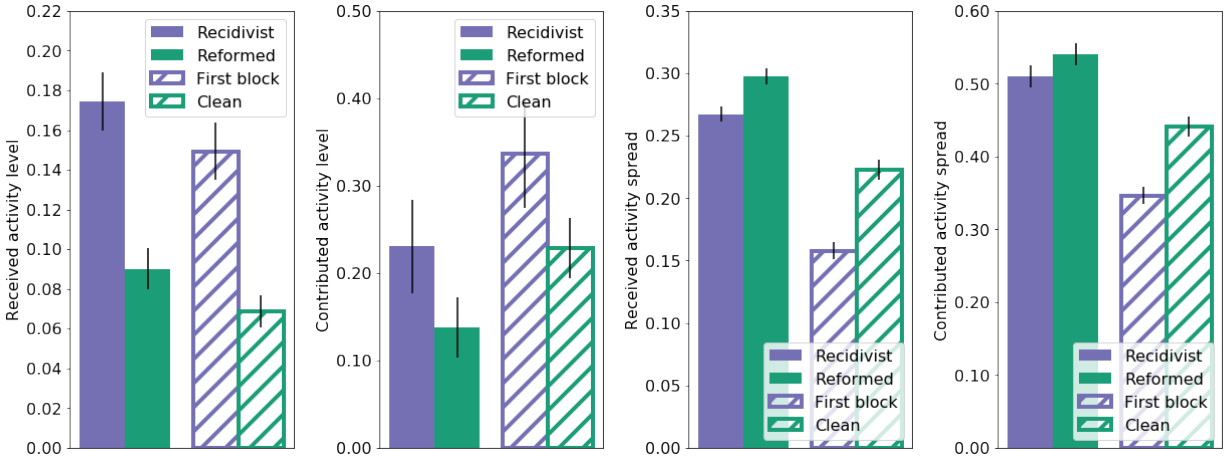

Figure 5: Difference between the community engagement patterns of recidivist and reformed users (solid bars). From left to right: receiving activity level, contributed activity level, receiving activity spread, contributed activity spread. For reference, hashed bars compare users that get blocked for the first time with those that never get blocked.

Feature set	Departure	Long-term recidivism	Short-term recidivism
Baseline: reason	59.0%	52.9%	51.9%
Baseline: duration	56.7%	50.0%	43.8%
Community age	58.6%	58.7%*	56.3%*
Engagement patterns	61.4%*	59.0%*	59.1%*
Engagement + Age	66.2%*	60.6%*	58.8%*

Table 2: Accuracies on three post-block trajectory prediction tasks (random baseline is 50%). *s indicate results that are significantly outperforming the best performing baseline for the respective task ($p < 0.05$).

development set, and accuracy is reported using leave-one-out cross-validation on the rest of the data.

We consider as features the user characteristics introduced earlier, calculated based only on information available *before* the block: community age and engagement patterns (activity level and spread). We compare their predictive power to two natural baselines that indicate the type and duration of the initial block. These account for the fact that certain kinds of offenses might be inherently more or less likely to lead to departure or recidivism.

Table 2 summarizes the results of the prediction experiments. We find that both community age and engagement patterns outperform baselines in all three prediction settings, showing they encode additional information about the future trajectory of the individual. Furthermore, they also combine to outperform each individual feature, showing that they capture different aspects of the phenomenon.

Overall, these results demonstrate that forecasting the future post-block trajectory of a user is at least a feasible and well-formed task. While our main goal in formulating these prediction tasks is to better understand the relative importance of different factors, we advise against using the resulting classifiers for any applications of algorithmically-assisted moderation. Given the sensitive nature of such applications, a public-facing model would need to be thoroughly tuned to ensure fair outcomes and exhaustively studied to understand if any biases in the data are being encoded [7, 12, 54]. Understanding the sources of such potential biases in the data, and devising mechanisms to eliminate them, constitutes an important avenue for future work.

5 BLOCK CONTEXT

Having established the relation between general user characteristics and post-block trajectories, we now seek to understand how the nature and context of the block itself mediates recidivism. Deterrence and defiance theories contrast two possible factors that relate to future compliance [46]. The traditional perspective is that the more severe the punishment is, the more likely it is to deter the perpetrator from misbehaving in the future [16, 27]. More recent work, however, suggests that a factor that is at least as important is whether the perpetrator perceives the punishment to be fair and justified [40, 52]: intuitively, individuals are unlikely to follow rules that they perceive to be imposed by an unfair and antagonistic society. We explore both these perspectives in the context of online recidivism, and bring supporting evidence for the perceived fairness perspective.

Block severity

The severity of temporary blocks corresponds naturally to their duration. For the purposes of this analysis, we only consider blocks that never had their duration changed. Since block durations are highly concentrated on the shorter end of the scale, with extreme outliers being sparsely spread in a long tail, we binarize durations as short (1 day or less) and long (more than 1 day), where the cutoff of 1 day was chosen because it is the median duration. Perhaps surprisingly, we find no statistically significant difference (chi-squared test) between these two classes in terms of recidivism rates, neither for long-term blocks, nor for short-term blocks.

While block duration does not appear to impact future compliance, it does correlate with departure rates: 30% of the users receiving long blocks quit within one month after the start of the block, compared with 24% for short blocks (significant at $p < 0.001$).[7] This result holds even when controlling for the age and activity of the blocked individual.

Perceived fairness

Considering that in our online setting the actual severity of a block does not appear to impact its effectiveness, we can investigate how the way a user *perceives* their block relates to their future compliance with community rules.[8]

The main challenge in addressing questions related to user perception is capturing such a subjective notion at a sufficiently large scale. Unlike offline studies that rely on interviews with punished individuals to assess their perception of the fairness of the punishment [40], our observational data does not provide direct access to such variables. We can, however, leverage a specific Wikipedia mechanism in order to estimate them for a subset of users: block appeals.

A block appeal is a formal avenue through which a blocked user can contest the block, admit their wrongdoing, or ask for clemency. In response to an appeal, any moderator—not necessarily the one responsible for the original block—may choose to reduce the duration of the block. This happens rather rarely, with only 15% of blocked users having their block duration reduced. As described on Wikipedia's official policy page on block appeals,[9] there are two reasons a moderator may choose to grant an appeal. The most common reason is clemency: if the blocked user takes responsibility for their offense, acknowledges that they were in the wrong, and convincingly argues that they will not offend again, the reviewing moderator may grant a shortened block. The other reason is if the moderator judges the original block to be in error, e.g., due to a case of mistaken identity. However, according to the cited Wikipedia policy, the latter scenario is "extremely rare", due in part to the public nature of the moderation in Wikipedia and to the strict procedure which blocking moderators need to undergo in order to block somebody, which involves identifying a specific reason.

Linguistic signals. Block appeals provide two separate opportunities to (admittedly imperfectly) estimate how users perceive the block. The first one is through the language the blocked individual uses in their appeals. They can signal whether they perceived the block as being justifiable and acknowledge the wrongdoing or, conversely, whether they disagree with the justification for the block and contest it.

To capture such signals we consider three types of linguistic cues (Table 3) that are intuitively related to the user's perception of the fairness of the block. Users that apologize signal that they acknowledge their wrongdoing; we expect such users to perceive the block as being fair and thus to be less likely to recidivate. Conversely, users that openly and directly challenge their block, either by aggressively questioning the administrators or by explicitly claiming unjust treatment, signal that they perceive the block as unfair and thus we would expect that they are more likely to recidivate.

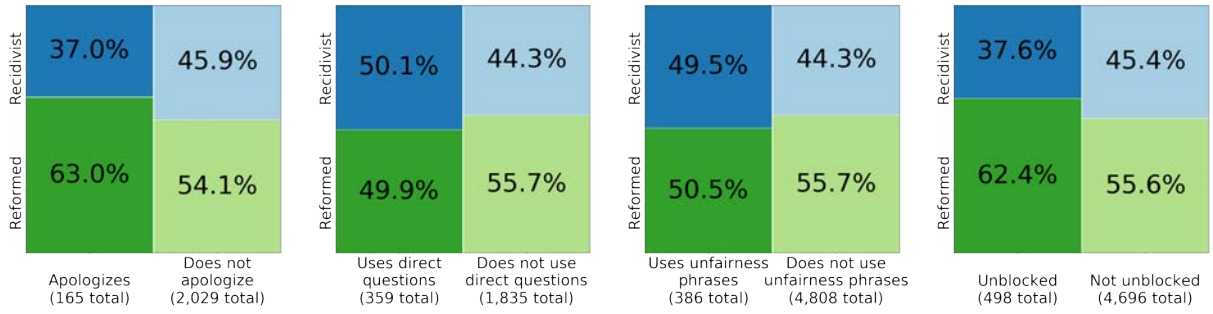
To capture apologizing and direct questioning we use off the shelf tools[10] that perform regular expression matching on dependency trees [9]. To capture explicit claims of unfairness we experimented with hand-building a small lexicon by examining a sample of examples from the data:[11] "unjust", "illegitimate", "illegal", "unfair", "not fair", "accuse" (and different forms), "wrongly", "falsely", "injustice", "unfounded", "allege" (and different forms), and "unwarranted".

We extract these linguistic cues from the messages recidivist and reformed users direct at moderators during their block, capturing their use in both formal and informal appeals. Figure 6 (a-c) compares the relative ratios of recidivist and reformed users among those that used a given type of fairness cue or not. Compared to a baseline ratio of 45% recidivism and 55% reform that consistently holds in all three cases, apologizing corresponds to a reduction in the rate of recidivism (chi-squared test $p < 0.05$), while direct questioning and explicitly calling for unfairness correspond to a moderate increase in the rate of recidivism ($p < 0.05$ and $p = 0.053$, respectively).

Granted appeals. A second opportunity to estimate the user's perception of a block is by analyzing *granted* appeals. When an appeal is granted, the duration of the block is shortened. This positive response from the moderators arguably signals to the user that the system is fair and that their views

[7] Rather than analyzing departure during of the block as in the previous analysis, we are constrained here to consider a fixed time window in order to account for the time a user has to depart.

[8] While for brevity we only discuss long-term recidivism, the same effects and statistically significant levels hold for short-term recidivism.



[9] https://en.wikipedia.org/wiki/Wikipedia:Appealing_a_block

[10] From ConvoKit: convokit.cornell.edu

[11] We also performed a Fightin' Words analysis [34] to identify salient cues not present in the sample data we examined.

Feature	Examples
Apologizing	It is true that the tag-war got out of hand. I **apologize** if it caused any disruption. I am deeply **sorry** for not understanding the whole situation, and ask for your forgiveness. Given the recent history on the article, **forgive me** if claims of lawyers are met with skepticism.
Direct questioning	**Why** was I blocked, when I had not the right, but rather the duty to remove BLP inaccuracies? **So what** policy, precisely have I violated? **How** is it this person won't leave me alone and I repeatedly ask to be left alone and I get blocked?
Unfairness lexicon	this block is **unjustified**. none of the changes were in violation of the 3rr rule. i have alerted another administrator about your blatent and **unwarranted** abuse of power. iv been **wrongly accused** of making up information

Table 3: Example blocked user messages exhibiting linguistic indicators of (un)fairness perception. Bolded words indicate matched patterns.

(a) Apologizing **(b) Direct questioning** **(c) Unfairness lexicon** **(d) Unblocks**

Figure 6: Normalized contingency tables showing the relative ratios of recidivist and reformed users conditioned on the presence or absence of fairness perception indicators. Table cell heights are scaled to the frequencies they represent in order to facilitate comparison between the two conditions (compare left to right in each figure).

are taken seriously. Paternoster et al. ([40], p. 169) shows that such perceptions about the enforcing authorities decrease the rate of recidivism offline, thus we hypothesize that this could hold true in online settings as well. Figure 6d shows that this principle is indeed echoed on Wikipedia; users who are unblocked are significantly more likely to reform ($p < 0.001$). This effect is even more striking when considering that, as discussed above, the duration of the block itself has no noticeable effect on recidivism and that granted appeals often shorten the duration of the block by less than one day (the median reduction is 22 hours).

Alternative explanations. One explanation that does not relate to perceived fairness could be that these appeal-based effects are simply differentiating between individuals who did not deserve to be blocked in the first place (and thus did not commit an offense and are unlikely to offend at all) and those that did commit an offense. While our observational approach precludes ruling out this alternative explanation completely, we argue that it is at least unlikely. First, as noted earlier, it is extremely rare for users to be blocked in error on Wikipedia. Second, some of the linguistic effects go in the opposite direction of what such an explanation would predict: for example, apologizing generally comes with an admittance of guilt, and under the alternative explanation we would not expect such guilty individuals to have a reduced rate of recidivism. In fact, we find that individuals who apologize are significantly ($p < 0.001$, by chi-squared test) more likely to get unblocked than ones who do not, a pattern that is consistent with what we would expect if unblocks tend to be granted because of clemency (acknowledgment of wrongdoing being one of the factors that moderators look for when deciding whether to grant an appeal).

In an attempt to further discard explanations based on user characteristics we also repeat these experiments after controlling for age and activity (i.e., pairing recidivist and reformed users based on these variables before conducting the analysis) and found similar trends, with exception of the unfairness lexicon (which had a moderate effect to start with and was likely sensitive to the sample size reduction).

We argue that these observations, while not of causal nature, at least motivate further investigations into the role of perceived fairness in online moderation.

6 FURTHER RELATED WORK

Antisocial behavior. Online moderation largely addresses the problem of antisocial behavior, which occurs in the form of harassment [50], cyberbullying [47], and general aggression [23]. Approaches to moderating such content include decentralized, community-driven methods [14], as well as top-down methods relying on designated community managers or moderators [33]. Prior research in this area ranges from understanding the actors involved in antisocial behavior [6, 28, 36, 42, 51] to analyzing its effects [39] to tools for identifying such behavior [38, 53], and even forecasting future instances [31, 55]. While inspired by this line of work, our present study extends it by focusing on what happens *after* a user is blocked for violating community rules.

Effects of moderation. Prior work has examined the effects of different kinds of moderation on online platforms. Community-driven moderation can affect overall user participation [8, 35] and comment quality [5] in conversations. Centralized moderation can also have effects on conversation, mainly through the moderator's role as an authority figure [44]. These existing studies of moderation effects have focused on the short term, largely operating at the level of individual conversations. By contrast, in this work we intend to study the long term, *user* level effects of moderation: what happens to a user in the days, weeks, and months after a moderator takes action against them?

Norms and engagement. A major factor governing engagement in online communities is a sense of belonging [37], which in many communities engenders the emergence of community-specific norms, such as specific patterns of language [3, 10, 19, 56]. Wikipedia is no exception: it relies on group dynamics to promote editing productivity [26] and quality [41], as well as participation in governance [1, 30].

Fairness in moderation. Moderation is fundamentally a difficult process, sparking discussions about design and best practices [2, 24], and moral questions regarding bias [45] and free speech [21]. One interesting avenue of research in this broad space deals with understanding the *perception* of fairness. Prior work has looked at this from the perspective of moderators, showing that moderators on the technology news forum Slashdot frequently judge each others' actions as unfair, but that this rarely leads to reversal of moderation decisions [29]. We instead explore the perspective of users, exploring ways to determine when a user regards a moderation decision as unfair.

7 DISCUSSION

We introduced a computational framework for characterizing the possible trajectory a user can take after a temporary block: departure, recidivism, or redemption. Taking inspiration from theories of offline punishment, our investigation focused on two types of factors that are tied to these outcomes: those related to a user's involvement in the community, and those related to their perception of the moderation action affecting them.[12] Overall, our work builds towards a more nuanced approach to moderation that more broadly accounts for the tradeoffs between possible outcomes and that considers how the affected individuals might perceive the moderators and their actions.

Our study has several limitations that naturally translate into opportunities for future work. First, while we have focused on the blocked users, it would be valuable to also understand the normative effect of blocks on other users that are witnessing them. Additionally, our study is limited to revealing correlational effects, and different methodologies (involving surveys or experimentation) would be necessary to study the underlying causal mechanism.

In terms of methodology, there are several ways in which the definitions of the post-block trajectories themselves could be refined. While we measure departure as a binary value, in reality community participation occurs on a variable scale and it is possible that blocked users do not depart, but drastically reduce their participation (or conversely, increase it). Similarly, defining recidivism in terms of a second block is an imperfect approach because it is possible that some users reoffend without getting blocked. This is especially true in the case of personal attacks, where each individual's threshold of acceptable behavior may vary. One possible way of addressing this would be to combine our approach with prior work in automated detection of toxic language [11, 42, 53].

We also note possible ways in which the factors we explore could be expanded upon. The activity features we introduced in Section 4 effectively serve as crude approximations of network effects. Future work could apply a more formal network analysis to uncover more powerful representations of activity. Similarly, our linguistic measures of fairness are currently limited. One immediate way of expanding them would be to build a more comprehensive lexicon of unfairness, perhaps using a semi-automated approach based on word co-occurrences with the currently existing lexicon items. A more sophisticated approach might involve engineering dependency-based features similar those used to extract apologies and direct questioning. Understanding whether a user feels they are treated unfairly constitutes an interesting research question on its own.

ABSTRACT

We consider the problem of regulating products with negative externalities to a third party that is neither the buyer nor the seller, but where both the buyer and seller can take steps to mitigate the externality. The motivating example to have in mind is the sale of Internet-of-Things (IoT) devices, many of which have historically been compromised for DDoS attacks that disrupted Internet-wide services such as Twitter [5, 26]. Neither the buyer (i.e., consumers) nor seller (i.e., IoT manufacturers) was known to suffer from the attack, but both have the power to expend effort to secure their devices. We consider a regulator who regulates payments (via fines if the device is compromised, or market prices directly), or the product directly via mandatory security requirements.

Both regulations come at a cost—implementing security requirements increases production costs, and the existence of fines decreases consumers' values—thereby reducing the seller's profits. The focus of this paper is to understand the *efficiency* of various regulatory policies. That is, policy A is more efficient than policy B if A more successfully minimizes negatives externalities, while both A and B reduce seller's profits equally.

We develop a simple model to capture the impact of regulatory policies on a buyer's behavior. In this model, we show that for *homogeneous* markets—where the buyer's ability to follow security practices is always high or always low—the optimal (externality-minimizing for a given profit constraint) regulatory policy need regulate *only* payments *or* production. In arbitrary markets, by contrast, we show that while the optimal policy may require regulating both aspects, there is always an approximately optimal policy which regulates just one.

1 INTRODUCTION

The Tragedy of the Commons is a well-documented phenomenon where agents act in their own personal interests, but their collective action brings detriments to the common good [13]. One motivating example that we will keep referencing in the paper is the sale of Internet-of-Things (IoT) devices, such as Internet-connected cameras, light bulbs, and refrigerators. Recent years have seen a proliferation of these "smart-home" devices, many of which are known to contain security vulnerabilities that have been exploited to launch high-profile attacks and disrupt Internet-wide services such as Twitter and Reddit [5, 26]. Both the owners and manufacturers of IoT devices have the ability to protect the common good (i.e., Internet-wide service for all users) from being attacked by securing their devices, but have little incentive to do so. For the manufacturers, implementing security features, such as using encryption or having no default passwords, introduces extra engineering cost [2]. Similarly, security practices, such as regularly updating the firmware or using complex and difficult-to-remember passwords, can be a costly endeavor for the consumers [9, 27]. The results of their actions cause a negative *externality*, where Internet service is disrupted for other users.

One way to reduce the negative externality is regulation. In the context of IoT sales, a regulator can, for instance, set minimum security standards for the manufacturers or impose fines on owners of hacked IoT devices that engage in attacks. Fines could come in a few forms: direct levies on the consumer, or indirect monetary incentives. For instance, ISPs could offer discounts to users whose networks have not displayed any signs of malicious activities. One might argue that such penalty-based policies could be too futuristic, but it is worth noting that similar practices are being adopted in other industries to mitigate negative externalities [3]. One example

is the levying of fines on users (such as cars and factories) that cause pollution [11]. While there are a lot of practicalities that have to be kept in mind and the decision of when to implement consumer/user fines depends on various factors, this is certainly one of the various policy alternatives that is worthwhile to study. Such regulations, however, can potentially increase the cost of production, discourage consumers from purchasing IoT devices, and reduce the manufacturer's profit. Our focus is to compare the *efficiency* of various regulatory policies: for two policies which equally hurt the seller's profits, which one better mitigates externalities? We will also be interested in understanding the *optimal* policy: the minimum security standards for the manufactures and fines on owners that together best mitigate externalities subject to a minimum seller's profit.

We first develop a model that consists of a buyer (e.g., consumers interested in purchasing IoT devices) and a single product for sale (e.g., IoT device). The product may come with some (costly to increase) level of security, c, and a consumer purchasing the device may choose to spend additional effort h to further secure the device. We consider a mechanism for regulating the market through incentives, for example, by requiring that the product being sold implement security features that cost the seller c dollars, imposing a fine of y dollars on the buyer if the product is later compromised and used in attacks, or both. Which intervention is more appropriate depends on how efficient buyers are in securing the product. The goal of the regulator is to minimize the negative externalities subject to a cap on the negative impact on the seller's profits—the idea being that any policy which too negatively impacts the seller could be unimplementable due to industry backlash.

Understanding the effects of such regulations on the behavior of a *single* consumer is relatively straightforward. For example: as fines go up, consumers adjust (upwards) the optimal level of effort to expend, lowering their total value for the item. Yet, reasoning about how an entire market of consumers will respond to changes, and how these responses impact seller profits becomes more complex.

Our contributions are as follows: (i) We model the sale of a single item with negative externalities, using the sale of IoT devices as the motivating example (Section 3). (ii) We show in Sections 5 and 6 that when the population of consumers is *homogeneous* (i.e., all consumers are comparably effective at translating effort into security) that optimal policies need only to regulate *either* the product (via minimum security standards) *or* the payments (via fines). (iii) We provide an example of non-homogeneous markets where the optimal policy regulates both product and payments, but prove that in *all* markets, it is always approximately optimal to regulate only one (Sections 7.1 and 7.2). The technical sections additionally contain numerous examples witnessing the subtleties in reasoning about these problems, and that any assumptions made in our theorem statements are necessary.

2 RELATED WORK

Auction Design with Externalities. There is ample prior work studying auction design with network externalities in the following sense: if the item for sale is a phone, then one consumer's value for the phone increases when another consumer purchases a phone as well (which is a positive externality, because they can talk to more people). Similarly, the item could be advertising space, in which case one consumer's value for advertising space could decrease as other consumers receive space (which is a negative externality, as now each unit of space is less likely to grab attention) [4, 6, 12, 15, 17, 23]. Our work differs in that it is a third party, who is neither selling nor purchasing an item, who suffers the externalities.

Improving the Commons. There is also a large body of work studying the regulation of common goods (e.g., clean air, security, spectrum access) in the form of taxes or licenses. For example, a government agency can regulate the emission of pollution by auctioning licenses (perhaps towards minimizing the total social cost—regulation cost plus negative externalities) [10, 19, 22, 24, 28, 29]. Our work differs in that our regulations are constrained to guarantee minimum profit to the seller, rather than focusing exclusively on the social good.

Approximation in Auction Design. Owing to the inherent complexity of optimal auctions for most settings of interest, it is now commonplace in the Economics and Computation community to design simple but approximately auctions. Our work too follows this paradigm. We refer the reader to previous work [16] for an overview of this literature.

Mitigating Security Problems. Computer security is a particular example of the Tragedy of the Commons, where a software or hardware provider sells an insecure product, and where consumers may purchase the product without considering or taking actions to reduce the security risks. In addition, users might be unable to distinguish insecure products from insecure ones [1]. One mitigation strategy is to have the vendor release updates with security features, although this could be a costly process, as August observes [2]. However, identifying the existence of security vulnerabilities in the first place may take time for the vendors; for instance, a common software vulnerability known as buffer overflow remained in more than 800 open-source products for a median period of two years before the vendors fixed the problems, according to a study by Li [21].

An alternative to relying on a vendor to implement security features or releasing updates is to incentivize the users to follow security practices. Redmiles has found that users who adopt security practices, like using two-factor authentication, have a lower overall utility for themselves than if they adopt no security practices at all, as security practices may introduce inconvenience [27]. Even if users were notified of security problems that they were presumably unaware of, it took as long as two weeks for fewer than 40% of the users to take remedial actions, according to a study [20]. To introduce incentives, vendors could, for instance, offer discounts to users who adopt security behaviors [2]; regulators, on the other hand, could incur fines to users whose software or devices were hacked [18], which is a part of our model in this paper.

3 MODEL

In this section, we introduce our model, which consists of a population of rational buyers and a single item for sale. After introducing each of the concepts one-by-one, we include a table (Table 1) at the end of this section to remind the reader of each of the components.

Buyer properties. Buyers in our model have two parameters: $(v, k) \in \mathbb{R}^2_+$. v denotes the buyer's value for the item (i.e., how much value does the buyer derive from the IoT device in isolation, independent of fines, etc.). k denotes the buyer's *effectiveness* in translating effort into improved security. That is, a buyer with high k can spend little effort and greatly reduce the risk of being hacked (e.g. because they are well-versed in security measures). A buyer with low k requires significant effort for minimal security gains. We will often use $t := (v, k)$ to denote a buyer's *type*.

Security. A buyer who chooses to purchase an item will spend some level of effort $h \geq 0$ securing it, which causes disutility h to the buyer. The seller may also include some default security level c. If the buyer has effectiveness k, we then denote the combined effort by $\textsc{effort}(k, c, h) := c + kh$. The idea is that buyers with higher effectiveness are more effective at securing the device for the same disutility. Note that buyers with effectiveness $k > 1$ are more effective than the producer, and buyers with effectiveness $k < 1$ are less effective. Highly effective buyers should not necessarily be interpreted as "more skilled" than producers, but some security measures (e.g., password management) are simply more effective for consumers than producers to implement.

We model the probability that a device is compromised as a function $g(\cdot)$ of $\textsc{effort}$, with $g(x) := e^{-x}$. This modeling decision is clearly stylized, and meant as an approximation to practice which captures the following two important features: (a) as effort x approaches ∞, $g(x) \to 0$ (that is, it is possible to shrink the probability of being compromised arbitrarily small with sufficient effort), and (b) $g''(x) \geq 0$. That is, the initial units of effort are more effective (i.e. $g'(x)$ is larger in absolute value) than latter ones (when $g'(x)$ is smaller in absolute value). The idea is that consumers/producers will take the highest "bang-for-buck" steps first (e.g., setting a password). Note that our results do not qualitively change if, for instance, $g(x) := \lambda_1 e^{\lambda_2 x}$ for some constants $\lambda_1 \in (0, 1], \lambda_2 > 0$, but since the model is stylized anyway we set $\lambda_1 = \lambda_2 = 1$ for simplicity of notation.

Regulatory Policy. The regulator selects a policy/strategy $s = (y, c, p) \in \in \mathbb{R}^3_+$. Here, c denotes the security standards the producer must include which is equivalent to the production cost. y denotes the fine the consumer pays should their device be compromised. p denotes the price of the item. Conceptually, one should think of the regulator inducing the producer to set security standard c and price p via particular regulatory policies (e.g., requiring a minimum security level c', or mandating purchase of insurance). Mathematically, we will not belabor exactly how the regulator arrives at (y, c, p). We will also be interested in "simple" policies, which regulate either y or c.

Definition 3.1 (Simple Policy). For a policy $s = (y, c, p)$, we say s is a *fine policy* if $c = 0$, a *cost policy* if $y = 0$ and a *simple policy* if s is either a *fine policy* or a *cost policy*.

Utilities. Recall that so far our buyer has value v and efficiency k, and chooses to put in effort h. The regulator mandates security c (which is equivalent to the production cost) on the item (which has price p) and imposes fine y for compromised items. The probability that an item is compromised is $g(\textsc{effort}(k, c, h)) = e^{-c-kh}$. The buyer's utility is therefore: $v - p - h - y \cdot e^{-c-kh}$. Observe that the buyer is in control of h (but not v, p, y, c, k). So the buyer will optimize over $h \geq 0$ to minimize $h + y \cdot e^{-c-kh}$. By taking the derivative with respect to h, we get a closed form for the choice of effort $h^*(t, s)$ (recalling that we denote the buyer's type $t = (v, k)$ and the regulator's strategy $s = (y, c, p)$):

$$h^*(t, s) = \max\left(0, \frac{\ln(yk) - c}{k}\right) \tag{1}$$

We can now see that the probability that the buyer's item is compromised, conditioned on expending the optimally chosen effort is:

$$\textsc{risk}(t, s) := \min\left\{e^{-c}, \frac{1}{yk}\right\}. \tag{2}$$

We will additionally refer to the buyer's (security) *loss* as the expected fines they suffer plus the effort they spend. That is:

$$\ell(t, s) := y \cdot \textsc{risk}(t, s) + h^*(t, s) := \begin{cases} \frac{\ln(yk)-c+1}{k}, & yk \geq e^c \\ ye^{-c}, & yk < e^c \end{cases} \tag{3}$$

It then follows that the buyer's utility (value minus price minus expected fines) is:

$$u(t, s) := v - p - \ell(t, s) = \begin{cases} v - p - 1/k - \frac{\ln(yk)-c}{k}, & yk \geq e^c \\ v - p - ye^{-c}, & yk < e^c \end{cases} \tag{4}$$

Population of Buyers. We model the population of buyers as a distribution D over types t. Additionally, we make the now-typical assumption in the multi-dimensional mechanism design literature (e.g. [8, 14, and follow-up work]) that the parameters v and k are drawn independently, so that $D := D_v \times D_k$.[1] The seller's profits are then:

$$\textsc{Prof}_D(s) := (p - c) \cdot \Pr_{t \leftarrow D}[u(t, s) \geq 0] \tag{5}$$

Externalities. Finally, we define the externalities caused and the regulator's objective function. Each device sold has some probability of being compromised, and the regulator wishes to minimize the total fraction of compromised devices.[2] That is, we measure the externalities caused as:[3]

$$\textsc{Ext}_D(s) := \frac{\mathbb{E}_{t \leftarrow D}[\textsc{risk}(t, s) \cdot \mathbb{I}(u(t, s) \geq 0)]}{\Pr_{t \leftarrow D}[u(t, s) \geq 0]} \tag{6}$$

Optimization. The regulator's objective is to propose an $s = (y, c, p)$ that minimizes $\textsc{Ext}_D(s)$. Observe that, if left unconstrained, the regulator can simply propose $c \to \infty$, resulting in 0 externalities. Such a policy is completely unrealistic, as it would cause costs to approach ∞ and destroy the industry. Similarly, taking $y \to \infty$ would cause consumers to have negative utility even to get the item for free (again destroying the industry). We therefore impose a minimum profit constraint for a policy to be considered feasible. Indeed, this forces the regulator to trade off profits for externalities

[1] This assumption is even more justified in our setting than usual, as it is hard to imagine correlation between the *value* a consumer derives from using a smart refridgerator and their *ability* to secure IoT devices.

[2] It would be equally natural for the regulator to aim to minimize the total mass of compromised devices. Most of our results do not rely on optimizing one objective versus the other, but we stick with one in order to unify the presentation.

[3] Below, $\mathbb{I}(\cdot)$ denotes the indicator function, which takes value $\mathbb{I}(X) = 1$ whenever event X occurs, and 0 otherwise.

as effectively as possible. Therefore, our regulator is given some profit constraint R, and aims to find:

$$\arg\min_{s,\textsc{Prof}_D(s)\geq R}\{\textsc{Ext}_D(s)\}$$

We will only consider cases where there is *some* feasible s (that is, we will only consider R such that there exists a p with $R \leq \textsc{Prof}_D(0,0,p)$. If no such p exists, then the profit constraint exceeds the optimal achievable profit without regulation, and the problem is unsolvable).

Recap of model. Table 1 recaps the parameters of our model for future reference. Note also that many parameters (e.g. $\ell(\cdot,\cdot)$ are formally defined as a function of $t = (v,k)$ and $s = (y,c,p)$, but only depend on (e.g.) k, y, c. As such, it will often be clearer to overload notation and write $\ell(k,y,c)$, rather than defining a new $t = (v,k)$ with a meaningless parameter. Sometimes, though, it will be clearer to use the defined notation for a type t that was just defined. In the interest of clarity, we will overload notation for these variables, but it will be clear from context what they refer to.

Table 1: Model Variables

Variable	Text Definition	Formal Definition
$t = (v,k)$	(value, effectiveness)	N/A
$D := D_v \times D_k$	buyer population	N/A
$s = (y,c,p)$	(fine, security, price)	N/A
$h^*(t,s)$	buyer optimal effort	$\max\{0, \frac{\ln(yk)-c}{k}\}$,(1)
$\textsc{risk}(t,s)$	compromise prob.	$\min\{e^{-c}, \frac{1}{yk}\}$, (2)
$\ell(t,s)$	buyer security loss	Equation (3)
$u(t,s)$	buyer utility	$v - p - \ell(t,s)$, (4)
$\textsc{Prof}_D(s)$	seller profits	Equation (5)
$\textsc{Ext}_D(s)$	frac. compromised	Equation (6)

Final Thoughts on Model. We propose a stylized model to capture the following salient aspects of this market: (a) neither buyer nor seller suffer externalities when the item is compromised, (b) the regulator can regulate both the product (via c) and payments (via y, p), (c) there is a population of buyers, each with different value v and effectiveness k at translating effort into security, and (d) the regulator must effectively trade off externalities with profits by minimizing negative externalities, subject to a minimum profit constraint R. The goal of this model is not to capture every potentially relevant parameter, but to isolate the salient features above.

3.1 An Intuitive Example

In this section, we provide one example to help give intuition for the interaction between the fines y, default security c, and seller's profits $\textsc{Prof}_D(s)$. In particular, Figure 1 plots the maximum achievable $\textsc{Prof}_D(s)$ over all s with a fixed c (the x-axis) and y (the color of the plot). In all three examples, D_v is the uniform distribution on $[0,20]$, and k is drawn from either the uniform distribution on $[0,1]$, $[0,3]$, or $[2,3]$, respectively. Note that $k \geq 1$ is the threshold when a buyer is more efficient than the seller in mitigating externalities, so these examples cover two *homogeneous* populations, where all consumers are more (respectively, less) efficient than the producer, and one *heterogeneous* population, where some consumers are more efficient, and others are not.

For each possible (partial) regulation (y,c), the profit-maximizing choice of p is essentially a classic single-item problem (e.g. [25]), as the buyer's "modified value" v' is simply $v - \ell(t,s) - c$, and the seller's profit for setting price p is just $p \cdot \Pr_{t\leftarrow D}[v' \geq p]$. Therefore, for each partial regulation (y,c), we can construct the modified distribution and simply maximize $p \cdot \Pr_{t\leftarrow D}[v' \geq p]$ as above.

Observe in Figure 1, when $y = 0$, the seller gets greater profits with lower c. This should be intuitive, as neither the buyer nor seller suffer when the device is compromised. When $y > 0$, and $D_k = U([0,1])$, the seller's profits can increase with c. This should also be intuitive: now that the buyer suffers when the device is compromised, they prefer to buy a secure device.

On the other hand, when the market contains only efficient buyers ($k > 1$ always), the buyer prefers to provide her own security; any increased cost will always decrease the buyer's utility. Indeed, observe that $\frac{\partial \ell(t,s)}{\partial c}$ is either 0 (if $yk < e^c$) or $1 - 1/k$ (otherwise). If $k > 1$, then this is always positive, so higher c results in (weakly) higher loss for the consumer, and lower utility.

3.2 Preliminary Observations

We conclude with two observations which allow an easy comparison between the profits of certain policies. Intuitively, Observation 1 claims that any policy which makes *every single* consumer in the population have lower loss generates greater profits for the seller. We will make use of Observation 1 repeatedly throughout the technical sections to modify existing policies into ones which improve profits (ideally while also improving externalities, although that is not covered by Observation 1).

Observation 1. *Let $s = (y,c,p)$, $s' = (y',c',p')$ be such that $p' - c' = p - c \geq 0$ and for all $k \in$ support(D_k), $\ell(k,s) + c \leq \ell(k,s') + c'$. Then for all D_v, $\textsc{Prof}_{D_v\times D_k}(s) \geq \textsc{Prof}_{D_v\times D_k}(s')$.*

Proof. Observe that for both s and s', the seller's profit per sale is identical (as $p' - c' = p - c$). So we just wish to show that the probability of sale for s' is larger than that for s. Indeed, observe that for all t:

$$\begin{aligned} u(t,s) &= v - \ell(k,s) - p \\ &= v - (\ell(k,s) + c) + c - p \\ &\geq v - (\ell(k,s') + c') + c' - p' \\ &= v - \ell(k,s') - p' = u(t,s'). \end{aligned}$$

Therefore, any consumer (v,k) who chooses to purchase the item under policy s' will also choose to purchase under policy s, and therefore the probability of sale is at least as large for s as s'. □

Observation 2 below claims that the profit of any policy s is larger in populations D where every consumer is more effective than in D'.

Observation 2. *Let D_k* stochastically dominate *D'_k.*[4] *Then for all policies $s = (y,c,p)$ with $p \geq c$, and all D_v, $\textsc{Prof}_{D_v\times D_k}(s) \geq \textsc{Prof}_{D_v\times D'_k}(s)$.*

[4]That is, it is possible to couple draws (k,k') from (D_k, D'_k) so that $k \geq k'$ with probability 1. Equivalently: for all x, $\Pr[k \geq x, k \leftarrow D_k] \geq \Pr[k' \geq x, k' \leftarrow D'_k]$.

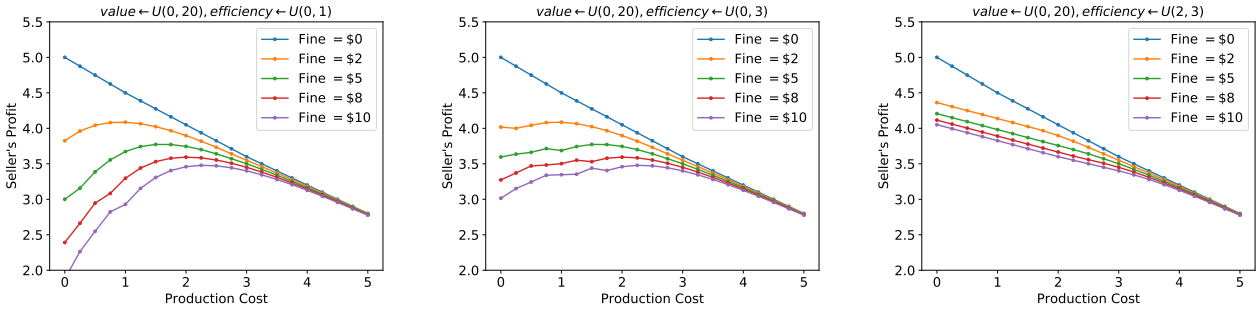

Figure 1: Seller's optimal profits under different distributions for efficiency, k. We plot the seller's profits on the vertical axis and the default security c on the horizontal axis. Each curve corresponds to different fines, y. Importantly, observe that when the fine is zero, the seller achieves greatest profits with lower default security. However, when the fine is non-zero, the seller may actually *increase* their profits with default security, but the benefits (to the seller) of default security decrease as the buyer population becomes more efficient.

Proof. As D_k stochastically dominates D'_k, it is possible to couple draws (t, t') from $(D_v \times D_k, D_v \times D'_k)$ such that $v = v'$ and $k \geq k'$. Observe simply that $u(t, s) \geq u(t', s)$ always. Therefore, $\Pr[u(t, s) \geq 0] \geq \Pr[u(t', s) \geq 0]$, and $\textsc{Prof}_{D_v \times D_k}(s) \geq \textsc{Prof}_{D \times D'_k}(s)$. □

Observe, however, that Observation 2, perhaps counterintuitively, does *not* hold if we replace profits with externalities. That is, for a fixed policy s, we might *increase* all consumers' effectiveness yet also *increase* the externalities caused. Intuitively, this might happen (for instance) in a fine policy which successfully only sells the item to extremely effective consumers who effectively secure their purchase. Ineffective consumers choose not to purchase the product to avoid fines. However, if these ineffective consumers are instead somewhat effective, they may now choose to purchase the item, thereby increasing externalities. Below is a concrete instantiation:

Example 3.2. Consider the population where D_v is a point-mass at e, and D_k takes on effectiveness 0 with probability $1/2$ and $x > 1$ with probability $1/2$. Consider the policy $s = (e, 0, e - 2.5)$. Then the $(e, 0)$ consumer chooses not to purchase: $\ell(e, 0, s) = e$, so their utility would be $e - e - (e - 2.5) < 0$. The (e, x) consumer chooses to purchase, as their loss is $\frac{2+\ln(x)}{x} < 2$ (as $x > 1$). So $\textsc{Ext}_{D_v \times D_k}(s) = \frac{1}{ex}$.

Consider now improving the effectiveness of the $k = 0$ consumers to $k = 1$ (so D'_k now takes on 1 with probability $1/2$ and x with probability $1/2$). The $(e, 1)$ consumer now chooses to purchase, as their loss is 2 (so their utility is $e - 2 - (e - 2.5) = 1/2$). So now $\textsc{Ext}_{D_v \times D'_k}(s) = (\frac{1}{e} + \frac{1}{ex})/2$. As $x > 1$, the externalities have gone up. If $x \geq 1$, the externalities may have gone up quite significantly.

In Example 3.2, of course "the right" thing to do is to also change the policy. Indeed, it is still the case that, for a *fixed consumer who purchases the item*, increasing effectiveness can only decrease externalities. But without fixing whether the consumer has purchased the item or not, the claim is false. Observation 3 captures what we can claim about risk, loss, etc. on a per-consumer basis. Proofs for the claims in Observation 3 all follow immediately from the definitions in Section 3.

Observation 3. *Let $k > k'$, then for all s:*

- $\textsc{risk}(k, s) \leq \textsc{risk}(k', s)$.
- $\ell(k, s) \leq \ell(k', s)$.
- $h^*(k, s) \geq h^*(k', s)$.
- $u(k, s) \geq u(k', s)$.

4 ROADMAP OF TECHNICAL SECTIONS

Now that we have the appropriate technical language, we provide a brief roadmap of the results to come.

- In Section 5, we provide a technical warmup to get the reader familiar with how to reason about our problem. The main result of this section is Theorem 5.1, which claims that the optimal policy when D_k is a point-mass is simple. The proof of this theorem helps illustrate one key aspect of our later arguments, and will also be used as a building block for later proofs.
- In Section 6, we prove our first main result (Theorem 6.1): as a function of R and D_v, there exists a cutoff T. If D_k is supported on $[0, T]$, then a cost policy is optimal. If D_k is supported on $[T, \infty)$, then a fine policy outperforms all *profits-maximizing* policies (we define this term in the relevant section — intuitively a policy is profits-maximizing if the price is the seller's best response to (y, c)). Section 6 also contains a surprising example witnessing that the additional profits-maximizing qualification is necessary.
- In Section 7, we consider general distributions. Unsurprisingly, simple policies are no longer optimal. Perhaps surprisingly, if one insists on exceeding the profits benchmark *exactly*, no simple policy can guarantee any bounded approximation to the optimal externalities (Corollary 7.5). However, we also show (Theorem 7.6) that it is possible to get a bicriterion approximation: if one is willing to approximately satisfy the profits constraint, it is possible to approximately minimize externalities with a simple policy. That is, for any s, D, there is a simple policy s' with $\textsc{Prof}_D(s') = \Omega(1) \cdot \textsc{Prof}_D(s)$ and $\textsc{Ext}_D(s') = O(1) \cdot \textsc{Ext}_D(s)$.

- We include complete proofs for most of our results on point-mass and homogeneous distributions, as these convey many of the key ideas. By Theorem 7.6, the proofs get quite technical so we provide a sketch of the main ideas. This and other omitted proofs can be found in [7].

5 WARM-UP: POINT-MASS EFFECTIVENESS

As a warm-up, we first study the case where D_k is a point mass (that is, all buyers in the population have the same effectiveness k). In this case, we show that a simple policy is optimal. The proof is fairly intuitive, with one catch. The intuitive part is that every consumer will put in the same effort, conditioned on buying the item. It therefore seems intuitive that if $k < 1$, it is better for all parties involved if any effort spent by the consumer is transferred to the producer instead (and this is true). It also seems intuitive that if $k > 1$, it is again better for all parties involved if any effort spent by the producer is "transferred" to the consumer instead (e.g. by raising fines so that the consumer chooses to spend the desired level of effort). This is not quite true: the catch is that the fine required to induce the desired buyer behavior may be too high to satisfy the profit constraint. But, the above argument does work for sufficiently large k. Importantly, there is some cutoff T such that for all $k \le T$, the optimal policy is a cost policy ($y = 0$), while for all $k \ge T$, the optimal policy is a fine policy ($c = 0$). Below, when we write $D_v \times \{k\}$, we mean the distribution which draws v from D_v and outputs (v, k).

Theorem 5.1. *For all D_v, R, and k, the externality-minimizing policy for $D_v \times \{k\}$ is a simple policy. Moreover, for all R, D_v, there is a cutoff T such that if $k \le T$, then the optimal policy is a cost policy. If $k \ge T$, then the optimal policy is a fine policy.*

Proof. Consider any policy $s = (y, c, p)$. Because all consumers have the same effectiveness k, s induces the same loss for all consumers. We first claim the following: □

Lemma 5.2. *Let $k \le 1$. Then for all D_v and any policy $s = (y, c, p)$, there is an alternative policy $s' = (0, c', p)$ with $\textsc{Prof}_{D_v \times \{k\}}(s') \ge \textsc{Prof}_{D_v \times \{k\}}(s)$ and $\textsc{Ext}_{D_v \times \{k\}}(s') \le \textsc{Ext}_{D_v \times \{k\}}(s)$.*

Proof. In policy s, all consumers have the same loss $\ell(k, s)$. This therefore is a good opportunity to try and make use of Observation 1. First, consider the possibility that $yk < e^c$. In this case, $h^*(k, s) = 0$, $\ell(k, s) = ye^{-c}$, and $\textsc{risk}(k, s) = e^{-c}$. This implies that $\textsc{Ext}_{D_v \times \{k\}}(s) = e^{-c}$. Consider instead the policy $s' = (0, c, p)$. Then $\ell(k, s') = 0$, but $\textsc{risk}(k, s) = e^{-c}$ and $\textsc{Ext}_{D_v \times \{k\}}(s) = e^{-c}$ like before. So the externalities are the same. An application of Observation 1 concludes that the profits have improved (indeed, (c, p) are the same in both policies, and the loss decreases as we switch from policy s to s').

Consider now the possibility that $yk \ge e^c$. In this case, $h^*(k, s) = \frac{\ln(yk) - c}{k}$, $\ell(k, s) = \frac{\ln(yk) - c + 1}{k}$, and $\textsc{risk}(k, s) = \frac{1}{yk}$. Consider instead the policy $s' = (0, \ln(yk), p - c + \ln(yk))$. In this new policy, $\ell(k, s') = 0$ and $\textsc{risk}(k, s') = \frac{1}{yk}$. So indeed, the new policy has the same externalities. We just need to ensure that we can apply Observation 1. To this end, observe that:

$$\begin{aligned}\ell(k, s) + c - (\ell(k, s') + c') &= \frac{\ln(yk) - c + 1}{k} + c - \ln(yk) \\ &= (1/k - 1) \cdot (\ln(yk) - c) + 1/k \\ &\ge 0.\end{aligned}$$

The last line follows because $k \le 1$ and $\ln(yk) \ge c$ (because $yk \ge e^c$). So the hypotheses of Observation 1 hold, and we can apply Observation 1 to conclude that the profits improve from s to s' as well. □

Lemma 5.2 covers the cases when $k \le 1$: there is always an optimal cost policy. We now move to the case when $k > 1$. There are two cases to consider: one where the optimal policy will be a cost policy, and one where the optimal policy will be a fine policy. The distinguishing feature between these cases will be for a given c, how big of a fine is necessary to incentivize the consumer to put in effort c/k, and what the consumer's loss looks like for this choice of y. Below, c^* is defined to be the maximum c such that there exists a p such that $\textsc{Prof}_{D_v \times \{0\}}(0, c, p) \ge R$. Observe that c^* is also equal to the maximum ℓ such that there exists a p such that $\textsc{Prof}_{(D_v - \ell) \times \{0\}}(0, 0, p) \ge R$ (here, $D_v - \ell$ denotes the distribution which samples v from D_v and then subtracts ℓ, taking a maximum with 0 if desired). That is, c^* is the maximum loss that can be uniformly applied to all consumers (drawn from D_v) while still resulting in a distribution for which profit $\ge R$ is achievable.

Lemma 5.3. *Let c^* denote the maximum c such that there exists a p such that $\textsc{Prof}_{D_v \times \{0\}}(0, c, p) \ge R$. Then a cost policy is optimal for $D_v \times \{k\}$ if $k \in [1, 1 + 1/c^*]$.*

Proof. First, observe that the lemma hypothesis implies that *any* feasible policy must have $\ell(k, s) + c \le c^*$ (if not, then an application of Observation 1 lets us contradict the lemma's hypothesis with a feasible $c' = \ell(k, s) + c > c^*$).

Consider now $k \in [1, 1 + 1/c^*]$, and start from some policy $s = (y, c, p)$. If this policy has $h^*(k, s) = 0$, then certainly we can just update $s' = (0, c, p)$ and get better profits with the same externalities (by Observation 1). If instead $h^*(k, s) > 0$, then $\ell(k, s) = \frac{\ln(yk) - c + 1}{k}$, and $\textsc{risk}(k, s) = \frac{1}{yk}$. Consider instead $s^* = (0, c^*, p^*)$, for whichever p^* witnesses $\textsc{Prof}_D(s^*) \ge R$ (we know that such a p^* exists by the lemma's hypothesis). So now we just need to compare externalities. Assume for contradiction that $\textsc{risk}(k, s^*) > \textsc{risk}(k, s)$. Then we get:

$$\begin{aligned}\textsc{risk}(k, s^*) > \textsc{risk}(k, s) &\Rightarrow e^{-c^*} > \frac{1}{yk} \\ &\Rightarrow c^* < \ln(yk) \\ &\Rightarrow \frac{\ln(yk) - c + 1}{k} > \frac{c^* - c + 1}{k} \\ &\Rightarrow \ell(k, s) + c > \frac{c^* - c + 1}{k} + c \\ &\Rightarrow \ell(k, s) + c > \frac{c^* + 1}{k} \\ &\Rightarrow \ell(k, s) + c > c^* \Rightarrow\Leftarrow .\end{aligned}$$

The last implication uses the fact that $k \le 1 + 1/c^*$. The line before this uses that $k \ge 1$. The contradiction arises because this would imply a scheme (s) with profit $\ge R$ with loss $> c^*$, contradicting

the definition of c^* by the reasoning in the first paragraph of this proof. □

Lemma 5.4. *Let c^* denote the maximum c such that there exists a p such that $\text{Prof}_{D_v \times \{0\}}(0, c, p) \geq R$. Then a fine policy is optimal for $D_v \times \{k\}$ if $k \geq 1 + 1/c^*$.*

Proof. Again start from some policy $s = (y, c, p)$, inducing some loss $\ell(k, s)$. First, maybe $h^*(k, s) > 0$. In this case, the risk is $\frac{1}{yk}$ and the loss plus cost is $\frac{\ln(yk)-c+1}{k} + c$. In particular, observe that the partial derivative of the loss plus cost with respect to c is $1-1/k > 0$. So the policy $s' = (y, 0, p - c)$ has $\text{risk}(k, s') = \text{risk}(k, s)$ but also $\ell(k, s') + c' < \ell(k, s) + c$. So Observation 1 claims that this policy gets at least as much profits (and the risk is the same).

If instead, $h^*(k, s) = 0$, then the risk is e^{-c} and the loss is $y \cdot e^{-c}$. In this case, consider instead y^* such that $\frac{\ln(y^*k)+1}{k} = c^*$ and using $s^* = (y^*, 0, p^*)$, for the p^* satisfying $\text{Prof}_D(s^*) \geq R$ (again, such a p^* must exist by definition of c^*, and the fact that $\ell(k, s^*) = c^*$, plus Observation 1). We just need to analyze the risk. Similar to the previous proof, assume for contradiction that $\text{risk}(k, s^*) > \text{risk}(k, s)$. Then:

$$\begin{aligned}
\text{risk}(k, s^*) > \text{risk}(k, s) &\Rightarrow e^{-c} < \frac{1}{y^*k} \\
&\rightarrow c > \ln(y^*k) \\
&\Rightarrow \frac{\ln(y^*k) + 1}{k} < \frac{c+1}{k} \\
&\Rightarrow c^* < \frac{c+1}{k} \\
&\Rightarrow c^* > c^* \cdot \frac{c+1}{1+c^*} \Rightarrow\Leftarrow .
\end{aligned}$$

The last inequality uses the fact that $k \geq 1 + 1/c^*$, and derives a contradiction as $c \leq c^*$ (if $c > c^*$, then certainly $\ell(k, s) + c > c^*$, contradicting the definition of c^*). □

All three cases together prove Theorem 5.1. The T prescribed in the theorem statement is exactly $1 + 1/c^*$, where c^* is the maximum c such that there exists a p for which $\text{Prof}_{D_v \times \{0\}}(0, c, p) \geq R$.

We conclude with one last proposition regarding the behavior of the threshold with respect to the profits constraints R. Proposition 5.5 below states that as R increases, the threshold beyond which a fine policy is optimal increases as well.

Proposition 5.5. *Let $T(D_v, R)$ denote the threshold such that both a fine policy and cost policy are optimal for $D_v \times \{T(D_v, R)\}$ subject to profits constraints R. Then $T(D_v, R)$ is monotone increasing in R.*

Proof. To see this, let $c^*(D_v, R)$ denote the maximum c such that there exists a p such that $\text{Prof}_{D_v \times \{0\}}(0, c, p) \geq R$. Then $c^*(D_v, R)$ is *decreasing* in R (as the profits constraint goes up, we can't afford as much security). So $1 + 1/c^*(D_v, R)$ is *increasing* in R. This means that the threshold $T(D_v, R)$ beyond which a fine policy is optimal for $D_v \times \{T\}$ is increasing as a function of the profits constraint R (because $T = 1 + 1/c^*(D_v, R)$). □

This concludes our treatment of the case where k is a point-mass. Theorem 5.1 should both be viewed as a warm-up to introduce some of our core techniques, and also as a building block towards our stronger theorems (in the following sections). The main technique we introduced is the ability to reduce risk and loss simultaneously to improve both profits and externalities. The idea was that if the buyer is less effective than the seller, everyone prefers that the seller put in effort ($y = 0, c > 0$). If the buyer is more effective than the seller, everyone prefers that the buyer put in effort. However, the regulator can not directly mandate that the buyer put in effort, and unfortunately the fines required to extract the desired buyer behavior may too negatively affect the profit. This is why the transition from cost to fine policies is $1 + 1/c^*$ instead of 1.

6 HOMOGENEOUS DISTRIBUTIONS

In this section, we show that for populations that are sufficiently homogeneous in effectiveness, the optimal policy remains simple. The second half of Theorem 6.1 requires a technical assumption. Specifically, we say that a policy (y, c, p) is *profits-maximizing* if, conditioned on y, c, p is set to maximize the seller's profits (that is, $\text{Prof}_D(y, c, p) \geq \text{Prof}_D(y, c, p')$ for all p').

Theorem 6.1. *For all D_v, R, there exists a cutoff T such that*

- *For all D_k supported on $[0, T]$, the externality-minimizing policy for $D_v \times D_k$ subject to profits R is a cost policy.*
- *For all D_k supported on $[T, \infty)$, the externality-minimizing policy for $D_v \times D_k$ subject to profits R is either a fine policy, or it is* not *profits-maximizing.*

The proof of Theorem 6.1 will follow from Lemmas 6.3 and 6.7, which handle the two claims in the theorem separately. Finally, we show in Section 6.3 that the profits-maximizing qualification in part two of Theorem 6.1 is necessary:

Proposition 6.2. *There exist distributions D_v, D_k, and profits constraint R such that:*

- *T is such that for all $k \geq T$, the externality-minimizing policy for $D_v \times \{k\}$ subject to profits constraints R is a fine policy.*
- *D_k is supported on $[T, \infty)$.*
- No *fine policy is externality-minimizing policy for $D_v \times D_k$ subject to profits constraints R.*
- *The externality-minimizing policy for $D_v \times D_k$ subject to profits constraints R is not simple, and not profits-maximizing (the latter is implied by the second bullet of Theorem 6.1).*

Proposition 6.2 is perhaps surprising: a fine policy is externality-minimizing for $D_v \times \{T\}$, and D_k stochastically dominates T, so the same fine policy has *even lower* externalities, and potentially greater profit for $D_v \times D_k$. Indeed, the optimal fine policy for $D_v \times D_k$ achieves lower externalities than that of $D_v \times \{T\}$. The catch is that an *even better* non-simple policy becomes viable, and achieves *still lower* externalities. Theorem 6.1 claims, however, that the optimal non-simple policy must not be profits-maximizing.

6.1 Extension Lemma for small k

The small k case follows roughly from the following intuition. For cost policies, neither the buyer's loss nor her risk depend on k. So whichever cost policy is optimal for $D_v \times \{T\}$ achieves the same profits and externalities as $D_v \times D_k$. Intuitively, going from $\{T\}$ to D_k supported on $[0, T]$ cannot possibly *increase* the profits of any scheme (formally: Observation 2), so the initial cost policy should remain optimal.

Lemma 6.3 (Extension of Cost Policy). *Let s be a cost policy that is optimal for $D_v \times \{T\}$ subject to profits R. Then for all D_k supported on $[0, T]$, s is optimal for $D_v \times D_k$ subject to profits R.*

Proof. First, we observe that $\text{Prof}_{D_v \times \{T\}}(s) = \text{Prof}_{D_v \times D_k}(s)$. This is simply because the loss of consumers is independent of k (as $y = 0$). Similarly, $\text{Ext}_{D_v \times \{T\}}(s) = \text{Ext}_{D_v \times D_k}(s)$. This is again because the risk of consumers is independent of k.

Now, assume for contradiction that there is some policy s' with profits $\text{Prof}_{D_v \times D_k}(s') \geq R$ and also $\text{Ext}_{D_v \times D_k}(s') < \text{Ext}_{D_v \times \{T\}}(s)$. Then we have the following inequality from Observation 2:

$$R \leq \text{Prof}_{D_v \times D_k}(s') \leq \text{Prof}_{D_v \times \{T\}}(s').$$

Therefore, as s is optimal for $D_v \times \{T\}$ subject to profits R, we must have:

$$\text{Ext}_{D_v \times \{T\}}(s') \geq \text{Ext}_{D_v \times \{T\}}(s).$$

This now lets us conclude the following chain of inequalities, where the first line is a corollary of Observation 3: the consumer in a population with D_k supported on $[0, T]$ whose device is least likely to be compromised is a consumer with $k = T$. The third line follows from the reasoning above (that s' achieves profits at least R on $D_v \times \{T\}$, and is therefore feasible). The final line follows because the externalities of a cost policy are independent of k.

$$\begin{aligned}
\text{Ext}_{D_v \times D_k}(s') &\geq \text{risk}(T, s') \\
&= \text{Ext}_{D_v \times \{T\}}(s') \\
&\geq \text{Ext}_{D_v \times \{T\}}(s) \\
&= \text{Ext}_{D_v \times D_k}(s).
\end{aligned}$$

□

Lemma 6.3 proves the first bullet of Theorem 6.1.

6.2 Extension Lemma for large k

In this section, we sketch the proof for the large k case of Theorem 6.1. Refer to Section 6 of [7] for omitted proofs. The proof will be a little more involved this time, since we can no longer claim that the externalities of a fine policy are independent of k (whereas this does hold for cost policies). The intuition for this case is the same though: if a fine policy is optimal for $D_v \times \{k\}$ for all $k \geq T$, and D_k is supported on $[T, \infty)$, fine policies should remain optimal for $D_v \times D_k$. Most of the proof does not make use of the technical assumption that the s we are competing with is a profits-maximizing policy: this assumption only arises at the very end.

The first step in our proof is the following concept, which captures the change in loss for a consumer (v, k) for regulation s versus s':

Definition 6.4 (Policy Comparison Function). For two policies s and s', we define the *policy comparison function* $g_{s,s'}(\cdot)$ so that $g_{s,s'}(k) = \ell(k, s) - \ell(k, s')$.

The policy comparison function takes as input an effectiveness k, and outputs the change in loss for a consumer under one policy versus another. Our first lemma argues that for certain pairs (s, s'), the policy comparison function is monotone in k. That is, consumers with more effectives have greater preference for one policy over another.

Lemma 6.5. *Let $s = (y, c, p)$ and $s' = (y', c', p')$ be such that $ye^{-c} \leq y'e^{-c'}$. Then $g_{s,s'}(\cdot)$ is monotone non-decreasing. Observe that the hypothesis holds if $y \leq y'$ and $c \geq c'$.*

We use Lemma 6.5 to claim the following corollary, which essentially states that if a policy change universally lowers loss *and* risk, then it is possible to adjust the price so that the profits go up and externalities go down.

Corollary 6.6. *Let $(y, c), (y', c')$ be such that (a) $ye^{-c} \leq y'e^{-c'}$ and (b) for all k in the support of D_k, $\ell(k, y, c) + c \geq \ell(k, y', c') + c'$ and $\text{risk}(k, y, c) \geq \text{risk}(k, y', c')$. Then for all p and all D_v, there exists a p' such that:*

$$\textit{Prof}_{D_v \times D_k}(y', c', p') \geq \textit{Prof}_{D_v \times D_k}(y, c, p),$$

$$\textit{Ext}_{D_v \times D_k}(y', c', p') \leq \textit{Ext}_{D_v \times D_k}(y, c, p).$$

Now we are ready to formally state the extension lemma for large k.

Lemma 6.7 (Extension of Fine Policy). *Let D_k be supported on $[T, \infty)$, where T is such that a fine policy is optimal for $D_v \times \{T\}$ subject to profits R. Then there is a fine policy s' with $\textit{Prof}_D(s') \geq R$ such that for all profits-maximizing s with $\textit{Prof}_D(s) \geq R$, $\textit{Ext}_D(s') \leq \textit{Ext}_D(s)$.*

Proof Sketch. Consider any proposed optimal policy $s = (y, c, p)$. We first consider the case where $\ell(T, s) + c \geq \ell(T, s^*)$ where s^* is the optimal fine policy on $D_v \times \{T\}$. If that is the case, then consider a fine policy $s' = (y', 0, p - c)$ where $\ell(T, s') = \ell(T, s) + c$. Observe we must have $y' \geq y$ since we can only obtain equality by increasing fines, then by Lemma 6.5, we have $\ell(k, s') \leq \ell(k, s) + c$ for all k in the support of D_k and the profit under s' can only be higher.

Now, we need to show that the risk is only lower for all $k \geq T$. First, as $\ell(T, s') \geq \ell(T, s^*)$ we conclude that $y' \geq y^*$. Next, we can argue (see [7] for the full proof) that we must have $\frac{1}{y^*T} \leq e^{-c}$. This allows us to conclude that $\frac{1}{y'T} \leq e^{-c}$, and we already have that $y' \geq y$ so $\frac{1}{y'k} \leq \frac{1}{yk}$. This gives us that $\text{risk}(k, s') \leq \text{risk}(k, s)$ for all $k \geq T$. Then Corollary 6.6 let's us claim that there exists a price p' for which both the profits and the externalities are better for $(y', 0, p')$ than s.

For the case where $\ell(T, s) + c < \ell(T, s^*)$, observe that $\ell(D_k, s) + c$ is strictly stochastic dominated by $\ell(D_k, s^*)$; therefore, there is a price $\hat{p}$ where the profit strictly higher than R. Lemma 6.9 bellow, allows us conclude that if s is optimal, then $\text{Prof}_{D_v \times D_k}(s) = R$; otherwise, we can compromise $\varepsilon > 0$ fraction of the profit to strictly improve externalities. This implies that if the policy s we start with is optimal, then it is not profits-maximizing. □

Definition 6.8 (Invariant Transformation). Given a policy $s = (y, c, p)$, define

$$\text{Inv}(s, \alpha) := \left(ye^{(p-c)(1-\alpha)}, \alpha c + (1 - \alpha)p, p\right)$$

where $\alpha \in [0, \frac{p}{p-c}]$.

Lemma 6.9 (Invariant Property). *Let $s' = \textsc{Inv}(s, \alpha)$, then for all $k \in \mathbb{R}^+$*

- $h^*(k, s') = h^*(k, s)$.
- $\ell(k, s') = \ell(k, s)$.
- $u(t, s) = u(t, s')$.

In addition,

$$\textsc{Prof}_D(s') = \alpha \textsc{Prof}_D(s)$$
$$\textsc{Ext}_D(s') = e^{-(1-\alpha)(p-c)} \textsc{Ext}_D(s, p)$$

Proof Sketch. By applying the definition of buyer's efficiency, we can see that for all k, $h^*(k, s') = h^*(k, s)$ which implies $\ell(k, s') = \ell(k, s)$, and $\textsc{risk}(k, s') = e^{-(1-\alpha)(p-c)} \textsc{risk}(k, s)$. □

This concludes the proof of bullet two of Theorem 6.1.

6.3 Example: The Profits-Maximizing Qualification is Necessary

In this section we provide the example promised in Proposition 6.2. Refer to Section 6 of [7] for omitted proofs. Consider the following distribution, and profits constraint $R := 0.5$:

$$D_v = \begin{cases} v_1 = 1 & \text{w. p. } \frac{1}{2} \\ v_2 = 16/15 & \text{w. p. } \frac{1}{2} \end{cases}$$

$$D_k = \begin{cases} k_1 = 3 & \text{w. p. } \frac{1}{2} \\ k_2 = x \to \infty & \text{w. p. } \frac{1}{2} \end{cases}$$

Above, x will be finite, but approaching ∞, and ε will be finite but approaching 0). The proposition will follow from the following sequence of claims. First, we will establish bullet one for $T := 3$.

Claim 4. *A fine policy is optimal for $D_v \times \{3\}$.*

Bullet two now immediately follows, as D_k is indeed supported on $[3, \infty)$. We now just need to find the optimal fine policy for $D_v \times D_k$, and establish a better policy that is not simple. We now search for the optimal fine policy. Such a policy might sell only to $(16/15, x)$, but then the profits is at most $4/5$, which is too little. Such a policy might sell only to $(16/15, x)$ and $(1, x)$. But since x is finite, such a policy certainly charges price < 1 (unless $y = 0$, in which case the policy sells to all four types), and sells with probability $\leq 1/2$, so the profits are also too small. Such a policy might sell to all four types, which we analyze below. Or it might sell to all types except $(1, 3)$, which we analyze after.

Claim 5. *The optimal fine policy s which sells to all four types has $\textsc{Ext}_{D_v \times D_k}(s) \geq \frac{1}{2\sqrt{e}}$.*

Claim 6. *The optimal fine policy s which sells to all types except $(1, 3)$ has $\textsc{Ext}_{D_v \times D_k}(s) \geq e^{-1/5}/3$.*

Corollary 6.10. *The optimal fine policy s has $\textsc{Ext}_{D_v \times D_k}(s) \geq e^{-1/5}/3$.*

Here's now some intuition for how we're going to design a better non-simple policy: given that we wish to sell to all types except $(1, 3)$, we can set y very close to 0 and have $\textsc{risk}(x, s) \approx 0$, because x is so large. The remaining question is then whether we wish to use y or c to make the risk of $(16/15, 3)$ as small as possible. Note that we must keep their loss under $2/5 < 1/2$ (as above). But for $k = 3$, a loss of $1/2$ is *exactly* the cutoff when it becomes more efficient to use a fine policy instead of a cost policy. So if we use c instead, we can get the risk lower for the same loss.

Claim 7. *Let ε be such that $\frac{\ln(x)+1}{x} \leq \varepsilon$. Then set $c = 1/3 - \varepsilon$, and $y = (2/5 - c)e^c$. Then $\textsc{Ext}_{D_v \times D_k}(y, c, 2/3 + c) = \frac{2}{3yx} + e^{-1/3+\varepsilon}/3$ and $\textsc{Prof}_{D_v \times D_k}(y, c, 2/3 + c) = 1/2$.*

Now, we just need to compare $e^{-1/5}/3$ and $e^{-1/3+\varepsilon}/3 + \frac{2}{3yx}$. Observe that as $x \to \infty$, $\varepsilon \to 0$ and $e^{-1/3+\varepsilon}/3$ approaches $e^{-1/3}/3$. So $\frac{2}{3yx} + e^{-1/3+\varepsilon}/3 \to 0 + e^{-1/3}/3 < e^{-1/5}/3$, and the externalities are indeed lower.

As a sanity check, we'll show that $((2/5-c)e^{1/3-\varepsilon}, 1/3-\varepsilon, 2/3+c)$ is not profits-maximizing (technically, Theorem 6.1 doesn't imply this, since we didn't prove that the scheme is optimal. But as this scheme is better than all fine policies, certainly the optimal policy is not simple, and therefore not profits-maximizing by Theorem 6.1. So the fourth bullet is already proven).

Claim 8. *$((2/5 - c)e^{1/3-\varepsilon}, 1/3 - \varepsilon, 2/3 + c)$ is not profits-maximizing.*

7 GENERAL DISTRIBUTIONS: AN APPROXIMATION

In this section, we consider general distributions. Clearly, one should not expect a simple policy to be optimal in general. Given that simple policies are optimal for homogeneous populations, one might reasonably expect that simple policies are approximately optimal for general distributions by simply ignoring half of the population and targeting the half that is responsible for most of the externalities. This idea works in one direction: if the "low k" region is responsible for most of the externalities in the optimum solution, then using a cost policy for the entire distribution is a good idea: the high k consumers may have significantly higher risk than previously, but this doesn't outweigh the original risk from the low k region.

This idea fails horribly, however, if the "high k" region is responsible for most of the externalities in the optimum solution. The problem is that while we can choose a policy to exclusively target this subpopulation, any low k (think: $k = 0$) consumers who choose to purchase anyway may have enormous risk in comparison to before (i.e. it could now be 1 when it was previously e^{-c} for large c). We first show that this intuition can indeed manifest in a concrete example by presenting a lower bound in Section 7.1. This rules out a *single-criterion* approximation that satisfies the profits constraint exactly, and approximates the externalities. In Section 7, we present a bicriterion approximation which approximately satisfies the profits constraint and also approximately minimizes externalities. This approximation is our most technical result. As such, we provide mainly proof sketches to overview the key steps.

7.1 Lower Bound on Heterogeneous Distributions

The key insight for our example is to make the profits constraint so binding that the only way to match it exactly is for the entire population to purchase the item. Part of the population will have $k = 0$, and part will have $k \to \infty$. With both c and y, it will be

feasible to get the $k \to \infty$ consumers to have risk essentially 0, while the $k = 0$ consumers will have reasonably small risk. But with either $c = 0$ or $y = 0$, one of these will be lost, which causes significant risk increase.

Example 7.1. Let D_v be a point mass at $v_0 = 2e^{x/2} \cdot (x + e^{-x})$. Let D_k be a distribution with two point masses, one at $k = 0$ with probability $e^{-x/2}$, one at $e^{xe^{x/2}}$ with probability $1 - e^{-x/2}$. Let $R := v_0 - e^{-x} - x$.

Lemma 7.2. *The policy $(1, x, R+x)$ achieves profit R in Example 7.1, and has externalities $\leq e^{-x/2} \cdot e^{-x} + 1 \cdot e^{-xe^{x/2}}$.*

Proof. The utility of $(v_0, 0)$ is exactly $v_0 - e^{-x} - R - x = 0$, so they will choose to purchase. $(v_0, e^{xe^{x/2}})$ has only larger utility, so they will purchase as well. Therefore, the profit is indeed R.

The externalities are computed simply as the probability of having consumer $(v_0, 0)$ times their risk (e^{-x}) plus (upper bound on the) probability of consumer $(v_0, e^{xe^{x/2}})$ times their risk $(e^{-xe^{x/2}})$. □

Lemma 7.3. *Any cost policy that achieves profit R has externalities at least e^{-x+1}*

Proof. The maximum security we can set and still have profit R is $x + e^{-x}$. If we set this, then the risk of all consumers (which is now independent of k) is $e^{-x+e^{-x}} \geq e^{-x+1}$. □

Lemma 7.4. *Any fine policy that achieves profit R has externalities at least $e^{-x/2}$.*

Proof. To achieve profit R, the policy must sell to the entire population. The consumer with $k = 0$ will not put in any effort, and therefore their risk will be one, and the externalities will be at least $e^{-x/2}$. □

Corollary 7.5. *For all x, there exists a distribution $D_v \times D_k$ and profits constraint R such that the optimal policy is not simple, and any simple policy that satisfies profits constraints R has externalities at least a factor of x larger than the optimum.*

Corollary 7.5 is the main result of this section. Clearly the distribution witnessing Corollary 7.5 is highly contrived and unrealistic. And clearly, the way to get around this is to allow for a slight relaxation in the profits constraint so that we don't have to sell to the entire market (indeed, even allowing to relax the constraint by a $(1 - e^{-x/2})$ fraction in this case would suffice). So the subsequent section shows that by relaxing the profits constraint, an approximation guarantee is possible.

7.2 A Bicriterion approximation

Given the lower bound in Section 7.1, we show that simple policies guarantee a bicriterion approximation. As is traditional with worst-case approximation guarantees, our constants are not particularly close to 1, but are still relatively small. This is not meant to imply that the seller should be happy with (e.g.) a 1/8-fraction of the original profits, but more qualitatively to conclude that simple policies can reap many of the benefits of optimal ones (see [16] for further discussion about the role of approximation in mechanism design). As referenced previously, the proof of Theorem 7.6 is quite technical, so we sketch the key steps. The complete proof can be found on [7].

Theorem 7.6. *For all distributions D, and all policies s, there exists a simple policy s' such that*

$$\textsc{Prof}_D(s') \geq \textsc{Prof}_D(s)/8,$$

$$\textsc{Ext}_D(s') \leq 40/3 \cdot \textsc{Ext}_D(s).$$

Proof Sketch. Given an arbitrary policy $s = (y, c, p)$, consider the conditional distribution of buyers that purchase under s. If with constant probability a buyer has efficiency $k \leq 1$, then we output the cost policy $s_1 := (0, c + \ell(\sigma, s), p + \ell(\sigma, s))$ where σ is chosen such that a buyer continues to purchase with constant probability. We can show that $c + \ell(\sigma, s)$ is sufficiently large such that $\textsc{risk}(D_k, s') \leq \textsc{risk}(D_k, s)$ with constant probability.

For the case where with constant probability a buyer has efficiency $k > 1$, we define a blowup of the fines such that with constant probability a buyer continues to purchase but with the hope that inefficient buyers stop to purchase. The blowup can fail in two conditions: (1) D_k is not heavy tail, (2) D_v is heavy tail. For (1), we cannot derive a significant blowup if D_k is concentrated close to 1. For (2), we cannot drive inefficient buyers out of the market if they have high value. Either condition allow us to construct cost policies that give good externality guarantees. □

8 SUMMARY

We propose a stylized model to study regulation of single item sales with negative externalities, from which neither the buyer nor seller suffer. We first show that a simple policy is optimal in homogenous markets: That is, for all D_v, R, there exists a cutoff T such that when the effectiveness of consumers ranges in $[0, T]$, the optimal policy regulates only the product (and does not impose fines). Similarly, if all consumers have effectiveness in $[T, \infty)$, a policy which regulates only payments (via fines, and does not impose default security features) outperforms all profits-maximizing policies. Importantly, T is not necessarily the cutoff at which the consumers are more effective than the producer (which would be $T = 1$), but actually depends on the value distribution D_v and profit constraint R.

We then show in general markets that while a simple policy may not be optimal, one is always approximately optimal. In particular, we show that while no simple scheme can guarantee any finite approximation while satisfying the profit constraint exactly, a bi-criterion approximation exist, which approximately satisfies the profit constraint and also approximately minimizes externalities. Going forward, we must better understand the effectiveness of consumers to decide which regulation strategy is more appropriate to approximately minimizes externalities.

While stylized, our model captures the key salient features of this problem. We chose to study the single seller/single item setting in order to isolate these features without bringing in additional complexities (and the numerous examples throughout our paper demonstrate that even the single seller/single item setting is quite rich). Now that our results develop this understanding, a good direction for future work is to consider competing sellers or multiple items.

ABSTRACT

Online advertising is one of the primary sources of funding for content, services, and applications on both web and mobile platforms. Mobile in-app advertisements are implemented on top of existing web technologies with the same ad-serving model (i.e., users - publishers - ad networks - advertisers). Even so, in-app advertising is different from traditional web advertising. For example, malicious mobile app developers can generate fraudulent ad clicks in an automated fashion, but malicious web publishers have to leverage bots to launch click fraud. In spite of using the same underlying web infrastructure, these ad threats behave differently on different platforms.

Existing works have separately studied click fraud and malvertising in mobile settings. However, it is not known if there is a strong relationship between these two dominant threats. In this paper, we develop an ad collection framework – MAdLife– on Android to capture all in-app ad traffic generated during each ad's entire lifespan. We revisit both threats in a fine-grained manner with MAdLife to determine the relationship between them. Furthermore, MAdLife also allows us to explore other threats related to landing pages.

We analyzed 5.7K Android apps crawled from Google Play store, and collected 83K ads and their landing pages with MAdLife. 58K ads land on a web page, which is similar to traditional web ads. We discovered 37 click-fraud apps, and revealed that 1.49% of the 58K ads are related to malvertising. We also found a strong correlation between fraudulent apps and malicious ads. Specifically, over 15.44% of malicious ads originate from the fraudulent apps. Conversely, 18.36% of the ads displayed in the fraudulent apps are malicious, compared to only 1.28% found in the rest apps. Due to fraudulent apps, users are much more (14x) likely to encounter malvertising ads. Additionally, we discovered 243 popular JavaScript snippets embedded by over 10% of the landing pages are malicious. Finally, we also present the first analysis on inappropriate mobile in-app ads.

CCS CONCEPTS

• **Information systems → Online advertising**; • **Security and privacy → Software and application security**.

1 INTRODUCTION

Online digital advertising is the primary way to monetize content, services, and applications (apps) on the Internet. Companies like Google and Facebook generated 85-95% of their revenues through running the largest digital advertising platforms in Q2 2018 [1, 21]. Traditionally, these ad platforms, or ad networks, display advertisements (ads) from advertisers on a publisher's website that is part of the network. This practice is known as web advertising, which has generated over $35B in revenue per year in the last five years according to recent IAB reports [28]. Meanwhile, web advertising has rapidly expanded to mobile platforms. Mobile advertising revenue experienced a substantial (7x) growth from $7.1B in 2013 to $49.9B in 2017.

Mobile in-app ads are usually implemented on top of existing web technologies by rendering an HTML ad within a mobile app's WebView. Although sharing many underlying technologies, mobile in-app advertising is different from traditional web advertising. A website includes a JavaScript snippet to display ads, whereas a mobile app embeds a custom SDK to load the JavaScript code and ads in a special WebView – AdView. To date, ad blocking solutions, such as DNS66[1], DISCONNECT[2], NoMoAds [43], [6], are not widely used by real users for in-app ads, but ad blockers are very popular for traditional web advertising. As a result, the abusive practices in web advertising, such as *click fraud* and *malvertising*, exhibit different characteristics on mobile platforms. In particular, a web browser allows an ad script to detect automatically generated fraudulent ad clicks. Therefore, malicious publishers have to leverage bots instead of real users to automate ad clicks, which can be easily detected by ad networks. On the contrary, mobile users need to interact with HTML ads through their app's user interface (UI). This enables a malicious app developer to automatically generate fraudulent ad clicks, which are difficult for the restricted JavaScript running in the AdView to detect. Therefore, it is easier to launch click fraud from a genuine user device with the help of UI automation on mobile platforms. Malvertising on both platforms behaves very similarly. By clicking on an ad, a user may be brought to a malicious page that serves drive-by-downloads or scams. In particular, drive-by downloads have been the primary form of malvertising for web advertising, according to the study in [31]. Scams are, however, the dominating malvertising form for mobile in-app ads [39].

The abusive practices in mobile advertising have been explored by prior works. Crussell et al. examined click fraud in each app's

[1] https://f-droid.org/en/packages/org.jak_linux.dns66/
[2] https://disconnect.me

first/main activity by running in an emulator without UI intervention [15]. However, their work did not reveal how the fraudulent apps initiate automatic ad clicks. Rastogi et al. [39] detected malvertising cases by collecting and scanning redirect chains using VirusTotal[3]. However, their work did not look into JavaScript code loaded from external sources, which can also be malicious. Overall, both frameworks are time consuming for app collection. Also, click fraud and malvertising may happen together, and these tools cannot be used to study both threats altogether.

To overcome the above limitations, we present MAdLife, a framework for studying mobile in-app advertising. It can record all necessary data generated during each ad's entire lifespan (i.e., request → load/render → click → redirect → land) on Android. Specifically, we modify the Android WebView to collect pre-click data. After each ad is completed, we automatically trigger a click through lightweight UI automation, and then redirect the post-click traffic to our data collection app. The two datasets allow us to conduct a more fine-grained study on click fraud and malvertising. We can also investigate other related threats in mobile in-app advertising. Usually, advertisers' landing pages embed external JavaScript code. Unlike the prior work on mobile malvertising, we reveal that the external JavaScript snippets can also be malicious even though the embedding landing pages are considered benign. Besides, following up with two trending news event related to political advertising on Facebook [13, 41], we recognize that the contents appear in advertising have been receiving more and more public concerns. Thus, we also take a first attempt to analyze inappropriate content for mobile in-app ads. Specifically, by employing content analysis techniques, we are able to detect and classify inappropriate ads into two categories: 1) policy non-compliant [20, 24, 25, 46], which are ads that do not comply with the policies of ad networks (e.g., including age-restricted content); and 2) controversial, which are ads that are generally believed inappropriate to some population groups (e.g., promoting online gambling).

We used MAdLife to collect 84K ads from 5.7K Android apps from January to February in 2018. First, we identified that 37 apps had committed click fraud, and 1.49% of ads were malicious according to the VirusTotal query results on their landing pages. Second, we discovered a strong statistical relation between click-fraud apps and malicious ads. On one hand, over 15.44% of infected ads originated from those fraudulent apps. On the other hand, 18.36% of the ads displayed by click-fraud apps are malicious, whereas in non click-fraud apps only 1.25% of ads are malicious. Therefore, users of the click-fraud apps are much more (14x) likely to be exposed to malicious ads than other users. Also, we found over 32 cryptojacking ads in our dataset. Moreover, we discovered 243 (0.21%) of the 115K external JavaScript snippets are unsafe. They are very popular and were used in over 10% of the landing pages in our dataset. Finally, we identified that around 8% of ad landing pages were inappropriate – 7.9% are non-compliant with ad policies, and 0.266% are controversial.

Our contributions are threefold:

1) We developed MAdLife– the first framework to monitor an ad' entire life span on the mobile platform. As a result, we are able to build a panoramic view for digital ads.

2) We explored the abusive practices involved in mobile in-app advertising, and demonstrated a strong statistical relation between click fraud and malvertising. We discovered that due to click fraud, mobile app users are much more likely to experience malvertising. Moreover, we also found several emerging threats (i.e, cryptojacking ads) in mobile in-app advertising.

3) We are the first to extend the research scope of analyzing landing pages from two aspects. First, we discovered that a few unsafe external JavaScript code may occur in a great number of landing pages. Second, we classified inappropriate ads into two categories (i.e., policy non-compliant, and controversial).

In summary, previous works treated click fraud and malvertising as two independent mobile ad threats, and thus studied them separately. In contrast, MAdLife allows us to study mobile ad threats comprehensively. Therefore, researchers can have a broader view of mobile ad threats and thus build a safer mobile ad ecosystem.

2 BACKGROUND

2.1 Android WebView

Android apps are usually required to include custom AdViews, and the underlying implementation of most AdViews is based on WebView. While transparent to app developers and mobile users, the nature of the WebView component has been changed a lot with the evolution of Android OS. Since Android 4.4, it has moved from using the WebKit rendering engine to sharing the same Chromium-based codebase with Chrome for Android. In Android 5.0, the component came out as a standalone APK, where mobile users can find its updates on Play Store. Starting from Android 6.0, only prebuilt WebView versions are shared within the Android Open Source Project (AOSP). Afterward in Android 7.0, the Chrome APK is used for provide and render WebView. Recently, the Safe Browsing feature has been available in WebView with Android 8.0.

Based on Chromium source tree, WebView depends on a C++-compiled shared library and a source set. Within the source set, Java code encapsulates C++ and provides an AwContents object. By adding logcat messages for function calls within AwContents, we can thus use adb to communicate with an Android emulator and view the device log in real-time.

As a View object that displays webpages, WebView cannot be used standalone without an Activity component. With UI Automation tools, developers can access, identify, and manipulate the UI elements. However, such tools cannot access the Document Object Model (DOM) within a WebView. Unlike ads in a browser where researchers can directly resolve ad URLs from their DOM trees, when an ad WebView receives a touch event, it triggers an AwContents object's `onTouchEvent()` first, and then consecutively tops down to the Blink rendering engine for resolving the embedded URL from its DOM tree.

2.2 Mobile Advertising

Serving in-app ads is a pervasive approach to app monetization for *publishers*/*developers*. In order to get continuous revenue, app developers register their apps, and app store links to one or several *ad networks*. In turn, the developers receive a unique identifier per ad space, all related *ad libraries*, which fetch ads with the resolved URLs at runtime, and common guidelines. For example, an ad's

[3]https://www.virustotal.com

standard Cascading Style Sheets (CSS) size, which is different from a smartphone's resolution size, could be recommended. While developers have rights to choose ad types, including video ads and display ads (i.e., small-size banner ads, and full-screen interstitial ads) shown on their apps and earn from displaying/clicking ads, *advertisers* sit on the other end to provide funds for spreading out the content they wish to publicize. Together with innocent users downloading and launching apps, all other players, including publishers/developers, ad networks/ad libraries, and advertisers, form a perfect ecosystem in the mobile settings [9].

However, such an ecosystem may temporarily be interrupted, when a user launches an app, the app requests an ad for a vacant space from the linked ad network, but the ad network has nothing in its inventory when the app is launched. As a result, the user may see a void ad slot. In the case that ads are not loaded within the WebView, we call it *incapable ad loading*. Otherwise, different *ad syndications* are created by ad networks in order to fill the gap in time. Therefore, when the subscribed ad network does not find an ad for the ad slot, the ad request will be forwarded to syndicated ad networks. Imaginably, communications between the app and multiple ad networks under the ad syndication lead to a longer *redirect chain*, before arriving at the final *landing page*. Also, an ad may not be properly displayed at a WebView, due to network overload or ad networks' backend algorithms. We call that *improper ad rendering*. As for *app install ads*, their final destination may end up with Play Store.

2.3 Ad Threats

Click fraud. In order to earn more, unscrupulous app developers use click fraud to programmatically trigger fake ad clicks.
Malvertising. Due to untrusted ad networks, or unwanted redirect chains, malvertising may result in either drive-by downloads, or scams and phishing (e.g., pornography).
Vulnerable External JavaScript Code. Usually, advertisers use JavaScript snippets to track user behaviors, or more. However, landing pages containing vulnerable external JavaScript code may be exposed to both security and privacy risks.
Ad Inappropriateness. Ad networks regulate advertised content, but untrusted advertisers can still smuggle inappropriate ads. It is infelicitous, especially for children. That's why Unity Ads [47] talk about COPPA [12] within their common guidelines.

2.4 Public APIs

VirusTotal aggregates over 60 scanners, and offers APIs to analyze files/URLs. A rationale behind using a cluster of antivirus scanners is to fight against mistaken detection by individual scanning tool, or so called *false positive*.
Google Cloud APIs[4] uses REST calls to automate different workflows. We used the Natural Language API to reveal the structure and meaning of text from different aspects (e.g., "entity analysis" and "content classification"). Also, we called the Vision API to find similar images and web entities as well as detect explicit content (i.e., adult, medical, spoof, and violence), respectively.

[4]https://cloud.google.com/apis/

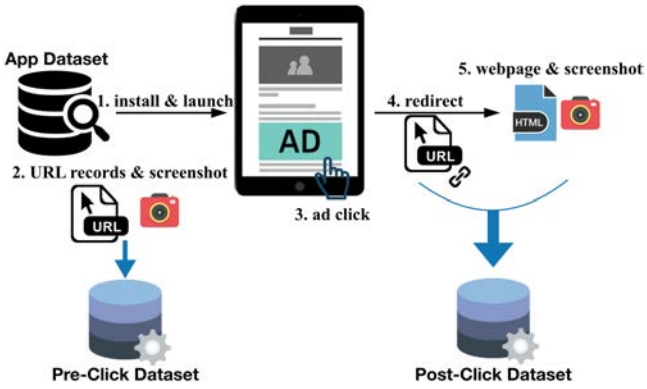

Figure 1: Workflow for data collection

3 METHODOLOGY

In this section, we present the design and implementation of MAdLife (Section 3.1), the steps we took to select our app dataset (Section 3.2), and the statistics about that dataset (Section 3.3).

3.1 MAdLife

MAdLife is a data collection framework on a mobile platform for in-app ads. It can record all necessary data generated within each ad's entire lifespan (i.e., request → load/render → click → redirect → land). Figure 1 demonstrates the workflow of MAdLife. First, MAdLife uses the AndroidViewClient[5] tool (version 13.6.0) to install and launch an app automatically. Afterwards, an ad is returned from a remote host. Second, MAdLife listens to the ad traffic at the same time, and then stores the *pre-click* data into a table in our database. Third, MAdLife clicks the ad. Fourth, the embedded ad URL is sent to our data collection app – Depot, and then redirected to the landing page. Fifth, MAdLife stores the *post-click* data into another table in our database. Finally, MAdLife stops all launched activities after the post-click data is collected. A timeout is set to stop the data collection when no ad is loaded or rendered.

We designed and implemented MAdLife on top of an Android emulator – Genymotion[6] 2.11. We did not select the AOSP emulators and those provided by Android Studio, because apps running in these emulator can receive only test ads for the AdMob SDK, which is the most widely seen ad SDK on Android. Instead, we equipped our testbed with Android 7.1 (API level 25) on Genymotion. After installing Play Store, we set the "Parental Controls" setting to the most restrictive level[7]. We took this step to ensure that we do not reach an age-restricted Play Store page via clicking the ads. We will show later in Section 4.3.3 that age-restricted ads cannot be avoided. Also, we enabled the ARM translator to run ARM apps on an x86 machine.

In order to collect the pre-click data, we modified the Android WebView (20 LOC in Java) to intercept a WebView's network traffic. This allowed us to determine if WebView is used to communicate

[5]https://github.com/dtmilano/AndroidViewClient
[6]https://www.genymotion.com
[7]"Apps & games": Everyone, "Movies": G, "TV": C, and restrictions on: "Books" and "Music".

Table 1: Our collected datasets

Pre-click Data		package name, ad size, ad screenshot, pre-click URLs, pre-click time
Post-click Data	Browser	screenshot of the landing page, HTML source of the landing page, URL redirect chain, post-click time
	Play Store	screenshot of the landing page, maturity rating

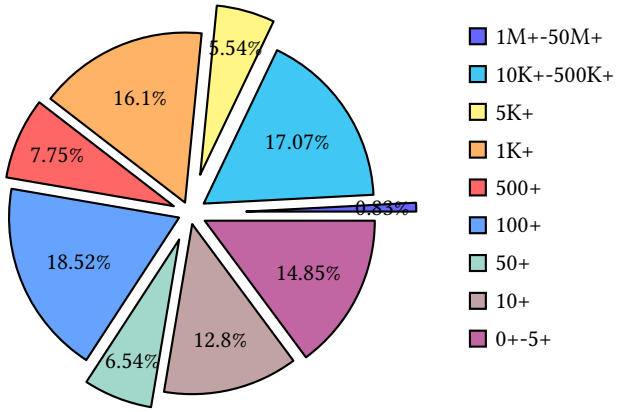

Figure 2: Distribution by app downloads

with a known ad host. After an ad is returned from a remote host, MAdLife saves the ad's screenshot and logs all pre-click URLs when several methods[8] related to ad rendering are called.

In order to collect the post-click data, we replaced each ad navigation URL with a custom URL scheme (i.e., MAdLife://) to direct the navigation to Depot, instead of the default mobile web browser. MAdLife generates an ad click to let the app switch to Depot or Play Store for post-click data collection. In case of switching to Depot, the app will take a screenshot of the landing page, save its HTML source, and records the redirects if there are any. However, it cannot directly identify which app initiates the ad click. To solve this problem, we link the pre-click data and post-click data based on their timestamps. In the case of switching to Play Store, MAdLife will take a screenshot of the Play Store page, and log the advertised app's maturity rating (e.g., Everyone, Teen, Mature 17+).

MAdLife also handles special cases where some ads require users to click on a control button or require more than one click to trigger a redirection. In particular, almost all full-screen interstitial ads require a click on a control button (e.g., "INSTALL", "Visit Site", "Learn More", and "Click Now"). Further, a few banner ads require to click twice, first to display a control button, and second to trigger the redirection. Therefore, MAdLife calls AndroidViewClient's `dump()` to discover the button with keywords, and then programmatically clicks such ads. The record for an ad click consists of two parts, as shown in Table 1.

[8]Methods include `loadUrl()`, `didFinishNavigation()`, `onTouchEvent()`, `didFinishLoad()`, `didStopLoading()`, `shouldIgnoreNavigation()`, `shouldInterceptRequest()`, and `loadDataWithBaseUrl()`.

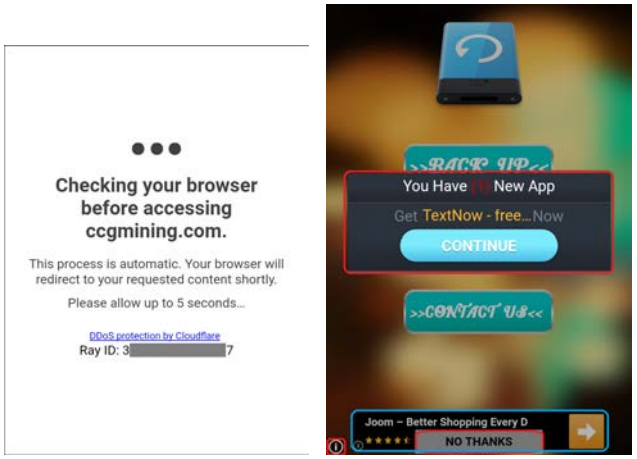
3.2 App Selection

Initially, we crawled 143K free Play Store apps in December 2016 and March 2017. Due to the fact that not all of these apps have ads, it is not necessary to analyze the entire app dataset. Additionally, we were not able to analyze all of them due to our limited computing power. Thus, we decided to narrow down our analysis space by applying an app selection procedure. Also, it is not practical to analyze all ads displayed within one app, which requires complex UI automation. Given that the subsequent requests are similar to their first ad-related HTTP request for 94.7% of the top 3K ad-supported free apps [36], we focused on the apps that display ads in their first activities.

First, we excluded any apps whose first activities do not contain a WebView, with AndroidViewClient. We also removed apps with multiple WebViews in the first activities, because it cannot distinguish which WebView is clicked for data generation. As a result, 29.3K apps were kept.

Second, we further excluded apps that do not communicate with a known ad domain. In particular, we constructed a list of 1,183 known ad domains[9]. Only 11.8K apps were observed to communicate with one of the domains within 15 seconds. We set this 15-second threshold, since "most apps make the first ad request during launch time", as observed in [36]. However, we discovered that around 50% of the 11.8K apps did not display an ad in their first activity. It might be possible that those requests in the first activities were sent for tracking purposes, and the ads might be shown in other activities.

Last, we ruled out apps that do not exhibit any changes in their first activity after the ads are clicked, because users will normally be redirected to either a landing page or the Play Store app after an ad click. We finally retained 5.7K apps. Moreover, we tried the method in [19] to identify ads by using WebView sizes. However, we found that this method may not be robust because we identified more than 300 different WebView sizes in the 11.8K apps' first activities. For example, 320x50 is a standard CSS size for mobile ads, but we also observed ad sizes such as 320x49 and 320x51.



The selected 5.7K apps, developed by over 2.5K developers, exhibit high diversity, in terms of both app categories[10] and number of app downloads (Figure 2). According to [3, 4, 44], we believe that our app dataset is unbiased.

3.3 Ad Collection

We deployed MAdLife in two locations in the United States and one location in Canada between mid January and late February in 2018. According to [36], even though the subsequent requests are similar to their first ad request, ads returned by similar requests can be different. Therefore, in order to make sure our ad collection was unbiased, we crawled ads for each app in 10 runs at a time, of which each takes about 32-45 seconds to complete. It is worth pointing out that, MAdLife is more efficient, as it takes at least 2 minutes for other frameworks [15, 37, 39] to complete. At the end, we collected nearly 48GB of data, representing over 84K ads.

[9]https://adaway.org/hosts.txt, https://filters.adtidy.org/windows/filters/11.txt?id=11

[10]The apps are in 47 categories, including one in "Dating", four in "Casino", and over 300 in "Books & References", "Education", "Entertainment", "Lifestyle", "Music & Audio", "Personalization", and "Tools".

(a) Landing page redirect (b) Overlapped red and blue ads

Figure 3: Special cases encountered during our ad collection

During the ad collection phase, we encountered a great number of special cases (e.g., "incapable ad loading", and "improper ad rendering"). Additionally, we encountered two special situations. First, an ad may have more than one landing page due to *landing page redirect*, as shown in Figure 3(a). Such a redirection would occur after the initial landing page is loaded in Depot. As a result, MAdLife could collect two post-click records for that ad, but in such cases, we retain only the final landing page as the post-click record.

Second, the pre-click data we collected may sometimes come from different sources. Overlapped ads, a kind of ad fraud behavior in [32], may be the cause. For example, as shown in Figure 3(b), a sample app may satisfy all the criteria we define in Section 3.2. It contains a full-screen ad WebView (red) and another WebView (blue) which is covered by the top ad WebView. The pre-click data we collected from this app could contain ad traffic from the top ad WebView as well as background traffic from the blue WebView. We are not able to distinguish the exact WebView URLs from all the labeled network traffic in the pre-click data. It is a limitation of our framework. Therefore, we only used pre-click URLs for identifying the communications with one of the ad domains.

4 EVALUATION

In this section, we talk about how to preprocess our collected initial data, then analyze the security issues in mobile advertising, and finally study new threats related to advertisers.

4.1 Ad Dataset

Our pre-click data matched 133 rules of 97 ad networks in the list of ad-related domains. For example, Leadbolt uses four different domains (i.e., *leadbolt.net*, *leadboltads.net*, *leadboltmobile.net*, and *leadboltapps.net*). The matched ads in our pre-click data are in 103 distinct sizes. Meanwhile, we observed Google's ad domains (i.e., *admob.com*, and *doubleclick.net*) in over 90% of all ads. As for our post-click data, we got 58,876 unique redirect chains, which totaled 203,783 unique URLs. Excluding URLs from well-known domains (e.g., *doubleclick.net*, *google.com*, *facebook.com*, *amazon.com*, and *yahoo.com*), we still have 56,914 URLs left for our malvertising analysis (Section 4.2.2). The landing pages collected in Depot belong to nearly 3.4K distinct advertisers.

In order to conduct further analysis, we matched both pre- and post-click data. In [15], the authors used a fixed time window to group all data generated by each Android app. However, we could not apply a fixed time window, since the time of each ad collection varied. Therefore, we devised a heuristic strategy to match pre-click ads and their post-click landing pages. For the pre-click data of a particular ad, its post-click data should be generated within 45 seconds in our data collection process. Therefore, we gradually increased the window size from 32 to 45 seconds until a match is found. Finally, we got over 83K matched ads after linking the pre- and post-click data. In particular, 25,764 ads landed at Play Store, and 57,880 ads ended up with Depot.

4.2 Click Fraud & Malvertising

Here we revisited the two prominent ad threats. After revealing their own trends, we further explore their interconnection.

4.2.1 *Click Fraud.*

Identifying click fraud is more or less related to detecting fraudulent app developers and their apps. Ad networks provide their own WebView-based AdView. In our settings, if an app automatically clicks an ad right after the app starts, the foreground running view may have already been switched to Depot before MAdLife calls AndroidViewClient's `dump()` to log the pre-click data. MAdLife would take a screenshot of the landing page as usual. However, MAdLife may also accidentally record the landing page in both the pre- and post-click data of an ad. Therefore, we took both situations into account: 1) post-click data from the unmatched collection, where we found 356 apps from 575 cases; and 2) pre-click data from the matched dataset, whose screenshots have the same resolution size as Depot, and where we got 38 apps from 132 cases. Both situations totaled 372 unique apps. We run our test with these samples at a slower speed in order to properly trigger click fraud. Still, 81 apps fell into one of the above situations. We could run such tests recursively, until their click-fraud behaviors were confirmed. But after our manual inspection we found 37 click-fraud apps. These click-fraud apps experienced more than 660K total downloads, and two of them obtained over 100K downloads each.

According to Table 2, we saw that click fraud is still not a well-solved problem. Surprisingly, one of the seven fraudulent app developers owns 30 out of the 37 apps. After checking with VirusTotal, we obtained three benign apps within them. We further looked into their network traffic by running our framework again. Our test showed that all samples have only three origins, and two of the three sources are fed by the apps' local files, including those 30 apps.

4.2.2 *Malvertising.*

We used VirusTotal to analyze the 56,914 URLs to determine if the associated ads are malicious or not. Specifically, we got 1,127 positive URL cases, in which 248 were flagged by at least three scanners. We call these cases *malicious* URLs. These 248 URLs belonged to 65 unique domains, and also resulted in 199 redirect

Table 2: MAdFraud [15] vs. MAdLife (click fraud)

	MAdFraud	MAdLife
# Samples	130K from third-party markets + 35K malware	143K from Play Store
# Positive Cases	13 from third-party markets + 3 from Play Store + 6 malware	37 from Play Store

Table 3: Rastogi et al. [39] vs. MAdLife (malvertising)

	[39] (US & CN)	MAdLife (US & CA)
# Samples	600K from 5 markets	5.7K from Play Store
# Collected Links	1M (US)+415K (CN)	203.7K (US & CA)
# Malicious URLs	948 (US)+1,475 (CN)	248 (US & CA)
# Unique Domains	64 (US)+139 (CN)	65 (US & CA)

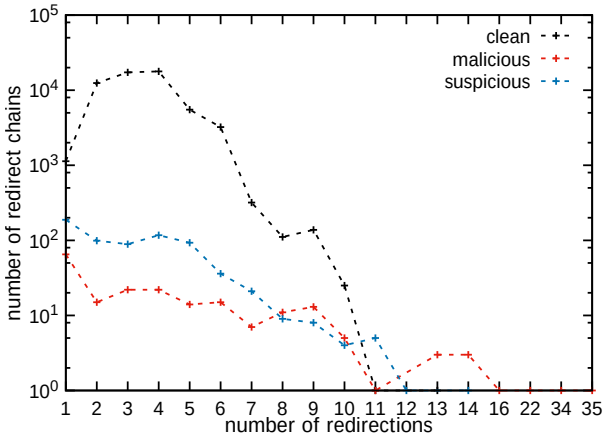


Figure 4: Statistics about different types of redirect chains

chains. The rest of those 1,127 URLs are flagged by one or two scanners. We call them *suspicious* URLs. They came from 147 unique domains, and resulted in the other 669 redirect chains[11]. Therefore, 1.49% of the 57,880 ads were from malicious or suspicious redirect chains. In Table 3, comparing with the findings from [39] in 2016, we found relatively more malvertising domains. However, we analyzed less apps in our experiment and got less links crawled from mobile ads. Therefore, we believe that more attackers are getting into this battlefield, and the situation related to malvertising is becoming worse.

Afterwards, we looked into the results from four aspects. First, we made an observation similar to the ones in [31, 39] that, longer redirect chains are more likely to be malicious. It is even more evident with our dataset. For the three kinds of redirect chains, we plot their relations between number and length in Figure 4. Accordingly, while only two cases with all benign URLs have more than 10 hops, the length of a malicious chain can even reach 35 redirections.

Second, only 32.16% of the malicious, and 64.87% of the suspicious redirect chains had non-blank landing pages. Moreover, two of the

[11] Among these 879 links flagged by less than three scanners, we excluded those URLs appeared in the previously mentioned 199 redirect chains.

Table 4: Malvertising traffic from the click-fraud apps

	Malicious	Suspicious
# Post-click	199	669
# Pre-click	187	580
# Unmatched Post-click	12	89
# Matched Pre-click	11	22
Percentage	11.56%	16.59%
Overall Percentage	15.44%	

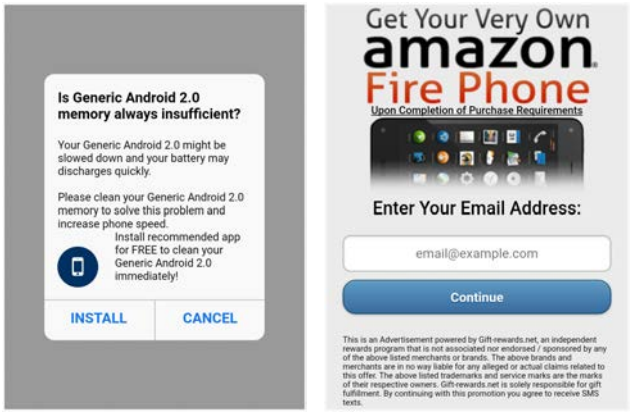
locations where we collected ads used the Palo Alto Firewall[12], which blocked 26 ad clicks. 14 of these 26 problematic cases are malicious, and 11 have no redirections. During our ad collection process, no drive-by-download case was encountered.

Third, we discovered 92 from the 199 malicious, and 166 advertisers from the 669 suspicious redirect chains, respectively. There were 236 unique advertisers in total.

Last, malicious and suspicious redirect chains came from 134 and 263 apps, respectively. Also, 74 of the malicious , and 133 of the suspicious apps were detected by VirusTotal. We found that, 168 unique apps getting at least one positive from VirusTotal contributed to malvertising.

4.2.3 *Correlation.*

We found statistical correlations between click fraud and malvertising. According to Table 4, after giving equal opportunities to run target apps, we found that 134 malvertising cases (15.44%) came from the click-fraud apps, including 11.56% of the malicious and 16.59% of the suspicious redirect chains, respectively. Furthermore, as over 730 ads are generated by the 37 click-fraud apps in the dataset, these apps have a 18.36% chance to initiate malvertising. Also, since the other 734 malvertising cases came from the rest 57,150 ads, the non click-fraud apps merely had a 1.28% chance to initiate malvertising. As a result, a user of a click-fraud app, is 14.34x more likely to be shown a malicious ad compared to a user of a legitimate app.



Why are the two ad-related security issues more likely correlated? A mobile user needs to interact with an HTML ad through the app's UI. It enables attackers to generate fraudulent ad clicks automatically, which is difficult to detect for the restricted JavaScript running in the app's WebView. Such attackers may usually select ad networks with poor SDK implementations and vulnerable scrutiny processes for malvertising. Therefore, ad networks should take on more responsibility to mitigate such risks, as they are responsible for strengthening their SDKs and scrutinizing malvertising instances.

4.2.4 *Scam Cases.*

Although scam cases have been well studied [39], we found new and interesting observations by looking into the HTML files of our scam cases. Figure 5(a) illustrates the first case, an ad for a fake anti-virus app. No matter whether users click "Install" or "Cancel", the same malicious link will be triggered.It reveals that, ad viewers are more likely to enter a malicious website with such a trick.

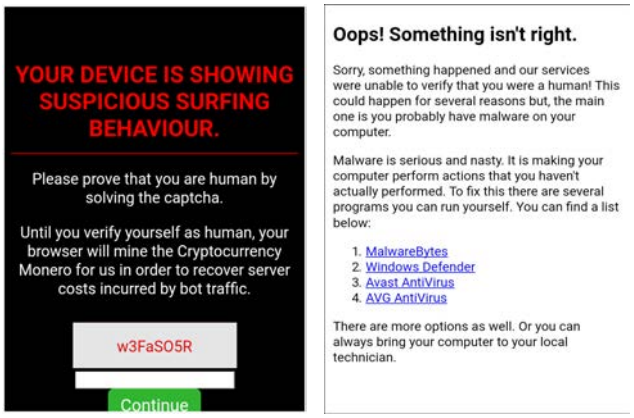


Figure 5(b) shows an unexpected prize and lottery scam, which is alleged to offer a free phone. In our dataset, we found two ads

[12] http://www.paloalto-firewalls.com

(a) Ad with deceptive download (b) Ad with fraudulent reward

Figure 5: Scam examples

(a) Drive-by cryptomining (b) Deceptive cryptojacking

Figure 6: Cryptojacking examples

with the same image. However, these screenshots were loaded from two different malicious domains (i.e., *primerewardz.com* and *premiumrewardsusa.com*), with no redirections. Users should refrain from surrendering their private information, as some scams ask for emails to get a fraudulent reward.

```
<script>
  ...
  var miner = new CoinHive.User("...", "tt", {throttle:0});
  miner.start(CoinHive.FORCE_EXCLUSIVE_TAB)
</script>
```

      .jsecoin.com/load/.../0/0/"></script>
<iframe src="https://claimers.io/a-mining?address=..." style="
      visibility: hidden;"></iframe>
```

Listing 2: Two cryptomining scripts found in Figure 6b

4.2.5 *Cryptojacking Cases.*

Here we show two cryptojacking instances, in which attackers secretly mine cryptocurrency with victims' computing power. While we discovered over 25 obvious drive-by cryptomining cases, as seen in Figure 6(a), we also found 7 subtle examples like that in Figure 6(b).

The former case, with up to 9 redirections, was not from a single domain, but 13 different ad domains[13]. However, all these redirections finished at one of the two websites (i.e., *rcyclmnr.com*, and *rcyclmnrepv.com*). Code 1 shows that the COINHIVE[14] script was used in 6(a). We submitted the embedded JavaScript file[15] to VirusTotal, where 33 out of 58 scanners detected this script. We later found out that our discovery was confirmed by both Symantec [30] and Malwarebytes [40].

The latter case includes at most 2 redirections, originates from the same domain (i.e., *ezanga.com*), and ends up with *dropped-click.com*. A closer inspection revealed two interesting tactics used by these developers: 1) the website provided benign links for users to click; and 2) the website used three different cryptomining scripts. According to the HTML files, the other two cases were undergoing landing page redirects; therefore, we had no further information for those webpages. One example was with *coinhive*, two instances were with *jsecoin.com*, and another two cases were with *claimers.io*. See Code 2. To the best of our knowledge, we were the first to find these samples, while no scanner of VirusTotal flagged the *claimers.io* domain as a potential risk yet.

Furthermore, we looked into the issues from two aspects. First, we examined the 49 apps where these cryptojacking sample were found. Surprisingly, 21 of the sample apps were benign after scanning with VirusTotal. Thus, the malvertising cases found in these apps were solely due to untrusted ad networks.

Second, fraudulent app developers contributed to the issues as well. Specifically, the aforementioned developer, who owned 30 click-fraud apps, has raised our attention again due to the 6 apps among our revisited samples. Our first impression of the developer's apps is about click fraud: after launching any of these apps, users would sometimes be automatically redirected to a landing page showing arbitrary content (e.g., automotive sales, lottery rewards, and pornographic chat rooms). We found that a local file, named EXIT.HTML, was called in each of the 6 apps. Although the file is totally clean under VirusTotal, it calls the `doStartAppClick()` method at every app start, to automatically trigger a call to visit an ad URL[16]. Ironically, this URL also seemed benign under VirusTotal, but it could serve as an entry point for redirecting users to different sites, either dirty or clean. We loaded the URL in a web browser, and were redirected to a couple of automatic malware downloading pages[17]. At the time of this writing, these apps were still listed on

[13] Domains of the first link in a redirect chain include: *leadbolt.net*, *tc-clicks.com*, *apperol.com*, *shootmedia-hk.com*, *despiteracy.com*, *leadzuaf.com*, *spxtraff.com*, *smartoffer.site*, *bestperforming.site*, *mobcampaign.site*, *tracknet.site*, *topcampaign.site*, and *ads.gold*

[14] https://coinhive.com

[15] Its VirusTotal SHA-256 is 5d514880ad502302dd4bf0ef8da5d38356385d1c43689f6739f6771ed7a4ef73

[16] The URL, *http://pub.reacheffect.com/ra/878/1042/p/m/%7Bcampaign_id%7 D/CA*, was taken down in April, 2018

[17] Their VirusTotal SHA-256's are 0c6e40eb1c3b00de1c72f22dec5cffddc3df66672360f79d54d9922c018f4aa6 and 1654cf25365332198c84f7e1e17b237abf0447a97e18800cc349e91cc2eb9a71

Play Store, although on January 15th, 2018 the developer switched to other ad networks, and then finally disabled the auto click feature.

To sum up, the tricks of fraudulent app developers and of untrusted ad networks were continuously evolving. It is not limited to only deceiving users but also developing new techniques to hijack their computing power.

4.3 Other Threats

Besides the previous two well-known threats, we have also studied two new types of ad threats on a large scale: 1) malicious external JavaScript on landing pages; and 2) inappropriate ads.

4.3.1 *Data Preparation.*

In order to facilitate our analysis, we removed duplicates from both landing pages and screenshots. First, as the HTML files of the same website we crawled might contain different metadata, we were not able to use the traditional cryptographic hashing algorithm to classify websites. Therefore, we used the CETD algorithm [45] to extract text content and anchored links from webpages. We finally retained 12,036 distinct documents.

Second, the same website with a countdown timer may be photo-taken differently in two ad instances. Therefore, in order to retain useful content, we filtered out pictures with pure white or black background. The file size of such images is usually less than 15KB in size. Afterwards, we consecutively employed three image fingerprinting methods[18] (i.e., wavelet hashing, perception hashing, and difference hashing), which generate similar output hashes between two cognate input files. The process produced 6,337 unique images.

4.3.2 *Malicious External JavaScript Code.*

Advertisers may embed JavaScript code from their own host or a third-party host in their landing pages. Some external scripts could be malicious. However, VirusTotal scanners would report the results for the only submitted URL, not including its embedded external scripts. Especially, it is very hard for VirusTotal scanners to detect a known malicious JavaScript snippet after code obfuscation. As a result, this approach would miss malicious content presented to users on a landing page. Therefore, we further leveraged VirusTotal to scan all external scripts of each landing page.

After extracting 146K unique external script URLs and distilling 115K URLs starting with HTTP(S) from almost 58K HTML files, we found only 243 positively flagged URLs (0.21%) with VirusTotal. Surprisingly, these scripts were used in more than 5,880 landing pages (i.e., 10.16% of the 57,880 HTML file). Among these 5,880 landing pages, we discovered 53 malvertising cases and 5,827 benign landing pages. Lastly, after running the CETD algorithm, we got 1,384 unique documents (i.e., 11.5% of the 12,036 distinct documents).

External JavaScript code can be loaded either from the same domain or from third-party domains. For example, we witnessed that a "benign" landing page consisted of more than 41 positively flagged URLs for the advertiser's own JavaScript code. That is to say, illicit advertisers may use such tricks to avoid traditional scrutiny techniques. Third-party JavaScript code is usually dynamically loaded; therefore, it may be subject to change on the third-party side. In our dataset, we discovered that a few snippets from Google-registered domains (e.g., gstatic.com, and ytimg.com) were also positively flagged. Table 5 shows the statistics of positively flagged URLs.

Table 5: Top 10 domains with positively flagged URLs

# Occurrences	# Unique URLs	Domain
409	6	gstatic.com
287	4	ytimg.com
84	1	adroll.com
64	1	engagio.com
50	1	parastorage.com
44	1	bootstrapcdn.com
18	1	bkrtx.com
14	1	googleapis.com
13	1	roberthalfgcs.com
10	1	ucarecdn.com

4.3.3 *Ad Inappropriateness.*

The issue of inappropriate ads on the Internet has existed for a long time but has not yet been fully explored. Legislatures in the United States have created various acts (e.g., COPPA [12], CIPA [11]) to safeguard children online, including from ad views/clicks. In addition, well-known ad networks [20, 23–25, 46] also establish content policies for advertisers. But, self regulation is not enough. Here we took the first step to analyze and classify inappropriate ad content on a large scale.

We used the Google Cloud Natural Language API to get known entities and content categories. After identifying documents with the same known entities, we reduced duplicate files with a list of the same entities from 12,036 to 7,067. These documents contain all 27 level-1 categories[19]. We selected a few sensitive categories (i.e., Adult, and Sensitive Subjects) for our analysis. Afterwards, we used known entities to recursively select other sensitive categories.

Determining the inappropriateness of an ad could be very subjective. Therefore, we adhered to the following guidelines based on ad network policies and public opinion to identify inappropriate ads. First, AdWords does not allow "collecting personal information from children under 13 or targeting interest content to children under the age of 13" [25]. Thus, we listed all ads related to age-restricted content. Second, well-known ad networks [17, 18, 22] announced their plan of blocking cryptocurrency-related ads, one after another, as the content is often associated with deception and fraud [38]. Thereafter, we labeled all related ads. Third, due to Russian agents-used political ads and the Cambridge Analytica scandal, Facebook received criticism and modified its policy for political ads [5]. Therefore, we put all political ads into the "public concerns" category. Accordingly, we classified inappropriate ads into two severity levels:

Policy Compliance: adult (e.g., pornography), criminal record, cryptocurrency, drug (e.g., marijuana), prize (e.g., fake awards), security (e.g., fake antivirus), store (e.g., age-restricted product)

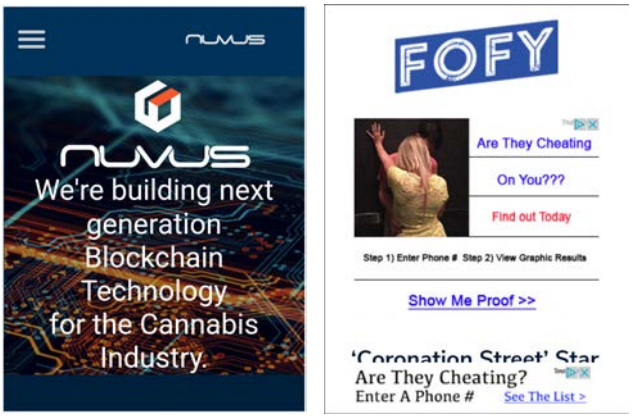
Public Concerns: age (e.g., tattoo), extramarital affair (e.g., Ashley Madison), gambling (e.g., casino), health (e.g., plastic surgery), political campaign (e.g., voting), privacy (e.g., phone number)

The result is depicted in Table 6. In summary, 345 out of 7,067 unique ad landing pages are in the "Policy Compliance" category,

[18] https://github.com/JohannesBuchner/imagehash

[19] https://cloud.google.com/natural-language/docs/categories

Table 6: Inappropriate ads and their categories



Ad Category			Unique Ads (#)	Full Dataset (%)
Policy Compliance	345 & 7.9%	adult	14	0.33%
		criminal record	7	1.44%
		cryptocurrency	146	63.49%
		drug	3	0.17%
		prize	46	2.43%
		security	6	0.33%
		store	123	31.81%
Public Concerns	24 & 0.266%	age	2	1.30%
		extramarital affair	3	0.26%
		gambling	5	20.78%
		health	3	5.19%
		political campaign	8	33.12%
		privacy	3	31.82%

and 24 are in the "Public Concerns" category; 4,577 (7.9%) out of 57,880 ad landing impressions are in the "Policy Compliance" category, and 154 (0.26%) are in the "Public Concerns" category.

We also leveraged the Google Vision API on our screenshots to detect offensive contents and find web entities with similar images. We found the API performed quite well in detecting pornography. The API was also good at finding similar images that contain very few characters. For example, a prize wheel image with barely any characters was flagged as potentially dangerous by the API, because similar images were found at some malicious websites. However, it was difficult to accurately detect any other kinds of offensive ad content using the Vision API in general. Thus, we used only the Natural Language API in our analysis.

4.3.4 Case Studies.
Unlike click fraud and malvertising which affect all users, inappropriate ads may merely influence a specific subset of population. Here we exemplify two cases to show the aggravating circumstances, as depicted in Figure 7. First, along with their price volatility, cryptocurrencies attract attention from people all over the world. As a result, the entire industry suddenly booms. During our ad collection, we collected mobile ads of 39 different cryptocurrencies and of 27 cryptocurrency-related reports from 15 online media. One of such ads, shown in Figure 7(a), publicized its cryptocurrency for the cannabis industry. As we learned from the Internet, marijuana is not legalized at the federal level in the United States and in Canada [48] at the time of our experiment. Such ads should thus be prohibited.

Second, it is even worse that *nested ads* can bypass all restrictions. Figure 7(b) illustrates the landing page of a blog website, where another ad is nested. Although ad networks can scrutinize matches between ads and their landing pages, their arms may not be able to reach at nested ads. To the best of our knowledge, we did not find any policies to directly regulate such a situation. As a result, inappropriate ad content may be broadcast within landing pages subscribed to well-known ad networks. Moreover, we considered it as an adware, because for more than 30 FOFY ads we collected, only ads were shown within the screenshots but their real content displayed underneath. Accordingly, the situation of inappropriate ads is getting worse.

(a) Controversial topics in an ad (b) Ads within an adware

Figure 7: Examples for ad inappropriateness

4.3.5 Takeaways.
Our studies revealed that embedded external scripts in landing pages should also be examined for two reasons: 1) illicit advertisers may use this approach to escape from ad networks' security lookups; and 2) third-party JavaScript links may change their backend code for their own interests. Therefore, rather than only checking inappropriate ad content, ad networks should also scrutinize the JavaScript files embedded by advertisers.

Last but not the least, after Google blocked cryptocurrency ads in June 2018 [18], we utilized MAdLife again to crawl ads in the next month. We did not find any cryptocurrency ad in this crawl. In reverse, after banning cryptocurrency ads for a few months, Facebook gave Coinbase a privileged position to allow its crypto-related ads again in July 2018 [29]. Ad policies thus may be more inconsistent than what we expected. More importantly, nested ads could be used to bypass new content-based regulations.

5 DISCUSSION

Ethics. Our ad collection experiment may inflate advertisers' budgets, like other studies [7, 10, 31, 36, 39, 50]. However, we tried to reduce the impact on the real ad ecosystem in our research. On one hand, MAdLife clicked less than 15 ads within each app and visited the landing page of each advertiser for less than 25 times on average. Therefore, each individual app developer's income and each individual advertiser's cost would not be significantly affected. On the other hand, clicking the ads is necessary for studying these ad threats. Although our research might have inflated the budgets of some advertisers, our findings can benefit the whole ad ecosystem in the long run from a broader perspective. We believe that a better ad ecosystem will be more cost-efficient for advertisers. Moreover, we designed our experiment in a way that MAdLife's artificial behaviors can be easily detected by ad networks (e.g., 10 successive clicks within one app and from the same IP addresses). A responsible ad network shall be able to detect them as invalid clicks, and thus invalidate any charges incurred to advertisers.

Limitations. First, we run the experiment on API 25 with Genymotion 2.11.0. Nowadays, Android 8.0 (API level 26) has enabled

safe browsing on WebView. If ad networks adapt the feature, the malvertising issues could be somewhat mitigated. Second, our pre-click data may contain URLs other than those we expect, since we cannot detect WebViews underneath a full-screen WebView and separate each WebView's logcat traffic. Third, to the best of our knowledge, the Google Cloud APIs are among the best APIs available on the market. We also have tested APIs provided from two other services, which did not outperform Google's APIs. However, we cannot measure the accuracy of Google's APIs as we are unable to manually build ground truth for thousands of images and webpages. Last, Google asks that, ads displayed in family apps are expected to be consistent with their maturity ratings [26]. In [10], authors talk about this issue. However, whether the parental control settings are on or off, children are able to access all installed apps on a device. Therefore, our studies only focus on inappropriate ads in general instead of with age-restricted apps.

6 RELATED WORK

Ad Collection. Due to the fact that ad content is dynamically generated, various methodologies are used to crawl ads. Collecting online ads is relatively easy when not in mobile settings. In online advertising, researchers can either run scripts with their add-ons [7, 31] or build a Selenium-based crawler [50], with Alexa's top-ranked website lists. Also, the researchers can either intercept HTTP traffic [31, 50] or only harvest ad-related visual elements [7]. Nevertheless, ads' life spans can be easily deduced without triggering ad clicks. Whereas, in mobile advertising, researchers are still able to analyze HTTP traffic [15, 36, 39], but it's more difficult to track ads' lifespans. For example, since no user interaction (except for click fraud) is involved in [15], their studies stop at ad loading/rendering. Besides, both [36] and [39] consider every touch event as a starting point.

Click Fraud. Ad fraud can be conducted with [2, 32] or without [15, 35] human intervention. Likewise, researchers reveal that such attacks in web browsers [2, 35] are technically more advanced than with handheld devices [15, 32]. While [35] depicts two clickbot families, [2] traces from an IP back to the conspiracy with DNS hijacking. In mobile advertising, the term can be subdivided into display fraud [32] and click fraud [15]. Other than these, researchers in [51] detected duplicate clicks in pay-per-click streams with two bloom filter related algorithms.

Malvertising. Malvertising lurks at the pre-click phase, but is exposed at the post-click phase. Researchers, who collect ads in online advertising, focus on either ad networks [50] or redirect chains [31]. Likewise, such research works in mobile advertising result in the exploration of either ad networks [27, 52] or redirect chains [39]. Because of ad syndication, we believe that the use of redirect chains would be more beneficial. With the help of studies like [33], authorities will be able to take down malvertising networks without a case-by-case investigation.

Dangerous JavaScript Detection. The studies of detecting dangerous JavaScript code are numerous. JSAND [14] conducts classification based on static and dynamic features, and instruments JavaScript runtime environments to detect the execution of malicious scripts. Prophiler [8] statically analyze features of the HTML page, of the embedded JavaScript code, and of the associated URL, and examines malicious content on massive webpages with obfuscated JavaScript. Similarly, ZOZZLE [16] leverages features associated with JavaScript context to detect unobfuscated exploits. As for code obfuscation, Sharif et al. [42] revealed that conditional code obfuscation could be used to hinder malware analysis.

Content Analysis. Nowadays, contextual advertising is used to target users. [49] describes a feature-based keyword extraction system for online contextual advertising. In order to analyze web content, [34] uses the Alchemy API to label all crawled webpages, and categorizes them into different topic categories. Likewise, we use Google Cloud's Natural Language API to analyze our dataset, besides using the CETD algorithm [45] to only encompass web content and anchored links. Similar to finding resolved ad URLs, content scraping in the mobile settings is not so easy as that in a browser. Therefore, both [32] and [37] capture third-party apps' page contents on Windows-based mobile platforms. While the former extracts page information with the UI extraction channel, the latter instruments app binaries to insert custom logging code. Unlike our work that evaluates ad inappropriateness in general, [10] studies whether ads are consistent with host apps' maturity ratings on a small scale that is below 4K ads. Also, their "topic classification" part is not well elaborated; therefore, we are thus unable to make any technical comparison.

7 CONCLUSION

While implemented on top of existing web technologies, mobile in-app ads face similar threats in different forms. In this paper, we implemented MAdLife– a data collection framework on Android to record all necessary data generated within each ad's entire lifespan. By using MAdLife, we explored the abusive practices, including click fraud, malvertising, and other threats on landing pages, with 84K ads. We discovered 37 click-fraud apps and over 860 malvertising redirect chains. More importantly, we revealed that a user of a click-fraud app is 14.34x more likely to be shown with a malicious ad comparing with a user of a legitimate app. Further, we revealed that 250 widely used JavaScript snippets are actually harmful to users. These snippets were used on over 10% of our collected landing pages. Lastly, we identified that 8% ads are inappropriate, either not complying with ad policies or showing controversial content. We suggest that ad networks should, and only they can, take more effective measures to protect mobile users and themselves from the above ad threats.

ABSTRACT

Modeling the behaviors of drug-target-disease interactions is crucial in the early stage of drug discovery and holds great promise for precision medicine and personalized treatments. The growing availability of new types of data on the internet brings great opportunity of learning a more comprehensive relationship among drugs, targets, and diseases. However, existing methods often consider drug-target interactions or drug-disease interactions separately, which ignores the dependencies among these three entities. Also, many of them cannot directly incorporate rich heterogeneous information from diverse sources.

In this work, we investigate the utility of tensor factorization to model the relationships of drug-target-disease, specifically leveraging different types of online data. Our motivation is two-fold. First, in human metabolic systems, many drugs interact with protein targets in cells to modulate target activities, which in turn alter biological pathways to promote healthy functions and to treat diseases. Instead of binary relationships of <drug, disease> or <drug, target>, a tighter triple relationships <drug, target, disease> should be exploited to better understand drug mechanism of actions (MoAs). Second, medical data could be collected from different sources (i.e., drug's chemical structure, target's sequence, or expression measurements). Therefore, effectively exploiting the complementarity among multiple sources is of great importance. Our method elegantly explores a <drug, target, disease> tensor together with complementarity among different data sources, thus improves prediction accuracy. We achieve this goal by formulating the problem into a coupled tensor-matrix factorization problem and directly optimize it on the nonlinear manifold. Experimental results on real-world datasets show that the proposed model outperforms several competitive methods. Our model opens up opportunities to use large Web data to predict drugs' MoAs in pharmacological studies.

1 INTRODUCTION

Targeted therapies and personalized treatments are the most promising approaches to treat complex human diseases such as cancer. Clear understanding of drugs' mechanism of actions (MoAs) is a critical step in drug discovery [21]. Traditional high-throughput screening methods are desirable to identify a new drug against a chosen target (most time a druggable protein) for a special disease. However, the process has been costly and lengthy. A conservative estimate is that it takes $ 2.87 billion and more than 10 years to bring a new drug into market [26]. On the other hand, statistical and machine learning models provide an alternative way to accelerate the process of understanding drugs' MoAs by mining bioinformatics, cheminformatics, and Web data sources [3, 4, 7, 16, 25, 32, 37]. Learning tasks have been proposed from different angles, such as exploring drug behaviors [15, 38, 46], assessing target activities [19, 34, 37], and understanding disease models [33, 44, 47]. Two of the most prominent formulations among these recent advancements are the drug-target [16] prediction and drug-disease prediction, also known as drug repositioning [25]. In these two tasks, researchers have attempted to collect a variety of omics data from scientific literature and online Web sources, and discover new interactions between drugs and targets/diseases through different statistical models [9, 24, 35, 46]. For example, a network-based inference method was proposed to infer new targets for known drugs by leveraging the drug-target bipartite network [13]. The method Decagon modeled drug polypharmacy side-effect via graph convolutional networks [46]. Another approach, PREDICT, integrated multiple drug-drug and disease-disease similarities to infer potential drug-disease interactions [20]. Approaches based on multiple kernel learning were developed to predict drug-target [30] or drug-disease [9] relationships, by integrating additional heterogeneous information sources.

However, despite the obvious connections, most existing work treat drug-disease and drug-target predictions as two independent tasks, which is viewed as a major shortcoming. Indeed, the therapeutic effect of drugs on a disease is through their abilities to bind and to modulate biological targets that involve the disease pathways, which in turn promote healthy function of the metabolic system and cure the disease [21]. Therefore, instead of a binary relationship such as <drug, disease> or <drug, target>, a strong

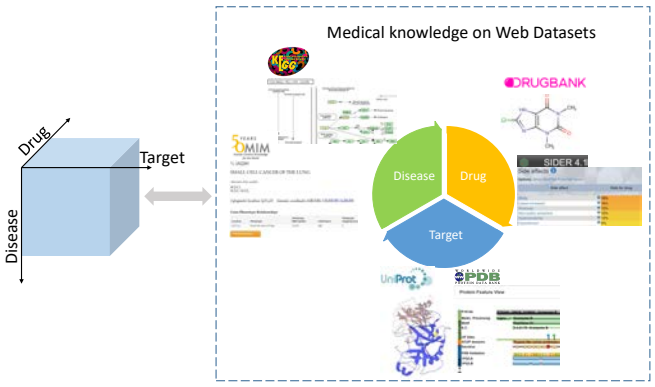

Figure 1: Illustration of DTD. Our model jointly explores the $drug \times target \times disease$ tensor along with rich existing medical knowledge on the Web.

triple relationship <drug, target, disease> should be considered to better model their interplay. In addition, the growing availability of new types of data on the web (Figure 1) brings new opportunities to learn a more comprehensive relationship among drugs, targets, and diseases [3, 4, 11, 30, 32, 45]. Incorporating such heterogeneous information can significantly improve our understanding of the underlying biological processes. For example, joint analysis of drugs' chemical structures, drugs' side-effects, and protein-protein networks can improve success rates of finding novel drug-target interactions [20, 30, 45].

In this work, we propose a tensor completion method, termed **DTD**, to model **D**rug-**T**arget-**D**isease interactions, with the help of existing data from the Web. DTD explicitly learns a third-order $drug \times target \times disease$ tensor using Tucker Decomposition [23]. In addition, to alleviate the data sparsity issue, DTD incorporates multiple auxiliary information sources of drugs, targets, and diseases. For example, in Figure 1, in addition to $drug \times target \times disease$ tensor, there are rich data on the Web describing drugs (e.g., chemical structures in DrugBank and side-effects in SIDER database), targets (e.g., protein sequence in Uniprot), and diseases (phenotype description in OMIM or KEGG). The tensor and multiple feature matrices are coupled in the "drug", "target", and "disease" mode, respectively. These feature matrices from Web sources are very useful to learn extra static information about each mode of the tensor. Fusing those datasets together can lead to better interpretations of the complex biological processes. To achieve this goal, DTD further explores the correlations among the latent matrices from the tensor and these multiple data sources via a coupled tensor-matrix factorization. This ensures that knowledge in the tensor aligns more closely with existing medical knowledge of each of the entities.

Another critical challenge is how to solve the tensor completion problem effectively. Because of the nonlinear and non-convex orthogonality constraints in the tensor Tucker model, the solutions of the popular HOSVD and HOOI Euclidean solvers are not unique, which makes it hard to couple with auxiliary information [23]. Motivated by the fast growing Riemannian optimization [1, 22, 43], we cast the coupled tensor-matrix factorization problem as a nonlinear program with the factor matrices constrained to the Grassmann manifold. Rather than a special non-uniqueness solution in Euclidean solvers, DTD obtains an equivalence class of matrices on Grassmann manifold, which leads to more meaningful subspace representations of factor matrices and can be well coupled with auxiliary information. Moreover, empirical studies have shown that nonlinear Riemannian solvers are significantly faster comparing to the Euclidean solvers [22, 43]. Our contributions are summarized as follows.

- We investigate the relationships of drug-target-disease by utilizing a tensor completion method. Integration of all these biological entities naturally leads to more meaningful interpretations of the results.
- We further explore the correlations among latent matrices from $drug \times target \times disease$ tensor and multiple data sources via a coupled tensor-matrix factorization, which ensures that the sparse tensor is supplemented using existing knowledge of the three entities.
- We directly optimize the tensor completion problem by adopting an optimization technique on Grassmann manifold, which obtains more reliable subspace representations of the tensor and can be well coupled with spectral embeddings of auxiliary information.
- We conduct extensive experiments on real-life datasets. Experimental results demonstrate DTD outperforms several state-of-the-art comparative models. It shows that DTD can effectively utilize rich information on the Web to ease the issue of sparsity.

The rest of the paper is organized as follows. Sec. 2 gives the background and task. Sec. 3 and Sec. 4 introduce DTD method in details. Sec. 5 evaluates the experimental performance. Sec. 6 provides a short review of related work. Sec. 7 concludes the paper.

2 BACKGROUND AND TASK DESCRIPTION

2.1 Tensor Algebra

In this study, we follow the notations introduced by Kolda and Bader [23]. We denote matrices by boldface uppercase letters (e.g., $\mathbf{A}$). *Tensors* are multidimensional arrays that extend the concept of matrices, and they are represented by boldface caligraphic letters (e.g., $\boldsymbol{\mathcal{X}}$). The *order* of a tensor is the number of its dimensions, also known as ways or modes. A *fiber* is a vector extracted from a tensor by fixing every index but one. A *slice* is a matrix extracted from a tensor by fixing all but two indices. Note that an N-way tensor $\boldsymbol{\mathcal{X}} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$ reduces to a vector when $N = 1$, and a matrix when $N = 2$. The $(i_1, \ldots, i_N)$-th element of $\boldsymbol{\mathcal{X}}$ is denoted as $\boldsymbol{\mathcal{X}}_{i_1,\ldots,i_N}$. *Matricization*, also known as unfolding or flattening, is the process of reordering the elements of a tensor into a matrix. The mode-n matricization of an N-way tensor $\boldsymbol{\mathcal{X}} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$ is represented as $\mathbf{X}_{(n)} \in \mathbb{R}^{I_n \times I_1 \ldots I_{n-1} \times I_{n+1} \ldots I_N}$ and is arranging the mode-n fibers of the tensor as columns of the long matrix. The *n-mode matrix product* of a tensor $\boldsymbol{\mathcal{X}} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$ with a matrix $\mathbf{U} \in \mathbb{R}^{J \times I_n}$ is denoted as $\boldsymbol{\mathcal{X}} \times_n \mathbf{U}$ with size of $I_1 \cdots \times I_{n-1} \times J \times I_{n+1} \cdots \times I_N$. We also give the definition of Tucker decomposition and coupled tensors for third-order tensors.

Definition 1. ***(Tucker Decomposition)***. *The Tucker decomposition is a form of higher-order PCA. It decomposes a tensor into a core tensor multiplied by a matrix along each mode. For a three-way tensor* $\mathcal{X} \in \mathbb{R}^{I \times J \times K}$*, its Tucker decomposition is*

$$\mathcal{X} \approx \mathcal{G} \times_1 \mathbf{A} \times_2 \mathbf{B} \times_3 \mathbf{C}$$

where $\mathbf{A} \in \mathbb{R}^{I \times R_1}$, $\mathbf{B} \in \mathbb{R}^{J \times R_2}$ *and* $\mathbf{C} \in \mathbb{R}^{K \times R_3}$ *are the factor matrices (which are usually orthogonal) and can be regarded as the principal components in each mode. The tensor* $\mathcal{G} \in \mathbb{R}^{R_1 \times R_2 \times R_3}$ *is the core tensor and captures interactions between factor matrices.*

Definition 2. ***(Coupled Tensors)***. *If a tensor shares one or more modes with other matrices or other tensors, they are called coupled tensors or coupled tensor-matrices. For example, in a recommender system, a triple relationship user* $\times$ *movie* $\times$ *review tensor and a user* $\times$ *movie rating matrix are coupled because they share user and movie modes.*

2.2 Task Description

Our aim is to infer potential drug-target-disease interactions for rational drug repositioning. We formulate the task as a tensor completion problem. To be specific, the input can be organized as a three-way *drug* $\times$ *target* $\times$ *disease* tensor $\mathcal{X}$ of size $n_1 \times n_2 \times n_3$, in which n_1, n_2, and n_3 denote the number of drugs, targets, and diseases, respectively. An entry $\mathcal{X}_{ijk} = 1$ if drug i binds to target j and treats disease k. Otherwise, the entries are set to 0. In practice, we can only observe part of the tensor $\mathcal{X}$ and this partially observed tensor is denoted as $\mathcal{T}$. Our goal is to predict the potential concurrences of <drug, target, disease>, which can be achieved by completing tensor $\mathcal{X}$ given the incomplete tensor $\mathcal{T}$.

In real-world applications, tensor $\mathcal{T}$ is often sparse with a large number of unknown entries. Recovering tensor $\mathcal{X}$ is challenging when relying only on the observed tensor $\mathcal{T}$. Fortunately, for *drug* $\times$ *target* $\times$ *disease*, there exist many additional data sources on the Web to describe drugs, targets, and diseases. For example, for most drugs, their chemical structures and side-effects can be obtained from online databases, which represent different views of drugs. Datasets regarding targets and diseases are also available online. In most cases, one can further summarize such auxiliary data as drug-drug, target-target, and disease-disease similarity/kernel matrices, which can be incorporated in the learning process. Formally, let $\mathcal{S}_A = \{\mathbf{S}_A^{(1)}, \ldots, \mathbf{S}_A^{(n_a)}\}$ denote the similarity matrices constructed from n_a views of drugs. $\mathcal{S}_B = \{\mathbf{S}_B^{(1)}, \ldots, \mathbf{S}_B^{(n_b)}\}$ and $\mathcal{S}_C = \{\mathbf{S}_C^{(1)}, \ldots, \mathbf{S}_C^{(n_c)}\}$ are defined similarly from n_b views of targets and n_c views of diseases, respectively. All of them are assumed to be symmetric and non-negative. The details of their constructions will be presented in Sec. 5. The proposed DTD framework jointly explores the main tensor $\mathcal{X}$ together with multi-view auxiliary information $\mathcal{S}_A$, $\mathcal{S}_B$ and $\mathcal{S}_C$ to predict more meaningful interactions of drug-target-disease.

3 THE DTD MODEL

In this section, we propose an effective coupled tensor-matrix factorization formulation named DTD and show how different data sources can be included in a principled way. Notations used throughout the paper are summerized in Table 1.

Table 1: Main Notation

Symbol	Description
$\mathcal{X}$, $\mathcal{T}$	Full recovery tensor and observed tensor
$\mathcal{G}$	Core tensor in Tucker model
$\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$	Drug, target, disease factor matrix
$\mathbf{L}_A^{(i)}$, $\mathbf{A}^{(i)}$	Laplacian matrix and its spectral embedding from i-th view of drug auxiliary information
$\mathbf{L}_B^{(j)}$, $\mathbf{B}^{(j)}$	Laplacian matrix and its spectral embedding from j-th view of target auxiliary information
$\mathbf{L}_C^{(k)}$, $\mathbf{C}^{(k)}$	Laplacian matrix and its spectral embedding from k-th view of disease auxiliary information

3.1 Recover the Main Tensor

To complete the tensor $\mathcal{X} \in \mathbb{R}^{n_1 \times n_2 \times n_3}$ described in Sec. 2.2, we adopt the Tucker Decomposition (Definition 1), which can be represented by the following optimization problem:

$$\min_{\mathcal{X}, \mathcal{G}, \mathbf{A}, \mathbf{B}, \mathbf{C}} \|\mathcal{X} - \mathcal{G} \times_1 \mathbf{A} \times_2 \mathbf{B} \times_3 \mathbf{C}\|_F^2 \quad s.t. \quad \mathcal{P}_\Omega(\mathcal{X}) = \mathcal{P}_\Omega(\mathcal{T}) \tag{1}$$

where $\|\cdot\|_F$ is the Frobenius norm. Recall that $\mathcal{G}$ is the core tensor; $\mathbf{A} \in \mathbb{R}^{n_1 \times r_1}$, $\mathbf{B} \in \mathbb{R}^{n_2 \times r_2}$, and $\mathbf{C} \in \mathbb{R}^{n_3 \times r_3}$ are the factor matrices with respect to the drug, target, and disease mode. Ω is the set that contains the indices of observed entities and $\mathcal{P}_\Omega(\cdot)$ keeps the entries in Ω and zeros out others [22, 41]. The equality constraint ensures that the corresponding elements of the recovering tensor $\mathcal{X}$ should match the observed elements in tensor $\mathcal{T}$.

In addition, the factor matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ are orthogonal matrices, i.e., $\mathbf{A}^T\mathbf{A} = \mathbf{B}^T\mathbf{B} = \mathbf{C}^T\mathbf{C} = \mathbf{I}$ and $\mathbf{I}$ is the identity matrix. The orthogonal constraints ensure that matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ are well defined on the so-called *Stiefel manifold* [1], which contains a set of $n \times m$ orthonormal matrices and is defined as:

$$St(m, n) = \{\mathbf{U} \in \mathbb{R}^{n \times m} | \mathbf{U}^T\mathbf{U} = \mathbf{I}_m\}$$

We will show the advantage of Stiefel manifold when coupling the tensor with auxiliary information.

3.2 Coupled with Auxiliary Information

To incorporate multi-view auxiliary information, we adopt the idea of spectral clustering, due to its flexibility and ease of implementation [28, 31]. We first give a brief introduction of spectral clustering. Suppose $\mathbf{S} \in \mathbb{R}^{N \times N}$ is the similarity/affinity matrix for N objects, where $\mathbf{S}_{ij}$ measures the similarity between object i and object j. One can then compute the normalized Laplacian matrix: $\mathbf{L} = \mathbf{I} - \mathbf{D}^{-\frac{1}{2}}\mathbf{S}\mathbf{D}^{-\frac{1}{2}}$, in which $\mathbf{D}$ is the diagonal matrix with $\mathbf{D}_{ii} = \sum_{j=1}^{N} \mathbf{S}_{ij}$. The spectral clustering is to solve the following optimization:

$$\min_{\mathbf{U} \in \mathbb{R}^{N \times k}} \quad \langle \mathbf{U}\mathbf{U}^T, \mathbf{L} \rangle \quad s.t. \quad \mathbf{U}^T\mathbf{U} = \mathbf{I} \tag{2}$$

where $\langle \cdot, \cdot \rangle$ denotes the matrix inner product. $\mathbf{U}$ can be regarded as the low-dimensional spectral embedding of N objects. For clustering task, the k-means algorithm can be then applied to $\mathbf{U}$ to get the clustering indicators. Furthermore, the orthogonal constraint indicates that the spectral embedding $\mathbf{U}$ is also well defined on the Stiefel manifold. Therefore, it is reasonable to jointly consider the factor matrices in Eq. (1) together with the spectral embedding in Eq. (2) when performing the coupled tensor-matrix factorization in the sense that both of embeddings are on the Stiefel manifold.

For the drug mode of tensor $\mathcal{X}$, considering drug factor matrix $\mathbf{A} \in St(r_1, n_1)$ and its multi-view auxiliary information $\mathcal{S}_A = \{\mathbf{S}_A^{(1)}, \ldots, \mathbf{S}_A^{(n_a)}\}$, we extend the single-view spectral embedding to the follow multi-view co-training optimization function as [10, 28]:

$$\min_{\mathbf{A}, \mathbf{A}^{(i)} \in St(r_1, n_1)} \sum_{i=1}^{n_a} (\langle \mathbf{A}^{(i)} \mathbf{A}^{(i)^T}, \mathbf{L}_A^{(i)} \rangle + \|\mathbf{A}^{(i)} \mathbf{A}^{(i)^T} - \mathbf{A}\mathbf{A}^T\|_F^2) \quad (3)$$

where $\mathbf{L}_A^{(i)}$ is the normalized Laplacian matrix of $\mathbf{S}_A^{(i)}$ and $\mathbf{A}^{(i)}$ is the corresponding spectral embedding. The key idea behind Eq. (3) is that all the spectral embeddings $\mathbf{A}^{(i)}$ $(0 \le i \le n_a)$ from auxiliary information should be close to the drug factor matrix $\mathbf{A}$ since they all represent the same drugs. We achieve this by minimizing the disagreements $d(\mathbf{A}^{(i)}, \mathbf{A}) = \|\mathbf{A}^{(i)} \mathbf{A}^{(i)^T} - \mathbf{A}\mathbf{A}^T\|_F^2$. The reason for choosing $d(\mathbf{A}^{(i)}, \mathbf{A})$ is two-fold: (i) the reconstruction of similarity/kernel matrix $\mathbf{A}^{(i)} \mathbf{A}^{(i)^T}$ from spectral embedding is expected to be consistent with similarity $\mathbf{A}\mathbf{A}^T$ from tensor factor matrix, which is our assumption. (ii) we later show that the joint optimization is further defined on the Grassmann manifold, the quotient space of Stiefel manifold [1]. $d(\mathbf{A}^{(i)}, \mathbf{A})$ exactly measures the *geodesic distance* between two Grassmannian points $\mathbf{A}^{(i)}$ and $\mathbf{A}$ [14].

The same analysis can be applied to the target and disease factor matrices $\mathbf{B}$ and $\mathbf{C}$ with auxiliary information $\mathcal{S}_B$ and $\mathcal{S}_C$. We leave the details in the unified model in Eq. (4) later.

3.3 Overall Model

We propose the coupled tensor-matrix factorization model by combining the loss functions in Eq. (1) and Eq. (3). In addition to two functions, to better represent drugs, we further add l_1-norm on $\mathbf{A}\mathbf{A}^T$ [28]. We argue that this type of regularization does make sense. It has been shown that the new affinity/similarity matrix $\mathbf{A}^{(i)} \mathbf{A}^{(i)^T}$ in Eq. (3) implies the true membership of data clusters, and it is naturally *sparse* in an ideal case [28, 31]. Because the geodesic distance measurement $d(\mathbf{A}^{(i)}, \mathbf{A})$ is included in the overall objective function for minimization, the matrix $\mathbf{A}\mathbf{A}^T$ is also expected to be sparse. Similar arguments can be made for the target's and disease's factor matrices. Putting everything together, our method DTD tries to minimize the following onjective function:

$$\begin{aligned} \min f = {} & \|\mathcal{X} - \mathcal{G} \times_1 \mathbf{A} \times_2 \mathbf{B} \times_3 \mathbf{C}\|_F^2 + \rho \cdot (\|\mathbf{A}\mathbf{A}^T\|_1 + \|\mathbf{B}\mathbf{B}^T\|_1 + \|\mathbf{C}\mathbf{C}^T\|_1) \\ & + \alpha \cdot \sum_{i=1}^{n_a} (\langle \mathbf{A}^{(i)} \mathbf{A}^{(i)^T}, \mathbf{L}_A^{(i)} \rangle + \|\mathbf{A}^{(i)} \mathbf{A}^{(i)^T} - \mathbf{A}\mathbf{A}^T\|_F^2) \\ & + \beta \cdot \sum_{j=1}^{n_b} (\langle \mathbf{B}^{(j)} \mathbf{B}^{(j)^T}, \mathbf{L}_B^{(j)} \rangle + \|\mathbf{B}^{(j)} \mathbf{B}^{(j)^T} - \mathbf{B}\mathbf{B}^T\|_F^2) \\ & + \gamma \cdot \sum_{k=1}^{n_c} (\langle \mathbf{C}^{(k)} \mathbf{C}^{(k)^T}, \mathbf{L}_C^{(k)} \rangle + \|\mathbf{C}^{(k)} \mathbf{C}^{(k)^T} - \mathbf{C}\mathbf{C}^T\|_F^2) \\ s.t. \quad & \mathbf{A}, \mathbf{A}^{(i)} \in St(r_1, n_1);\ \mathbf{B}, \mathbf{B}^{(j)} \in St(r_2, n_2);\ \mathbf{C}, \mathbf{C}^{(k)} \in St(r_3, n_3) \\ & \mathcal{P}_\Omega(\mathcal{X}) = \mathcal{P}_\Omega(\mathcal{T});\ \mathcal{G} \in \mathbb{R}^{r_1 \times r_2 \times r_3} \end{aligned} \quad (4)$$

where parameter ρ controls the sparsity of factor matrices. And α, β and γ represent the impact of auxiliary information on each mode of tensor, i.e., how important such knowledge is to improve the performance. At first glance, the objective function f is complicated with nonlinear and non-convex orthogonality constraints. Next, we provide an effective algorithm to solve the problem.

4 OPTIMIZATION ALGORITHM

In this section, we develop an alternating minimization algorithm to optimize the objective function in Eq. (4). To be specific, the objective function f is successively minimized with respect to one variable while fixing others until convergence. To deal with orthogonality constraints, we directly optimize it on a Grassmann manifold, which is an emerging topic in nonlinear programming that leverages the smooth geometry of the search space with guaranteed convergence [1, 22, 39, 43].

Updating core tensor $\mathcal{G}$: The objective with respect to $\mathcal{G}$ is:

$$\min f(\mathcal{G}) = \|\mathcal{X} - \mathcal{G} \times_1 \mathbf{A} \times_2 \mathbf{B} \times_3 \mathbf{C}\|_F^2$$

The core tensor $\mathcal{G}$ is obtained as the closed form solution

$$\mathcal{G} = \mathcal{X} \times_1 \mathbf{A}^T \times_2 \mathbf{B}^T \times_3 \mathbf{C}^T \quad (5)$$

Updating factor matrices A, B and C: For matrix $\mathbf{A}$, the objective $f(\mathbf{A})$ can be regarded as an unconstrained manifold optimization problem on the Stiefel manifold:

$$\begin{aligned} \min_{\mathbf{A} \in St(r_1, n_1)} f(\mathbf{A}) = {} & \|\mathcal{X} - \mathcal{G} \times_1 \mathbf{A} \times_2 \mathbf{B} \times_3 \mathbf{C}\|_F^2 + \rho \|\mathbf{A}\mathbf{A}^T\|_1 \\ & + \alpha \sum_{i=1}^{n_a} \|\mathbf{A}^{(i)} \mathbf{A}^{(i)^T} - \mathbf{A}\mathbf{A}^T\|_F^2 \end{aligned}$$

The above optimization can be further converted into the following [23]:

$$\min_{\mathbf{A} \in St(r_1, n_1)} f(\mathbf{A}) = -\|\mathbf{A}^T \mathbf{W}\|_F^2 + \alpha \sum_{i=1}^{n_a} \|\mathbf{A}^{(i)} \mathbf{A}^{(i)^T} - \mathbf{A}\mathbf{A}^T\|_F^2 + \rho \|\mathbf{A}\mathbf{A}^T\|_1 \quad (6)$$

where $\mathbf{W} = \mathbf{X}_{(1)}(\mathbf{C} \otimes \mathbf{B})$, in which $\mathbf{X}_{(1)}$ is the mode-1 matricization of tensor $\mathcal{X}$ and $\otimes$ is the Kronecker product. However, simply optimizing problem (6) on Stiefel manifold may result in identifiability issue [1]. We next analyze problem (6) more deeply.

Consider the r_1-order group $\mathcal{S}(r_1) = \{\mathbf{Q} \in \mathbb{R}^{r_1 \times r_1} | \mathbf{Q}^T \mathbf{Q} = \mathbf{I}\}$ that contains all the $r_1 \times r_1$ orthogonal matrices. With $\mathcal{S}(r_1)$, we can define an equivalent relation $\sim$ on the Stiefel manifold $St(r_1, n_1)$ in the sense that $\mathbf{A} \sim \mathbf{A}'$ if there exists a $\mathbf{Q} \in \mathcal{S}(r_1)$ such that $\mathbf{A} = \mathbf{A}'\mathbf{Q}$. The quotient space of Stiefel manifold $St(r_1, n_1)$ under this equivalence relation is exactly the *Grassmann manifold* $Gr(r_1, n_1)$ [1], which consists of all the r_1-dimensional subspaces in n_1-dimensional Euclidean space $\mathbb{R}^{n_1}$ $(0 \le r_1 \le n_1)$. Moreover, it is interesting to observe that for any $\mathbf{Q} \in \mathcal{S}(r_1)$, we have the following invariance property:

$$f(\mathbf{A}) = f(\mathbf{A}\mathbf{Q})$$

Above equivalence indicates that the function $f(\mathbf{A})$ is independent from the choice of basis spanned by $\mathbf{A}$ and it is thus well defined on the Grassmann manifolds. Instead of optimizing $f(\mathbf{A})$ on Stiefel manifold, a better strategy is thus to regard the problem (6) as an unconstrained Grassmann manifold optimization problem:

$$\min_{\mathbf{A} \in Gr(r_1, n_1)} f(\mathbf{A}) = \underbrace{-\|\mathbf{A}^T \mathbf{W}\|_F^2 + \alpha \sum_{i=1}^{n_a} \|\mathbf{A}^{(i)} \mathbf{A}^{(i)^T} - \mathbf{A}\mathbf{A}^T\|_F^2}_{\mathcal{J}_1(\mathbf{A})} + \rho \|\mathbf{A}\mathbf{A}^T\|_1 \quad (7)$$

Problem (7) can then be efficiently solved by using standard gradient descent algoirthms on the Grassmann manifold such as

Riemannian conjugate gradient descent algorithm or trust region algorithm [1]. For Grassmann manifold, its Riemannian gradient is the projection of Euclidean gradient into relevant tangent space of the manifold. We next compute the Euclidean gradient of function $f(\mathbf{A})$.

For the first two terms in the problem (7), we have:

$$\nabla \mathcal{J}_1(\mathbf{A}) = -2\mathbf{W}\mathbf{W}^T\mathbf{A} + \alpha \sum_{i=1}^{n_a}(4\mathbf{A}\mathbf{A}^T\mathbf{A} - 4\mathbf{A}^{(i)}{\mathbf{A}^{(i)}}^T\mathbf{A}) \tag{8}$$

The third term $\|\mathbf{A}\mathbf{A}^T\|_1$ in objective function (7) is not differentiable when the elements of $\mathbf{A}\mathbf{A}^T$ are zeros, we consider the sub-differential. According to the chain rule:

$$\mathrm{vec}\left(\frac{\partial \|\mathbf{A}\mathbf{A}^T\|_1}{\partial(\mathbf{A})}\right)^T = \mathrm{vec}(\mathrm{sgn}(\mathbf{A}\mathbf{A}^T))^T \frac{\partial \mathbf{A}\mathbf{A}^T}{\partial \mathbf{A}} \tag{9}$$

where $\mathrm{sgn}(\cdot)$ denotes sign function and $\mathrm{vec}(\cdot)$ is vectorize operator that stacks all columns of a matrix into a long vector. Also, from the partial equation: $\partial(\mathbf{A}\mathbf{A}^T) = (\partial\mathbf{A})\mathbf{A}^T + \mathbf{A}\partial(\mathbf{A}^T)$, we can get:

$$\begin{aligned}\partial\,\mathrm{vec}(\mathbf{A}\mathbf{A}^T) =& (\mathbf{A}\otimes\mathbf{I}_{n_1})\partial\,\mathrm{vec}(\mathbf{A}) + (\mathbf{I}_{n_1}\otimes\mathbf{A})\partial\,\mathrm{vec}(\mathbf{A}^T)\\ =& \left((\mathbf{A}\otimes\mathbf{I}_{n_1}) + \mathbf{K}_{(n_1^2,n_1^2)}(\mathbf{A}\otimes\mathbf{I}_{n_1})\right)\partial\,\mathrm{vec}(\mathbf{A})\\ =& (\mathbf{I}_{n_1^2} + \mathbf{K}_{(n_1^2,n_1^2)})(\mathbf{A}\otimes\mathbf{I}_{n_1})\partial\,\mathrm{vec}(\mathbf{A})\end{aligned}$$

From above equation, the derivative part in Eq. (9) is

$$\frac{\partial \mathbf{A}\mathbf{A}^T}{\partial \mathbf{A}} = (\mathbf{I}_{n_1^2} + \mathbf{K}_{(n_1^2,n_1^2)})(\mathbf{A}\otimes\mathbf{I}_{n_1})$$

where $\mathbf{I}_{n_1^2}$ is the identity matrix with size $n_1^2 \times n_1^2$ and $\mathbf{K}_{(n_1^2,n_1^2)}$ is the commutation matrix. Although both matrix $\mathbf{I}_{n_1^2}$ and $\mathbf{K}_{(n_1^2,n_1^2)}$ are large, they are very sparse with a large number of zeros. In practice, they can be encoded in a sparse matrix form, which can greatly save the computational space.

Define the column vector $\mathbf{d}$ as

$$\mathbf{d} = (\frac{\partial \mathbf{A}\mathbf{A}^T}{\partial \mathbf{A}})^T \mathrm{vec}(\mathrm{sgn}(\mathbf{A}\mathbf{A}^T)) \tag{10}$$

Combining Eq. (8) and (10), the Euclidean gradient of the objective function $f(\mathbf{A})$ is

$$\nabla f(\mathbf{A}) = \nabla \mathcal{J}_1(\mathbf{A}) + \rho \cdot \mathrm{ivec}(\mathbf{d}) \tag{11}$$

where $\mathrm{ivec}(\cdot)$ is the inverse vectorize operator, i.e., $\mathrm{ivec}(\mathrm{vec}(\mathbf{X})) = \mathbf{X}$. With the Euclidean gradient $\nabla f(\mathbf{A})$, the Riemannian gradient with respect to $\mathbf{A} \in Gr(r_1, n_1)$ can be computed as

$$\mathrm{grad}\, f(\mathbf{A}) = (\mathbf{I} - \mathbf{A}\mathbf{A}^T)\cdot\nabla f(\mathbf{A}) \tag{12}$$

With the Riemannian gradient, we can use the popular nonlinear ManOpt solver to solve problem (7) effectively [6].

For updating factor matrices $\mathbf{B}$ and $\mathbf{C}$, their objective function $f(\mathbf{B})$ and $f(\mathbf{C})$ share the similar optimization structure as $f(\mathbf{A})$. Therefore, they can be solved in the same way with corresponding Riemannian gradients. The details are omitted here.

Updating spectral embedding $\mathbf{A}^{(i)}$,$\mathbf{B}^{(j)}$ and $\mathbf{C}^{(k)}$: For matrix $\mathbf{A}^{(i)}$, the objective $f(\mathbf{A}^{(i)})$ is

$$\min_{\mathbf{A}^{(i)}\in St(r_1,n_1)} f(\mathbf{A}^{(i)}) = \langle \mathbf{A}^{(i)}{\mathbf{A}^{(i)}}^T, \mathbf{L}_A^{(i)}\rangle + \|\mathbf{A}^{(i)}{\mathbf{A}^{(i)}}^T - \mathbf{A}\mathbf{A}^T\|_F^2 \tag{13}$$

The objective function $f(\mathbf{A}^{(i)})$ is also invariant to $\mathbf{Q} \in \mathcal{S}(r_1)$, i.e., $f(\mathbf{A}^{(i)}) = f(\mathbf{A}^{(i)}\mathbf{Q})$. Therefore, problem (13) can be also regarded as an unconstrained Grassmann manifold optimization problem. The Euclidean gradient of the objective function $f(\mathbf{A}^{(i)})$ is

$$\nabla f(\mathbf{A}^{(i)}) = 2\mathbf{L}_A^{(i)}\mathbf{A}^{(i)} + 4\mathbf{A}^{(i)}{\mathbf{A}^{(i)}}^T\mathbf{A}^{(i)} - 4\mathbf{A}\mathbf{A}^T\mathbf{A}^{(i)} \tag{14}$$

The Riemannian gradient grad $f(\mathbf{A}^{(i)})$ can be obtained in the same way as in Eq. (12). The Riemannian trust-regions algorithm is then used to compute the optimal solution since the objective function $f(\mathbf{A}^{(i)})$ in Eq. (13) is smooth. The initial $n_1 \times r_1$ spectral embedding $\mathbf{A}^{(i)}$ can be approximated by the r_1 eigenvectors of $\mathbf{L}_A^{(i)}$ corresponding to the first r_1 smallest eigenvalues. The objective function $f(\mathbf{B}^{(j)})$ and $f(\mathbf{C}^{(k)})$ can be solved in a similar fashion.

Updating tensor $\mathcal{X}$: The optimization problem with respect to $\mathcal{X}$ is formulated as follows:

$$\min_{\mathcal{X}} \|\mathcal{X} - \mathcal{G}\times_1\mathbf{A}\times_2\mathbf{B}\times_3\mathbf{C}\|_F^2 \quad s.t. \mathcal{P}_\Omega(\mathcal{X}) = \mathcal{P}_\Omega(\mathcal{T})$$

The optimal solution is given by:

$$\mathcal{X} = \mathcal{P}_\Omega(\mathcal{T}) + \mathcal{P}_{\Omega^c}(\mathcal{G}\times_1\mathbf{A}\times_2\mathbf{B}\times_3\mathbf{C}) \tag{15}$$

where Ω^c is the complement of Ω, i.e., the set of indexes of the unobserved elements.

According to above analysis, we summarize the algorithm for solving the tensor completion problem (4) in Algorithm 1.

Remark: Comparison with Euclidean solvers that usually deal with the orthogonality constraints by solving eigenvalue decomposition problem [23], our solver seeks to find concise subspace on the Grassmann manifold for all factor matrices. As pointed out in spectral clustering [31], when the leading eigenvalues are almost equal, the best spectral embedding is better determined by the subspace rather than a particular eigenvector as most of Euclidean solvers do. The same analysis can be analogously applied to solve Tucker decomposition in Euclidean space, i.e., using eigenvalue decomposition. The Riemannian solver is thus more interpretable in a straightforward way.

5 EXPERIMENTS

5.1 Datasets

We collect data from a variety of public sources. We first download the drug-disease associations from the Comparative Toxicogenomics Database [1] (CTD). The original dataset contains 1,048,547 pairs of drug-disease associations. Here, we only focus on those drugs with DrugBank [2] identifier and diseases with OMIM [3] identifier for conveniently integrating with auxiliary information on other public datasets. As discussed before, the drug's targets, usually proteins that drugs can bind, through which drugs interact with biological pathways and possibly change their behaviors and functions, are crucial in drug discovery. The drug's targets can be collected from the DrugBank database to obtain drug-target interactions. To get dense data, we only include those drugs that interact with at least two targets. We then merge the drug-disease and drug-target interactions into data schema $< drug, target, disease >$. The

450	708	1,267	188,479	0.047%

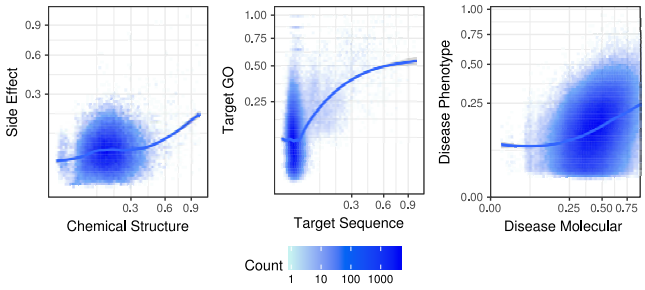

Figure 2: The pairwise scatter plots among different views of drugs, targets and diseases.

dataset contains 188,479 drug-target-disease interactions, involving 450 drugs, 708 targets and 1,267 diseases. Data statistics are shown in Table 2.

The data are then encoded into a $drug \times target \times disease$ tensor $\mathcal{X}$. An entry $\mathcal{X}_{ijk} = 1$ in the tensor indicates that drug i binds to target j and it can treat disease k; $\mathcal{X}_{ijk} = 0$ otherwise. The tensor is very sparse (with sparsity rate 0.047%). We further collect auxiliary information to align each mode of tensor with existing medical knowledge.

Auxiliary information: Following several previous studies [7, 9, 20, 30, 45], we collect auxiliary information from different datasets with respect to drugs, targets, and diseases. For drugs, we define two drug-drug similarities based on drugs' chemical structures and drugs' side effects [7]. For targets, two target-target similarities are considered based on target amino acid sequences and Gene Ontology (GO) terms, both of which can directly be obtain from Uniprot [4] database [20, 45]. For diseases, two disease-disease similarities are computed according to disease molecular profiles from biomedical literatures [8] and disease phenotypes on OMIM datasets [9].

Each view of data contains its own features and emphasizes different aspects. Different views may share some consistency and complementary properties. We begin our investigation by examining the strength of the associations among those different views of drugs, targets, and diseases. The scatter plots of the pairwise similarity scores are shown in Figure 2. We further assess the strength of their associations by calculating the correlation coefficient between two views of similarity scores, respectively. All correlations are positive with the correlation coefficient values of 0.148 (drug chemical structures vs. drug side effects), 0.372 (target sequences vs. target GO terms), and 0.374 (disease molecular profiles vs. disease phenotypes). Despite small values in some of the coefficients, all of them are significant because of the large sample sizes (e.g., 802, 011 data instances in the disease scatter plot). Therefore, it's reasonable to integrate the multi-view auxiliary information in the DTD framework and to improve the overall performance for modeling drug-target-disease interactions, as shown later.

5.2 Comparison Methods

As mentioned earlier, many existing methods can only handle the binary relationships of drug-target or drug-disease. We mainly compare with existing tensor completion approaches due to their abilities to represent the triple relationships of drug-target-disease. To show the effectiveness of the proposed DTD model, we compare with several existing models as described below.

- **Tucker decomposition** (TD): It only decomposes the tensor without any auxiliary information for each mode.
- **CMTF** [2]: CMTF constructs common latent factors shared by a tensor and single-view of auxiliary information by using coupled matrix-tensor CP-decomposition.
- **ConCMTF** [5]: A novel constrained tensor model with non-negativity, sparsity and orthogonality constraints. Similar to CMTF, it can incorporate single-view of auxiliary information but with Tucker tensor decomposition as base.
- **FaLRTC** [27]: FaLRTC can estimate the low rank structure by imposing the trace norm on its unfolding matrices and the algorithm is based upon alternating direction method of multipliers (ADMM).
- **TFAI** [29]: it recovers the tensor by incorporating within-mode auxiliary information and adopt alternating least squares algorithm to solve its problem.
- **Rubik** [41]: A novel knowledge-guided tensor factorization and completion framework to fit electronic health record data with non-negativity and sparsity constraints. It is also solved by ADMM algorithm.

[4] https://www.uniprot.org/

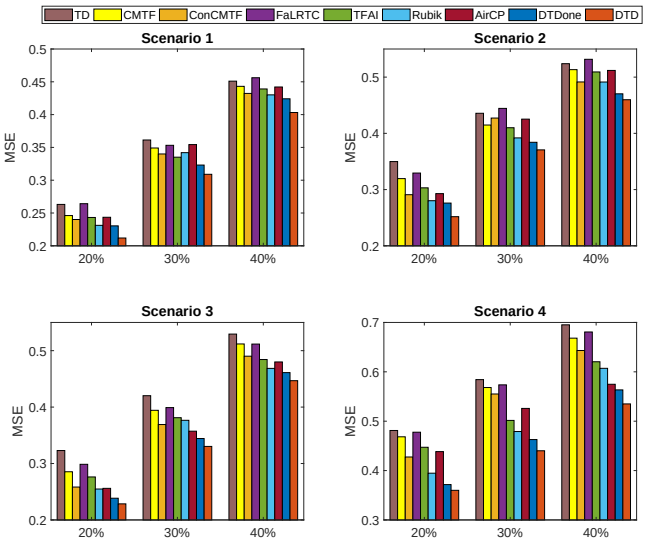

Figure 3: Comparison of recovery results over four scenarios with 20%, 30% and 40% test dataset.

- **AirCP** [18]: Another tensor model that integrates single-view auxiliary information using Laplacian regularization and it is optimized by ADMM algorithm.
- **DTDone**: A degraded version of our DTD model with single-view auxiliary information for each mode of tensor.

Note that the approaches TD and FaLRTC cannot integrate any auxiliary information when completing the tensor. The rest of comparison methods can only incorporate single-view auxiliary information for each mode. One has to either only include single-view for each mode, or a straightforward concatenation (e.g., average) of all similarity matrices into one. We tries both ways but the performance do not show much differences. The reason is that concatenation of all views may not be physically meaningful because each view has its owns specific statistical property. For these single-view models, we thus chose the drug chemical structure, target sequence, and disease phenotypes, all of which have long been considered valuable knowledge in drug discovery [20, 30, 45].

For all Tucker-based tensor models, we set the rank of core tensor $\mathcal{G}$, $r_i = 0.05n_i$ $(1 \leq i \leq 3)$; For CP-based tensor models, we set CP-rank $r = 0.05 \min(n_1, n_2, n_3)$. The regularization parameters of all comparison methods are tuned using the grid-based search algorithm for optimal performance. All methods use the same stopping threshold for a fair comparison, *i.e.*, the variation of two consecutive objective value is less than 10^{-4}. For the proposed DTD and DTDone model, we manually set the parameters $\alpha = \beta = \gamma = \rho = 0.01$. The impact of the regularization parameters on the performance of DTD will be discussed later.

5.3 Experimental Performance

To investigate the performance of different methods, we randomly selected a subset $\Omega' \in \Omega$ to be used as the unobserved elements (that is the test dataset), and evaluated the *mean squared errors* (MSE) between true values $\mathcal{T}_{\Omega'}$ and predicted values $\mathcal{X}_{\Omega'}$ [29]. We mainly consider the following random selection scenarios [18]: (i) Scenario 1 (random selection): we randomly select a fraction of elements across drug-target-disease tensor and assume that these are unobservable. (ii) Scenario 2 (random selection in drug mode): we randomly select a fraction of drugs, and assume that those drugs are completely unobservable across the whole tensor. (iii) Scenario 3 (random selection in target mode): similarly, we randomly select a fraction of targets. (iv) Scenario 4 (random selection in disease mode): A fraction of diseases are randomly selected. For each method, the experiment is repeated ten times independently and the average result is reported.

Figure 3 shows the performance of all the methods with different sampling ratios 20%, 30% and 40% (i.e., the fractions of test dataset). DTD consistently performs better than all the comparison methods within a wide range of sampling ratios. In addition, we have the following observations. First, the methods that integrate single-view or multi-view auxiliary information achieve better performance than TD and FaLRTC, indicating the importance of those auxiliary information. With the guidance of extra knowledge, these tensor models keep their performance even with a very sparse input tensor. Second, ConCMTF (Tucker decomposition) perform slightly better than CMTF (CP decomposition) in many situations. The main difference between them is that ConCMTF seeks to find as many non-overlapping structures as possible. Such non-overlapping latent structures are more concise and become specially favorable when jointly decomposing the tensor and matrices. The proposed DTD and DTDone also preserve such non-overlapping structures by imposing orthogonality constraint on factor matrices, which leads to better representations of data. Third, the proposed DTDone further achieves better performance than ConCMTF with an average improvement of 5.76%. As discussed before, the solutions of DTDone, both factor matrices and spectral embeddings, are exactly on the Grassmann manifold and can be well coupled together with each other to obtain better performance. And such advantages make DTDone generally outperform other single-view tensor completion methods such as TEAI, Rubik and AirCP. Finally, the proposed DTD method integrating all available auxiliary information achieves better performance than those only integrating single-view auxiliary information, which illustrates that DTD successfully makes use of all useful information sources to perform effective recovery for the drug-target-disease tensor. In summary, DTD can effectively predict potential interactions of drug, target and disease by leveraging multiple auxiliary data sources and has great potential to accelerate the drug development.

Top-k Prediction: In clinics, given a disease, it is critical to know which drugs can treat this disease as well as the targets involved in the disease pathway. These pairs of <drug, target> related to a special disease are very important in personalized treatments. We further evaluate the performance of top-k prediction for Scenario 4. Recall that we randomly select a subset of diseases and remove all of their interactions in the Scenario 4. For each disease, we can predict a top-k list of <drug, target> candidates.

We adopt Precision@k and Recall@k as our evaluation metrics for different methods. Both of them have been widely used to evaluate the quality of top-k predictions [18, 36]. In our experiments,

Table 3: Precision@k and Recall@k for different methods.

Methods	Prec@5	Rec@5	Prec@10	Rec@10

Table 4: Top 10 novel triple relationship of (drug→target→disease) by DTD model.

Carbamazepine→ Nuclear receptor subfamily 1 group I member 2 → Osteoporosis
Testosterone→ Estrogen receptor→Myocardial infarction
Nefazodone→D(2) dopamine receptor→Schizophrenia
Raloxifene→Estrogen receptor→Obesity
Fenofibrate→Matrix metalloproteinase→Psoriatic arthritis
Acetazolamide→Estrogen receptor→Amyotrophic lateral sclerosis
Raloxifene→Androgen receptor→Breast cancer
Amoxapine→Potassium voltage-gated channel subfamily H member 2 →Hepatocellular carcinoma
Nefazodone→Histamine H1 receptor→Schizophrenia
Promethazine→Muscarinic acetylcholine receptor M3→Obesity

we evaluate those tensor models with auxiliary information and test for k at 5 and 10 for both precision and recall.

Table 3 shows the top-k prediction performance of all the methods with 20% fractions of test dataset. Overall, the proposed DTD model performs the best among all methods in terms of both precision and recall with different values of k. The trend is very similar to the results based on the MSE metric. For example, DTD performs better than CMTF with an average improvement of 16.8% in precision and 15.3% in recall. We attribute the poor performance of the CMTF approach to the sparseness of tensor and its weak abilities of coupling tensor with auxiliary matrices (e.g., overlap structure). Moreover, DTD has a better performance than DTDone, indicating the superiority of a tensor model integrating rich multi-view auxiliary information. All these results illustrate that the proposed method can successfully predict top-k <drug, target> pairs by exploiting the compatible and complementary information from multi-view data sources.

Given these encouraging results, we use DTD model to predict novel triple relationships of drug-target-disease by leveraging all the observed data. The top-10 novel triple relationships are listed in Table 4. The results can then be evaluated by domain experts to see whether such interactions are clinically meaningful. Also, such top-k candidates can be further validated *in vitro* and *in vivo*. In summary, our proposed model efficiently predict potential interaction candidates with high accuracy, providing a systematic approach to narrow down the search space for further wet-lab investigations.

5.4 Parameter Studies

We further analyze the effect of key hyperparameters, the rank of core tensor (r_1, r_2, r_3) and the regularized parameters α, β, γ, and ρ.

5.4.1 The impact of tensor rank: In Tucker-based tensor decomposition, the hyperparameter (r_1, r_2, r_3) controls the rank of the core tensor $\mathcal{G}$, which also decides the number of latent features for each mode, i.e., **A**, **B** and **C**. In contrast to Tucker model, the CP decomposition only have one hyperparameter r, the CP-rank. In the experiments, we set the rank $r_i = \delta \cdot n_i$ $(1 \le i \le 3)$ for Tucker-based model and $r = \delta \cdot \min(n_1, n_2, n_3)$ for CP-based model. The δ is the ratio varying within $[0.05, 0.1, 0.15, 0.2, 0.25]$. We then evaluate all methods for scenario 4 with 20% as the test dataset. Figure 4 shows that our model benefits slightly from larger numbers of latent dimensions in terms of MSE and Prec@5 metric. But generally speaking, both DTD and DTDone are fairly robust with respect to δ.

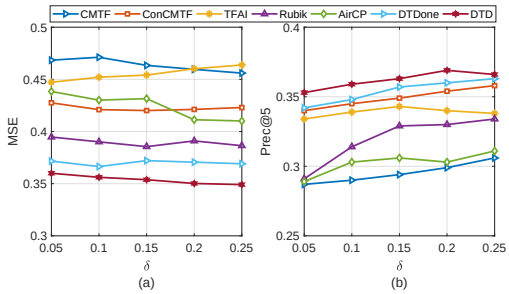

Figure 4: Effect of the tensor rank in scenario 4.

5.4.2 The impact of regularized parameters. Finally, we explore the impact of the regularization parameters on the quality of tensor completion. Recall that α, β and γ control the contributions of auxiliary information of drugs, targets, and disease, respectively. ρ controls the sparsity of factor matrices. In order to better understand the effect of these parameters, we vary their values in the range $[0.001, 0.01, 0.1, 1, 10]$, and then evaluate DTDone and DTD for scenario 4 with 20% as testing data. When studying one variable (e.g., α), we fix all the rest variables to be 0.01. As shown in Figure 5, DTDone and DTD are stable over a wide range of α, β and γ in terms of MSE. Specifically, a relatively low MSE can be achieved when those regularized parameters are around 0.01.

6 RELATED WORK

We review related research on computational predictions of drugs, targets, and diseases, as well as on tensor completion for high-dimensional structured data.

Modeling drug-target-disease. Treating human diseases caused by complex biological processes involves activities of many biological entities such as drugs and targets. Methods in computational pharmacology aim to find associations among those entities, and understand drug's MoAs [21]. Two excellent surveys [25], [16] provide a very detailed overview of different computational methods

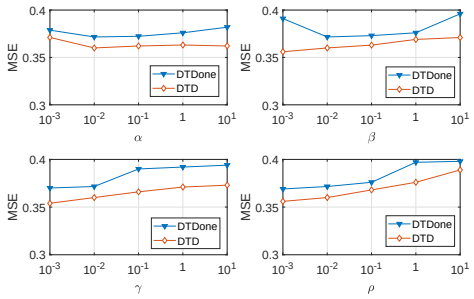

Figure 5: Effect of regularized parameters:α, β, γ and ρ .

for predicting drug-disease and drug-target relationships, respectively. Among existing approaches, one very popular method is network-based inference models, e.g., a bipartite network consisting of one layer for drugs and one layer for diseases (targets). Different machine learning algorithms, such as random-walk [12], matrix factorization [17], and support vector machine [42], have been applied to predict novel interactions of drug-disease (or target). In addition to network topology, existing medical knowledge, such as a variety of omics data, on the Web can be incorporated to better understand complex human metabolic systems [9, 30, 45, 46]. For example, a multiple kernel learning method has been developed to predict drug-target relationships by integrating multiple similarities of drugs and targets [30]. Decagon models drug polypharmacy side effects via graph convolutional networks with additional drug-drug and protein-protein interactions [46].

However, current studies generally considered drug-disease and drug-target predictions as two independent tasks and the relationships of drug-target-disease is typically ignored. There exist several studies incorporating target information in the task of drug-disease predictions [13, 40, 46]. However, their extensions are unsatisfactory because their goals are still on modeling binary relationships, not on the triple drug-target-disease patterns we aim to learn.

Tensor completion. Tensors are very powerful in real-world applications because of their ability to represent multi-aspects or high-dimensional data [23]. In many applications, we are often interested in analyzing tensors together with matrices from additional information, such as computational phenotyping [41], recommender system [18], and time-evolving topic discovery [5]. This coupled tensor-matrix factorization method has been developed over the years. For example, Acar et. al. proposed a gradient-based algorithm for coupled matrix-tensor factorization [2]. Narita et. al. incorporated valuable auxiliary information to further improve the quality of tensor recovery [29]. Wang et. al. proposed a knowledge guided tensor factorization model for health data analysis [41]. Ge et. al. proposed a spatiotemporal dynamics recovery framework, which could capture the latent relationships among locations, memes, and times by coupled factorization [18]. However, none of these methods are guaranteed to non-overlapping structures in both tensor and matrices and can only integrate single-view of additional information for *each mode* of tensor. Some models [5, 23, 29] try to impose orthogonality constraint on factor matrices. However, their solutions are usually not unique, which is hard to couple with auxiliary information. Recently, concrete tensor/matrix representations on the manifold is a fast growing research topic [1, 22, 43]. Kasai et. al. recently developed a novel Riemannian manifold preconditioning approach for tensor completion [43], but they did not take the auxiliary information into account. The proposed approach is innovative and properly addresses the challenges in coupled tensor-matrix factorization with multi-view auxiliary information.

7 CONCLUSION

Modeling drug-target-disease interactions is important for understanding drugs' MoAs in drug development. The problem has conventionally been addressed separately by considering associations of drug-target or drug-disease, and most existing methods cannot leverage intrinsic interactions among these three biological entities. Here we present a novel approach DTD, which explicitly explores a three-way drug-target-disease tensor via coupled tensor-matrix factorization. Completing such tensor is challenging because of its large sparsity. DTD elegantly integrates multiple Web data to align existing knowledge with the tensor. With the guidance of auxiliary information, DTD infers the concurrence of drug-target-disease more accurately than do baselines. Another distinguishing aspect of DTD is that it directly optimizes on the Grassmann manifold, which is more effective than Euclidean solvers. Experimental results on a real-world dataset demonstrate the effectiveness and efficiency of the proposed method.

The proposed DTD can easily incorporate additional domain knowledge and can be extended to detect high-order tensor (e.g., four-way *drug-target-gene-disease* tensor) with relatively little effort. Future work should aim to extend this model to simulate human metabolic systems by considering more biological entities (e.g., gene) as well as other domain knowledge (e.g., gene expression data). Deep understanding of those entities opens up opportunities to use rich Web data to assist follow-up analysis via formal pharmacological studies.

ABSTRACT

Recommendation from implicit feedback is a highly challenging task due to the lack of reliable negative feedback data. Only positive feedback are observed and the unobserved feedback can be attributed to two reasons: *unknow* or *dislike*. Existing methods address this challenge by treating all the un-observed data as negative (dislike) but downweight the confidence of these data. However, this treatment causes two problems: (1) Confidence weights of the unobserved data are usually assigned manually, which lack flexible and may create empirical bias in evaluating user's preference. (2) To handle massive volume of the unobserved feedback data, most of the existing methods rely on stochastic inference and data sampling strategies. However, since users are only aware of a very small fraction of items in a large dataset, it is difficult for existing samplers to select *informative* training instances in which the user really dislikes the item rather than does not know it.

To address the above two problems, we propose a new recommendation method SamWalker that leverages social information to infer data confidence and guide the sampling process. By modeling data confidence with a social context-aware function, SamWalker can adaptively specify different weights to different data based on users' social contexts. Further, a personalized random-walk-based sampling strategy is developed to adaptively draw informative training instances, which can speed up gradient estimation and reduce sampling variance. Extensive experiments on three real-world datasets demonstrate the superiority of the proposed SamWalker method and its sampling strategy.

1 INTRODUCTION

With the exponential growth of information on electronic commerce websites such as Amazon and Taobao, recommender systems are drawing more attention from both academia and industry [6, 15, 16, 25, 27, 39, 56, 61]. Collaborative filtering (CF), as the prevalent recommendation model in these systems, infers user's preference and produces recommendations based on user's historical behaviors. Early work on CF mainly focused on explicit feedback, where the numerical ratings which directly reflect users' preference are provided.

However, explicit feedback may not be available in many applications. We usually only have access to implicit feedback derived from user actions, e.g. users' video viewing and product purchasing history. Although implicit feedback is abundant in practice, recommendation from implicit feedback is more difficult than from explicit feedback. The reason is that learning from implicit feedback lacks reliable negative feedback data, i.e. only the positive feedback are observed in the implicit feedback data. The un-observed user-item feedback data (e.g. a user has not bought an item yet) are a mixture of real negative feedback (a user does not like it) and missing values (a user just does not know it). While the positive feedback suggests that the user likes the item, the un-observed feedback does not necessarily mean the user dislikes the item. In most cases, users may just not know the items that they have not consumed.

Existing methods address this problem by treating all the unobserved data as negative (dislike) but downweight the confidence of these data. Most of these methods rely on the careful assignment of confidence weights to the data. Although it may be effective, choosing these weights usually involves heuristic alterations to the data and thus need expensive exhaustive grid search via cross-validation. Furthermore, it is unrealistic for researchers to manually set flexible and diverse weights for millions of data. In practical scenarios, different data may have different confidence on estimating users' preference. Some unobserved feedback data may be attributed to users' preference, while others are the result of users' limited awareness. Coarse-grained manual confidence weights will create empirical bias on estimating user's preference.

Another problem in recommendation from implicit feedback is learning efficiency. Due to the lack of reliable negative feedback data, all the un-observed data need to be considered to learn users' preference [4]. However, this degrades the learning efficiency

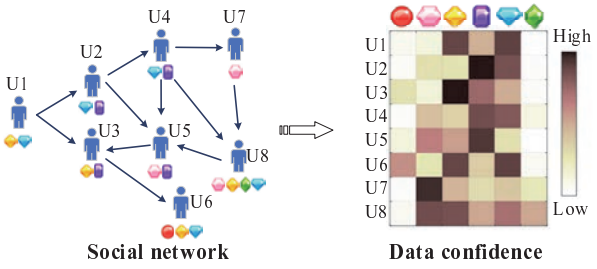

Figure 1: SamWalker estimates data confidence based on user's social relations. The left part of the figure illustrates a social network including implicit feedback expressed by users. The consumed items (i.e. the items with positive feedback) are shown below the users. The right part shows our inferred data confidence.

because of the large number of unobserved data. For efficient recommendation, most of the existing methods employ stochastic gradient descent solvers and corresponding data sampling strategies (e.g.uniform, item popularity-based). However, in real world, users typically are only aware of a relatively small fraction of the potential items [31]. In such cases, existing samplers usually select uninformative data with low confidence weight in which the user just does not know the item rather than dislikes it. This will affect the convergence and recommendation performance of the methods.

To deal with these problems, we propose a novel recommendation method SamWalker that leverages social information to simultaneously learn the personalized data confidence and draw informative training instances. With the development of online social websites, social relations have become a major information resource when users select items to consume [36]. Users usually get item information from social friends (neighbors) [10] and their *exposure* to items (i.e. whether a user knows the items) will inevitable be dominated by their *social contexts* (i.e. whether their direct or indirect social neighbors have consumed the items). Thus, users' social contexts can affect how users are exposed to the items and suggest the confidence of the data. It is consistent with our intuitions. Note that there exists two reasons for negative feedback: unknown or dislike. When an item is more popular among the user's social neighbors (e.g. the purple gem comparing with the green gem for user U1 in Figure 1), the user is more likely to know the item and his feedback is more attributed to his preference. Correspondingly, the data will be more reliable in deriving user's preference. To capture this insight, as illustrated in Figure 1, SamWalker simulates item information propagation along the social network and models individual confidence weights as a social context-aware function. By iteratively learning transformation function and user's preference based on EXMF framework (exposure-based matrix factorization [30]), SamWalker can adaptively specify different weights to different data based on user's social contexts.

Due to the large number of unobserved data, developing an efficient informative sampling strategy is challenging. It is apparently inefficient to estimate and rank the current learned confidence weights for every data to select informative data. Instead, we propose an efficient sampling strategy based on the random walk along the social network. Intuitively, if our more and closer social friends (neighbors) have consumed the item, we are more likely to know it due to the information sharing in the social network. Our feedback on this item can thus be attributed to our preference with more confidence and the corresponding user-item feedback data is more informative. Consequently, we conduct personalized random walk for each user to explore his local social contexts and pick out items consumed by these close direct or indirect social neighbors. theoretical analysis proves that the distribution of the proposed sampling strategy is proportional to the data confidence, which can reduce the sampling variance and speed up gradient estimation.

It is worthwhile to highlight the following contributions:

- We propose a new recommendation method SamWalker that adaptively learns the data confidence based on users' social context.
- We propose an efficient social-based sampling strategy to draw informative training instances, which can both reduce sampling variance and speed up gradient estimation.
- Our experimental evaluation on three well-known benchmark datasets demonstrates that SamWalker outperforms a range of state-of-the-art methods and analyzes the superiority of the proposed social-based sampling strategy.

The rest of this paper is organized as follows. We briefly review related works in section 2. We give the problem definition and background in section 3. The SamWalker model is introduced in section 4. The experimental results and discussions are presented in section 5. Finally, we conclude the paper and present some directions for future work in section 6.

2 RELATED WORK

In this section, we review the most related works from the following three perspectives.

Recommendation from implicit feedback data. Due to the lack of reliable negative feedback data, existing recommendation methods for implicit feedback data treat all the un-observed data as negative but downweight the confidence of these data. However, most of the existing methods manually assign coarse-grained confidence weights. For example, the classic weighted factorization matrix model (WMF) [22] and many neural-based collaborative methods (e.g. CDAE[49], NCF[17]) used a simple heuristic where all negative feedback data are equally downweighted vis-a-vis the positive feedback data. [18] and [54] also manually assign the confidence weights based on item popularity.

More recently, a new probabilistic model EXMF[30] was proposed to incorporate user's exposure to items into the CF methods. When inferring user's preference, EXMF can translate user's exposure as data confidence. However, this method suffers from the efficiency problem. We will analyze EXMF model in details in section 3.

Some other pair-wise methods treat negative feedback data in a different way. Bayesian personalized ranking (BPR) [38] focuses on the learning of relative preferences and aims at maximizing the AUC objective function. They believe that user's preference on his consumed items is above un-consumed items. Similarly, the weighted approximated ranking pairwise (WARP) loss proposed in [48] optimizes Precision@K.

Efficient Recommendation. For efficient recommendation, most of the existing methods rely on the stochastic optimization and corresponding data sampling strategy. The most popular sampling strategy is to draw un-observed feedback data uniformly, which has been widely adopted by WMF [22], BPR [38],CDAE [49], NCF [17], etc. Also, [54] and [19] further propose item popularity-based and item-user co-bias sampling strategy to reduce sampling variance. A detailed comparison of these sampling methods is presented in Table 4. However, as users are only exposed to very small fraction of the items, these samplers usually select uninformative data to estimate user's preference, which affects convergence and recommendation performance.

Some other sampling strategies are proposed to improve convergence and accuracy from different perspectives. [37, 55, 57] propose subtle dynamic sampling strategies to oversample the "difficult" negative examples in which the prediction is much different from the ground-truth. Although effective, sampling these "difficult" data for advanced preference model (e.g. BMF [19] or neural-based CF) still suffer from low efficiency [12]. Besides, the stochastic gradient estimator is biased and may amplify the natural noise in user-item feedback data [29]. [55] also proposes to draw positive data based on random walk along user-item bipartite graph. Our sampling strategy differs [55] in that we pay more attention to sample informative negative data. [9] proposes several sampling strategies to balance backward computation of the item-dependent neural network and the user-item interaction function. [12] proposes an effective sampling strategy by leveraging view data.

Also, [4, 18, 22] propose memoization strategies (e.g. ALS, eALS) to speed up inference. However, these strategies are just suitable for the model with K-separable property and L2 loss function (Guassian likelihood). In fact, cross-entropy loss function (Bernoulli likelihood) is more natural for the binary implicit feedback data and has been validated better performance than L2 [26].

Social recommendation. Social information has been utilized to improve recommendation performance in recent works. These methods mainly assume that connected users will share similar preference [2, 13, 14, 23, 41, 44, 52, 53, 60, 62]: Sorec [33], TrustMF [51], PSLF [40], jointly factorize rating matrix and trust (social) matrix by sharing a common latent user space; In [3, 7, 32, 42, 46, 50], users' feedback is considered as synthetic results of their preference and social influence; [24, 46] utilize a social regularization term to constrain user's latent preference close to his trusted friends; [47, 58] extend pair-wise BPR framework by further assuming that for all items with negative feedback, a user would prefer the items consumed by their friends over the rest.

Also, there are two recent works believe that comparing with users' preference, users' exposure is more influenced by their social friends (neighbors). Thus, [45] and [26] integrate social influence on user's exposure into the generative process of EXMF model. [45] extends EXMF with social regularization (SERec-Re) and social boosting (SERec-Bo). [26] integrates social knowledge influence and social consumption influence into EXMF model. However, these two methods need to infer $n \times m$ parameters of user's exposure, which will suffer from overfitting and become the efficiency bottleneck for practise application. SamWalker employs social-based variational posterior of user's exposure, which requires much fewer parameters and better captures heterogenous influence from both direct and indirect social neighbors. Further, SamWalker uses a social-based sampler to speed up inference and reduce sampling variance.

3 PRELIMINARIES

In this section, we first give the problem definition of implicit recommendation. Then, we introduce exposure-based matrix factorization (EXMF) [30] framework from variational perspective to provide usual insight about the relation between user's exposure and data confidence.

3.1 Problem definition

Suppose we have a recommender system with user set U (including n users) and item set I (including m items). The implicit feedback data is represented as $n \times m$ matrix X with entries x_{ij} denoting whether or not the user i has consumed the item j. Social information indicates the connections between users, represented as $n \times n$ matrix T. Also, $\mathcal{T}_i$ denotes the set of the connected social friends (direct neighbors) of user i. The task of a recommender system can be stated as follow: recommending items for each user that are most likely to be consumed by him.

3.2 Exposure-based matrix factorization (EXMF)

EXMF [30] directly incorporates user's exposure into collaborative filtering. Firstly EXMF generates the latent variable a_{ij}, which indicates whether user i has been exposed to item j. Then, EXMF models user's consumption x_{ij} based on a_{ij},

$$a_{ij} \sim Bernoulli(\eta_{ij}) \tag{1}$$

$$(x_{ij}|a_{ij} = 1) \sim Bernoulli(\sigma(u_i^\top v_j)) \tag{2}$$

$$(x_{ij}|a_{ij} = 0) \sim \delta_0 \approx Bernoulli(\varepsilon) \tag{3}$$

where δ_0 denotes $p(x_{ij} = 0|a_{ij} = 0) = 1$; η_{ij} is the prior probability of exposure. Here we relax function δ_0 as $Bernoulli(\varepsilon)$ to make model more robust, where ε is a small constant (e.g. ε=0.001). When $a_{ij} = 0$, we have $x_{ij} \approx 0$, since the user does not know the item and he can not consume it. When $a_{ij} = 1$, when the user has learned the item, he will decide whether or not to consume the item based on his preference. Thus, x_{ij} is modeled as the classic preference model[1] and factorized by the latent vectors u_i and v_j, which respectively characterize the latent preferences of user i and latent attributes of item j. To facilitate the description, here we collect the parameters of the preference model as $\theta = \{u_i, v_j\}_{i \in U, j \in I}$.

3.3 Analyses of EXMF from variational perspective

The marginal likelihood of EXMF is composed of a sum over the marginal likelihood of individual datapoint $\log p(X) = \sum_{ij} \log p(x_{ij})$,

[1]Here the preference model is slightly different from the original model presented in work [30] in that we employ Bernoulli likelihood instead of Gaussian likelihood on x_{ij}. In fact, Bernoulli likelihood is more natural for the binary variable [26].

which can be rewritten as:

$$\begin{aligned}\log p(x_{ij}) &= E_q[\log p(x_{ij}, a_{ij}) - \log q(a_{ij}|x_{ij})] \\ &\quad + E_q[\log p(a_{ij}|x_{ij}) - \log q(a_{ij}|x_{ij})] \\ &= L(\theta, q; x_{ij}) + KL(q(a_{ij}|x_{ij})||p(a_{ij}|x_{ij}))\end{aligned} \tag{4}$$

where $q(a_{ij}|x_{ij})$ is defined as an approximated variational posterior of a_{ij}. The second term is the KL divergence of the approximate variational posterior from the true posterior. Since the KL-divergence is non-negative, the first term $L(\theta, q; x_{ij})$ is the evidence lower bound on (ELBO) the margin likelihood. Thus, optimizing marginal likelihood can be translated as optimizing the lower bound $L(\theta, q; x_{ij})$ w.r.t. both the variational posterior and the preference parameters θ. Classic variational methods [20] usually employ conjugate variational distribution and individual variational parameters[2], i.e. $q(a_{ij}|x_{ij}) = Bernoulli(\gamma_{ij})$. For convenience we collect variational parameters γ_{ij} for every user-item pairs (i, j) as matrix Y. Then, the ELBO can be transferred into:

$$\begin{aligned}L(\theta, Y; X) &= \sum_{ij} E_q[\log p(x_{ij}, a_{ij}) - \log q(a_{ij}|x_{ij})] \\ &= \sum_{ij} \gamma_{ij} \ell(x_{ij}, \sigma(u_i^\top v_j)) + \sum_{ij} g(\gamma_{ij})\end{aligned} \tag{5}$$

The EBLO is composed of the two terms, the first term is a weighted cross-Entropy loss for the predicted preference, where $\ell(a, b) = alog(b) + (1 - a)log(1 - b)$. The second term is a loss function w.r.t γ_{ij}:

$$g(\gamma_{ij}) = (1 - \gamma_{ij})\ell(x_{ij}, \varepsilon) + \ell(\gamma_{ij}, \eta_{ij}) - \ell(\gamma_{ij}, \gamma_{ij}) \tag{6}$$

Exposure probability as the data confidence. From equation (5), a good property is observed that the variational parameters γ_{ij}, which characterize the probability that user i is exposed to item j, act as the confidence of the corresponding data to infer the preference parameters θ ($\theta = \{u_i, v_j\}_{i \in U, j \in I}$). This is clear by considering the following fact: when γ_{ij} becomes larger (or smaller), the inferred user and item factors θ make more (or less) contributions on the objective function. This finding is consistent with our intuitions. Only if the user has been exposed to the item, he can decide whether or not to consume the items based on his preference. Thus, the data with larger exposure is more reliable in deriving user's preference.

Weaknesses. However, although EXMF can adaptively derive the confidence of the data, we emphasize two latent weaknesses of the EXMF model: (1) EXMF is costly in accounting for all unobserved data ($O(n \times m)$) and is thus unrealistic for practical use. Although some sampling strategies can be used to speed up the algorithm, the gradient estimator exhibits high variance. Typically, in real world large datasets, each user will only be exposed to or be aware of a relatively small fraction of the potential items that they could interact with. That is, the γ_{ij} of most data are small and these data make limited contribution on updating parameter θ. Existing coarse-grained sampling strategy will usually draw uninformative data with small γ_{ij}, which affects the convergence and the recommended performance of the methods. (2) EXMF assumes user-independent posteriors of user's exposure. On the one hand, the number of variational parameters γ_{ij} grows quickly with the number of users and items ($n \times m$). This will suffer from serious overfitting and become the efficiency bottleneck for practise recommender systems. On the other hand, social network enable effective information sharing [1, 10]. Users' exposure to items will be influenced by their social contexts. Independent assumption of users' exposure is not practical in real world.

Thus, we are interested in, and propose a solution to two related problems:

(1) A social-based variational distribution of user's exposure that can both model the social influence between users and employ fewer variational parameters to speed up inference and alleviate overfitting.
(2) A sampling strategy that can draw informative training instances to speed up gradient estimation and reduce sampling variance.

4 SAMWALKER

For the purpose of solving the above problems, as illustrated in Figure 2, we propose a new recommendation method SamWalker that replaces individual variational parameter with a social context-aware function: $\gamma_{ij} = g_\varphi(X, T)$, where φ are replaced variational parameters. That is, we design an transformation function g_φ that maps the local social context of the user, i.e. whether his direct or indirect social friends (neighbors) have consumed the item, into the probability of user's exposure to the item. It is reasonable since users usually get item information from social network and their exposure to items depend on their local social contexts. An idea of modeling transformation function g_φ is to iteratively simulate the information spread via the social network. Similar to PageRank algorithm [34], we initially set the label of user's exposure according to his consumption. Then, all users spread their item information to their connected friends via the social network. The spread process is repeated until a global stable state is achieved. Concretely, in each step, users collect information from the connected social friends (neighbors) and reconstruct their exposure as follows:

$$\gamma_{ij}^{(t+1)} = (1 - c)x_{ij} + \sum_{k \in \mathcal{T}_i} c\varphi_{ik}\gamma_{kj}^{(t)} \tag{7}$$

The parameter c ($0 \le c \le 1$) specifies the relative contributions from the social influence and the initial label. φ_{ik} is defined as tie strength, which balances the heterogenous influence from different neighborhoods ($k \in \mathcal{T}_i$) and meets $\sum_{k \in \mathcal{T}_i} \varphi_{ik} = 1$. Overall, SamWalker replaces γ_{ij} with a social context-aware function g parameterized by φ, to which the equation (7) converges:

$$Y = g_\varphi(X, T) \equiv \lim_{t \to \infty} Y^{(t)} = (I - c\Phi)^{-1}(1 - c)X \tag{8}$$

where we collect variables $\gamma_{ij}^{(t)}$ for every user-item pairs (i, j) as a matrix $Y^{(t)}$. Also, we collect φ_{ik} as a matrix Φ, in which $\Phi_{ij} = \varphi_{ij}$ for connected user pairs and $\Phi_{ij} = 0$ for others. As we can see from equation (8), SamWalker replaces the posterior expectation of user's exposure with a weighted combination of the users' consumption in his social network. The weight matrix $(I - c\Phi)^{-1}$ is a graph or diffusion kernel [59], which has been widely adopted to measure nodes proximity in the network and depends on the tie strength parameters φ for every social ties. Overall, SamWalker can capture

[2]Note that the EM algorithm presented in [30] is a special case of the classic variational inference.

the heterogeneous social influence between users and reduce the number of variational parameters from $O(n \times m)$ to $O(|E|)$, where $|E|$ denotes the number of ties. By iteratively learning the transformation function and user's preference, SamWalker can adaptively specify different weights to different data based on users' social contexts.

4.1 Informative Sampler based on personalized random walk

As mentioned above, inferring user's preference from implicit feedback data is time-consuming due to the massive volume of the unobserved data. Thus, for efficient recommendation, SamWalker employs stochastic inference based on data sampling. That is, in each iteration, we update the preference parameters θ based on the estimated gradient from only a subset of the data. Note that different data may have different confidence weights. This makes the data sampling strategy important because it determines which data are used to update parameters and how often. Intuitively, the informative data with larger confidence γ_{ij} should be sampled with larger probability, since these terms make more contribution to the objective function. In fact, we have the following lemma:

Lemma 1. *To evaluate the unbiased gradient of L w.r.t θ, the sampling strategy with distribution $p_{ij} \propto \gamma_{ij}$ can reduce sampling variance.*

The proof are presented in appendix.

Also, the sampler with distribution $p_{ij} \propto \gamma_{ij}$ can speed up gradient estimation. As we can see from the following equation (9) (here ℓ_{ij} as shorthand for $\ell(x_{ij}, \sigma(u_i^T v_j))$), when the data sampling probability is proportional to the data confidence ($p_{ij} = \gamma_{ij}/G$), the confidence weights γ_{ij} can be absorbed into the sampling bias. Thus, in each iteration the gradient estimator does not need to calculate current learned confidence weights γ_{ij} to scale down the contribution from different data, which saves much time.

$$\frac{\partial L}{\partial \theta} = \sum_{i \in U, j \in I} \gamma_{ij} \frac{\partial \ell_{ij}}{\partial \theta} = \sum_{i \in U, j \in I} \frac{p_{ij}}{G} \frac{\partial \ell_{ij}}{\partial \theta} = E_p[\sum_{(a,b) \in p} \frac{1}{G} \frac{\partial \ell_{ab}}{\partial \theta}] \quad (9)$$

A naive implement of informative sampler with distribution $p_{ij} \propto \gamma_{ij}$ is to estimate and rank the current learned confidence weights γ_{ij} for every user-item pairs and then pick out the informative data based on γ_{ij}. It is apparently inefficient and can't satisfy practical requirement. To avoid having to estimate $n \times m$ confidence weights, we propose a subtle sampling strategy based on random walk along the network. Here we do some transformation of equation (8) to bring some insights:

$$\begin{aligned} Y &= (I - c\Phi)^{-1}(1-c)X \\ &= (1 + c\Phi + (c\Phi)^2 + (c\Phi)^3 \ldots)(1-c)X \end{aligned} \quad (10)$$

We can simulate the equation (10) and develop following sampling strategy:

For target user i, we perform the personalized random walk from user i to sample the informative feedback data of user i. At each step t of random walk, we are at a certain user u. We have two options: (1) With probability c, we do not continue the random walk. We stay at user u and randomly (uniformly) select a portion of (N_u/β) items that have been consumed by user u, where N_u denotes the number of items consumed by user u. Then we add the feedback data of user i on these selected items into sampled set S. (2) With probability $(1-c)$, we continue our random walk. We randomly select one of u's connected friends v ($v \in \mathcal{T}_u$) based on personalized tie strength (transition probability) φ_{uv} and walk to v for the next walk step.

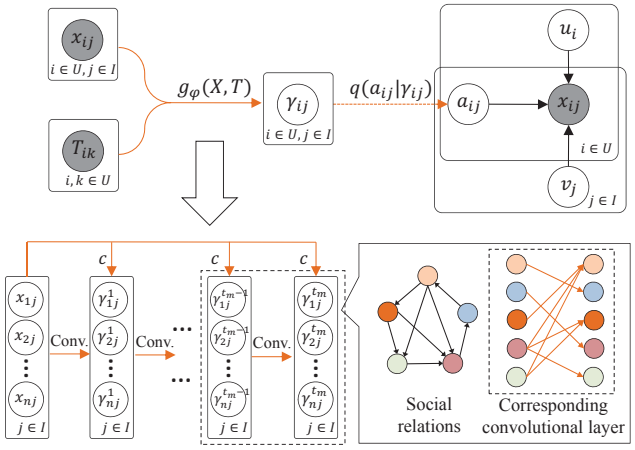

Figure 2: A schematic view of proposed model SamWalker (upper), the transformation function $g_\varphi(X, T)$ based on multi-layer convolutions (bottom-left), and the convolutional layer for the specific social network (bottom-right).

It is easy to check that the (i, v)-th element of matrix $(c\Phi)^t(1-c)$ is the probability of starting from source user i and terminating at user v in step t. Further, the (i, j)-th element of matrix $(c\Phi)^t(1-c)X$ represents the sampled probability of the user-item feedback data x_{ij} in step t. Sum over the probability in different step, we have the sampled probability of the data as follow:

$$P = \sum_{t=0}^{\infty} (c\Phi)^t (1-c)X/\beta \propto Y \quad (11)$$

which is proportional to the data confidence. Overall, our sampling strategy can efficiently draw informative training instances to speed up inference and reduce sampling variance.

In practice, we usually conduct α times random walk for each user to achieve more reliable mini-batch stochastic optimization. The paremeters α and β control the batch size. Note that there is a chance for a single random walk to continue forever. In fact, we pay more attention to user's local social context and thus terminate the random walk when we go very far from the source user ($t > t_m$). Concretely, when $t > t_m$, we walk to random user in the system (uniformly) and generated sampled data as option (1).

4.2 Inference of the personalized tie strength φ

Chaney et al. [7] and Wang et al. [46] claim that different social ties may have different influence strength. For example, we are more likely to get information from our close friends than from our acquaintances. Thus, the parameters φ of tie strength in transformation function tend to be diverse and is thus hard to be assigned manually. To deal with this problem, SamWalker fits transformation function and learns its parameters φ from the data.

Algorithm 1 Inference of SamWalker

1: Initialize parameters randomly;
2: **while** not converge **do**
3: Sample a set of data S based on the random walk as mentioned in subsection 4.1.
4: Update parameters θ of the preference model based on the estimated gradient from the sampled data (equation (9)).
5: randomly select a portion of N_{SI} items.
6: update personalized tie strength φ based on backward propagation along the neural network for the selected items.
7: **end while**

We achieve this by optimizing the lower bound of margin likelihood (equation 5) w.r.t tie strength φ_{ij} based on gradient methods. However, directly deriving gradient from transformation function g_φ (equation (8)) involves matrix inversion and suffers from low efficiency. Alteratively, as illustrated in Figure 2, SamWalker iteratively simulates information spread as equation (7), and constructs equivalent social-based convolutional neural network [28, 56] to infer the personalized tie strength. In fact, using convolutional neural network to model information spread in social network is natural: The nodes in t-th layer can represent users' exposure $\gamma_{ij}^{(t)}$ in t-th iteration. The forward process from layer t to $t+1$ models t-th information spread. That is, nodes/users collect the information from their social connected friends (neighbors) and generate new representation in $t+1$ layer:

$$\gamma_{ij}^{(t+1)} = \rho\Big(\sum_{k\in N_i} c\varphi_{ik}\gamma_{kj}^{(t)} + (1-c)x_{ij}\Big) \tag{12}$$

where $\rho(.)$ is an activation function. In SamWalker, we use identity activation function $\rho(x) = x$. In fact, other activation function can be employed for different prorogation pattern (e.g. sigmoid function for Linear Threshold [11]). Further, attentive mechanism has been employed to balance the social influence from different social friends (neighbors). Here we simply use independent attention and reparameterize $\varphi_{ik} = \frac{\exp(w_{ik})}{\sum_{k\in N_i}\exp(w_{ik})}$ using a Softmax transformation. In fact, more sophisticated attentive network can be employed to capture complex and context-aware tie strength [8, 21]. We will leave it in the future work.

With above neural network, backward prorogation can be conducted to infer tie strength φ, without requiring time-consuming matrix inversion. Further, mini-batch-based stochastic gradient methods can be employed to speed up the inference. That is, in each step, we randomly (uniformly) select a portion of N_{SI} items and update tie strength based on users' exposure on these selected items. Overall, the inference of our SamWalker is presented in Algorithm 1.

4.3 Discussion of the SamWalker

Global influence Vs. local influence. If a user has no connections with others, the method will face degeneration when estimating user's exposure or conducting random walk. To deal with this problem, we borrow the idea from Pagerank and consider a user may also get information from a random user. That is, when estimating user's exposure, users are assumed to link out to all other users but with very weak common tie strength. Thus, we revise equation (7) as follow:

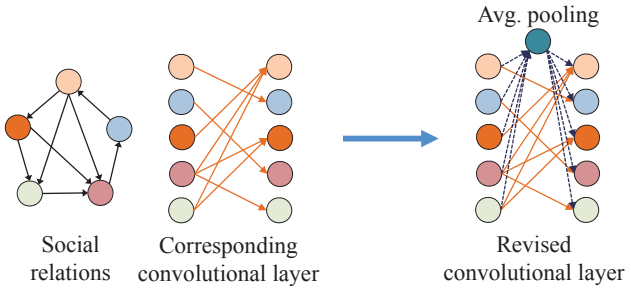

Figure 3: The revised convolutional layer for modeling both local influence and global influence.

$$\gamma_{ij}^{(t+1)} = (1-c)X_{ij} + c\Big(\sum_{k\in\mathcal{T}_i}\varphi_{ik}\gamma_{kj}^{(t)} + \frac{\varphi_{i0}}{n}\sum_{k\in U}\gamma_{kj}^{(t)}\Big) \tag{13}$$

where we introduce the influence from all other users to iteratively reconstruct user's exposure. Also, the parameters $\varphi_{i0}, \varphi_{ik}$ have been employed to balance the local social influence from connected users and the global social influence from all other users (i.e. $\varphi_{i0} + \sum_{k\in\mathcal{T}_i}\varphi_{ik} = 1$). From another perspective, the additional global term can be considered as the mean priori of users' exposure. As claimed by [36], users' selection behaviour is mainly driven by the local social influence among friends while the global popularity plays a supplementary role driving the behaviour only when there is little local information for the user to refer to. Thus, On the one hand, we introduce the global influence to pull user's exposure closer to the global average. On the other hand, users have their personalized local social contexts and thus are exposed to diverse item information. Correspondingly, local social influence term has been introduced to push users' exposure away from average and towards diversity. Overall, we combine these two effects to better capture user's exposure.

Correspondingly, to let our sampling strategy adapt to the revised data confidence, we add random transition into random walk. That is, in each step of random walk, we add another option (3): With probability $c\varphi_{i0}$, we walk to another user ($v \in U$) in the network by random (uniformly) and continue the random walk on v.

Also, as illustrated in Figure 3, with additional pooling units, global influence can be easily integrated into the social-based convolutional neural network to infer the tie strength $\varphi_{i0}, \varphi_{ik}$. Formally, we revise equation (12) as:

$$\bar{\gamma}_j^{(t)} = \frac{1}{n}\sum_{k\in U}\gamma_{kj}^{(t)}$$
$$\gamma_{ij}^{(t+1)} = \rho\Big(c\Big(\sum_{k\in N_i}\varphi_{ik}\gamma_{kj}^{(t)} + \varphi_{i0}\bar{\gamma}_j^{(t)}\Big) + (1-c)x_{ij}\Big) \tag{14}$$

Complexity Analysis. The computational time of the inference of SamWalker consists of three parts: (1) In sampling, we need to conduct α times random walk for each user to get sampled data set S. The time for sampling is $O(\alpha n t_m + |S|)$, where n denotes the number of users in the system, t_m denotes the max depth of random walk

Table 1: Statistics of three datasets.

Datasets	#Users	#Items	#Links	#User-item interactions
LastFM	1,892	4,489	25,434	52,668
Ciao	5,298	19,301	106,640	138,840
Epinions	21,290	34,075	414,549	333,916

and $|S|$ denotes the number of data in the set S. (2) When inferring the preference parameters θ, we just estimate loss and gradient for the sampled data based on equation (9). The time to update these parameters is $O(|S|d)$. (3) We infer the tie strength φ based on the gradient back propagation along the neural network for the selected N_{SI} items. The complexity for this part is $O(N_{SI}|E|)$. Hence, the overall computational complexity is $O(\alpha n t_m + |S|d + N_{SI}|E|)$. In practise, we usually let $|S|$ be five times as large as the number of observed data and let the number of selected items N_{SI} be 100. Thus, our algorithm is efficient on sparse implicit feedback data.

5 EXPERIMENTS AND ANALYSES

In this section, we conduct experiments to evaluate the running time and the recommendation quality of SamWalker. Our experiments are intended to address the following questions:

(Q1) Does SamWalker outperform state-of-the-art recommendation methods?
(Q2) How does the proposed social-based sampling strategy perform?
(Q3) Is it beneficial to model the personalized tie strength? Is it beneficial to model the both local social influence and global popularity influence?
(Q4) How does the parameter t_m (the max depth of random walk) affect the recommendation performance?

5.1 Experimental protocol

Datasets. Three datasets Epinions[3], Ciao[4], LastFM[5] are used in our experiments. These datasets contain users' feedback and social relations. Specifically, the datasets Epinions and Ciao contain users' ratings on movies, while the dataset LastFM contains users' clicks on music. The dataset statistics are presented in Table 1. Similar to [18, 50], we preprocess the datasets so that all items have at least three interactions and "binarize" user's feedback into implicit feedback. That is, as long as there exists some user-item interactions (ratings or clicks), the corresponding implicit feedback is assigned a value of 1. Also, we drop out items that have been consumed by too many (larger than 100) or too few (smaller than 3) users to moderate the popularity biases [5] in estimation. Grid search and 5-fold cross validation are used to find the best parameters. In our experiments, we set $\eta_{ij} = 0.1$, $\alpha = 100$, $\beta = 20$, $c = 0.9$, $t_m = 5$. All experiments are conducted on a server with 2 Intel E5-2620 CPUs and 256G RAM[6].

Compared methods. We compare SamWalker with following baseline methods. Table 2 concludes the characteristics of them.

[3]http://www.trustlet.org/epinions
[4]http://www.cse.msu.edu/~tangjili/trust
[5]https://grouplens.org/datasets/hetrec-2011/

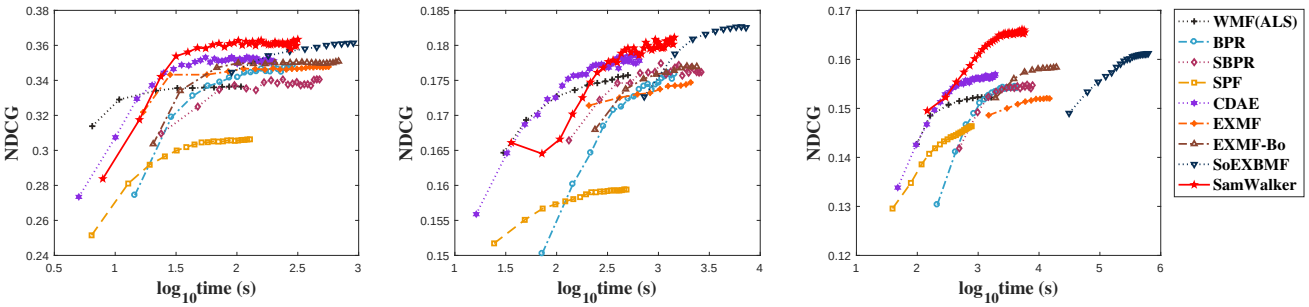
SamWalker	√	√	√	$O(\alpha n t_m + \|S\|d + N_{SI}\|E\|)$

- WMF(ALS) [22, 35]: The classic weighted matrix factorization model for implicit feedback data. The corresponding ALS-based [22] algorithm can reduce inference complexity.
- BPR [38]: The classic pair-wise method for recommendation, coupled with matrix factorization. For efficient recommendation, BPR employs uniform sampling strategy to draw the training instances.
- SBPR[58]: SBPR integrates social information into BPR by assuming that the items consumed by connected friends are ranked higher than those not.
- SPF [7]: A social recommendation model that incorporates social influence with users' latent preference based on poisson factorization.
- CDAE [49]: The advanced recommendation method based on Auto-Encoders, which is a generalization of WMF with more flexible components. However, efficient ALS-based inference algorithm are no longer suitable. Thus CDAE employs uniform sampling strategy to draw the training instances.
- EXMF [30]: A probabilistic model that directly incorporates user's exposure to items into traditional matrix factorization. EXMF does not utilize social information and chooses an item-dependent prior of user's exposure.
- SERec-Bo[45]: A probabilistic model that extends the EXMF model with social influence on user's exposure. Note that in [45] the authors reported that the performance of SERec-Bo is consistently better than their other model SERec-Re. Thus, here we choose SERec-Bo as a comparison.
- SoEXBMF [26]: A probabilistic model that further extends the EXMF model with both social knowledge influence and social consumption influence on user's exposure.



Evaluation Metrics. We adopt four well-known metrics Recall@K (Rec@K), Precision@K (Pre@K), Normalized Discounted Cumulative Gain (NDCG) and Mean Reciprocal Rank (MRR) to evaluate recommendation performance: Recall@K (Rec@K) quantifies the fraction of consumed items that are in the top-K ranking list sorted by their estimated rankings; Precision@K (Pre@K) measures the fraction of the top-K items that are indeed consumed by the user; NDCG and MRR evaluate ranking performance of the methods, which can be interpreted as the ease of finding all consumed items, as higher numbers indicate the consumed items are higher in the list. Refer to [47] for more details about these metrics.

5.2 Performance comparison (Q1)

Table 3 presents the performance of the compared methods in terms of three evaluation metrics. The boldface font denotes the winner in that column. Overall, with few exceptions, SamWalker outperforms

Table 3: The performance metrics of the compared methods. The boldface font denotes the winner in that column. The row 'Impv-e' indicates the relative performance gain of our SamWalker compared to the best results among these efficient baselines including WMF(ALS), BPR, CDAE, SPF, SBPR. The row 'Impv-a' indicates the relative performance gain of our SamWalker compared to the best results among all the baselines.

Figure 4: NDCG for each method in different steps versus time

all compared methods on all datasets for all metrics. For the sake of clarity, the last two rows of Table 3 also show the relative improvements achieved by SamWalker over the efficient baselines (Impv-e) and over all baselines (Impv-a) respectively. The improvement of SamWalker over the efficient baselines is apparent. Especially on the large dataset Epinions, the improvement is 56.0%, 64.2%,5.5%,40.9% in terms of Pre@5, Rec@5, NDCG, MRR respectively. The improvement of SamWalker over these efficient baselines can be attributed to two aspects: (1) In the real world, users have personalized social contexts and thus are exposed to diverse information. Correspondingly, data have diverse confidence for estimating user's preference. That is, some un-observed feedback are more likely attributed to user's preference while others are the results of users' awareness. By adaptively fitting fine-grained data confidence weights based on users' social contexts, SamWalker achieves better performance than those baselines with manually coarse-grained confidence weights. (2) Instead of employing pre-defined coarse-grained sampling methods, SamWalker employs random walk-based sampler to adaptively draw informative data, which can reduce sampling variance and achieve better performance. We also conduct specific experiments for different samplers in subsection 5.3 to validate this point.

Also, even although SamWalker employs stochastic optimization to reduce time complexity, SamWalker still beat these exposure-based methods (EXMF, SERec-Bo, SoEXBMF). This result validate the effectiveness of employing social-based variational posterior of user's exposure, which models the heterogenous influence from both direct and indirect social friends (neighbors). Although SoEXBMF can also capture such influence, it costs much more running time and requires pre-defined community distribution. In fact, accurate community distribution is not easy to get, which affects the performance of SoEXBMF model.

Runtime vs. NDCG. Figure 4 depicts running time (X-axis) vs. NDCG (Y-axis) of the nine compared recommendation methods. As we can see, generally, SamWalker achieves best performance. The powerful competitor is CDAE, which models user's preference based on collaborative auto-encoder. Although CDAE has better NDCG than SamWalker at first, SamWalker overtakes CDAE soon and before CDAE gets convergence. Especially on large dataset Epinions, SamWalker outperforms CDAE almost in all time and achieves much better performance than CDAE when they get convergence. Also, we observe that these exposure-based methods (EXMF,SERec,SoEXBMF) achieve good performance but cost a lot of time. Although these methods can learn the personalized confidence of the data, they need infer $n \times m$ parameters of user's exposure, which will suffer from low efficiency and overfitting. By employing social-based posterior structure of exposure and random walk-based sampler, our method SamWalker can beat

Table 4: Average empirical variance of the estimated gradients using different sampling strategies. Here $X^{(1)}$, $X^{(0)}$ denote the number of ones or zeros in the matrix X. Similarly, $r_i^{(1)}$, $r_i^{(0)}$ denote the number of ones or zeros in the i-th row of matrix X and $c_j^{(1)}$, $c_j^{(0)}$ denote the number of ones or zeros in the j-th column of matrix X.

5.3 Performance of the different samplers (Q2)

In this subsection, we compare our sampler with other sampling strategies including: (1) S-allunion, the uniform sampling strategy; (2) S-balunion [19, 35], which samples un-observed data (zeros) and observed data (ones) with equal probability to deal with unbalance data problem; (3) S-itempop [54], which samples data based on item popularity; (4) S-cobias [19], whose probability of sampling a un-observed data (zero) at location (i, j) is proportional to the number of ones in the i-th row (the number of user's consumption) and the number of zeros in the j-th colunm (item popularity). Also, an equivalent bias is introduced for the observed data. The detailed distributions of these sampling strategies are presented in Table 4.

Variance. We first empirically compare the variance of the estimated gradient of our objective w.r.t θ by using different sampling strategy. To do this, we train our model for 50,100 or 500 epochs on dataset LastFM. After training, we generate mini-batch with various sampling strategy and calculate un-biased estimated gradients of our objective w.r.t θ. We repeat this proceeding for 1000 times and calculate the variance of the estimated gradients for different sampling strategy. The final results presented in Table 4 are averaged over various preference parameters. Table 4 shows that our random walk-based sampling strategy achieves the lowest average variance among various samplers for all conditions. This result is coincide with our theory analysis in section 4.1. Our sampler, whose sampling probability is proportional to the data confidence, can indeed reduce the sampling variance. Also, we observe the following interesting phenomenon: With more training epoches, the variance will become larger, not smaller as usual. It may be explained as follow: SamWalker models the diverse data confidence and the personalized tie strength. At first, SamWalker keeps relative similar data confidence. With training proceeding, driven by the data, the confidence weights and the tie strength in SamWalker exhibit more and more heterogeneity. Thus, the variance of the estimated gradients will become larger.

Performance. Figure 5 presents the NDCG of SamWalker on dataset LastFM with different sampling strategies versus the number of iteration and running time. As we can see, our adaptive random walk-based sampler performs better than others in all convergence, speed and recommended performance. One reason is that our sampler has low variance, as presented in Table 4. Another reason is that in our sampler the confidence weights γ_{ij} are absorbed into the bias of the sampling distribution. Thus, the gradient estimator does not need to calculate γ_{ij} in each iteration to scale down the contribution from the different data, which saves much time.

5.4 Heterogenous social influence (Q3)

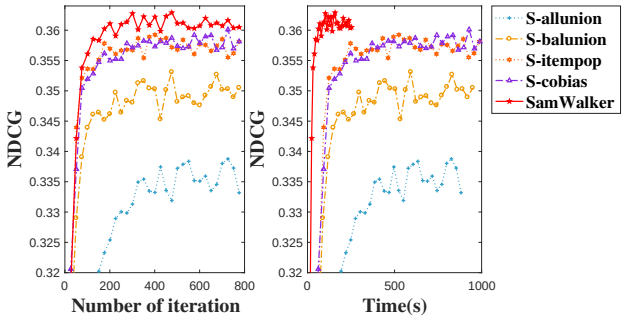
To show the effect of modeling heterogenous social influence, we compare SamWalker with its three special case: (1) SamWalker-ho, the special case of SamWalker with homogeneous tie strength. (2) SamWalker-g (item-pop): the special case which leave out heterogenous local social influence and models user's exposure just based on item popularity. (3) SamWalker-l: the special case which leaves out global influence. The performance of these special cases comparing with SamWalker is presented in Figure 6.

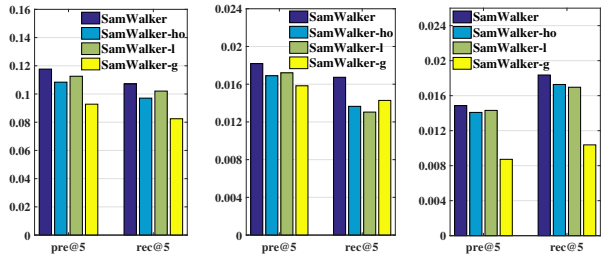
Personalized tie strength. As shown in Figure 6, SamWalker with personalized tie strength consistently achieves better performance than its special case SamWalker-ho with the homogeneous tie strength in all three datasets. These results support our intuition that different ties may have different influence strength. For example, the items consumed by our close friends that have high frequency of interactions, are more likely to come to our attention than those items consumed by our acquaintances.

Global influence Vs. local influence. Figure 6 also shows that SamWalker outperforms its special cases SamWalker-g and SamWalker-l. The result validates our point that user's exposure will be affected by both local social influence and global popularity influence. Especially, as claimed by some sociologic related works [36], user's social relations have become a major information resource when he select items to consume. Thus, we observe the apparent improvement of SamWalker over the special case SamWalker-g (item-pop) which leaves out local social influence.

5.5 Effect of parameter t_m (Q4)

It will be interesting to explore how parameter t_m affects the performance of SamWalker, where t_m indicates the max depth of the random walk. As we can see from Figure 7, as t_m become larger, with few exception, the performance will become better first. The





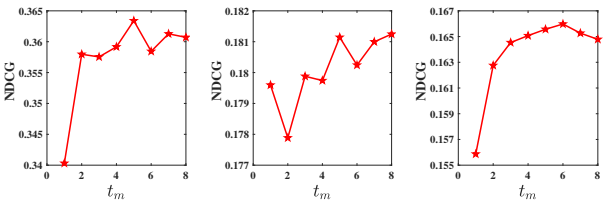


Figure 5: NDCG for different sampling strategy versus the number of iterations and running time

Figure 6: Performance comparison of SamWalker with its three special cases

(a) On dataset LastFM (b) On dataset Ciao (c) On dataset Epinions

Figure 7: Performance comparison with varying t_m

reason is that the information about items propagates along the social network. User's exposure will also be influenced by his high order neighbors. However, when t_m surpasses a threshold ($t_m > 5$), the performance becomes unaffected or even worse with further increase of t_m. In fact, based on the idea of "six-degrees of separation [43]", the random walk with length 5 can visit most of the nodes in the social network. Too deep random walk will not bring more usual information and sometimes bring some noises.

6 CONCLUSIONS

In this paper, we present a novel recommendation method SamWalker that leverages social information to simultaneously learn the personalized data confidence and draw informative training instances. On the one hand, SamWalker models the posterior of user's exposure with a social context-aware function, which can reduce the number of learned parameters and adaptively specify different confidence weights to different data. On the other hand, we propose a personalized random walker-based sampling strategy to draw informative training instances to speed up inference and reduce sampling variance. The personalized transition probability (tie strength) can be inferred efficiently based on our attentive neural network. The experimental results on three real-world datasets demonstrate the superiority of SamWalker over existing methods.

One interesting direction for future work is to explore dynamic exposure-based recommendation. In the real world, users' preference, exposure and relations may evolve over time. Further, we did not examine other attentive structure when modeling tie strength. It will be also interesting to develop more complex attentive model and explore context-aware social influence.

A PROOF OF LEMMA 1

Given the confidence weights γ_{ij}, we have the following un-biased gradient estimator of the objection (equation 5) based on the specific sampler p_{ij}:

$$\nabla_\theta L = \sum_{i\in U, j\in I} \gamma_{ij} \nabla_\theta \ell_{ij} = E_p[\frac{nm}{|S|} \sum_{a,b\in p} \frac{\gamma_{ab} \nabla_\theta \ell_{ab}}{p_{ab}}] \quad (15)$$

where ℓ_{ij} is shorthand for $\ell(x_{ij}, \sigma(u_i^T v_j))$ and $|S|$ denotes mini-batch size. Then, we have following variance of the gradient estimator:

$$\begin{aligned} & Var_{(a,b)\sim p}[\frac{nm}{|S|} \sum_{a,b\in p} \frac{\gamma_{ab} \nabla_\theta \ell_{ab}}{p_{ab}}] \\ &= \frac{n^2 m^2}{|S|} Var_{(a,b)\sim p}[\frac{\gamma_{ab} \nabla_\theta \ell_{ab}}{p_{ab}}] \\ &= \frac{n^2 m^2}{|S|} (E_p[(\frac{\gamma_{ab} \nabla_\theta \ell_{ab}}{p_{ab}})^2] - {E_p}^2[\frac{\gamma_{ab} \nabla_\theta \ell_{ab}}{p_{ab}}]) \\ &= \frac{n^2 m^2}{|S|} E_p[(\frac{\gamma_{ab}^2}{p_{ab}^2} \nabla_\theta^2 \ell_{ab}] - (\sum_{i\in U, j\in I} \gamma_{ij} \nabla_\theta \ell_{ab})^2 \end{aligned} \quad (16)$$

It is untractable to find optimized p_{ij} based on equation (16) due to the unknown of the terms $\nabla_\theta^2 \ell_{ab}$. But we can derive the tight upper-bound of the variance based on Cauchy inequality as follow:

$$\begin{aligned} & Var_{(a,b)\sim p}[\frac{nm}{|S|} \sum_{a,b\in p} \frac{\gamma_{ab} \nabla_\theta \ell_{ab}}{p_{ab}}] \\ &= \frac{n^2 m^2}{|S|} E_p[(\frac{\gamma_{ab}^2}{p_{ab}^2} \nabla_\theta^2 \ell_{ab}] - (\sum_{i\in U, j\in I} \gamma_{ij} \nabla_\theta \ell_{ab})^2 \\ &\le \frac{n^2 m^2}{|S|} \sum_{ij} \frac{\gamma_{ij}^2}{p_{ij}} \times E_{p,\ell_{ab}}[\nabla_\theta^2 \ell_{ab}] - (\sum_{i\in U, j\in I} \gamma_{ij} \nabla_\theta \ell_{ab})^2 \end{aligned} \quad (17)$$

Also, we can find the minimum of $\sum_i \frac{\gamma_{ij}^2}{p_{ij}}$ as follow:

$$\sum_i \frac{\gamma_{ij}^2}{p_{ij}} = \sum_i \frac{\gamma_{ij}^2}{p_{ij}} \sum_i p_{ij} \geq (\sum_i \frac{\gamma_{ij}}{\sqrt{p_{ij}}} \sqrt{p_{ij}})^2 = (\sum_i \gamma_{ij})^2 \quad (18)$$

The equation holds if and only if $p_{ij} \propto \gamma_{ij}$. Now, the sampling strategy has the lowest upper-bound of the variance.

ABSTRACT

Recommendation serendipity is being increasingly recognized as being equally important as the other beyond-accuracy objectives (such as novelty and diversity), in eliminating the "filter bubble" phenomenon of the traditional recommender systems. However, little work has empirically verified the effects of serendipity on increasing user satisfaction and behavioral intention. In this paper, we report the results of a large-scale user survey (involving over 3,000 users) conducted in an industrial mobile e-commerce setting. The study has identified the significant causal relationships from novelty, unexpectedness, relevance, and timeliness to serendipity, and from serendipity to user satisfaction and purchase intention. Moreover, our findings reveal that user curiosity plays a moderating role in strengthening the relationships from novelty to serendipity and from serendipity to satisfaction. Our third contribution lies in the comparison of several recommender algorithms, which demonstrates the significant improvements of the serendipity-oriented algorithm over the relevance- and novelty-oriented approaches in terms of user perceptions. We finally discuss the implications of this experiment, which include the feasibility of developing a more precise metric for measuring recommendation serendipity, and the potential benefit of a curiosity-based personalized serendipity strategy for recommender systems.

1 INTRODUCTION

Recommender systems have been popularly used in many Web applications to eliminate users' information overload, with recommended items/information being tailored to the users' individual interests. Traditionally, accuracy is the primary metric for judging a recommender system's effectiveness [15, 28, 40]. However, it may cause the "filter bubble" phenomenon in which users are trapped in a subspace of options that are too similar to their profile, and hence lose the opportunity to explore outside alternatives that may potentially match their preferences [26, 28, 34].

Therefore, some beyond-accuracy objectives, especially *diversity*, *novelty*, and *serendipity*, have been emphasized in the recent literature, because they are targeted to allow users to discover new and different items to broaden their horizons [12, 15, 26]. By definition, *diversity* refers to the difference between the current recommendation and the user's profile (e.g., the user's previously purchased items) or the system's prior recommendations [21][1]. *Novelty* stresses whether the item is unknown to the user. *Serendipity* emphasizes whether the user feels surprised when s/he sees a relevant recommendation, which implies that the item should not only be relevant to the user's interests, but also be unexpected (i.e., not intentionally looked for by the user). Therefore, different from diversity and novelty that may compromise accuracy to a certain degree, serendipity aims to preserve both accuracy and positive emotional response evoked by the recommendation [19, 20, 24].

However, because the "surprising" nature of serendipity is difficult to measure and simulate [6, 15, 29], the actual benefit of serendipity for recommender systems is still unclear. It is not conclusive whether the increased serendipity of recommendation would

[1] Another definition of diversity refers to the intra-list diversity within a set of recommended items [48], which is beyond the scope of this paper.

necessarily lead to users' higher satisfaction with the recommendation [19], and even their higher intention to purchase the recommended item if in an e-commerce domain.

In this study, we conducted a large-scale user survey (involving over 3,000 participants) to measure users' perceptions of recommendations, in relation to serendipity and its components (unexpectedness and relevance), novelty, diversity, user satisfaction, and purchase intention. The results are thus likely to help identify the causal relationships among these factors. For example, *are diversity and novelty significantly related to serendipity?* And *does serendipity significantly improve user satisfaction and purchase intention?* To design the questionnaire, we selected the popularly used questions from related literatures and translated them into Chinese (because our experimental system was plugged into a Chinese industrial mobile e-commerce app called *Mobile Taobao*). It is worth noting that the Chinese translation of the term "serendipity" is "惊喜" that contains two characters: '惊' (surprising) and '喜' (relevant), so it would be intuitive for Chinese users to easily interpret the meaning of "serendipity" when they answer the related questions.

In addition to acquiring users' perceptions of recommendations, we included a curiosity quiz to measure whether they have a strong desire for new knowledge or experiences in general. Indeed, curiosity has been widely regarded as an important antecedent of users' appetite for novelty in the field of psychology [2, 23, 39]. It can greatly affect the level of pleasure a user experiences when s/he explores new and surprising things. For instance, if an item under or over matches her/his curiosity, s/he may feel bored or overwhelmed, rather than pleasant [29, 47]. In this sense, the degree in which a recommendation is perceived as serendipitous might be more or less dependent on the user's curiosity. To verify this point, we integrated curiosity as a moderating factor into our path model to test its effects.

Our third contribution lies in the comparison of four recommender algorithms in relation to user perceptions, which include a non-personalized popularity-based approach, and three variants of the collaborative filtering (CF) based method that are respectively relevance-, novelty-, and serendipity-oriented. To the best of our knowledge, most of the existing algorithm evaluations for e-commerce products have relied on offline metrics [1, 12, 15, 30]. Given there is often a gap between offline measurements and user perceptions (especially regarding the beyond-accuracy objectives) [37], we believe it should be meaningful to conduct an online user study to evaluate whether users would be practically more satisfied with an algorithm's recommendation if it is perceived of higher serendipity. The results could also help improve the existing offline metrics (e.g., more precisely measuring serendipity).

In short, this study makes four major contributions. First, we conducted a large-scale online user survey in an industrial mobile e-commerce setting to collect user feedback on various beyond-accuracy assessments. Second, we validated a hypothesized path model that reveals the causal relationships from novelty, unexpectedness, relevance, and timeliness to serendipity, and from serendipity to user satisfaction and purchase intention. Third, we identified the moderating effects of user curiosity on the relationships from novelty to serendipity and from serendipity to satisfaction. Fourth, we experimentally compared four algorithms for recommending e-commerce products, and found a serendipity-oriented approach is significantly more effective in terms of enhancing user perceptions of the recommendation.

The remainder is organized as follows. We first introduce the related works on serendipity in recommender systems and those considering user curiosity to improve recommendations (Section 2). We then present our user survey, including the experimental procedure, data collection, questionnaire design, and hypothesized model (Section 3). The results are then analyzed through model validation, moderation test, and algorithm comparison (Section 4). We discuss the practical implications of our findings in Section 5, and draw the final conclusions in Section 6.

2 RELATED WORK

2.1 Serendipity in Recommender Systems

The original definition of serendipity is "[...] *making discoveries, by accidents and sagacity, of things which they were not in quest for* [...]" [3, 24, 42]. [12] is one of earlier papers to list serendipity as one of the beyond-accuracy objectives for recommender systems. Since then, serendipity has been used to measure how surprising and relevant a recommendation is [6, 20, 28]. In other words, this factor is comprised of two core components: *surprise* in the sense of unexpected (i.e., different from the user's expectations) and *relevance* (i.e., useful to the user).

However, the assessment of *surprise* is not straightforward because it involves the user's emotional response to a recommendation. In previous work, surprise (or called unexpectedness) was defined as the deviation from a primitive prediction method that produces expected recommendations [10, 30]. For example, [10] proposed a formulation that combines unexpectedness with item relevance, for which the set of unexpected recommendations is acquired by subtracting from those items generated by a primitive prediction model, and the relevance of a recommendation is approximated offline based on users' ratings. Considering this approach is sensitive to the choice of the primitive prediction model, [1] regarded items rated by the user and those similar to the rated ones to be the expected recommendations.

As stated in [15], evaluations of recommendation serendipity that do not involve user feedback can be unreliable, because it is not evident whether the recommended item would be perceived to be serendipitous by the user, even though some objective metric indicates it is. So far, few studies have empirically measured recommendation serendipity and its actual benefits from users' perspective. For instance, [46] conducted a small-scale user study (with 21 participants) to evaluate user perceptions of a serendipity-enhancing system that recommends music artists. The results showed most of the users overall preferred the serendipity-oriented system to the accuracy-oriented baseline especially in terms of serendipity and novelty, but gave lower ratings to serendipity-based recommendations. The authors concluded that the users are willing to compromise accuracy for serendipity, which nevertheless is contrary to the original definition of serendipity as comprising both relevance and unexpectedness. [33] designed a fusion-based recommender interface that allows users to experience extrinsic and intrinsic accidents for discovering serendipitous books. They recruited 9 users to evaluate the interface, which demonstrated its advantage over the standard Amazon interface as for serendipity.

In a more recent work, [6] combined the questionnaire and facial expression detection approaches in a preliminary user experiment (involving 40 subjects) performed on their proposed graph-based random walk algorithm. Two questions were asked to respectively assess a user's perceived relevance of a recommended movie and its unexpectedness. The user's facial expression was detected simultaneously to implicitly infer her/his degree of surprised when seeing the item. The experimental results showed their algorithm was perceived to be more relevant and serendipitous than a random recommendation method. They also found a moderate agreement between the questionnaire answers and facial expression detection results.

Given that there are different interpretations of serendipity in the related literature, [19] conducted a user survey (participated by 475 users) to acquire users' responses to eight different serendipity definitions in a movie recommender. The survey also aimed to verify whether it is meaningful to recommend serendipitous items. Specifically, by running a regression model on the users' answers to various serendipity assessments with the two dependent variables *preference broadening* and *user satisfaction*, the authors found that most definitions of serendipity helped broaden user preferences, but none of them affected user satisfaction.

The novelty of our work lies in revealing the relationships among the three beyond-accuracy factors, *novelty*, *diversity*, and *serendipity*, and their respective impacts on *user satisfaction* and *purchase intention*. From the algorithm's perspective, we compared a serendipity-oriented approach with three related methods, focusing on identifying their differences in terms of user perceptions. In addition, differing from the small-scale user studies in the related work, our study, to the best of our knowledge, is the first one performed on an industrial mobile e-commerce platform for a large-scale user experiment.

2.2 Recommendation based on User Curiosity

Curiosity, as a particular psychological trait that can affect a user's desire for exploration, has been found to likely influence the user's reaction to recommendations [29]. For example, it was shown that more curious people prefer recommendations containing some unexpected items, but less curious individuals prefer recommendations that are mostly similar to what they experienced before [29, 47].

Thus, some studies have attempted to incorporate curiosity into their recommendation methods. For example, [47] developed a curiosity-based music recommender, in which the recommendations can be personalized to the individual user's curiosity level. They mainly implemented a probabilistic curiosity model learnt for each user based on her/his access history. With this model, a curiousness score is computed for each item to indicate how curious the target user will be about it. Those items that are both relevant and suited to the user's curiosity level are then recommended. A major finding of their offline experiment is that the proposed method can improve the recommendation personalization and accuracy at the same time. In [29], a personalized recommendation architecture was presented in a tourism context, which aimed to adapt the degree of surprise of a recommended item to the user's curiosity. For this purpose, they proposed to predict a user's curiosity from her/his data shared on social network websites like Facebook, and then generate a recommendation list with the degree of unexpectedness tailored to the user's curiosity value. [24] also considered users' curiosity, with the objective of enhancing a TV program recommender. They adopted a psychological curiosity theory that defines two appraisals of curious emotion: *novelty check* and *coping potential check*. They then proposed to estimate the first appraisal based on an item's dissimilarity to those in the user profile and the second one based on the diversity of items within the user profile. A user study involving 165 participants showed that using curiosity to guide recommendations can be promising in terms of balancing serendipity and precision.

However, the above-described studies mostly inferred users' curiosity from their behavioral data and then incorporated the inferred curiosity into the process of generating recommendations. Little ground work has been done to verify the exact effect of curiosity on users' perceived recommendation serendipity. Therefore, we particularly investigated this effect in our user survey, which may be constructive for developing more personalized serendipity strategy based on user curiosity.

3 USER SURVEY

3.1 Setup and Measurement

We conducted a user survey on a popular mobile e-commerce platform in China (*Mobile Taobao*) from Dec. 21, 2017 to Jan. 11, 2018. The users were able to access the survey's link after they logged in the system. If a user volunteered to take part in, s/he first received a recommended product (that was generated by one of our tested algorithms, and was from one of various product domains such as "clothes," "toys," "home appliances," "foods," etc.) including its name, image, short description, and price. The user then completed a questionnaire that assessed her/his immediate feedback on this recommendation. S/he was also asked to answer several questions about her/his personal background (e.g., age, gender), and fill out a psychological curiosity quiz. As the incentive, all of the participants were placed in a lottery draw with customized presents as awards given to the winners.

3,039 users joined in our survey. We carefully checked their responses in order to filter out invalid answers. For example, if a user did not answer all of the questions, or gave the same rating to all the questions (some were asked in the reverse way), her/his response was deleted. We also removed redundant responses (by the same user) and only kept her/his first response. As a result, 2,401 users remained (1,651 females). An analysis of the users' historical behaviors over the past three months (from Oct. to Dec., 2017) showed that all of them had clicked at least one item before taking the survey (98.5% had more than 100 clicks).

In the following, we introduce the variables assessed in the user survey.

3.1.1 User Perceptions of Recommendation. Because the survey was completed on the user's mobile device, s/he would have been less patient in responding to a lengthy questionnaire consisting of many questions [41]. Therefore, to reduce the survey duration, we adopted a short version of ResQue (a widely used user-centric evaluation framework for recommender systems [36]), which, as

claimed by the authors, can provide a fast and reliable way to assess user perceptions of recommendations. Specifically, we used the suggested question for each of the four variables (see Table 1): *recommendation relevance* (Q1), *recommendation novelty* (Q2), *satisfaction* (Q8), and *purchase intention* (Q9). For recommendation diversity, because we emphasize the difference of the currently recommended item from those the user previously experienced, we included two specific questions: one is about the difference from the user's previously purchased product types (Q3: *pur_diversity*), and the other is about the difference from the system's prior recommendations (Q4: *rec_diversity*). In addition, we asked two questions particularly related to recommendation serendipity: *unexpectedness* (Q5) and *serendipity* (Q6). As mentioned before, there is a popularly used Chinese word "惊喜" that can well convey the meaning of serendipity to Chinese users, so we asked about the user's perceived serendipity directly, instead of choosing indirect statements designed to address the interpretation difficulty of the English word "serendipity" [19, 24, 37]. We also added a question about the recommendation's context compatibility [36], i.e., whether the item is recommended at the right time (Q7: *timeliness*).

Overall, nine questions were included in our survey to assess a user's perceptions of the recommendation (each responded on a 5-point Likert scale from "strongly disagree" to "strongly agree"). In Section 3.2, we present a hypothesized path model to depict their potential causal relationships.

3.1.2 Curiosity Instrument. According to the psychological theory [2, 23, 39], curiosity is an intrinsic human trait, triggered when there is a gap between the person's current knowledge level and the desired level. Because different people may have different desires for new knowledge, in recommender systems, some users may feel excited when they see an unexpected recommendation, while some may be reluctant to explore unfamiliar items [29, 47]. Thus, in our survey, we asked the participants to respond to a popular curiosity instrument, Curiosity and Exploration Inventory-II (CEI-II) [16] (an improved version of the original Curiosity and Exploration Inventory (CEI) [17]), because it was proven capable of assessing individual differences in the "general tendency to embrace novel or uncertain situations and to seek out new experiences." Specifically, it is a 10-item self-report scale embodying two factors: *Stretching* ("motivation to seek out knowledge and new experiences") and *Embracing* ("willingness to embrace the novel, uncertain, and unpredictable nature of everyday life"). Each item is rated on a 5-point Likert scale from "very slightly or not at all" to "extremely." This instrument has been shown to have acceptable internal reliability and stable validity across time. It is also short enough to be possibly completed within two minutes [5]. Another favorable consideration is that it was validated as having good psychometric properties in a Chinese context [45].

3.2 Hypothesized Path Model

Figure 1 shows our hypothesized path model covering all of the observed variables. We first linked the two major components, *unexpectedness* and *relevance*, to *serendipity*, because it has been claimed that a serendipitous recommendation should be not only unexpected (surprising), but also relevant to the user's preferences

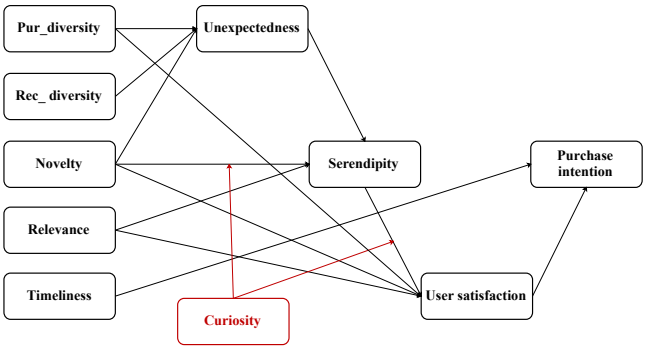

Figure 1: Hypothesized path model.

[15, 19, 24]. We were hence interested in verifying the two components' respective contributions to serendipity. In some related work, *novelty* has also been closely related to serendipity as one key component [12, 19, 28]. For example, [12] stated that a serendipitous item should be both novel (unknown to the user) and surprising. Therefore, we also linked novelty to serendipity, so as to identify to what degree a user may feel a recommendation is serendipitous when s/he perceives it as novel.

In addition, we postulated that *novelty* and *diversity* lead to *unexpectedness* [15]. That is, a novel item, or an item different from the user's previously purchased items (*pur_diversity*) or from the system's prior recommendations (*rec_diversity*), would make the user feel that it is unexpected. In this sense, unexpectedness may act as a mediator in passing some of the effect from novelty to serendipity, and also build a bridge between diversity and serendipity to reflect the diversity's indirect effect.

More importantly, we aimed to identify the factors that empirically influence *user satisfaction* with the recommendation. Although it has been recognized that accuracy alone does not always result in user satisfaction [12], few studies have verified whether and how the other beyond-accuracy factors, especially *serendipity*, have a positive effect in this regard. For instance, in a recent work [19], the effect of serendipity on satisfaction was not found to be significant. As for *diversity* and *novelty*, some user studies showed that diversity positively affects user satisfaction, whereas novelty has a negative effect [7]. However, in another work [36], novelty was demonstrated to have positively higher impact than diversity on satisfaction. We therefore expected that by collecting a larger amount of user feedback in a realistic recommending environment (e.g., mobile e-commerce in our experiment), we could empirically identify these factors' exact roles.

Finally, we postulated that the context compatibility and user satisfaction lead to higher *purchase intention* [36]. In particular, context compatibility refers to the timely compatibility (i.e., *timeliness*) of the current recommendation in our experiment. For example, although a user generally likes digital cameras, s/he may not want to buy a new one at present because s/he has already owned one. It was hence assumed that if one user is satisfied with a recommendation that also meets her/his current requirement, s/he would be more likely to purchase it.

Table 1: Assessment of user perceptions of the recommendation and descriptive statistics (of 2,348 responses after filtering out invalid records and outliers)

Subjective variable and assessment question	Mean	Std.	Median	Kolmogorov-Smirnov test	Skewness	Kurtosis
Relevance: *Q1. "The item recommended to me matches my interests."*	3.32	1.410	4.00	0.255^{***}	-0.419	-1.192
Novelty: *Q2. "The item recommended to me is novel."*	3.06	1.424	3.00	0.235^{***}	-0.146	-1.391
Pur_diversity: *Q3. "The item recommended to me is different from the types of products I bought before."*	3.39	1.215	4.00	0.221^{***}	-0.400	-0.813
Rec_diversity: *Q4. "The item recommended to me is similar to the system's prior recommendations."*(reversed)	2.93	1.302	3.00	0.206^{***}	0.214	-1.109
Unexpectedness: *Q5. "The item recommended to me is unexpected."*	3.16	1.437	3.00	0.207^{***}	-0.199	-1.337
Serendipity: *Q6. "The item recommended to me is a pleasant surprise."*	2.73	1.456	2.50	0.193^{***}	0.195	-1.400
Timeliness: *Q7. "The item recommended to me is very timely."*	3.00	1.484	3.00	0.207^{***}	-0.074	-1.450
User satisfaction: *Q8. "I am satisfied with this recommendation."*	3.21	1.140	3.00	0.210^{***}	-0.286	-0.466
Purchase intention: *Q9. "I would buy the item recommended, given the opportunity."*	2.83	1.456	3.00	0.191^{***}	0.003	-1.418
Curiosity: Curiosity and Exploration Inventory-II (CEI-II) with a 10-item self-report scale [16]	3.13	0.831	3.10	0.043^{***}	0.088	-0.402

Note: $^{***}p < 0.001$; all of the questions were accompanied by Chinese translations.

Furthermore, considering that *curiosity* is a personal trait, we incorporated it as a moderating factor into our path model. By definition, "moderation" means that this factor will moderate the effect of one variable on another variable [22]. For instance, highly curious users may be more inclined to perceive a novel item as serendipitous, because they tend to embrace uncertain situations (i.e., curiosity moderates the causal relationship *from novelty to serendipity*). Moreover, they may be more satisfied with a serendipitous item, compared to less curious users (i.e., curiosity moderates the relationship *from serendipity to satisfaction*).

3.3 Algorithms

Another objective of our user survey was to compare several recommender algorithms in terms of the users' perceived serendipity and the other subjective variables, which may help explain whether and why some particular algorithm would be preferred over others. Specifically, we implemented a popularity based approach as the baseline, and three variants of the collaborative filtering (CF) based method that are respectively tailored to highlight relevance, novelty, and serendipity of the recommendation.

(1) The baseline recommends a product with the most clicks to users (referred to as *HOT* henceforth), so it is purely popularity based without considering the target users's preferences.

(2) For the second method, we intended to strengthen a recommendation's relevance to the user's preferences. For this purpose, we revised the standard user-based CF by calculating a domain-specific similarity score $sim_d(u, v)$ between two users u and v (see Equation (1)), so that if they have often clicked the same item within the same domain (e.g., "clothes," "toys," "home appliances") and the clicking time is close, their overall similarity will be enhanced. This approach is shortened as *Rel-CF*.

$$sim_d(u,v) = \frac{\sum_{i \in I_{du} \cap I_{dv}} W_i^2 / (1 + \alpha \cdot |t_{ui} - t_{vi}|)}{\sqrt{\sum_{i \in I_{du}} W_i^2} \sqrt{\sum_{j \in I_{dv}} W_j^2}} \quad (1)$$

where I_{du} is the item set that the user u has clicked in domain d, and t_{ui} is the time stamp when u clicked i (so $|t_{ui} - t_{vi}|$ gives the time interval between u's and v's clicks on the same item i). W_i is the weight of an item i, computed via $W_i = \frac{1}{\log_2(3+q_i)}$, so it will be higher if the item has been less frequently clicked (q_i is the clicking frequency of i). The score for an unknown item for user u is predicted as:

$$score(u,i) = \sum_{d \in D} \sum_{\substack{v \in (U_i \\ \cap S_d(u))}} sim_d(u,v) * r(v,i) \quad (2)$$

where D is the set of all domains (36 domains in our experiment), $S_d(u)$ contains the top n users who are most similar to user u w.r.t. domain d according to $sim_d(u, v)$, U_i is the set of users who have clicked item i, and $r(v, i)$ is the rating score that v gave to i (that is the implicit clicking behavior in our case, i.e., 1 "clicked" and 0 "not clicked").

(3) The third method aims to be novelty oriented, by recommending an item from a category/domain outside of the user's profile (so unlikely known by the user). We adopted the item-based CF, but only calculated the similarity between two items if they belong to two different categories of a domain or two different domains (one domain can consist of multiple categories, e.g., the domain "clothes" includes the categories "T-shirt," "skirt," "sweater," etc.). This approach is shortened as *Nov-CF*.

$$sim(i,j) = \frac{\sum_{(c_i \neq c_j) \& (u \in U_i \cap U_j)} W_u^2 / (1 + \alpha \cdot |t_{ui} - t_{uj}|)}{\sqrt{\sum_{u \in U_i} W_u^2} \sqrt{\sum_{v \in U_j} W_v^2}} \quad (3)$$

where c_i is the category of i, and W_u is the weight of user u, computed via $W_u = \frac{1}{\log_2(3+q_u)}$, so if a user has clicked fewer items (i.e., q_u), her/his weight will be higher. The prediction score for an unknown item for user u is hence computed as:

$$score(u,i) = \sum_{j \in (S(i) \cap I_u)} sim(i,j) * r(u,j) \quad (4)$$

where $S(i)$ is the set of the top n items that are most similar to item i according to $sim(i, j)$, and I_u is the set of all items that have been clicked by user u.

(4) The fourth is more serendipity oriented (shortened as *Ser-CF*), because its recommendation's relevance to the target users's preferences is more strengthened on top of *Nov-CF*. Specifically, it considers the time sequence of two items clicked by a user as well as the other items clicked between them in the sequence:

$$sim_{seq}(i,j) = \sum_{(u \in U_i \cap U_j) \& (p_{uj} < p_{ui})} W_{uij} \cdot s_u(p_{ui}, p_{uj}) \quad (5)$$

where $s_u()$ gives the sum of similarities between any two adjacent items positioned from p_{uj} to p_{ui} (p_{uj} is the position of item j within the time sequence of items user u has clicked, and $p_{uj} < p_{ui}$ indicating that j was clicked before i). $W_{uij} = \frac{\sum 1/|I_u \cap I_v|}{|U_i \cap U_j| - 1}$ denoting the distance of u from other users who also clicked both items i and j (i.e., $v \in (U_i \cap U_j) \backslash \{u\}$), so that if the whole set of items s/he clicked (I_u) is largely different from other users', her/his weight will be higher.

$$s_u(p_{ui}, p_{uj}) = \sum_{\substack{(p_{uj} \le p_{um}, p_{un} \le p_{ui}) \\ \&(p_{un} = p_{um}+1)}} sim(m, n) \quad (6)$$

where $sim(m, n)$ is computed via Equation (3). The prediction score is thus computed as:

$$score(u, i) = \sum_{j \in (S(i) \cap I_u)} sim_{seq}(i, j) * r(u, j) \quad (7)$$

Each participant was randomly assigned one of the four algorithms' recommendations, which basically adheres to the between-subjects experimental design for simulating real-world experiences [11]. The numbers of users assigned to the four algorithms are respectively: 570 for HOT, 596 for Rel-CF, 589 for Nov-CF, and 593 for Ser-CF (out of 2,348 users after filtering out invalid records and outliers).

4 RESULTS ANALYSIS

We chose IBM SPSS Amos to run the path analysis [4], because it allows us to test the causal relations among the nine observed variables (see Table 1). We first checked whether our data meet its assumption of multivariate normality. The results show the multivariate kurtosis value is 7.749 (Mardia's coefficient), with a critical ratio (c.r.) of 5.798, which is greater than the desired level 1.96 [9]. Therefore, we deleted some obvious outliers with very large Malanobis d-squared distances (i.e., improbably far from the centroid). In consequence, there were 2,348 users' responses left (1,621 females), which were found to be normal by a Mardia's coefficient of 1.440 (c.r. = 1.904). We then conducted normality testing for each variable. The p values of the Kolmogorov-Smirnov test (suitable for sample size greater than 2,000 [25]) are all less than 0.001 (see Table 1), showing that the null hypothesis of normal distribution is rejected for each variable (including curiosity). Therefore, we chose non-parametric tests that do not assume normality for the following correlation and comparison analyses. But we still used Amos to test our path model, because the multivariate distribution of the observed variables is normal, and each variable's univariate skewnesses and kurtosis are in the acceptable ranges of -1.0 to 1.0 and -2.0 to 0 respectively (so not likely to inflate the Chi-squared statistics of path analysis according to [31]).

In addition, we checked whether there are high inter-correlations among those variables, because such multicollinearity phenomenon may cause disturbance and unreliability in the regression analysis [8]. For this purpose, we calculated the Spearman's correlation coefficients[2], which are all below 0.80 suggesting that there is no serious problem with multicollinearity (we later performed collinearity diagnostics for each outcome variable for further confirmation).

[2]Spearman's correlation is a non-parametric test used to measure the degree of association between two variables.

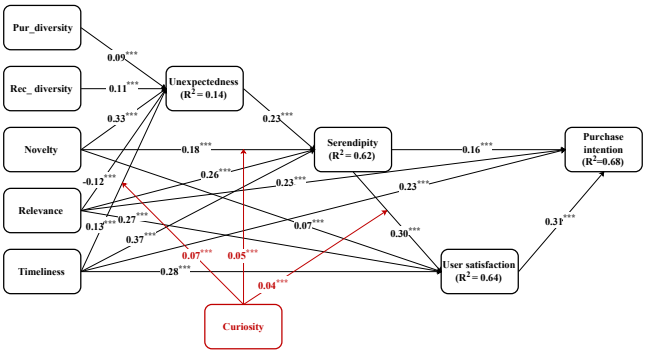

Figure 2: Path model fit. The value associated with each path is the standardized regression coefficient via bootstrap estimates, and the interaction term involving curiosity is standardized for moderation analysis (*$p < 0.001$, **$p < 0.01$, and *$p < 0.05$).**

4.1 Path Model Validation

We then tested our hypothesized path model (see Figure 1). To obtain unbiased estimates given univariate non-normalities, we performed bootstrapping (on 500 bootstrap samples at 95% biased-corrected confidence intervals) [4]. Figure 2 shows the model after the suggested modifications[3], which obtains superior goodness of fit: $\chi^2 = 8.608$ ($df = 7$, $p = 0.282$), $CFI = 1.000$, $AGFI = 0.995$, $RMSEA = 0.010$, all surpassing the suggested values of these model fit indices [13][4]. The measurement portion of the model is also good, with all of the R^2 estimates being larger than 0.10, and thus appropriate and informative to examine the significances of the paths associated with the outcome variables [36]. More notably, except that the R^2 estimate for *unexpectedness* is 0.14, the other R^2 values all exceed 0.60, indicating that the associated predictors can account for a large proportion of the variance in the corresponding outcome variable.

In more detail, we found there are significant causal relationships from *novelty*, *pur_diversity*, *rec_diversity*, *relevance*, and *timeliness* to *unexpectedness*, which implies that if a user perceives the recommended item as novel ($\beta = 0.327$ [5], $p = 0.002$), different from her/his previously purchased product types ($\beta = 0.095$, $p = 0.006$), different from the system's prior recommendations ($\beta = 0.108$, $p = 0.008$), not relevant to her/his preferences ($\beta = -0.119$, $p = 0.003$), or timely ($\beta = 0.134$, $p = 0.004$), s/he will be likely to perceive the item as unexpected. As a whole, all of these predictors account for 14% of the variance in unexpectedness.

Regarding *serendipity*, there are four significant predictors (in the descending order of influence): *timeliness* ($\beta = 0.369$, $p = 0.009$), *relevance* ($\beta = 0.264$, $p = 0.004$), *unexpectedness* ($\beta = 0.234$, $p = 0.004$), and *novelty* ($\beta = 0.181$, $p = 0.001$), which altogether

[3]We started with a full model and then went through model trimming by deleting one non-significant path at a time.

[4]χ^2, i.e., the chi-square value, should better be with probability $p \ge 0.05$ to indicate absolute fit; the cutoff values of the other fit indices CFI (Comparative Fit Index), AGFI (Adjusted Goodness of Fit), and RMSEA (Root Mean Square Error of Approximation) are respectively ≥ 0.90, ≥ 0.90, and ≤ 0.05 [13].

[5]This is the bootstrap estimate of the standardized regression weight (the same to the other β values).

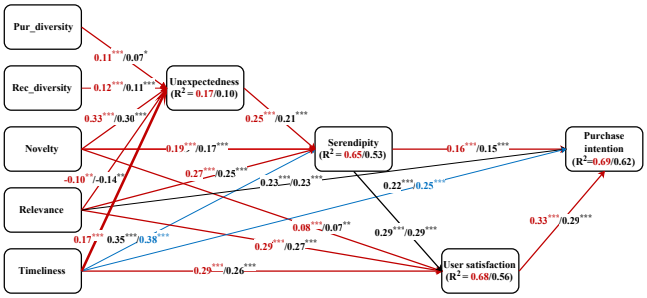

Figure 3: Multi-group path model analysis between *high* and *low* curiosity groups. Red highlights higher β coefficients and R^2 estimates in the *high* curiosity group, and blue highlights higher values in the *low* curiosity group.

account for 62% of the variance in serendipity, inferring that if a recommendation is timely, relevant, unexpected, and novel, the user will very likely perceive it as serendipitous. Because there are also direct paths from novelty, relevance, and timeliness to unexpectedness, it suggests that some of their effects on serendipity are partially mediated by unexpectedness.

Serendipity, allied with *timeliness*, *relevance*, and *novelty*, can be further used to predict *user satisfaction*, with standardized regression weights of $\beta = 0.305$ ($p = 0.006$), $\beta = 0.275$ ($p = 0.003$), $\beta = 0.273$ ($p = 0.003$), and $\beta = 0.075$ ($p = 0.003$) respectively. The R^2 value associated with user satisfaction is 0.65, indicating that 65% of its variance can be accounted for by the set of these four variables, among which the effects of serendipity, timeliness, and relevance are much higher than that of novelty. Here we also see the mediated paths passing through serendipity, suggesting that serendipity has a certain mediating effect on the causal relationships from timeliness, relevance, and novelty to user satisfaction.

The last outcome variable is *purchase intention*, which is significantly affected by *user satisfaction* ($\beta = 0.314$, $p = 0.004$), *timeliness* ($\beta = 0.232$, $p = 0.002$), *relevance* ($\beta = 0.228$, $p = 0.002$), and *serendipity* ($\beta = 0.161$, $p = 0.005$), with 68% of the variance explained by them. In combination with the results above, this suggests that timeliness and relevance can directly affect users' purchase intention, while serendipity and satisfaction mainly play mediating roles.

Collinearity diagnostics were then conducted for all of the four outcome variables (i.e., *unexpectedness*, *Serendipity*, *user satisfaction*, and *purchase intention*). Because the values of Tolerance and VIF ($Tolerance > 0.34$ and $VIF < 3$) all meet the desired standards[6], we can confirm there is no multicollinearity issue in our path analysis.

4.2 Moderating Effect of User Curiosity

Next, we conducted an in-depth investigation on the role of *curiosity* in affecting user perceptions of the recommendation, for which we first checked the internal reliability of our used curiosity instrument (10-item scale). Cronbach's alpha value is 0.876 and the item-total correlations are all between 0.381 and 0.701, which suggest that the 10 items all reliably measure the same variable [35]. We also performed principal components analysis (PCA), by which two factors were extracted: questions 1-3, 5 of higher loadings on one factor, and questions 4, 6-10 of higher loadings on the other factor (all exceeding the acceptable level of 0.5 [35]). However, because this 2-factor structure does not fully replicate the original Stretching/Embracing structure[7] [16], we used the 1-factor structure in our analysis (i.e., taking the 10 items together to represent *curiosity*).

We then performed two types of analysis. First, multi-group analysis enabled us to compare observations across two population groups (i.e., low curiosity vs. high curiosity). To divide all users into the two groups, we used the median split method [14], resulting in 1,132 users in the low curiosity group (< median 3.1 that is the cutoff point) and 1,216 in the high curiosity group (>= 3.1). Then, by imposing structural weights constraint on the path model, we found the Chi-square difference statistic is significant ($\chi^2 = 45.542$ with 17 *df*, $p < 0.001$), which implies significant inequalities of path coefficients across the two groups[8] (see Figure 3).

In particular, we detected three major differences between the two groups: 1. For the low curiosity group, there is no significant path relationship from timeliness to unexpectedness; 2. the regression weights of paths originating from *novelty*, *unexpectedness*, and *serendipity* are mostly higher in the high curiosity group; 3. the R^2 estimates for the outcome variables are all higher in the high curiosity group (for example, 0.65 for *serendipity* in the high curiosity group, vs. 0.53 in the low curiosity group), indicating that the associated predictor variables can be more accurate to estimate the corresponding outcome variable.

Second, we performed the moderation analysis, aiming to identify whether curiosity has actual moderating effects on the causal relationships in our path model[9]. The results show that it primarily acts as a moderator for three relationships (see Figure 2): *from timeliness to unexpectedness* (the standardized regression weight (s.r.w.) of the interaction term *curiosity×timeliness* is 0.073, $p = 0.006$), *from novelty to serendipity* (the s.r.w. of *curiosity×novelty* is 0.048, $p = 0.004$), and *from serendipity to satisfaction* (the s.r.w. of *curiosity×serendipity* is 0.041, $p = 0.005$). In other words, it suggests that more curious users are more likely to perceive a timely recommendation as unexpected, a novel recommendation as serendipitous, and be satisfied with the serendipitous item, while these relationships are not so strong for less curious people. The results hence validate the observations of the above multi-group analysis, implying the prominent role of curiosity in influencing users' perceived novelty, serendipity, and satisfaction with the recommendation.

[6] To be a problem, Tolerance has to approach 0 and VIF has to approach 10 [32].

[7] Similar phenomenon was found in [45] that was also tested in a Chinese context, so more studies might be needed to verify this 2-factor structure under different cultural backgrounds.

[8] We also conducted multi-group analyses with respect to age (young vs. old) and gender (female vs. male), but no significance was found ($\chi^2 = 17.059$ with 17 *df*, $p = 0.450$ w.r.t. age; and $\chi^2 = 16.943$ with 17 *df*, $p = 0.458$ w.r.t. gender).

[9] The path model still fits well after being incorporated with the curiosity and interaction terms ($\chi^2 = 25.466$ ($df = 18$, $p = 0.113$), $CFI = 0.999$, $AGFI = 0.992$, $RMSEA = 0.013$).

Table 2: Results of algorithm comparison by Kruskal-Wallis 1-way ANOVA test (the superscript indicates that the corresponding algorithm significantly outperforms the numbered one, with $p < 0.05$ adjusted by the Bonferroni correction)

Subjective variable	Mean rank				Sig.
	HOT[1]	Rel-CF[2]	Nov-CF[3]	Ser-CF[4]	
Relevance	1047.61	1168.76[1]	1130.39	**1346.05**[1,2,3]	0.000
Novelty	1079.22	1148.04	1182.39[1]	**1284.84**[1,2,3]	0.000
Pur_diversity	1201.83	1164.10	1182.21	1151.03	0.578
Rec_diversity	**1391.74**[2,3,4]	1203.96[3,4]	1092.20	1017.82	0.000
Unexpectedness	**1300.69**[2,3,4]	1178.18	1101.88	1121.64	0.000
Serendipity	1062.11	1142.97	1182.73[1]	**1306.05**[1,2,3]	0.000
Timeliness	1002.74	1110.57[1]	1182.43[1]	**1395.98**[1,2,3]	0.000
User satisfaction	1013.12	1154.61[1]	1184.08[1]	**1340.10**[1,2,3]	0.000
Purchase intention	1033.38	1142.73[1]	1162.42[1]	**1354.07**[1,2,3]	0.000

4.3 Algorithm Comparison

The third objective of this experiment was to compare the four recommender algorithms (see Section 3.3) in terms of user perceptions. We used the Kruskal-Wallis 1-way ANOVA test[10] to handle the non-normally distributed dependent variables. As above mentioned, there were 570, 596, 589, and 593 users respectively assigned to the HOT, Rel-CF, Nov-CF, and Ser-CF algorithms. Table 2 reports the results. It can be seen that there is very strong evidence of differences among the four algorithms, in terms of *novelty*, *relevance*, *rec_diversity*, *timeliness*, *unexpectedness*, *serendipity*, *satisfaction*, and *purchase intention*. Moreover, the mean rank of Ser-CF seems to perform the best compared to the other three, except unexpectedness and rec_diversity. It is interesting to see that the HOT algorithm was perceived the most unexpected and the most different from the system's prior recommendations, but it was the worst as for most of the other variables including user satisfaction and purchase intention. Because this method only returns the most popular item without taking into account the user's preferences, it implies that unexpectedness can reflect unpleasant surprise in this condition.

We further ran the Mann Whitney Wilcoxon test[11] for the pairwise comparisons. The results show strong evidence ($p < 0.05$ adjusted by the Bonferroni correction for multiple tests) of the differences between Ser-CF and the other three algorithms. Specifically, Ser-CF is significantly better than HOT, Rel-CF, and Nov-CF, in respect of *novelty*, *relevance*, *timeliness*, *serendipity*, *satisfaction*, and *purchase intention*. The comparison between Nov-CF and HOT shows that the former obtains significantly higher mean ranks regarding *novelty*, timeliness, serendipity, satisfaction, and purchase intention; while the comparison between Rel-CF and HOT reveals the former is particularly better at *relevance* and timeliness, which also results in increased satisfaction and purchase intention. However, there are no significant differences between Rel-CF and Nov-CF as for most of the variables. One more interesting observation is that unexpectedness and rec_diversity are significantly higher for HOT relative to the other three algorithms.

[10] A nonparametric test used to compare the mean ranks of more than two independent groups, when the dependent variable is ordinal or not normally distributed [27].
[11] It is also a nonparametric test for comparing two independent groups.

All of the results suggest that the Ser-CF algorithm is capable of accommodating both *novelty* and *relevance* to more effectively increase users' perceived recommendation *serendipity* and *satisfaction*, compared to Rel-CF that is more relevance focused, and Nov-CF that is more novelty focused. In addition, we found that people with a high curiosity level were more satisfied with Ser-CF, because its differences from Nov-CF and Rel-CF are significant in the high curiosity group regarding *user satisfaction* (Ser-CF vs. Nov-CF: 686.59 mean rank vs. 611.69, $p = 0.032$; Ser-CF vs. Rel-CF: 686.59 vs. 595.45, $p = 0.004$), but not significant in the low curiosity group (Ser-CF vs. Nov-CF: 630.68 vs. 580.93, $p = 0.365$; Ser-CF vs. Rel-CF: 630.68 vs. 565.39, $p = 0.082$). These results imply the effect of curiosity on users' evaluation of a particular recommender algorithm.

We also recorded all participants' post-survey behavior to see whether they revisited the recommended item after the survey[12]. A Chi-square test reveals a significant association between the algorithms and users' revisiting behavior ($\chi^2 = 188.027, p < 0.001$). The values of Phi and Cramer's V again indicate that the strength of this association is strong (both are 0.283, $p < 0.001$). More specifically, more Ser-CF users (over 17%) clicked the recommended item after the survey, whereas fewer users who used algorithms Nov-CF (6.1%), Rel-CF (1.0%), and HOT (0%) revisited their recommendations. However, because the revisiting behavior did not occur immediately after our experiment (e.g., one user revisited the item 6 hours after taking the survey), we cannot claim it was necessarily caused by the recommendation. Therefore, in the future, we will conduct more studies to measure the correlation between users' perceptions of a recommendation and their actual behavior (e.g., clicking and purchasing).

5 DISCUSSION

In this section, we summarize the major findings of our experiment and their practical implications, and discuss the limitations of our work.

5.1 Serendipity and User Satisfaction

One major finding is that serendipity significantly positively affects user satisfaction and purchase intention. Its contribution is largely higher than that of novelty, more direct relative to diversity's, and comparable to those of relevance and timeliness. As a result, more than 60% of the variance in the two outcome variables (satisfaction and purchase intention) can be explained by the associated predictors.

Moreover, as relevance, timeliness, and novelty can directly affect serendipity, it discloses serendipity's mediating role in transmitting part of their effects on user satisfaction. However, two diversity related variables (i.e., pur_diversity and rec_diversity) are not directly related to serendipity, but have a positive influence on unexpectedness. This suggests that if the recommendation is different from the user's previously purchased product types or the system's prior recommendations, s/he may first feel surprised, which will then combine with the other factors (i.e., relevance, timeliness, novelty) to induce serendipity (altogether accounting for over 60% of the variance in serendipity).

[12] We measured a user's revisiting behavior during the day s/he took part in the survey.

Compared with the related work that primarily takes unexpectedness, novelty, and relevance as principal components of serendipity [6, 20, 28], we have two new observations. First, ***timeliness*** can be more important than unexpectedness, novelty, and relevance, in terms of affecting serendipity. However, this factor is often neglected in the related literature. For example, in [36], this variable was eliminated due to low correlations with other variables. In our study, we find it has a significantly positive impact on multiple perception variables, such as serendipity, satisfaction, and purchase intention. One possible explanation is that our experiment was conducted in a mobile e-commerce environment, so whether the recommendation was given at the best possible time can be regarded as critically important by users.

Second, we find that ***unexpectedness*** and ***novelty*** take different roles in influencing users' perceived serendipity. Novelty acts more positively as it has a significantly direct relationship with serendipity and user satisfaction, whereas unexpectedness is only related to serendipity. In addition, unexpectedness may reflect unpleasant surprise in some conditions (e.g., when the recommendation is not relevant to the user's preferences). Another finding is that although unexpectedness is affected by several variables, only 14% of its variance is explained by them all, suggesting that there would be other unexplored variables greatly impacting it.

For novelty, our results are basically consistent with those of [36] that also indicated a positive effect of novelty on user satisfaction, but contradict the findings of [7] that showed its negative influence. As discussed in [15], this may be caused by the studied product domain (e-commerce products vs. movies in [7]), or the formulation of novelty-related question (positive tone such as "*The item recommended to me is novel*" vs. negative tone such as "*Which list has more movies you would not have thought to consider?*" in [7]). More studies are thus needed to verify these confounding effects.

Implication. Because the experiment shows there are four variables, namely *timeliness*, *relevance*, *unexpectedness*, and *novelty*, are significantly related to serendipity, we may improve the existing offline metrics of measuring serendipity [1, 10], in a more precise way. For instance, we could add the component *timeliness*, as well as more clearly distinguishing the roles of *unexpectedness* and *novelty* in the formulation. It would also be meaningful to introduce some indirectly related factors (such as *pur_diversity*), and other potential factors that may lead to unexpectedness.

5.2 The Role of User Curiosity

The second finding is about the exact role of user curiosity in moderating the effect of one perception variable on another. The results of moderation analysis show that curiosity can not only strengthen the positive effect of *novelty on serendipity*, but also that of *serendipity on satisfaction*. It hence implies that a more curious person will be more likely to perceive a novel recommendation as serendipitous, and be more satisfied with the serendipitous item.

Furthermore, we find that the path models are significantly different between the high and low curiosity groups of users through the multi-group analysis. In particular, *novelty*, *unexpectedness*, and *serendipity* behave more actively in positively affecting the other variables in the high curiosity group. The accuracy of predicting serendipity (and furthermore user satisfaction and purchase intention) can also be likely higher in the high curiosity group. Overall, these results verify our hypothesis about the effect of curiosity on users' appetite for serendipitous recommendations.

Implication. Recently, some studies have attempted to incorporate curiosity into recommendation generation [24, 29, 47], but their methods were mainly based on some assumption without empirical validation of the curiosity's actual effect. The results of our study could be constructive for the related work to further strengthen the role of curiosity in their recommender algorithms. For instance, given that curiosity significantly moderates the causal relationships from novelty to serendipity and from serendipity to satisfaction, a personalized recommendation strategy might be developed to dynamically adjust the serendipity degree according to the target user's curiosity value, instead of being simply maximized for everyone.

5.3 User Evaluation of Recommender Algorithms

This experiment also explains why a particular recommender approach is preferred to others. We compared four algorithms: HOT, Rel-CF, Nov-CF, and Ser-CF, which are respectively popularity, relevance, novelty, and serendipity oriented. The results show that Ser-CF is the best in terms of novelty, relevance, timeliness, serendipity, user satisfaction, and purchase intention; Nov-CF and Rel-CF lie in the middle; and HOT provides the most unexpected recommendations, but performs worst regarding most of the other variables. It thus infers that a serendipity-oriented algorithm might be more satisfying and stimulating users' intention to purchase its recommended items. The observations related to HOT suggest that unexpectedness can reflect users' unpleasant surprise if the recommendation is purely popularity based without taking into account the user's preferences.

Implication. The way we evaluated recommender algorithms might be referential to related researchers for assessing user perceptions of their algorithms. On the other hand, since the advantage of the serendipity-oriented algorithm (Ser-CF) is not very obvious among less curious users, it would be meaningful to have a personalized serendipity approach as we discussed above. Recently, a personality-based framework was proposed to adapt recommendations' diversity to individual users' intrinsic needs [44]. We could extend it to accommodate serendipity, so as to achieve optimal user satisfaction with the recommender system.

5.4 Limitations of Our Work

Our work has several limitations. First, the users who took part in our experiment mainly represent the population that has used mobile apps to buy products [43]. The results might have been different if it was conducted in another setting (e.g., traditional e-commerce) or even other domains (such as social media and tourism). Therefore, we are interested in performing a cross-platform validation in the future, so as to identify any platform-specific features. Second, a cross-cultural study would also be necessary, because our survey mainly involved Chinese users. It will be interesting to see whether similar findings would occur among users in other countries, or there would be any cultural differences. Third, we used the short

version of ResQue questionnaire [36] for the sake of mobile survey, which limited our statistical approach to path analysis that does not contain latent variables to account for measurement error [38]. It would therefore be better to verify the findings by using the complete version of ResQue [36], and the other user-centric evaluation frameworks [18] (given that different formulations of the survey questions may engender different user responses [15]). Fourth, we did not test the state-of-the-art algorithms, but emphasized on tailoring the classical CF methods to strengthen the recommendation's relevance, novelty, and serendipity respectively. For the future work, it will be useful to identify whether the results could be generalizable to other algorithms, especially those that are serendipity oriented [24, 33, 46].

6 CONCLUSIONS

Different from related work on recommendation serendipity that either focused on algorithm development or conducted small-scale user evaluations, we have been engaged in empirically revealing the causal relationships between serendipity and various user perceptions via a large scale online study performed on an industrial mobile e-commerce platform. The results show that there are four major components of serendipity, namely *timeliness*, *relevance*, *unexpectedness*, and *novelty*. Furthermore, *serendipity* behaves more effectively than the other two beyond-accuracy objectives (novelty and diversity) in affecting *user satisfaction* and *purchase intention*.

Additionally, this study verifies the moderating effects of *user curiosity* on the causal relationships from novelty to serendipity and from serendipity to satisfaction. This implies that more curious users will be more likely to perceive a novel item as serendipitous and be satisfied with a serendipitous recommendation. Last but not least, the user evaluation of four recommender algorithms indicates that a serendipity-oriented method (*Ser-CF*) performs the best. Inspired by those findings, we believe that a personalized serendipity approach based on curiosity would be potentially able to optimize user satisfaction with the recommender system.

ABSTRACT

Sentiment classification typically relies on a large amount of labeled data. In practice, the availability of labels is highly imbalanced among different languages, e.g., more English texts are labeled than texts in any other languages, which creates a considerable inequality in the quality of related information services received by users speaking different languages. To tackle this problem, cross-lingual sentiment classification approaches aim to transfer knowledge learned from one language that has abundant labeled examples (i.e., the source language, usually English) to another language with fewer labels (i.e., the target language). The source and the target languages are usually bridged through off-the-shelf machine translation tools. Through such a channel, cross-language sentiment patterns can be successfully learned from English and transferred into the target languages. This approach, however, often fails to capture sentiment knowledge specific to the target language, and thus compromises the accuracy of the downstream classification task. In this paper, we employ emojis, which are widely available in many languages, as a new channel to learn both the cross-language and the language-specific sentiment patterns. We propose a novel representation learning method that uses emoji prediction as an instrument to learn respective sentiment-aware representations for each language. The learned representations are then integrated to facilitate cross-lingual sentiment classification. The proposed method demonstrates state-of-the-art performance on benchmark datasets, which is sustained even when sentiment labels are scarce.

1 INTRODUCTION

Sentiment analysis has become a critical topic in various research communities, including natural language processing (NLP) [22, 26], Web mining [23, 38], information retrieval [14, 57], ubiquitous computing [30, 53], and human-computer interaction [24, 59]. Due to its effectiveness in understanding user attitudes, emotions, and even latent psychological statuses from text, sentiment analysis has been widely applied to all kinds of Web content such as blogs, Tweets, user reviews, and forum discussions, and it has been a critical component in many applications such as customer review tracking [27], sales prediction [39], product ranking [41], stock market prediction [54], opinion polling [45], recommender systems [55], personalized content delivery [29], and online advertising [52].

Similar to many other text mining tasks, existing work on sentiment analysis mainly deals with English texts [22, 26, 38, 57]. Although some efforts have also been made with other languages such as Japanese [51], sentiment analysis for non-English languages is far behind. This creates a considerable inequality in the quality of the aforementioned Web services received by non-English users, especially considering that 74.6% of Internet users are non-English speakers as of 2018 [9]. The cause of this inequality is quite simple: effective sentiment analysis tools are often built upon supervised learning techniques, and *there are way more labeled examples in English than in other languages.*

A straightforward solution is to transfer the knowledge learned from a label-rich language (i.e., the source language, usually English) to another language that has fewer labels (i.e., the target language), an approach known as *cross-lingual sentiment classification* [19].

In practice, the biggest challenge of cross-lingual sentiment classification is how to fill the linguistic gap between English and the target language. Many choose to bridge the gap through standard NLP techniques, and in particular, most recent studies have been using off-the-shelf machine translation tools to generate pseudo parallel corpora and then learn bilingual representations for the downstream sentiment classification task [50, 58, 62]. More specifically, many of these methods enforce the aligned bilingual texts to share a unified embedding space, and sentiment analysis of the target language is conducted in that space.

Although this approach looks sensible and easily executable, the performance of these machine translation-based methods often falls short. Indeed, a major obstacle of cross-lingual sentiment analysis is the so-called *language discrepancy* problem [19], which machine translation does not tackle well. More specifically, sentiment expressions often differ a lot across languages. Machine translation is able to retain the general expressions of sentiments that are shared across languages (e.g., "*angry*" or "怒っている" for negative sentiment), but it usually loses or even alters the sentiments in language-specific expressions [44]. As an example, in Japanese, the common expression "湯水のように使う" indicates a negative sentiment, describing the excessive usage or waste of a resource. However, its translation in English, "*use it like hot water*," not only loses the negative sentiment but also sounds odd.

The reason behind this pitfall is easy to explain: machine translation tools are usually trained on parallel corpora that are built in the first place to capture patterns shared across languages instead of patterns specific to individual languages. In other words, the problem is due to the failure to retain language-specific sentiment knowledge when unilaterally pursuing generalization across languages. A new bridge needs to be built beyond machine translation, which not only transfers "general sentiment knowedge" from the source language but also captures "private sentiment knowledge" of the target language. *That bridge can be built with emojis.*

In this paper, we tackle the problem of cross-lingual sentiment analysis by employing *emojis* as an instrument. Emojis are considered an emerging ubiquitous language used worldwide [16, 40]; in our approach they serve both as a proxy of sentiment labels and as a bridge between languages. Their functionality of expressing emotions [21, 34] motivates us to employ emojis as complementary labels for sentiments, while their ubiquity [16, 40] makes it feasible to learn emoji-sentiment representations for almost every active language. Coupled with machine translation, the cross-language patterns of emoji usage can complement the pseudo parallel corpora and narrow the language gap, and the language-specific patterns of emoji usage help address the language discrepancy problem.

We propose ELSA, a novel framework of *Emoji-powered representation learning for cross-Lingual Sentiment Analysis*. Through ELSA, language-specific representations are first derived based on modeling how emojis are used alongside words in each language. These per-language representations are then integrated and refined to predict the rich sentiment labels in the source language, through the help of machine translation. Different from the mandatorily aligned bilingual representations in existing studies, the joint representation learned through ELSA catches not only the general sentiment patterns across languages, but also the language-specific patterns. In this way, the new representation and the downstream tasks are no longer dominated by the source language.

We evaluate the performance of ELSA on a benchmark Amazon review dataset that has been used in various cross-lingual sentiment classification studies [50, 58, 62]. The benchmark dataset covers nine tasks combined from three target languages (i.e., Japanese, French, and German) and three domains (i.e., book, DVD, and music). Results indicate that ELSA outperforms existing approaches on all of these tasks in terms of classification accuracy. Experiments also show that the emoji-powered model works well even when the volume of unlabeled and labeled data are rather limited. To evaluate the generalizability of ELSA, we also apply the method to Tweets, which again demonstrates state-of-the-art performance. In summary, the major contributions of this paper are as follows:

- To the best of our knowledge, this is the first study that leverages emojis as an instrument in cross-lingual sentiment classification. We demonstrate that emojis provide not only surrogate sentiment labels but also an effective way to address language discrepancy.
- We propose a novel representation learning method to incorporating language-specific knowledge into cross-lingual sentiment classification, which uses an attention-based Long Short-Term Memory (LSTM) model to capture sentiments from emoji usage.
- We demonstrate the effectiveness and efficiency of ELSA for cross-lingual sentiment classification using multiple large-scale datasets. ELSA significantly improves the state-of-the-art results on the benchmark datasets.[1]
- The use of emojis as a bridge provides actionable insights into other Web mining applications that suffer from similar problem of inequality among languages.

The rest of this paper is organized as follows. Section 2 presents the related work. Section 3 formulates the problem and presents the proposed approach (ELSA) to cross-lingual representation learning. Section 4 evaluates ELSA and analyzes the effectiveness of emojis in the learning process. Section 5 discusses the scalability and generalizability of ELSA, followed by concluding remarks in Section 6.

2 RELATED WORK

We start with a summary of existing literature related to our study.

Emojis. Emojis, also known as ideograms or smileys, can be used as compact expressions of objects, topics, and emotions. Being encoded in Unicode, they have no language barriers and are diffused on the Internet rapidly [40]. The prevalence of emojis has attracted researchers from various research communities such as NLP, ubiquitous computing, human-computer interaction, multimedia, and Web mining [12, 16, 20, 21, 34, 40, 43]. Many efforts have been devoted to studying their usage across platforms [43], across genders [20], across languages [16], and across cultures [40]. The various non-verbal functions of emojis play an important role in their wide adoption. Emojis are used to replace content words, express situational and additional emotions, adjust tones, express intimacy, etc. [21, 34]. In particular, expressing sentiment is demonstrated to be the most popular intention for using emojis [34], so that emojis

[1]The benchmark datasets, scripts, and pre-trained models are available at https://github.com/sInceraSs/ELSA.

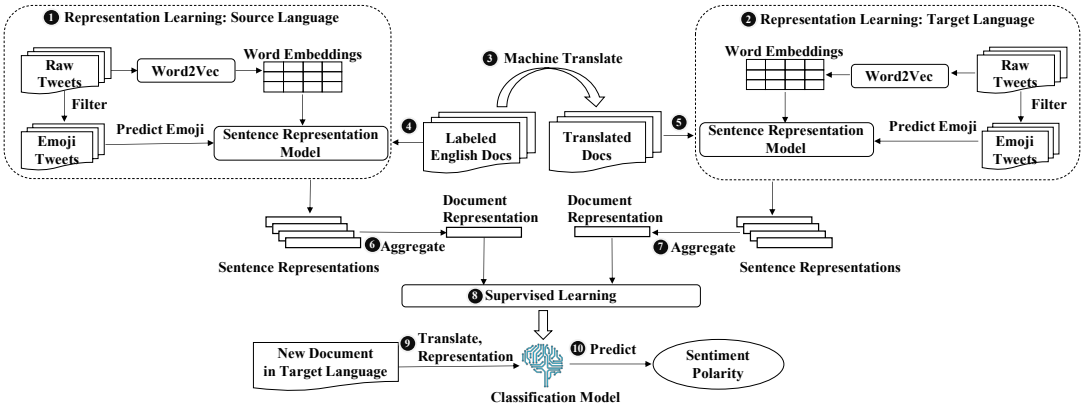

Figure 1: The workflow of ELSA.

can be used as effective proxies for sentiment polarities [26]. Considering the ubiquitous usage of emojis across languages and their functionality of expressing sentiments, we make the first effort to use emojis as an instrument to improve cross-lingual sentiment analysis.

Textual Sentiment Analysis. Sentiment analysis is a classical NLP task aiming to study the emotions, opinions, evaluations, appraisals, and attitudes of people from text data [37]. Many widely used tools, such as SentiStrength [56] and LIWC [49], simply aggregate the polarity of individual words to determine the overall sentiment score of a text. Better performance of sentiment classification is often obtained through supervised machine learning [46]. Recently, with the emergence of deep learning techniques, many researchers have attempted to use advanced neural network models for sentiment analysis [60]. Supervised machine learning methods, including deep learning models, usually require a large volume of labeled data for training. In reality, however, high-quality sentiment labels are often scarce due to the labor-consuming and error-prone human annotation process [26]. To address this limitation, researchers have used sentimental hashtags and emoticons as weak sentiment labels [22, 23]. These weak labels are usually language/community-specific. In addition, figuring out the sentiment polarities of certain hashtags or emoticons can be hard. In recent years, emoticons have been gradually replaced by increasingly popular emojis [48], and emojis have started to be explored as proxies of sentiment labels [26]. We follow the same intuition and utilize emojis as surrogate labels to learn per-language representations. Instead of attempting to directly map emojis to sentiment polarities, however, we integrate these language-specific representations and feed them through downstream tasks to predict real, high quality sentiment labels (in the source language).

Cross-Lingual Text Classification. There is a significant imbalance in the availability of labeled corpora among different languages: more in English, and much fewer in other languages. Cross-lingual learning is a common approach to tackling this problem in various text mining tasks such as Web page classification [36], topic categorization [61], and sentiment analysis [50, 58, 62]. Many researchers divide cross-lingual learning process into two stages: first encoding texts in the source and the target languages into continuous representations, and then utilizing these representations for the final classification task in the target language [50, 58, 62]. To bridge the linguistic gap between the source and the target languages, most studies introduce a translation oracle to project different languages' representations into a unified space at different (e.g., word or document) levels [18, 50, 58, 62]. The performance of these methods thus heavily depends on the quality of the machine translation tools and the pseudo parallel corpora they generate. Unfortunately, different from topical words, emotional language patterns like sentiment (or sarcasm, humor), which present strong language-specific characteristics, cannot be easily transferred in this way. We utilize the easily accessible emoji-texts to incorporate both cross-language and language-specific knowledge into the representations of the source and the target languages. The implicit sentiment knowledge encoded in the usage of diverse emojis solves both the label imbalance and the language discrepancy problems.

3 THE ELSA APPROACH

To better illustrate the workflow of ELSA, we first give a formulation of our problem. Cross-lingual sentiment classification aims to use the labeled data in a source language (i.e., English) to learn a model that can classify the sentiment of test data in a target language. In our setting, besides labeled English documents (L_S), we also have large-scale unlabeled data in English (U_S) and in the target language (U_T). Furthermore, there exist unlabeled data containing emojis, both in English (E_S) and in the target language (E_T). In practice, these unlabeled, emoji-rich data can be easily obtained from online social media such as Twitter. Our task is to build a model that can classify the sentiment polarity of document in the target language solely based on the labeled data in the source language (i.e., L_S) and the different kinds of unlabeled data (i.e., U_S, U_T, E_S and E_T). Finally, we use a held-out set of labeled documents in the target language (L_T), which can be small, to evaluate the model.

The workflow of ELSA is illustrated in Figure 1, with the following steps. In *step 1* and *step 2*, we build sentence representation models for both the source and the target languages. Specifically, for each language, we employ a large number of Tweets to learn word

embeddings (through Word2Vec [42]) in an unsupervised fashion. From these word embeddings, we learn higher-level sentence representation through predicting the emojis used in a sentence. This can be viewed as a distantly supervised learning process, where emojis serve as surrogate sentiment labels. In *step 3*, we translate each labeled English document into the target language, sentence by sentence, through *Google Translate*. Both the English sentences and their translations are fed into the representation models learned in steps 1 and 2 to obtain their per-language representations (*step 4* and *step 5*). Then in *step 6* and *step 7* we aggregate these sentence representations back to form two compact representations for each training document, one in English and the other in the target language. In *step 8*, we use the two representations as features to predict the real sentiment label of each document and obtain the final sentiment classifier. In the test phase, for a new document in the target language, we translate it into English and then follow the previous steps to obtain its representation (*step 9*), based on which we predict the sentiment label using the classifier (*step 10*).

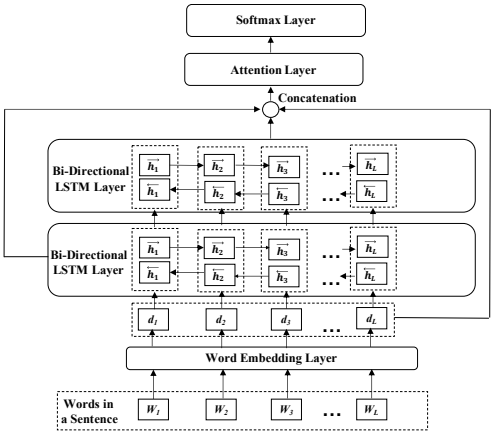

Figure 2: Network architecture for representation learning through emoji prediction.

3.1 Representation Learning

Representations of documents need to be learned before we train the sentiment classifier. Intuitively, one could simply use off-the-shelf word embedding techniques to create word representations and then average the word vectors to obtain document embeddings. Such embeddings, however, capture neither per-language nor cross-language sentiment patterns. Since emojis are widely used to express sentiments across languages, we learn sentiment-aware representations of documents using emoji prediction as an instrument. Specifically, in a distantly supervised way, we use emojis as surrogate sentiment labels and learn sentence embeddings by predicting which emojis are used in a sentence. This representation learning process is conducted separately in the source and the target languages to capture language-specific sentiment expressions.

The architecture of the representation learning model is illustrated in Figure 2. First, we pre-train low-level word embeddings using tens of millions of unlabeled Tweets (i.e., the word embedding layer). Then, we represent every single word as a unique vector and use stacked bi-directional LSTM layers and one attention layer to encode these word vectors into sentence representations. The attention layer takes the outputs of both the embedding layer and the two LSTM layers as input, through the skip-connection algorithm [31], which enables unimpeded information flow in the whole training process. Finally, the model parameters are learned by minimizing the output error of the softmax layer. The details of the architecture are elaborated below.

Word Embedding Layer. The word embeddings are pre-trained with the skip-gram algorithm [42] based on either U_S or U_T, which encode every single word into a continuous vector space. Words that commonly occur in a similar context are embedded closely in the vector space, which captures word semantic information. We leave the details of this standard Word2Vec process to the readers [42].

Bi-Directional LSTM Layer. As a special type of recurrent neural network (RNN), LSTM [33] is particularly suitable for modeling the sequential property of text data. At each step (e.g., word token), LSTM combines the current input and knowledge from the previous steps to update the states of the hidden layer. To tackle the gradient vanishing problem [32] of traditional RNNs, LSTM incorporates a gating mechanism to determine when and how the states of hidden layers can be updated. Each LSTM unit contains a memory cell and three gates (i.e., an input gate, a forget gate, and an output gate) [47]. The input and output gates control the input activations into the memory cell and the output flow of cell activations into the rest of the network, respectively. The memory cells in LSTM store the sequential states of the network, and each memory cell has a self-loop whose weight is controlled by the forget gate.

Let us denote each sentence in E_S or E_T as (x, e), where $x = [d_1, d_2, ..., d_L]$ as a sequence of *word* vectors representing the plain text (by removing emojis) and e as one emoji contained in the text. At step t, LSTM computes unit states of the network as follows:

$$
\begin{aligned}
i^{(t)} &= \sigma(U_i d_t + W_i h^{(t-1)} + b_i),\\
f^{(t)} &= \sigma(U_f d_t + W_f h^{(t-1)} + b_f),\\
o^{(t)} &= \sigma(U_o d_t + W_o h^{(t-1)} + b_o),\\
c^{(t)} &= f_t \odot c^{(t-1)} + i^{(t)} \odot tanh(U_c d_t + W_c h^{(t-1)} + b_c),\\
h^{(t)} &= o^{(t)} \odot tanh(c^{(t)}),
\end{aligned}
$$

where $i^{(t)}$, $f^{(t)}$, $o^{(t)}$, $c^{(t)}$, and $h^{(t)}$ denote the state of the input gate, forget gate, output gate, memory cell, and hidden layer at step t. W, U, b respectively denote the recurrent weights, input weights, and biases. $\odot$ is the element-wise product. We can extract the latent vector for each step t from LSTM. In order to capture the information from the context both preceding and following a word, we use the bi-directional LSTM. We concatenate the latent vectors from both directions to construct a bi-directional encoded vector h_i for every single word vector d_i, which is:

$$
\begin{aligned}
\overrightarrow{h_i} &= \overrightarrow{LSTM}(d_i), i \in [1, L],\\
\overleftarrow{h_i} &= \overleftarrow{LSTM}(d_i), i \in [L, 1],\\
h_i &= [\overrightarrow{h_i}, \overleftarrow{h_i}].
\end{aligned}
$$

Attention Layer. We employ a skip-connection that concatenates the outputs of the embedding layer and the two bi-directional LSTM

layers as the input of the attention layer. The i-th word of the input sentence can be represented as u_i:

$$u_i = [d_i, h_{i1}, h_{i2}],$$

where d_i, h_{i1}, and h_{i2} denote the encoded vectors of words extracted in the word embedding layer and the first and second bi-directional LSTMs, respectively. Since not all words contribute equally to predicting emojis or expressing sentiments, we employ the attention mechanism [13] to determine the importance of every single word. The attention score of the i-th word is calculated by

$$a_i = \frac{exp(W_a u_i)}{\sum_{j=1}^{L} exp(W_a u_j)},$$

where W_a is the weight matrix used by the attention layer. Then each sentence can be represented as the weighted sum of all words in it, using the attention scores as weights. That is,

$$v = \sum_{i=1}^{L} a_i u_i.$$

Softmax Layer. The sentence representation is then transferred into the softmax layer, which returns a probability vector Y. Each element of this vector indicates the probability that this sentence contains a specific emoji. The i-th element of the probability vector is calculated as:

$$y_i = \frac{exp(v^T w_i + b_i)}{\sum_{j=1}^{K} exp(v^T w_j + b_j)},$$

where w_i and b_i define the weight and bias of the i-th element. Finally, we learn the model parameters by minimizing the cross entropy between the output probability vectors and the one-hot vectors of the emoji contained in each sentence. After learning the parameters, we can extract the output of the attention layer to represent each input sentence. Through this emoji-prediction process, words with distinctive sentiments can be identified, and the plain text surrounding the same emojis will be represented similarly. Given the fact that the sentiment labels are limited, once the emoji-powered sentence representations are trained, they are locked in the downstream sentiment prediction task to avoid over-fitting.

3.2 Training the Sentiment Classifier

Based on the pre-trained, per-language sentence representations, we then learn document representations and conduct cross-lingual sentiment classification.

First, for each English document $D_s \in L_S$, we use the pre-trained English representation model to embed every single sentence in it. Second, we aggregate these sentence representations to derive a compact document representation. Because different parts of a document contribute differently to the overall sentiment, we once again adopt the attention mechanism here. Supposing the sentence vectors as v_i, we calculate the document vector r_s as:

$$r_s = \sum_{i=1}^{N} \beta_i v_i, \text{ where}$$
$$\beta_i = \frac{exp(W_b v_i)}{\sum_{j=1}^{N} exp(W_b v_j)},$$

Table 1: The sizes of the Tweets and emoji-Tweets.

Language	English	Japanese	French	German
Raw Tweets	39.4M	19.5M	29.2M	12.4M
Emoji-Tweets	6.6M	2.9M	4.4M	2.7M

where W_b is the weight matrix of the attention layer and β_i is the attention score of the i-th sentence in the document. Next, we use *Google Translate* to translate D_s into the target language (D_t). We then leverage the pre-trained target-language representation model to form representations for each translated document following the same process above. Supposing the text representations of D_s and D_t are r_s and r_t respectively, we concatenate them into a joint representation $r_c = [r_s, r_t]$, which contains sentiment knowledge from both English and the target language, ensuring that our model is not dominated by the labeled English documents. Finally, we input r_c into an additional softmax layer to predict the real sentiment label of D_s.

3.3 Sentiment Classification for Target Language

When we receive an unlabeled document in L_T, we first translate it into English. Based on the representation models trained above, the original document and its English translation can be represented as r_t and r_s. We represent this document as $[r_s, r_t]$ and input it into the classifier, which outputs a predicted sentiment polarity.

4 EVALUATION

In this section, we evaluate the effectiveness and efficiency of ELSA using standard benchmark datasets for cross-lingual sentiment classification as well as a large-scale corpus of Tweets.

4.1 The Dataset

The labeled data (L_S for training and L_T for testing) used in our work are from the Amazon review dataset [3] created by Prettenhofer and Stein [50]. This dataset is representative and used in a variety of cross-lingual sentiment classification work [50, 58, 62]. It covers four languages (i.e., English, Japanese, French, and German) and three domains (i.e., book, DVD, and music). For each combination of language and domain, the dataset contains 1,000 positive reviews and 1,000 negative reviews. We select English as the source language and the other three as the target languages. Therefore, we can evaluate our approach on nine tasks in total (i.e., combinations of the three domains and three target languages). For each task, we use the 2,000 labeled English reviews in the corresponding domain for training and the 2,000 labeled reviews in each target language for evaluation. The translations of the test reviews are already provided in this dataset, so we only need to translate the English reviews into target languages.

To achieve unlabeled data (U_S and U_T), we collect a sample of English, Japanese, French, and German Tweets between September 2016 and March 2018. All collected Tweets are used to train the word embeddings. As emojis are widely used on Twitter [48], we are able to extract emoji-labeled Tweets, which are used to learn emoji-powered sentence representations. For each language, we extract Tweets containing the top 64 emojis used in this language.

As many Tweets contain multiple emojis, for each Tweet, we create separate examples for each unique emoji used in it to make the emoji prediction a single-label classification task instead of more complicated multi-label classification.

We then conduct the following preprocessing procedures for the documents. We remove all Retweets, and Tweets that contain URLs, to ensure that words appear in their original contexts and that the meaning of the Tweets do not depend on external content. Then we tokenize all the texts (including reviews and Tweets) into words, convert them into lowercase, and shorten the words with redundant characters into their canonical forms (e.g., "cooooool" is converted to "cool"). As Japanese words are not separated by white spaces, we use a tokenization tool called *MeCab* [2] to segment Japanese documents. In addition, we use special tokens to replace mentions and numbers. The processed emoji-Tweets provide the E_S and E_T datasets, whose statistics are presented in Table 1.

4.2 Implementation Details

We learn the initial word embeddings using the skip-gram model with the window-size of 5 on the raw Tweets. The word vectors are then fine-tuned during the sentence representation learning phase. In the representation learning phase, to regularize our model, L2 regularization with parameter 10^{-6} is applied for embedding weights. Dropout is applied at the rate of 0.5 before the softmax layer. The hidden units of bi-directional LSTM layers are set as 1,024 (512 in each direction). We randomly split the emoji-Tweets into the training, validation, and test sets in the proportion of 7:2:1. Accordingly, we use early stopping [17] to tune hyperparameters based on the validation performance through 50 epochs, with mini-batch size of 250. We used the Adam algorithm [35] for optimization, with the two momentum parameters set to 0.9 and 0.999, respectively. The initial learning rate was set to 10^{-3}. In the phase of training the sentiment classifier, for exhaustive parameter tuning, we randomly select 90% of the labeled data as the training set and the remaining 10% as the validation set. The whole framework is implemented with TensorFlow [11].

4.3 Baselines and Accuracy Comparison

To evaluate the performance of ELSA, we employ three representative baseline methods for comparison:

MT-BOW uses the bag-of-words features to learn a linear classifier on the labeled English data [50]. It uses *Google Translate* to translate the test data into English and applies the pre-trained classifier to predict the sentiment polarity of the translated documents.

CL-RL is the word-aligned representation learning method proposed by Xiao and Guo [58]. It constructs a unified word representation that consists of both language-specific components and shared components, for the source and the target languages. To establish connections between the two languages, it leverages *Google Translate* to create a set of critical parallel word pairs, and then it forces each parallel word pair to share the same word representation. The document representation is computed by taking the average over all words in the document. Given the representation as features, it trains a linear SVM model using the labeled English data.

Table 2: The accuracy of ELSA (standard deviations in parentheses) and baseline methods on the nine benchmark tasks.

Language	Domain	MT-BOW	CL-RL	BiDRL	ELSA
Japanese	Book	0.702	0.711	0.732	**0.783 (0.003)**
	DVD	0.713	0.731	0.768	**0.791 (0.004)**
	Music	0.720	0.744	0.788	**0.808 (0.005)**
French	Book	0.808	0.783	0.844	**0.860 (0.002)**
	DVD	0.788	0.748	0.836	**0.857 (0.002)**
	Music	0.758	0.787	0.825	**0.860 (0.002)**
German	Book	0.797	0.799	0.841	**0.864 (0.001)**
	DVD	0.779	0.771	0.841	**0.861 (0.001)**
	Music	0.772	0.773	0.847	**0.878 (0.002)**

BiDRL is the document-aligned representation learning method proposed by Zhou *et al.* [62]. It uses *Google Translate* to create labeled parallel documents and forces the pseudo parallel documents to share the same embedding space. It also enforces constraints to make the document vectors associated with different sentiments fall into different positions in the embedding space. Furthermore, it forces documents with large textual differences but the same sentiment to have similar representations. After this representation learning process, it concatenates the vectors of one document in both languages and trains a logistic regression sentiment classifier.

As the benchmark datasets have quite balanced positive and negative reviews, we follow the aforementioned studies to use accuracy as an evaluation metric. All the baseline methods have been evaluated with exactly the same training and test data sets used in previous studies [62], so we make direct comparisons with their reported results. Unfortunately, we cannot obtain the individual predictions of these methods, so we are not able to report the statistical significance (such as McNemar's test [25]) of the difference between these baselines and ELSA. To alleviate this problem and get robust results, we run ELSA 10 times with different random initiations and summarize its average accuracy and standard deviation in Table 2, as well as the reported performance of the baselines.

As illustrated in Table 2, ELSA outperforms all three baseline methods on all nine tasks. Looking more closely, the performance of all methods in Japanese sentiment classification is worse than in French and German tasks. According to the language systems defined by ISO 639 [10], English, French, and German belong to the same language family (i.e., Indo-European), while Japanese belongs to the Japonic family. In other words, French and German are more in common with English, and it is expected to be easier to translate English texts into French and German and transfer the sentiment knowledge from English to them. Therefore, in fact, Japanese tasks are most difficult and none of the previous methods have been able to achieve an accuracy above 0.8. It is encouraging to find that ELSA achieves an accuracy of 0.808 on the Japanese music task and an accuracy close to 0.8 (0.791) on the Japanese DVD task. The 0.783 accuracy on the book task is also non-negligible as it improves on the best existing model by almost 7 percent. In addition, although the French and German tasks are a little easier than the Japanese ones, none of the existing approaches can achieve an accuracy over 0.85 on any of the six tasks. However, our approach can achieve a mean accuracy higher than 0.85 on all of the six tasks.

Next, we compare the results more thoroughly and further demonstrate the advantages of our approach. As is shown, the representation learning approaches (CL-RL, BiDRL, and ELSA) all

outperform the shallow method MT-BOW on most tasks. This is reasonable as representation learning approaches embed words into high-dimensional vectors in a continuous semantic space and thus overcome the feature sparsity issue of traditional bag-of-words approaches. Furthermore, we observe that the document-level representation approaches (BiDRL and ELSA) outperform the word-level CL-RL. This indicates that incorporating document-level information into representations is more effective than focusing on individual words. Finally, ELSA outperforms the BiDRL on all tasks. In order to narrow the linguistic gap, BiDRL leverages only pseudo parallel texts to learn the common sentiment patterns between languages. Besides the pseudo parallel texts, ELSA also learns from the emoji usage in both languages. On the one hand, as a ubiquitous emotional signal, emojis are adopted across languages to express common sentiment patterns, which can complement the pseudo parallel corpus. On the other hand, the language-specific patterns of emoji usage help incorporate the language-specific knowledge of sentiments into the representation learning, which can benefit the downstream sentiment classification in the target language. As a next step, we explore the role of emojis in the learning process with a more comprehensive investigation.

4.4 The Power of Emojis

To further evaluate the contribution of emojis in ELSA, we conduct subsequent experiments to investigate the effects of emojis from three perspectives, i.e., overall performance, effectiveness of representation learning, and text comprehension.

4.4.1 Overall Performance. To understand how emojis affect cross-lingual sentiment classification in general, a straightforward idea is to remove the emoji-prediction phase and compare simplified versions of ELSA:

N-ELSA removes the emoji-prediction phase of both languages and directly uses two attention layers to realize the transformation from word vectors to the final document representation. There is no emoji data used in this model.

T-ELSA removes the emoji-based representation learning on the English side. It uses the emoji-powered representations for the target language and translates labeled English documents into the target language to train a sentiment classifier for the target language. This model only leverages emoji usage in the target language.

S-ELSA removes the emoji-based representation learning in the target language. It uses the emoji-powered representations of English and trains a sentiment classifier based on labeled English documents. Documents in the target language are first translated into English and then classified. This model only leverages emoji usage in the source language (i.e., English).

Test accuracy of these models is illustrated in Table 3. We find that ELSA outperforms N-ELSA on all nine tasks. N-ELSA is only a little better than uniform guess (50%) since it learns the common patterns between languages only from pseudo parallel texts and does not incorporate sentiment information effectively. An alternative conjecture is that 2,000 reviews are insufficient to train such a complex model, which may have led to the problem of over-fitting.

To test between the two hypotheses, we mix up the labeled reviews in English and in the target language and randomly select 2,000 examples from the mixed set for training and use the remaining samples as a new test set. All other settings of the experiment are kept the same except for the new train/test split. Trained and tested in this way, the accuracy of N-ELSA becomes acceptable, with an average accuracy of 0.777 on all tasks. This indicates that over-fitting might not have been the major reason, while language discrepancy might be. Indeed, N-ELSA can still work well if we effectively incorporate cross-language sentiment information into the training process. More specifically, the original N-ELSA is dominated by English sentiment information learned from pseudo parallel texts and fails to generalize to the target language correctly. When we input the sentiment information (labeled documents) of both English and the target language into the model, performance improves. Unfortunately, in a cross-lingual sentiment classification setting, we can not acquire enough labels in the target language. Emojis help the model capture generalizable sentiment knowledge, even if there is no labeled example for training in the target language.

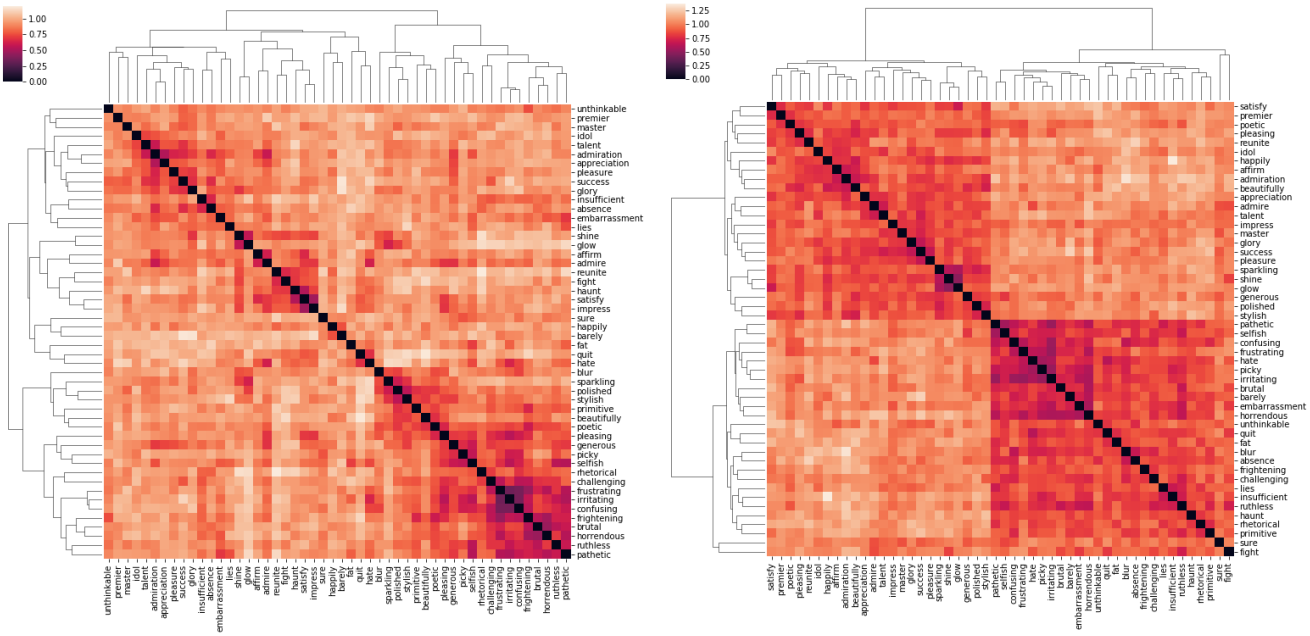

Table 3: Performance of ELSA and its simplified versions.

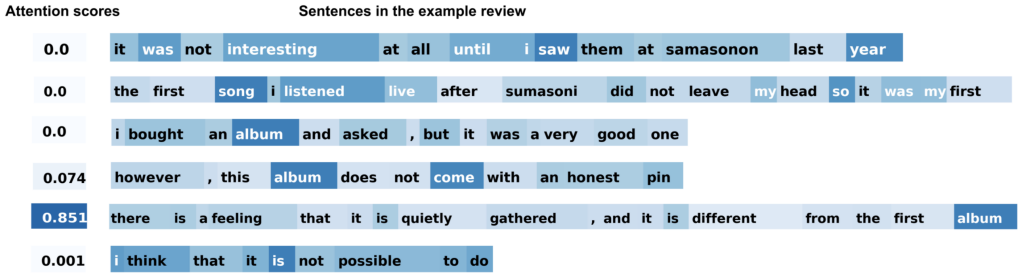
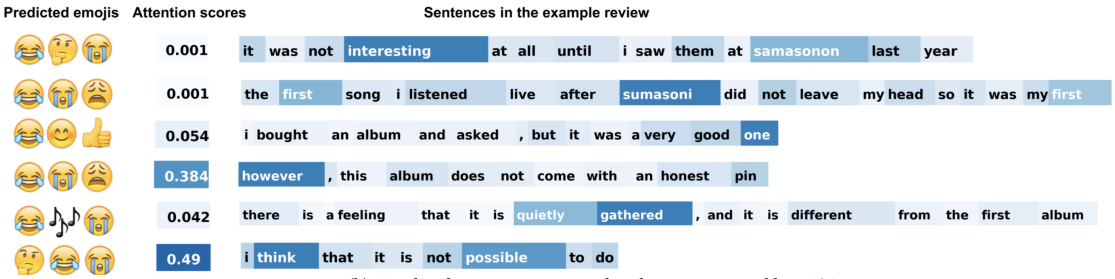
Language	Domain	N-ELSA	T-ELSA	S-ELSA	ELSA
Japanese	Book	0.527*	0.742*	0.753*	0.783
	DVD	0.507*	0.756*	0.766*	0.791
	Music	0.513*	0.792*	0.778*	0.808
French	Book	0.505*	0.821*	0.850*	0.860
	DVD	0.507*	0.816*	0.843*	0.857
	Music	0.503*	0.811*	0.848*	0.860
German	Book	0.513*	0.804*	0.848*	0.864
	DVD	0.521*	0.790*	0.849*	0.861
	Music	0.513*	0.818*	0.863*	0.878

* indicates the difference between ELSA and its simplified versions is statistically significant ($p < 0.05$) by McNemar's test.

In addition, ELSA also consistently achieves better accuracy compared to T-ELSA and S-ELSA on all tasks (McNemar's test [25] is performed and the differences are all statistically significant at the 5% level). The superiority of ELSA shows that only extracting sentiment information from one language is not enough for the cross-lingual sentiment task and that incorporating language-specific knowledge for both languages is critical to the model's performance. Indeed, S-ELSA fails to capture sentiment patterns in the target language; and T-ELSA falls short in extracting transferable sentiment patterns from English (indicating that emojis are still beneficial even if there are sentiment labels in a language).



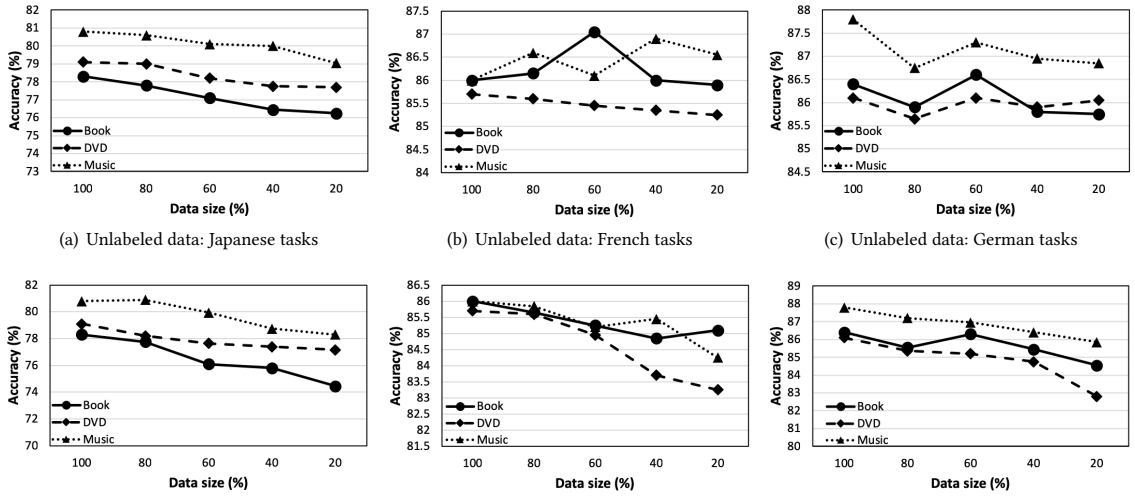
4.4.2 Effectiveness of Representation Learning. To better understand the sentiment information learned through the emoji usage, we then conduct an empirical experiment at the word representation level. Recall that after the word embedding phase, each individual word can be represented by a unique vector and that these word vectors are then fine-tuned in the emoji-prediction phase. Next, we would like to evaluate whether sentiment information is better captured by the new word representations under the effects of emojis. We sample 50 English words with distinct sentiments from the MPQA subjectivity lexicon [1] based on their frequencies in our corpus. These words are manually labeled in terms of positive or negative polarity from MPQA, and we regard these labels as the ground-truth for further evaluation.



(a) Clusters of selected words with Word2Vec representations.

(b) Clusters of selected words with emoji-powered representations.

Figure 3: Comparison of word representations *with* and *without* emoji prediction.



(a) Word and sentence attention distribution generated by N-ELSA.

(b) Word and sentence attention distribution generated by ELSA.

Figure 4: Case study: Effect of emojis on text comprehension.

We expect that an informative representation can embed words with same sentiment polarity closely in the vector space. To measure and illustrate the similarity, we calculate the similarity score between every two words using the cosine of the corresponding embedding vectors. Based on the cosine similarity, we perform a hierarchical clustering [15] and visualize the clustering results in Figure 3. The color scale of each cell indicates the similarity between the two words. The darker the cell, the more similar the representations of the two words.

(a) Unlabeled data: Japanese tasks (b) Unlabeled data: French tasks (c) Unlabeled data: German tasks

(d) Labeled English data: Japanese tasks (e) Labeled English data: French tasks (f) Labeled English data: German tasks

Figure 5: Accuracy of ELSA when size of unlabeled and labeled data changes.

In Figure 3(a), we use naive embeddings learned by Word2Vec (no emoji), and words with different sentiments cannot be clearly separated. Many words with different sentiments are embedded closely, for example, "generous" and "picky" in the bottom right section. This indicates that shallow word embeddings do not effectively capture the sentiment information.

In contrast, in Figure 3(b), we can easily observe two clusters after the fine-tuned emoji-prediction model. The top left corner cluster contains the positive words, while the bottom right corner contains the negative words. Only one positive word, "sure," is incorrectly clustered with negative words. By checking the contexts of this word in our corpus, we find it is usually co-used with both positive and negative words, making its polarity ambiguous. The correct clustering of nearly all the words indicates that emoji usage is an effective channel to capture sentiment knowledge, which is desirable for downstream sentiment classification.

4.4.3 Text Comprehension. We then explore how the emoji-powered representations benefit text comprehension. We select a representative case that is incorrectly classified by N-ELSA but correctly classified by ELSA. This case is selected from the Japanese test samples and we use the segment of its translated English version for illustration in Figure 4. Although the whole document expresses dissatisfaction with an album, it is not that easy to identify this intent directly from each single sentence due to the translation quality and the document's complex compositions. For example, if we consider only the third sentence without context, the author seems to express a positive attitude. However, in fact, the author expresses an obviously negative attitude in the fourth and sixth sentences.

In Figure 4, we present the attention distribution of words and sentences generated by N-ELSA and ELSA, which indicates how the two models comprehend this document, or the rationale behind their classification decisions. We use the color scale of the background to indicate the attention scores of words in each sentence. The darker the word, the more it is attended to. For each sentence, we list its attention score in this document. In Figure 4(b), we also list the top 3 emojis ELSA predicts for each sentence, which may indicate its sentiment polarity predicted by ELSA.

Let us first look at Figure 4(a), which demonstrates how N-ELSA processes the sentiment information. On the word level, N-ELSA tends to focus more on neutral words like "song" or "album" instead of sentimental words. On the sentence level, an extremely high attention is placed on the fifth sentence. However, the fifth sentence describes how the album is different from the first one and it does not express the obviously negative sentiment.

In contrast, after incorporating of emojis, ELSA is able to work with a proper logic (see Figure 4(b)). ELSA places its attention to the emotional adjectives, such as "interesting" and "not possible," and contrast conjunctions such as "however." Thus, it manages to identify the sentiment of each sentence as expected, which can be further explained by the predicted emojis on the left. Besides the most popular 😂 in our corpus, 😭 and 😩 predicted for the fourth and sixth sentence indicate the negative sentiment of the author, while 👍 and 😊 in the third sentence indicate positive sentiment. Then on the sentence level, ELSA places less attention to the positive third sentence, while centering upon the fourth and the sixth sentences. Through this comparison, we can see that emojis bring additional knowledge to the text comprehension and make the attention mechanism more effective.

5 DISCUSSION

So far, we have presented the performance of ELSA on benchmark datasets and demonstrated the power of emojis in our learning process. There are some issues that could potentially affect its effectiveness and efficiency, which call for further discussion.

5.1 Sensitivity on Data Volume

As we learn text representations from large amount of Tweets, we want to investigate whether ELSA works well with a smaller volume of data. First, we investigate the size of unlabeled data. The English representation model, once learned, can be reused by any other English-target language pair. We only need to scale down the Tweets and emoji-Tweets in the target language and observe the changes in performance on benchmarks. In details, we use 80%, 60%, 40%, and 20% of the collected Tweets to re-train the target-language representation model and keep the final supervised training fixed. We summarize the results in Figures 5(a), 5(b), and 5(c). For the Japanese tasks, when we scale down the unlabeled data, the performance gets slightly worse. Comparing the results using 20% and 100% of the Tweets, the accuracy differences in three domains are 0.021, 0.014, and 0.018, respectively. For French and German, the performance fluctuates less than 0.01. Most importantly, ELSA can outperform the existing methods on all nine tasks even with the 20% unlabeled data. This indicates that even though a target language is not as actively used on Twitter, our approach still works.

Furthermore, although there are more labeled examples in English than other languages, in general, labels are still scarce. Hence, if a model can rely on even fewer labeled English documents, it is very desirable. To test this, we scale down the labeled data by 80%, 60%, 40%, and 20%. As shown in Figures 5(d), 5(e), and 5(f), the performance of ELSA slightly declines with the decrease of labels, but even with 20% labels (i.e., 400 labeled English samples), ELSA outperforms the existing methods using all 2,000 labeled samples on almost all tasks. This shows that with the help of large-scale emoji-Tweets, the model is less dependent on sentiment labels.

5.2 Generalizability

Most previous cross-lingual sentiment studies [50, 58, 62] used the Amazon review dataset for evaluation. To compare with them, we also adopt this dataset in the main experiment of this paper. Sentiment classification in other domains such as social media is also important. Can ELSA still work well in a new domain? To evaluate the generalizability of our approach, we apply ELSA to a representative type of social media data – Tweets. As Tweets are short and informal, sentiment classification for them is considered to be a big challenge [28].

As cross-lingual studies on Tweets are very limited, we take only one recent cross-lingual method (MT-CNN) proposed by Deriu *et al.* [23] for comparison. It also relies on large-scale unlabeled Tweets and a translation tool. It first trains a sentiment classifier for English and then applies it to the translations of text documents in the target language. The training process for English Tweets contains three phases. First, it uses raw Tweets to create word embeddings just like our method. Second, it leverages ":)" and ":(" as weak labels and applies a multi-layer CNN model to adapt the word embeddings. Finally, it trains the model on labeled English Tweets. This work and our work both have coverage of French and German Tweets, so we use the two as the target languages for comparison.

As the sentiment-labeled Tweets used by [23] are released in forms of Twitter IDs and some of them are no longer available now, we cannot directly compare our model to the reported results in [23]. For fair comparison, we reproduce their method on the labeled Tweets that can still be collected. Based on the pre-trained representation models of MT-CNN [5] and ELSA, we use the same labeled English Tweets to train and validate the two classifiers and then test them on the same data (i.e., labeled French and German Tweets that can be collected). We list the sizes of the labeled English, French, and German Tweets we use in Table 4. From the distribution, a naive baseline using uniform guess would achieve an accuracy of 0.451 for French and 0.628 for German.

Table 4: The sizes of labeled Tweets collected.

Dataset	Language	Positive	Neutral	Negative
Training	English [8]	5,101	3,742	1,643
Validation	English [7]	1,038	987	365
Test	French [4]	987	1,389	718
	German [6]	1,057	4,441	1,573

Table 5: Classification accuracy on French and German Tweets.

Language	ELSA	MT-CNN	Uniform Guess
French	0.696	0.535*	0.451*
German	0.809	0.654*	0.628*

*indicates the difference between ELSA and the baseline methods is statistically significant ($p < 0.05$) by McNemar's test.

Results are summarized in Table 5. The two approaches both outperform uniform guess, and ELSA outperforms the MT-CNN by 0.161 on French task and 0.155 on German task. Although we use the same training, validation, and test set for both approaches, we are still concerned about whether the pre-trained representation models have introduced unfairness. Specifically, if we have used more unlabeled Tweets for representation learning than MT-CNN, our outstanding performance may simply attribute to the size of data. To answer this question, we refer to [23] about their data size. We find that they uses 300M raw Tweets and 60M Tweets containing ":)" and ":(" for representation learning. In contrast, we only used 81M raw Tweets and 13.7M emoji-Tweets in three languages combined. Considering that emoticons are significantly less used than emojis on Twitter [48], although they use about 4.4 times more weak-labeled Tweets, these Tweets had to be collected from much more than 4.4 times of raw Tweets than ours. It is clear ELSA outperforms MT-CNN and relies less on data size.

6 CONCLUSION

As a ubiquitous emotional signal, emojis are widely adopted across languages to express sentiments. We leverage this characteristic of emojis, both using them as surrogate sentiment labels and using emoji prediction an instrument to address the language discrepancy in cross-lingual sentiment classification. We have presented ELSA, a novel emoji-powered representation learning framework, to capture both general and language-specific sentiment knowledge in the source and the target languages for cross-lingual sentiment classification. The representations learned by ELSA capture not only sentiment knowledge that generalizes across languages, but also language-specific patterns. We evaluate ELSA with comprehensive experiments on various benchmark datasets, which outperforms the state-of-the-art cross-lingual sentiment classification methods

even when the size of labeled and unlabeled data decreases. The promising results indicate that emojis may be used as an a general instrument for text mining tasks that suffer from the scarcity of labeled examples, especially in situations where an inequality among different languages presents.

ABSTRACT

Graph smoothing methods are an extremely popular family of approaches for semi-supervised learning. The choice of graph used to represent relationships in these learning problems is often a more important decision than the particular algorithm or loss function used, yet this choice is less well-studied in the literature. In this work, we demonstrate that for social networks, the basic friendship graph itself may often not be the appropriate graph for predicting node attributes using graph smoothing. More specifically, standard graph smoothing is designed to harness the social phenomenon of homophily whereby individuals are similar to "the company they keep." We present a *decoupled* approach to graph smoothing that decouples notions of "identity" and "preference," resulting in an alternative social phenomenon of monophily whereby individuals are similar to "the company they're kept in," as observed in recent empirical work. Our model results in a rigorous extension of the Gaussian Markov Random Field (GMRF) models that underlie graph smoothing, interpretable as smoothing on an appropriate auxiliary graph of weighted or unweighted two-hop relationships.

1 INTRODUCTION

Graph-based learning describes a broad class of problems in which response values are observed on a subset of the nodes of a graph, and the learning objective is to infer responses for the unlabeled nodes. Inference methods for graph-based learning nearly unanimously derive their success from an assumption that connected nodes are correlated in their responses, akin to the social phenomenon of homophily whereby "birds of a feather flock together" [22]. Many varieties of models derived from this assumption have been studied and successfully applied. The most popular methods include the work of Zhu, Ghahramani, and Lafferty (ZGL) on semi-supervised learning using Gaussian Markov Random Fields [33], Zhou et al.'s related method for random walk smoothing [31], and Xu, Dyer, and Owen's work connecting the former two methods to methods for kriging from spatial statistics [30]. See [32] for a survey of semi-supervised learning methods on graphs.

While presented as graph-based methods, the graphs that underlie the typical applications of these methods are often synthetic in nature. For example, they may be derived from high-dimensional text or image data. These typical applications begin with a semi-supervised learning problem studying high-dimensional data points $x_i \in \mathbb{R}^D$ associated with response values $y_i \in \mathbb{R}$ (such as images x_i associated with quality scores y_i) and then induce a graph between the data points by taking a k-nearest neighbor graph in the space $\mathbb{R}^D$ to obtain a sparse similarity graph. Despite the synthetic nature of these graphs, graph-based learning methods have been highly effective for solving machine learning problems.

In this work, we focus on graph-based learning problems on social networks, where the relationship between the graph and the response variables can be quite different than the basic similarity relationship between responses on synthetic graphs produced by standard induction methods such as k-nearest neighbors. We rely on the recent observation that there are contexts where the fundamental assumption of correlation that drives graph-based learning—that connected nodes are correlated in their responses—may not be true or necessary for inference to succeed [1, 25]. The work in [1], which focused on the social structure of gender, observed a fundamental difference between similarities with "the company you keep" and "the company you're kept in" in social networks. That work found that the two-hop similarities implied by the latter can exist in the complete absence of any one-hop similarities. In the present work, we develop these differing social assumptions into an alternative semi-supervised learning problem, where correlations on the social networks are based on a decoupling of separate "real" and "target" responses of individuals corresponding to separated notions of social identity and social preference. The key principle is to allow the outcomes of an individual to be possibly different from the outcomes with which the individual prefers to associate.

The consequences of this decoupling between real and target responses is that individuals connected in the graph are only correlated in their responses if the real and target responses of the individuals are correlated with each other. But even if they are entirely uncorrelated, a subtler correlation is nonetheless induced, as pointed out in [1], which can be particularly useful for inference: even if an individual is not correlated with their graph neighbors, the fact that they have preferences for a target response will still imply that their neighbors are correlated with each other. As a

https://doi.org/10.1145/3308558.3313748

result, individuals can be similar to their friends-of-friends without necessarily being similar to their friends.

In this work we show that the above decoupling can be modeled in a very natural semi-supervised learning problem for an appropriately constructed auxiliary similarity matrix encoding two-hop similarities. The two-hop similarity matrix that we consider is derived from previously unrelated literature on combining estimators [8, 11, 12, 19, 23, 26], since the "real" and "target" state of each node must be estimated from the dispersed evidence surrounding them in the graph. By making this connection, our work also introduces an iterative procedure for the combining estimators problem when data is being collected on a graph.

As a byproduct of our investigation, we also strengthen the known connections between random walk-based methods (such as ZGL) and Kriging-based methods, introduce a procedure that maps any Kriging problem to a ZGL problem. This connection between the methods enables us to take a "decoupled" view of either problem class, and also allows us to use computationally expedient iterative solvers for standard ZGL-type problems to solve Kriging problems, coupled or decoupled.

2 GRAPH SMOOTHING PRELIMINARIES

In this section we review two standard formulations of graph smoothing, the semi-supervised learning problem of [33], which we refer to here simply as smoothing, and the graph regularization approach involving noisy observations that we refer to as soft smoothing. We review the closed form solutions, and later give recurrences that converge on the closed form solutions for both problems.

We assume that we observe a social network of n people with connections represented by an undirected, unweighted graph $G = (V, E)$. We let A and D denote the adjacency matrix and degree matrix of the graph, respectively, where D has diagonal entries $d_i = \sum_j A_{ij}$. We denote the neighborhood of node i by $\mathcal{N}_i = \{j : A_{ij} > 0\}$. Each person i has a outcome value of interest $\theta_i \in \mathbb{R}$; we write $\theta \in \mathbb{R}^n$ for the vector of response values. We only observe the labels θ_i for a subset of the nodes; we denote the set of labeled nodes V_0 and the set of unlabeled nodes $V_1 = V \setminus V_0$. Let $\mathcal{N}_i^0 = \{j : A_{ij} > 0, j \in V_0\}$ be the set of neighbors of i for which the labels are observed, and $\mathcal{N}_i^1 = \{j : A_{ij} > 0, j \in V_1\}$ be the set of neighbors of i for which the labels are unobserved. Correspondingly define $d_i^0 = |\mathcal{N}_i^0|$ and $d_i^1 = |\mathcal{N}_i^1|$, the "labeled degree" and "unlabeled degree," respectively. The vectors $\theta_0 \in \mathbb{R}^{|V_0|}$ and $\theta_1 \in \mathbb{R}^{|V_1|}$ represent the restriction of the response vector θ to the observed and unobserved node sets. In general, we reserve the subscripts 0 and 1 for subsetting on labeled and unlabeled nodes, respectively.

2.1 Smoothing

The standard formulation of graph smoothing, proposed in [33], is to solve the optimization problem

$$\min_{\theta} \sum_{(i,j)\in E} A_{ij}(\theta_i - \theta_j)^2, \qquad \text{subject to } \theta|_{V_0} = \theta_0. \tag{1}$$

The loss function in Equation (1) is $\theta^\top L\theta$, where $L = D - A$ is the graph Laplacian.

If we define the transition matrix $P = D^{-1}A$ and identify blocks of P according to the labeled nodes V_0 and unlabeled nodes V_1, the closed-form solution to Equation (1) for the unlabeled nodes is then:

$$\hat{\theta}_1 = (I - P_{11})^{-1}P_{10}\theta_0, \text{ where } P = \begin{pmatrix} P_{00} & P_{01} \\ P_{10} & P_{11} \end{pmatrix}. \tag{2}$$

This solution has a Bayesian interpretation [20, 30]. Suppose we place a Gaussian Markov Random Field (GMRF) on the node set by placing a prior $\theta \sim N\left(0, \tau^2(D - \gamma A)^{-1}\right)$ on θ. This prior is the *conditional autoregressive* (CAR) model popular in the spatial statistics literature [5, 6], and has the property that θ_i conditional on the other values of θ follows the distribution

$$\theta_i|(\theta_1, \ldots, \theta_{i-1}, \theta_{i+1}, \ldots, \theta_n) \sim N\left(\frac{\gamma}{d_i}\sum_{j\in\mathcal{N}_i}\theta_j, \frac{\tau^2}{d_i}\right). \tag{3}$$

Under this GMRF prior, the Bayes estimator of θ, conditional on having observed the labels θ_i, $i \in V_0$, is the solution to Equation (1), when $\gamma \to 1$. The parameter $\gamma < 1$ is a correlation parameter that is necessary for the distribution to be non-degenerate. In practice it is common to add a small ridge to the diagonal of the Laplacian when solving Equation (1) for numerical stability, which achieves a similar purpose.

2.2 Soft smoothing

A second approach to graph smoothing has its origins in graph-based regularization, as studied in [4]. In this problem, we no longer observe θ_0 directly but rather observe $y_0 = \theta_0 + \varepsilon$ where $\varepsilon \sim N(0, \zeta^2 I)$. We will refer to this problem as soft smoothing, to emphasize the close relationship to ordinary smoothing. Consider the estimator

$$\hat{\theta} = \operatorname*{argmin}_{\theta} \|y_0 - \theta_0\|_2^2 + \lambda\theta^\top(D - A)\theta. \tag{4}$$

Under the prior assumption $\theta \sim N(0, \tau^2(D - \gamma A)^{-1})$, which is equivalent to the conditional specification of the GMRF on the node set in Equation (3), the estimator $\hat{\theta}$ in Equation (4) is the Bayes estimator for this model with $\lambda = \zeta^2/\tau^2$ and $\gamma \to 1$. This estimator $\hat{\theta}$ has the following closed form solution when $\lambda > 0$:

$$\hat{\theta} = (J + \lambda L)^{-1}Jy^*, \text{ where } J = \begin{pmatrix} I & 0 \\ 0 & 0 \end{pmatrix}, \tag{5}$$

and y^* is a vector that agrees with the labeled points and takes on any value on the unlabeled points. If $\zeta^2 = 0$ (whereby $\lambda = 0$) then the optimization problem in Equation (4) reduces to the noiseless graph smoothing problem in Equation (1) [30]. Later, we will show that even when $\zeta^2 > 0$ there is a direct mapping between soft and "hard" smoothing problem instances.

3 DECOUPLED GRAPH SMOOTHING

Crucial to the performance of graph smoothing estimators like Equation (2) is a smoothness assumption positing that the response values vary smoothly across the topology of the graph. This assumption in often appropriate in synthetic graph applications like those constructed for image segmentation and changepoint detection problems, and smooth kernel edge weights are often assumed in theoretical studies of semi-supervised learning performance [13, 24].

However, this assumption can fail to hold in social networks. Indeed, [1] shows that even when homophily is minimal or nonexistent, additional variation known as *monophily* among friend-of-friend (two-hop) relations can be exploited to predict outcomes. Intuitively, if an unlabeled individual i is friends with person j who tends to befriend a high proportion of female individuals, then we might be more certain that the unlabeled individual i is female as well. In this case, what matters for classifying individual i is not the label of individual j, but rather individual j's preferences in her friends. In this work we propose *decoupling* the true parameter of interest θ_j from a *target parameter* ϕ_j that captures the true parameters of the neighbors of j. We now study a model that gives rise to such a decoupling.

Suppose we have a weight matrix W, and denote the row sums by $z_i = \sum_j W_{ij}$ and the column sums by $z'_j = \sum_i W_{ij}$. Our approach is to relate the real θ_i and target ϕ_i via W as follows:

$$\theta_i \approx \frac{1}{z_i} \sum_{j=1}^{n} W_{ij}\phi_j, \tag{6}$$

$$\phi_j \approx \frac{1}{z'_j} \sum_{i=1}^{n} W_{ij}\phi_i. \tag{7}$$

Note that W need not be symmetric. The choice of W is to be set by the researcher and may depend on the particular problem being solved. For example, if W is set to be the adjacency matrix A, then ϕ_i and θ_i become unweighted averages of peer values. Section 5 contains a discussion of alternative options for setting W, where we argue that more complex choices of W may indeed be desirable.

Expressions (6) and (7) are to be understood in an "average" and informal sense. Formally, we consider the Gaussian Markov random field model

$$\theta_i|\phi \sim N\left(\frac{\gamma}{z_i}\sum_{j=1}^{n} W_{ij}\phi_j, \frac{\tau^2}{z_i}\right), \quad \phi_j|\theta \sim N\left(\frac{\gamma}{z'_j}\sum_{i=1}^{n} W_{ij}\theta_i, \frac{\tau^2}{z'_j}\right), \tag{8}$$

where γ and τ^2 are constants. We now establish that this model is equivalent to marginally specifying the joint Gaussian distribution for θ and ϕ as follows. A proof of this equivalence is found in the appendix.

Theorem 3.1. *Let W be a weight matrix with row sums $z_i = \sum_j W_{ij}$ and column sums $z'_j = \sum_i W_{ij}$. Let $\tau^2 > 0$ and $\gamma \in (0, 1)$. Then the conditional specifications*

$$\theta_i|\phi \sim N\left(\frac{\gamma}{z_i}\sum_{j=1}^{n} W_{ij}\phi_j, \frac{\tau^2}{z_i}\right), \qquad \phi_j|\theta \sim N\left(\frac{\gamma}{z'_j}\sum_{i=1}^{n} W_{ij}\theta_i, \frac{\tau^2}{z'_j}\right)$$

define a valid, non-degenerate probability distribution over θ and ϕ with marginal distribution $\begin{pmatrix}\theta\\ \phi\end{pmatrix} \sim N(\mu, \Sigma)$, where $\mu = 0$ and

$$\Sigma = \tau^2 \begin{pmatrix} Z & -\gamma W \\ -\gamma W^\top & Z' \end{pmatrix}^{-1}, \tag{9}$$

where $Z = \mathrm{diag}(z_1, \ldots, z_n)$ and $Z' = \mathrm{diag}(z'_1, \ldots, z'_n)$.

Because our goal is to obtain predictions for the real attributes θ, we view the target attributes ϕ as nuisance parameters and marginalize them out. By studying the precision matrix $M = \Sigma^{-1}$ and applying the standard 2×2 block matrix inversion Schur complement

$$(M^{-1})_{11} = (M_{11} - M_{12}M_{22}^{-1}M_{21})^{-1},$$

we find the marginal prior for θ is then Gaussian with mean 0 and covariance matrix $\tau^2\left(Z - \gamma^2 W Z'^{-1} W^\top\right)^{-1}$. Therefore, minimizing the posterior log-likelihood conditional on observing values θ_i for $i \in V_0$ reduces to the optimization problem

$$\min_\theta \theta^\top L' \theta, \qquad \text{subject to } \theta|_{V_0} = \theta_0 \tag{10}$$

for the modified Laplacian

$$L' = (Z - \gamma^2 W Z'^{-1} W^\top). \tag{11}$$

We call this modified Laplacian the *decoupled Laplacian*, to emphasize the decoupling between the real responses θ and the target responses ϕ in the underlying model.

From this expression for the decoupled Laplacian we can view $\tilde{A} = WZ'^{-1}W^\top$ as a weighted adjacency matrix for an auxiliary graph that is essentially connecting nodes to their two-hop neighbors with appropriately weighted edges. With this modified auxiliary matrix, the solution to the decoupled smoothing objective is then

$$\hat{\theta}_1 = (I - P_{11})^{-1} P_{10}\theta_0, \tag{12}$$

as before in Equation (2), but now with $P = Z^{-1}(Z - \gamma^2 W Z'^{-1} W^\top)$. The closed form solution to the soft decoupled smoothing objective, as in Equation (5), becomes

$$\hat{\theta} = (J + \lambda(Z - \gamma^2 W Z'^{-1} W^\top))^{-1} J y^*. \tag{13}$$

We have intentionally kept the weight matrix W generic in these derivations. In Section 5, we use ideas from the literature on expert aggregation to motivate our choice of W.

3.1 Coupling $\theta = \phi$ reduces to the standard smoother

Here we further motivate the sense in which the above decoupled smoothing problem is strongly connected to the basic smoothing problem: by conditioning the distribution of the GMRF upon $\theta = \phi$, we recover the basic smoothing objective.

Under the transformation $\nu = \theta - \phi$, the log-likelihood of the vector (θ, ν) is

$$p(\theta, \nu) \propto \exp\Big\{ -\frac{1}{2\tau^2}\Big(\theta^\top(Z + Z' - 2\gamma W)\theta - 2\theta^\top(Z' - \gamma W)\nu + \nu^\top Z'\nu\Big)\Big\}.$$

If we let the weight matrix W be equal to the adjacency matrix A, so that the row and column sums reduce to the degree matrix $Z = Z' = D$, then the joint parameters (θ, ν) have the covariance matrix

$$\tau^2 \begin{pmatrix} 2(D - \gamma A) & -(D - \gamma A) \\ -(D - \gamma A) & D \end{pmatrix}^{-1}.$$

The upper left block, $2\tau^2(D - A)$, is the precision matrix of θ conditional on ν, which shows that θ follows the ordinary smoother distribution in Section 2.1 with τ^2 replaced by $2\tau^2$.

4 ITERATIVE PERSPECTIVE ON SMOOTHING

In this section we outline how the closed form solutions to the smoothing problems discussed in this work can be formulated as the solutions to the iterative application of recurrence relations. We first review the known iterative formulation of smoothing. We then contribute a reduction which shows that any *soft* smoothing problem can be written as a *hard* smoothing problem, and can thus be written iteratively as well. We formulate the recurrence relation that underlies the decoupled smoothing problem studied in this work. In the next section, Section 5, we will show how this recurrence can be interpreted in the language of expert opinion aggregation, giving us an intuition for how to choose the previously unspecified weight matrix W in the recurrence we derive here.

4.1 Iterative formulation of smoothing

The closed form solution to the smoothing objective in Equation (1) is known to arise from a repeated application of majority vote [7, 21] in the following sense: define the time 0 estimate $\hat{\theta}^0$ to agree with the true labels on V_0. Take the transition matrix $P = D^{-1}A$ and perform the updates

$$\hat{\theta}_1^t = P_{10}\theta_0 + P_{11}\hat{\theta}_1^{t-1}, \qquad \hat{\theta}_0^t = \theta_0, \tag{14}$$

where $P = \begin{pmatrix} P_{00} & P_{01} \\ P_{10} & P_{11} \end{pmatrix}$ has been partitioned into labeled and unlabeled blocks, as before. In other words, the time t estimate is the majority vote estimate using the time $t-1$ predictions, where after each step we replace the labeled predictions by their original, true labels. In the limit,

$$\hat{\theta}_1 = \lim_{t\to\infty} \hat{\theta}_1^t = (I - P_{11})^{-1}P_{10}\theta_0, \tag{15}$$

which is the solution to Equation (1) given in Equation (2).

4.2 Iterative formulation of soft smoothing

We now contribute an iterative algorithm for soft smoothing by showing that a soft smoothing solution is equivalent to a hard smoothing solution on an appropriate auxiliary graph. Consider an augmented graph $\tilde{G}$ formed by attaching a degree-one node to each labeled node on the original graph, with edge weight $\alpha > 0$. The vertex set of the resulting graph contains a copy of the labeled nodes, denoted $\tilde{V}_0$, in addition to the original labeled node set V_0 and unlabeled node set V_1.

This new graph has adjacency matrix

$$\tilde{A} = \begin{pmatrix} 0 & \alpha I & 0 \\ \alpha I & A_{00} & A_{01} \\ 0 & A_{10} & A_{11} \end{pmatrix},$$

where the first block corresponds to $\tilde{V}_0$, the second block corresponds to V_0, and the third block corresponds to V_1. If we compute the hard smoothing solution on this augmented graph treating $\tilde{V}_0$ as the labeled set and the entire original vertex set V as the unlabeled set, the corresponding random walk transition matrix is

$$\tilde{P} = \tilde{D}^{-1}\tilde{A} = \begin{pmatrix} 0 & I & 0 \\ \tilde{D}_0^{-1}A_{10} & \tilde{D}_0^{-1}A_{00} & \alpha\tilde{D}_0^{-1} \\ D_1^{-1}A_{10} & D_1^{-1}A_{11} & 0 \end{pmatrix},$$

where D_1 is the degree matrix of the original graph restricted to the unlabeled node set V_1, and $\tilde{D}_0 = D_0 + \alpha I$ is the degree matrix restricted to the labeled node set V_0, adjusted to account for the new auxiliary nodes.

The hard smoothing solution in Equation (15) is $\hat{\theta} = (I - P_{11})^{-1}P_{10}\theta_0$. Applying this solution to the above problem, we have

$$\begin{aligned} P_{11} &= (D + \alpha J)^{-1}A, \\ P_{10}\theta_0 &= \alpha(D_0 + \alpha I)^{-1}\theta_0 = \alpha(D + \alpha J)^{-1}Jy^*, \end{aligned}$$

which results in the estimator

$$\begin{aligned} \hat{\theta} &= (I - (D + \alpha J)^{-1}A)^{-1}\alpha(D + \alpha J)^{-1}Jy^* \\ &= (\alpha J + D - A)^{-1}\alpha Jy^* \\ &= (J + \alpha^{-1}L)^{-1}Jy^*. \end{aligned}$$

This estimator is precisely the soft smoothing closed-form solution in Equation (5) when $\alpha = \lambda^{-1}$. Notice the non-equivalence between this solution and the solution in the case of $\zeta^2 = 0$ (for which $\lambda = 0$).

For soft smoothing, the iterative update, Equation (14), then amounts to

$$\begin{aligned} \hat{\theta}^t &= \alpha(D + \alpha J)^{-1}Jy^* + (D + \alpha J)^{-1}A\hat{\theta}^{t-1} \\ &= (D + \alpha J)^{-1}(\alpha Jy^* + A\hat{\theta}^{t-1}), \end{aligned} \tag{16}$$

where $D + \alpha J$ is diagonal and therefore easily invertible, making for an expedient computational procedure for solving soft smoothing problems. This interpretation of soft smoothing connects to a related used of "shadow nodes" in the *adsorption* method of graph smoothing [3].

4.3 Iterative formulation of decoupled smoothing

Examining the decoupled Laplacian in Equation (11) alongside the iterative smoothing formulation provides an iterative algorithm for the decoupled smoother. We define an auxiliary weighted, directed graph with weighted adjacency matrix $\tilde{A} = WZ'^{-1}W^\top$, which has edge weight $\tilde{A}_{ij} = \sum_k \frac{W_{ik}W_{jk}}{z'_k}$. The out-degree of node i reduces to $\sum_j \tilde{A}_{ij} = z_i$, where z_i is the same row sum defined in Section 3. Hence the degree matrix of $\tilde{A}$ is Z, and the solution to the decoupled smoothing problem in Equation (10) results from performing the iterative one-hop majority vote updates, Equation (14), on the auxiliary, directed graph.

By employing the update equations in Equation (14) with the transition matrix $P = Z^{-1}WZ'^{-1}W^\top$, we can see that decoupled smoothing amounts to an iterative update of a weighted *two-hop* majority vote. The reduction from soft smoothing to ordinary smoothing in Section 4.2 also gives an iterative formulation of soft decoupled smoothing.

4.4 Improving majority vote with local regularization

The iterative perspective is not only useful for computational purposes but also gives insights into how to improve the basic iterated majority vote. Here we describe an improvement to the basic smoothing algorithm, inspired by the details of implementing the

iterative algorithm, which can be applied in either the standard, soft, or decoupled setting.

Limiting noise in early steps. Since iterative majority vote is recursively defined, it relies on defining an initial set of guesses for the unlabeled nodes; when $t = 1$, equation (14) requires a value for $\hat{\theta}_1^0$ which can be safely set to random initial labels without compromising the limiting result. Then, equation (14) can also be written element-wise as

$$\hat{\theta}_i^t = \frac{1}{|\mathcal{N}_i|} \sum_{j \in \mathcal{N}_i} \hat{\theta}_j^{t-1}. \tag{17}$$

for every unlabeled node $i \in V_1$. From here, one sees that the performance of the first few iterations can be quite unsatisfactory, because it depends strongly on the initial noise input $\hat{\theta}_1^0$.

An alternative strategy is to set the first iteration of the unlabeled nodes to be the average value of friends labelled at the previous time-step only. For $t = 1$ this technique gives:

$$\hat{\theta}_i^1 = \frac{1}{|\mathcal{N}_i^0|} \sum_{j \in \mathcal{N}_i^0} \theta_j, \tag{18}$$

for $i \in V_1$. Recall that $\mathcal{N}_i^0$ is the set of neighbors of i for which a label was observed. For nodes $i \in V_1$ with no labelled neighbors, we do not update $\hat{\theta}_i^1$. More generally, we can postpone making assignments $\hat{\theta}_i^t$ until a node has some neighbor with an estimate at time $t-1$. If using $\hat{\theta}^t$ to make predictions, for missing values we then guess randomly with the class proportions of the training sample.

This strategy, which sidesteps dependence on random initial $\hat{\theta}_1^0$, tends to lead to a slight bump in performance in early iterations; see Section 6 for example illustrations.

Local regularization towards true labels. We can further generalize this idea of upweighting the true labels when they should be trusted more than haphazard (random) guesses. Consider the convex combination update

$$\hat{\theta}_i^t = \lambda_i^t \frac{1}{d_i^0} \sum_{j \in N_i^0} \theta_j + (1 - \lambda_i^t) \frac{1}{d_i^1} \sum_{j \in N_i^1} \hat{\theta}_j^{t-1}, \tag{19}$$

where $\lambda_i^t \in [0, 1]$ are weight parameters that control the amount of trust to place in the guesses of previous iterations. This places weight λ_i^t on the true labels and weight $1 - \lambda_i^t$ on the predicted values for iteration $t-1$. Most generally λ_i^t may be indexed by both the unit i and the time step t, as it is reasonable to expect that this weight should be personalized to individuals (e.g., vary based on degree) and that estimates of later iterations should be trusted more (which would have λ_i^t decreasing in time t).

Decomposing the sum in equation (17) as

$$\hat{\theta}_i^t = \frac{1}{d_i} \left[\sum_{j \in \mathcal{N}_i^0} \theta_j + \sum_{j \in \mathcal{N}_i^1} \hat{\theta}_j^{t-1} \right],$$

we see that we recover equation (19) from equation (17) when $\lambda_i^t = d_i^0 / d_i$, which is constant in t.

The search space of weights λ_i^t is quite large and we leave a formal analysis of this space to future work, restricting ourselves here to providing intuition for choices of λ_i^t that appear to work well in our empirical experiments. The goal is to place more weight on labeled nodes in the early stages and less weight on labeled nodes at later iterations, which suggests λ_i^t decaying in t. Different choices of λ_i^t will lead to different limiting values $\lim_{t \to \infty} \hat{\theta}^t$, some of which appear to outperform the basic version of majority vote.

Consider parameterizing $\lambda_i^t = f_i(t)$ for a function $f_i(\cdot)$ that reduces the number of parameters. For example one may consider the choice $\lambda_i^t = (d_i^0 / d_i)^t$, which represents exponential decay in t. This extension can be written in matrix-vector form as follows. Let $D_1 = \text{diag}(d_i^1)$ and $D_0 = \text{diag}(d_i^0)$ be diagonal degree matrices restricted to the unlabeled and labeled node sets, respectively. Consider the transition matrices $T_{10} = (D_1^{-1} A)_{10}$ and $T_{11} = (D_0^{-1} A)_{11}$. Then we may write the update rule as

$$\hat{\theta}_1^t = \lambda_t T_{10} \theta_0 + (1 - \lambda_t) T_{11} \hat{\theta}_1^{t-1},$$

where $\lambda_t \in [0, 1]^U$ is a vector of penalty parameters for time t. Depending on the form of λ_t, this recursion may not reduce cleanly to a power series that can be written in closed form.

This approach is a form of regularization in the sense that it constrains the complexity of the fitting function θ and restricts how far it can deviate from the observed values θ_0.

The choice of weight $\lambda_i^t = (d_i^0 / d_i)^t$ is related to the sequence of weights commonly used on the popular personalized PageRank diffusion kernel for community detection [2], although it is used in a different way. While personalized PageRank uses the kernel to model decaying influence as a function of graph distance, here we use this kernel to define how much to regularize the solution towards labeled values as a function of time, thus representing the amount of trust placed in labeled nodes. The limiting solution, therefore, will not be the same as the personalized PageRank diffusion, but this conceptual link can be instructive for suggesting analogs of other diffusion kernels that may be used as well [17, 18]. While the discussion of this regularization has centered on standard (one-hop) graph smoothing, the same ideas can be applied to decoupled smoothing as well.

5 AGGREGATING EXPERT INFORMATION

In this section we suggest possible ways of selecting the weights W for the method described in Section 3. Recall that in the decoupled smoothing model, equation (8), we view the target attributes ϕ_j as capturing information from the true responses in the neighborhood $\mathcal{N}_j$, which are useful for estimating θ_i. As a thought experiment, supposing the target parameters ϕ are known. Then the conditional mean (when $\gamma = 1$) is

$$\mathbf{E}[\theta_i | \phi] = \frac{1}{z_i} \sum_{j=1}^{n} W_{ij} \phi_j. \tag{20}$$

Most simply, it may be reasonable in many cases to take $W = A$ to agree with the network structure so that $\hat{\theta}_i$ is just an unweighted average of the estimated target parameters of the neighbors unit i. More generally, however, the row $\{W_{ij} : j = 1, \ldots, n\}$ of weights should be chosen in a way that highlights the nodes j where ϕ_j is most useful for prediction θ_i. In many graph contexts there are highly-skewed degree distributions, and as a result we expect some friends of i to provide more accurate estimates than others of i's true state. Notice that W_{ij} may be asymmetric in general because

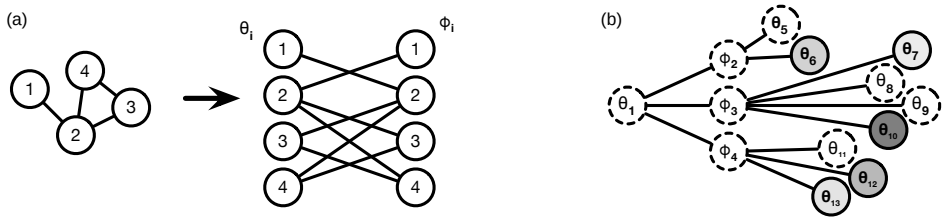

Figure 1: (a) An illustration of how an undirected graph can be decoupled into a bipartite graph with real responses θ_i and target responses ϕ_i. (b) An illustration of how two hop information can be used to estimate the expert opinions ϕ_j, which in turn inform the estimate of the unknown value θ_1.

the information provided by ϕ_i for estimating θ_j may not be the same as the information provided by ϕ_j for estimating θ_i, which is one of the key insights of the decoupled approach.

In this section we discuss how one may use an otherwise unrelated literature on expert opinion aggregation in the graph smoothing context. In this discussion we assume W has the same sparsity pattern as the adjacency matrix A, so that $W_{ij} \neq 0$ whenever $A_{ij} \neq 0$, although this need not generally be true; sometimes *not* being friends with someone can be highly informative as well.

The overall procedure of how a network is converted into a decoupled graph of real and target responses is illustrated schematically in Figure 1(a), and a schematic illustration of how the expert opinion aggregation pulls in information to a single node is illustrated in Figure 1(b).

5.1 Combining independent estimators

Consider that the information contributed by each expert (friend) j for estimating θ_i is in the form of the "observations" $\{\theta_k : k \in \mathcal{N}_j\}$, which are values located two steps away from unit i. One way to think about combining this information has been studied extensively in the statistics literature in the context of estimating a common location parameter from samples of varying precision [8, 11, 12, 14, 19, 23, 26].

Explicitly, suppose the variables in the set $\{\theta_k : k \in \mathcal{N}_j\}$ follow a distribution with mean θ_i and variance σ_j. That is, all observations contribute unbiased information for estimating θ_i, but they have varying precisions which are modulated by unit j (the "expert"). Then the weight matrix entry reduces to $W_{ij} = A_{ij}/\sigma_j^2$, with row sum $z_i = \sum_{\ell \in \mathcal{N}_i} \sigma_\ell^{-2}$ and column sum $z'_j = d_j/\sigma_j^2$. In this case, we now show that we obtain a concise recurrence recognizable as a particular weighting of 2-hop majority vote.

From Section 3, the auxiliary graph with this diagonal covariance specification has an adjacency matrix with entries

$$\tilde{A}_{ij} = \sum_k A_{ik}A_{jk}/(d_k\sigma_k^2), \tag{21}$$

with the smoothing update rule being $\hat{\theta}^t = Z^{-1}\tilde{A}\hat{\theta}^{t-1}$. For an unlabeled node i, if we employ the weights derived here we obtain the recurrence:

$$\begin{aligned}\hat{\theta}_i^t &= (Z^{-1}\tilde{A}\hat{\theta}^{t-1})_i = \frac{1}{z_i}\sum_{j=1}^n \tilde{A}_{ij}\hat{\theta}_j^{t-1} \\ &= \frac{1}{\sum_{\ell\in\mathcal{N}_i}\sigma_\ell^{-2}} \sum_{k\in\mathcal{N}_i}\frac{1}{d_k\sigma_k^2}\sum_{j\in\mathcal{N}_k}\hat{\theta}_j^{t-1}. \end{aligned}\tag{22}$$

By viewing the aggregation as performed on a graph, we can in fact turn this standard estimation procedure into an iterative procedure, linking to smoothing as shown in Section 4.

As a generic problem of aggregating estimators, if we observe $X_{jk} \sim N(\theta, \zeta_j^2)$, $k = 1, \ldots, d_j$, then the minimum variance, linear unbiased estimator (MVLUE) of θ when the ζ_j^2 are known is $\hat{\theta} = \sum_j w_j \bar{X}_j$ with weights given by $w_j = (d_j/\zeta_j^2)/\sum_k (d_k/\zeta_k^2)$. Our formulation of expert aggregation aligns with this view, where the expert variances are $\sigma^2 = \zeta_i^2/d_i$ and higher degree nodes therefore having appropriately more precise information.

In order to estimate σ_j^2 we can notice that it essentially represents the standard error for the expert estimate. Hence we can use the regular standard error estimate for the Gaussian sample mean, $\hat{\sigma}_j^2 = S_j^2/d_j$, where

$$S_j^2 = \frac{1}{d_j^0}\sum_{k\in\mathcal{N}_j^0}\left(\theta_k - \frac{1}{d_j^0}\sum_{\ell\in\mathcal{N}_j^0}\theta_\ell\right)^2$$

is the sample variance of the labeled nodes in the neighborhood of j (recall that $\mathcal{N}_j^0$ is the labeled neighborhood and $d_j^0 = |\mathcal{N}_j^0|$ is the labeled degree). We then use $\hat{\sigma}_j^2$ as a plugin estimate in the update rule in Equation (22), giving

$$\hat{\theta}_i^t = \frac{1}{\sum_{\ell\in\mathcal{N}_i}(S_\ell^2/d_\ell)^{-1}}\sum_{k\in\mathcal{N}_i}\frac{1}{S_k^2}\sum_{j\in\mathcal{N}_k}\hat{\theta}_j^{t-1}. \tag{23}$$

Alternatively, we can directly impose homogeneous standard errors, $\sigma_i^2 = \sigma^2/d_i$, in which case the normalization term reduces to $1/\sum_{\ell\in\mathcal{N}_i}\sigma_\ell^{-2} = 1/\sum_{\ell\in\mathcal{N}_i} d_\ell$, the number of nodes in the two-step neighborhood of i, and we obtain the update rule

$$\hat{\theta}_i^t = \frac{1}{\sum_{\ell\in\mathcal{N}_i} d_\ell}\sum_{k\in\mathcal{N}_i}\sum_{j\in\mathcal{N}_k}\hat{\theta}_j^{t-1}. \tag{24}$$

For exposition here we have let d_ℓ represent the total graph degree of unit ℓ, which disregards the number of labeled nodes. The shortcomings of this choice discussed in Section 4.4 still hold, and the improvements discussed in that section can be applied here.

We thus see how iterating a simple two-hop majority vote update can be motivated for graph smoothing, despite initial appearances as defining a "non-physical" process whereby information bypasses individuals. The simple recurrence in equation (24) emerges as the MVLUE under the assumption that expert friends contribute independent opinions, an assumption which appears to be reasonable for the graph-based learning problems we study.

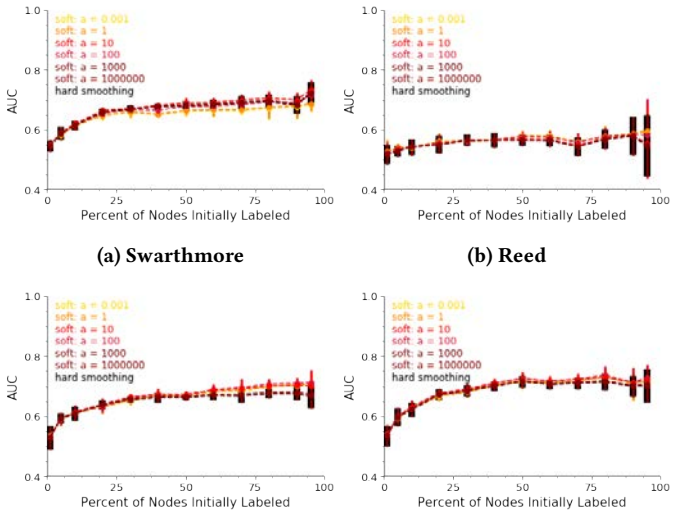
5.2 Risk analysis and Bayesian interpretation

This idea of combining information from different expert sources is also related to methods developed in the risk analysis literature [10]. Here we discuss graph analogs of the model and analysis of Halperin [15], later derived independently by Winkler [29]. In this model, expert opinions ϕ_j are viewed as unbiased samples from the true unknown response θ_i. That is, the expert predictions have the form

$$\phi_{\mathcal{N}_i} = \theta_i \mathbf{1} + \varepsilon_{\mathcal{N}_i},$$

where $\phi_{\mathcal{N}_i} \in \mathbb{R}^{d_i}$ is the restriction of the target vector ϕ to the neighborhood $\mathcal{N}_i$, $\mathbf{1}$ is the ones vector of length d_i, and $\varepsilon_{\mathcal{N}_i} \sim N(0, \Sigma_{\mathcal{N}_i})$ is Gaussian noise. The covariance matrix $\Sigma_{\mathcal{N}_i} \in \mathbb{R}^{d_i \times d_i}$ captures the variance and dependencies among the expert opinions, and is a generalization of the discussion in Section 5.1 in that expert opinions may be correlated with each other. Under this model and a flat prior on θ_i, the posterior distribution of θ_i given $\phi_{\mathcal{N}_i}$ with known covariance $\Sigma_{\mathcal{N}_i}$ is given by

$$\theta_i | \phi_{\mathcal{N}_i} \sim N\left(\frac{\mathbf{1}^\top \Sigma_{\mathcal{N}_i}^{-1} \phi_{\mathcal{N}_i}}{\mathbf{1}^\top \Sigma_{\mathcal{N}_i}^{-1} \mathbf{1}}, \frac{1}{\mathbf{1}^\top \Sigma_{\mathcal{N}_i}^{-1} \mathbf{1}} \right).$$



The Bayes estimator is then the posterior mean,

$$\hat{\theta} = (\mathbf{1}^\top \Sigma_{\mathcal{N}_i}^{-1} \phi_{\mathcal{N}_i}) / (\mathbf{1}^\top \Sigma_{\mathcal{N}_i}^{-1} \mathbf{1}).$$

From comparing to the conditional mean in Equation (20), the Bayes estimator suggests taking the weight W_{ij} to be element of the vector $(\mathbf{1}^\top \Sigma_{\mathcal{N}_i}^{-1})$ that corresponds to node j if i is connected to j, and $W_{ij} = 0$ otherwise. The normalization $z_i = \sum_{j \in \mathcal{N}_i} W_{ij} = \mathbf{1}^\top \Sigma_{\mathcal{N}_i}^{-1} \mathbf{1}$ then falls out naturally.

More general covariance structures. A principal outstanding question is determining which assumptions to place on each $\Sigma_{\mathcal{N}_i}$, which are unknown in practice. We notice that determining the $\Sigma_{\mathcal{N}_i}$ is equivalent to defining a single covariance matrix for the expert opinions $\Sigma \in \mathbb{R}^{n \times n}$ for the entire graph, where Σ_{jk} represents the covariance between the expert opinions provided by individuals j and k. The weight matrix results by taking $W = A\Sigma^{-1}$. The specification of the covariance matrix Σ is crucial for the form of the resulting decoupled smoothing estimator.

In practice on social networks, dependencies between expert opinions are bound to occur due to intersecting friendship neighborhoods. if the estimation target is i, and two neighbors j and k of i share many mutual friends other than i, then their estimates of θ_i will be dependent. The presence of such correlations indicates that aggregation and smoothing methods that are able to harness these arbitrary covariance matrices may yield a powerful tool for node classification in some application areas, and we leave a detailed study of such extensions to future work.

(a) Swarthmore (b) Reed

(c) Amherst (d) Haverford

Figure 2: Predicting gender based on soft smoothing. Horizontal axis displays initial proportion of unlabeled nodes and vertical axis displays AUC scores. Soft smoothing is essentially identical in performance to hard smoothing for the gender classification task.

6 EMPIRICAL ILLUSTRATIONS

We perform experiments on a sample of undergraduate college networks collected from a single-day snapshot of Facebook in September 2005 [27, 28]. We focus on the task of gender classification in these networks, restricting our analyses to the subset of nodes that self-reported their gender to the platform. We use the largest connected components from four medium-sized colleges, `Amherst`, `Reed`, `Haverford`, and `Swarthmore`. Amherst has 2032 nodes and 78733 edges, Reed has 962 nodes and 18812 edges, Haverford has 1350 nodes and 53904 edges, and Swarthmore has 1517 nodes and 53725 edges.

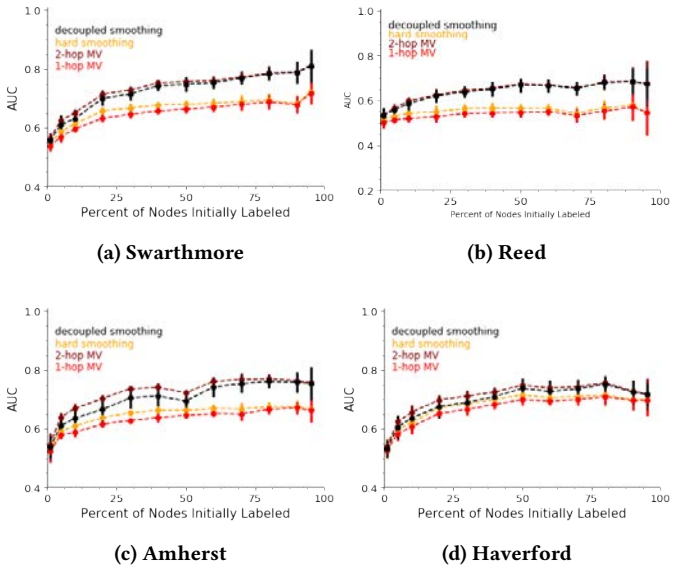
We varied the percentage of initially labelled nodes by selecting a labelled sample uniformly at random. We trained our models varying the percentage of initially labelled nodes in the network. For a given fixed percent of labelled individuals (training dataset), we measure classification performance (by AUC) on the remaining unlabelled nodes (testing dataset), using the same train/test splits across the different inference methods. For all plots in this section we attempt classification 10 times based on different independent labelled subsets of nodes using stratified sampling (stratified based on gender). We show the average AUC with error bars denoting the standard deviation across the 10 runs. We also provide results for synthetic networks generated from the stochastic block model [16] and the overdispersed stochastic block model [1].

6.1 Soft smoothing

We first run our soft smoothing algorithm on the four Facebook networks. As shown in Section 4, soft smoothing is equivalent to hard smoothing on a modified graph in which each originally labeled node has its label removed and is instead connected to a new degree-one node via an edge with weight $\alpha > 0$. Here we

choose a range of different α values to study its influence on the performance of soft smoothing method. The baseline algorithm is the hard smoothing approach of [33], which is the solution to Equation (15). Observe that α quantifies the impact of the new attached nodes on the original labeled nodes; therefore, the larger the value of α, the closer the soft smoothing result resembles the hard smoothing result.

In our experiments we observe that the outputs from soft smoothing are essentially identical to those from hard smoothing. As Figure 2 shows, since our goal is to classify gender, which is self-reported as a binary variable, adding a "noise" term to the labeled nodes has relatively little effect. Our hypothesis is that the soft smoothing method may achieve better performance when applied to real-valued outcomes.



6.2 Decoupled smoothing

In Figure 3 we see our experiments with decoupled smoothing, which indicate that the two-hop majority vote update given by Equation (24) outperforms both the standard 1-hop majority vote estimator and the corresponding (ZGL) smoothing estimator in terms of AUC, regardless of the percentage of initially labeled nodes. Meanwhile we also observe that decoupled smoothing performs slightly worse than the much simpler 2-hop majority vote estimator in some situations (namely `Amherst` and `Haverford`). Recall from Section 4.4 that decoupled smoothing can be interpreted as iterated 2-hop majority vote, but with randomly initialized guesses. We suspect that the better performance of the plain 2-hop majority vote is due to the fact that local information is more pertinent for this particular task (gender prediction) than global information, and the smoothing algorithms are inappropriately synthesizing information from local and global sources. This hypothesis motivates the improvements discussed in Section 4.4, the results for which are discussed in the following section.

6.3 Regularized iterations

In Section 4.4 we considered a modified iterated majority vote algorithm that includes a local regularization $\lambda_i^t = (d_i^L/d_i)^t$ for each unlabeled node i. This modification was inspired by the empirical observation that 2-hop majority vote outperforms the limiting iterated smoother. As a secondary inspiration, using equation (18) as the first iteration's update rule instead of (17) greatly reduces the number of iterations needed for convergence. In this section, we present experimental results from applying these modifications for both hard smoothing and decoupled smoothing on a synthetic stochastic block model graph as well as the on the Facebook networks.

6.3.1 Improved iterative hard smoothing. We first display results on a graph sampled from a stochastic block model (SBM). The particular SBM we use has two blocks with 500 nodes in each block, representing 500 male and 500 female individuals. The expected average degree is 42, so as to achieve the same edge density as used in [1]. In Figure 4 we plot the AUC corresponding to the predictions given by equation (14) for each iteration, $t = 1, 2, 3, \ldots$. Interestingly, in Figure 4(a), we see that some early iterations (in this case, iteration 2) actually outperform the limiting ZGL/hard smoothing solution. This suggests that improvements can be made

(a) Swarthmore **(b) Reed**

(c) Amherst **(d) Haverford**

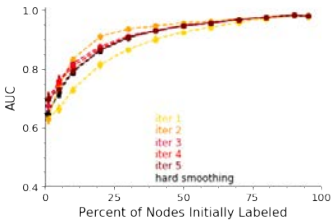


Figure 3: Predicting gender based on decoupled smoothing, compared with hard smoothing (ZGL) and 1-hop and 2-hop majority vote. The estimators based on two-step neighborhood information clearly outperform those based on one-step information, but 2-hop majority vote sometimes outperforms decoupled smoothing.

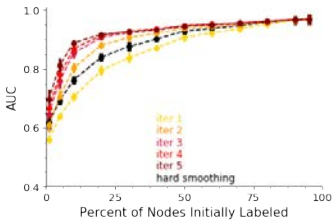
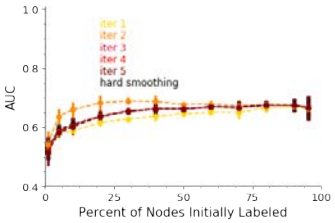
by teaching the classifier to hone in on these successful iterations and give them more weight, which is what the regularizer seeks to do. We next compare the original and regularized versions of the hard smoothing iterations. As shown in Figure 4(b), the regularization proposed in Section 4.4 improves the overall prediction accuracy for hard smoothing under the stochastic block model. The method is essentially converged after five iterations.

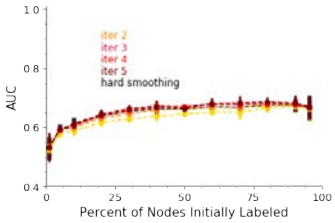


Results are more mixed on empirical networks; in Figure 4(c-d) we display performance for the `Amherst` Facebook network. We see that regularization does not significantly improve the performance over hard smoothing for gender prediction on this network.

6.3.2 Improved iterative decoupled smoothing. Our regularization ideas can also be applied to the decoupled smoother. We first test our modification in an overdispersed stochastic block model (oSBM), an extension of the stochastic blockmodel that contains an additional parameter to model *monophily*. It is thus designed to capture aspects of the network that are particularly well suited for 2-hop estimators. Again, we use two blocks with 500 nodes in each block representing 500 males and 500 females. The expected average degree is 42 and dispersion rate is 0.004, giving the same edge density and dispersion rate as in [1]. Here we compare the iterative method results for the original decoupled smoothing method against the regularized iterative decoupled smoothing method. As shown in Figure 5b, the regularization improves the overall prediction accuracy for decoupled smoothing under the overdispersed stochastic block model.

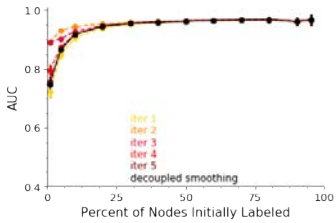


On the Facebook `Amherst` network we use the regularization $\lambda_i^t = (d_i^0/(rd_i))^{t-1}$, where r is the initial percent of labeled nodes.

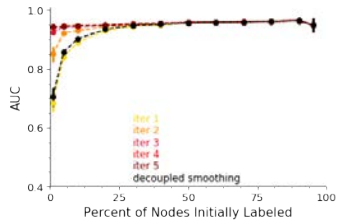


(a) SBM: hard smoothing

(b) SBM: regularized hard smoothing



(c) Amherst: hard smoothing



(d) Amherst: regularized hard smoothing

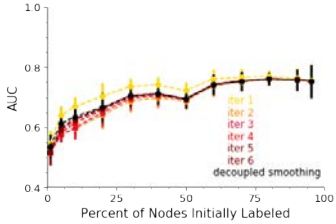


Figure 4: Hard smoothing iterations, with and without regularization, for classifying gender on an SBM graph and the `Amherst` dataset. Regularization mostly improves the predictive performance.

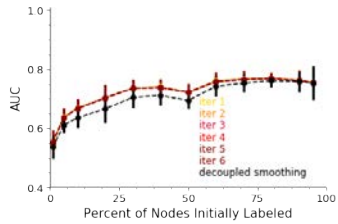

(a) oSBM: decoupled smoothing

(b) oSBM: regularized decoupled smoothing

(c) Amherst: decoupled smoothing

(d) Amherst: regularized decoupled smoothing

Figure 5: Decoupled smoothing iterations, with and without regularization, for classifying gender on an oSBM and the `Amherst` network. Regularization mostly improves the predictive performance.

This choice is motivated by the fact that the relative importance of local to global information should depend on the proportion of labeled nodes; if there is little local information available, then it makes sense to pull in information from farther away. We can see that with this particular regularization term, the smoother modestly improves the overall prediction accuracy for decoupled smoothing. It is encouraging that from pure intuition we can see better results; with a more careful optimization over the way λ_i^t is parameterized, it is possible that performance can be further improved.

7 DISCUSSION

In this work we investigate the use of graph-based smoothing for node attribute prediction on social networks, where a thoughtful understanding of social forces that underlie network formation can help inform the choice of the smoothing model. Our work is motivated by the investigation into empirical observations in [1], which highlights the distinction between "the company you keep" and "the company you're kept in." We develop a model for what we call *decoupled* graph smoothing that links this empirical observation to graph smoothing, semi-supervised learning, and diffusion algorithms popularly used for node classification tasks. We provide a Bayesian viewpoint of this model which is related to the literature on expert opinion aggregation.

As a part of our analysis, we contribute an iterative algorithm for soft smoothing, which allows us to solve soft smoothing problems efficiently on large datasets. We find that a close examination into the form of iteration is not only crucial for computational efficiency but also for efficacy of predictive performance, as the basic iterated majority vote algorithms make suboptimal choices in the initial iterations. We contribute a generalization that allows one to place greater weight on and regularize toward labeled values. This method displays improved performance on some simulated and real datasets. This generalization is flexible enough that the practitioner has a lot of control over the resulting algorithm. The best choices for regularization has yet to be fully explored and may well vary depending on the particular domain of application.

Graph-based semi-supervised learning is broadly applied to classification and prediction problems on derived graphs, typically from the nearest-neighbor graphs of point clouds in $\mathbb{R}^n$. In this work, we observe that classification and prediction problems involving explicit graph structure, such as predicting node attributes in social networks, can benefit from a careful consideration of how the prediction target quantity and the graph structure may be related. While our evaluation only touches gender, other attribute prediction tasks in social networks such as predicting abusive or spam accounts could also benefit from similar careful consideration. While our empirical improvements for gender are modest, our results on synthetic graphs suggest that decoupled graph smoothing has the potential to offer considerable improvements in other diverse network prediction tasks.

Code availability. Notebooks and code available online: https://github.com/YatongChen/decoupled_smoothing_on_graphs. All code was run using Python version 3.6.2.

APPENDIX

1 PROOF OF GMRF EQUIVALENCE

Theorem 3.1. *Let W be a weight matrix with row sums $z_i = \sum_j W_{ij}$ and column sums $z'_j = \sum_i W_{ij}$. Let $\tau^2 > 0$ and $\gamma \in (0, 1)$. Then the conditional specifications*

$$\theta_i|\phi \sim N\left(\frac{\gamma}{z_i}\sum_{j=1}^{n} W_{ij}\phi_j, \frac{\tau^2}{z_i}\right), \qquad \phi_j|\theta \sim N\left(\frac{\gamma}{z'_j}\sum_{i=1}^{n} W_{ij}\theta_i, \frac{\tau^2}{z'_j}\right)$$

define a valid, non-degenerate probability distribution over θ and ϕ with marginal distribution $\begin{pmatrix}\theta\\ \phi\end{pmatrix} \sim N(\mu, \Sigma)$, where $\mu = 0$ and

$$\Sigma = \tau^2 \begin{pmatrix} Z & -\gamma W \\ -\gamma W^\top & Z' \end{pmatrix}^{-1}, \tag{9}$$

where $Z = \mathrm{diag}(z_1, \ldots, z_n)$ and $Z' = \mathrm{diag}(z'_1, \ldots, z'_n)$.

Proof. We use Brook's lemma [9], which states that for any distribution such that $p(x) > 0$ for all x, then for any x and x',

$$\frac{p(x)}{p(x')} = \prod_{i=1}^{n} \frac{p(x_i|x_1, \ldots, x_{i-1}, x'_{i+1}, \ldots, x'_n)}{p(x'_i|x_1, \ldots, x_{i-1}, x'_{i+1}, \ldots, x'_n)}.$$

Applying Brook's lemma with $x = (\theta, \phi)$ and $x' = 0$, we see that

$$\begin{aligned} p(\theta, \phi) &\propto \prod_{i=1}^{n} \Bigg(\frac{p(\theta_i|\theta_1, \ldots, \theta_{i-1}, 0_{i+1}, \ldots, 0_{2n})}{p(0_i|\theta_1, \ldots, \theta_{i-1}, 0_{i+1}, \ldots, 0_{2n})} \times \\ &\qquad \frac{p(\phi_i|\theta_1, \ldots, \theta_n, \phi_1, \ldots, \phi_{i-1}, 0_{i+1}, \ldots, 0_{2n})}{p(0_i|\theta_1, \ldots, \theta_n, \phi_1, \ldots, \phi_{i-1}, 0_{i+1}, \ldots, 0_{2n})} \Bigg) \\ &= \prod_{i=1}^{n} \frac{p(\theta_i|\phi = 0)}{p(\theta_i = 0|\phi = 0)} \frac{p(\phi_i|\theta)}{p(\phi_i = 0|\theta)} \end{aligned}$$

where we have indexed the 0s for clarity. Substituting in the likelihood from the conditional models in Theorem 3.1,

$$\begin{aligned} p(\theta, \phi) &\propto \frac{\exp\left\{-\frac{z_i}{2\tau^2}\theta_i^2\right\}}{1} \frac{\exp\left\{-\frac{z'_i}{2\tau^2}\left(\phi_i - \frac{\gamma}{z'_i}\sum_j W_{ji}\theta_j\right)^2\right\}}{\exp\left\{-\frac{z'_i}{2\tau^2}\left(\frac{\gamma}{z'_i}\sum_j W_{ji}\theta_j\right)^2\right\}} \\ &= \exp\left\{-\frac{1}{2\tau^2}\sum_{i=1}^{n}\left(z_i\theta_i^2 + z'_i\phi_i^2 - 2\gamma\phi_i\sum_j W_{ji}\theta_j\right)\right\} \\ &= \exp\left\{-\frac{1}{2\tau^2}\left(\theta^\top Z\theta + \phi^\top Z'\phi - 2\gamma\theta^\top W\phi\right)\right\}, \end{aligned}$$

which is the likelihood corresponding to a mean zero Gaussian random vector with covariance given by Equation (9). □

ABSTRACT

Recently, data mining through analyzing the complex structure and diverse relationships on multi-network has attracted much attention in both academia and industry. One crucial prerequisite for this kind of multi-network mining is to map the nodes across different networks, i.e., so-called network alignment. In this paper, we propose a cross-network embedding method CrossMNA for multi-network alignment problem through investigating structural information only. Unlike previous methods focusing on pair-wise learning and holding the topology consistent assumption, our proposed CrossMNA considers the multi-network scenarios which involve at least two types of networks with diverse network structures. CrossMNA leverages the cross-network information to refine two types of node embedding vectors, i.e., *inter-vector* for network alignment and *intra-vector* for other downstream network analysis tasks. Finally, we verify the effectiveness and efficiency of our proposed method using several real-world datasets. The extensive experiments show that our CrossMNA can significantly outperform the existing baseline methods on multi-network alignment task, and also achieve better performance for link prediction task with less memory usage.

1 INTRODUCTION

The unprecedented growth of the diverse information has produced a large volume of networks, such as social networks, citation networks, and biological networks, etc. Nowadays, people usually participate in multiple networks, on the one hand, each network can depict the topological structure of all participants corresponding to some particular relationships; on the other hand, all the networks can be related by the same participants/nodes. In recent years, many approaches have been proposed to mine the potential information inherent in these related networks, such as cross-network recommendation [42], mutual community detection [39] and genetic diseases classification [33], etc. Although the related networks can share the same participants, they are mostly isolated in different networks without any known connections accordingly among them. Therefore, a crucial prerequisite for multi-network mining is to map the nodes/participants among these related networks, i.e., so-called network alignment. In the field of network alignment, the shared participants among the networks are defined as anchor nodes, as they act like anchors aligning the networks they participate in, and the relationships among anchor nodes across networks are called anchor links [12]. In many cases, a few anchor links can be known beforehand, for example, some users in Foursquare may leave their corresponding accounts of Twitter, but most of the correspondences are unknown. Therefore network alignment aims at inferring these unknown or potential anchor links among the networks.

In recent years, many literatures have been proposed to handle the network alignment problem [13, 16, 37, 40, 43, 44]. However, there still exist some issues that need further concern. First, most existing works only consider the two-network scenarios or perform

pair-wise learning in multi-network applications. However, in real-world a network is usually related to multiple networks. Thus the pair-wise learning methods can ignore much valuable complementary information across the multiple networks. Second, many previous works hold the assumption of **topology consistency**, which indicates that a node tends to have a consistent connectivity structure across different networks. Although the same node may show some similar features among the networks, the differences between the network semantic meanings can lead to quite diverse local structure of this node in each network, and this assumption can be easily violated in many applications [16, 23]. Thereby these methods can make misleading alignment in the multi-network scenarios. Third, most previous works heavily **rely on attributes**, e.g., the username, gender or other profile information. However, the attribute information is usually incomplete and unreliable [16] or unavailable [1], thus these attribute-based methods are not applicable in many realistic scenarios.

Keeping these problems in our mind, we, in this paper, study the network alignment problem in a multi-network scenario, wherein the number of networks is at least two with no attribute information available, in addition that the topology structure of each network can be diverse. Taking into account the effectiveness of preserving network structures and the efficiency of calculation in continuous vector space, we propose a novel **cross**-network embedding method for **m**ulti-**n**etwork **a**lignment, namely CrossMNA. CrossMNA can integrate cross-network information to refine much more powerful embedding vectors for alignment tasks, and can also be effectively applied to other downstream multi-network analysis tasks, such as link prediction. Compared to previous embedding-based network alignment methods [10, 15, 45] or multi-network embedding methods [19, 35, 38], CrossMNA can also dramatically decline the space overhead especially in large-scale multi-network scenarios.

In CrossMNA, an additional vector named *network vector* is proposed to extract the semantic meaning of the network, which can reflect the difference of global structure among the networks. What's more, two kinds of embedding vectors are refined for each node: (i) *inter-vector*, which reflects the common features of the anchor nodes in different networks and is shared among the known anchor nodes; and (ii) *intra-vector*, which preserves the specific structural feature for a node in its selected network and is generated through the combination of network vector and intra-vector. This combination strategy can save much more space overhead but not sacrifice the performance. We also propose a transformation matrix to align these vectors with different dimensions. We summarize our contributions as follows:

(i) We propose a novel cross-network embedding approach CrossMNA to deal with network alignment in a more general scenario, where the number of networks is at least two with no attribute information available, in addition that the structure of each network can be quite diverse.
(ii) CrossMNA declines the physical memory overhead for model storage to a large extent compared to other embedding based network alignment methods or multi-network embedding models, which enables our CrossMNA appropriate to tackle today's large-scale multi-network applications.
(iii) Extensive experiments show that our CrossMNA significantly outperforms existing network alignment methods, i.e., achieves 10% to 20% improvement with the Twitter dataset and 10% with the arXiv datasets. Furthermore, CrossMNA can achieve 5% improvement in link prediction mission with the Twitter dataset compared to existing multi-network embedding methods.

We organize the remains of our work as follows. Section 2 states the problems of multi-network alignment. We investigate several inherent vulnerabilities in previous works and propose the challenges in multi-network alignment. We formally describe our CrossMNA in Section 3, validate our approach by analyzing extensive experiments in Section 4, present related work in Section 5 and conclude our work in Section 6.

2 PROBLEM STATEMENT

As a crucial prerequisite for many cross-network applications, network alignment aims to establish the node correspondences across different networks. Therefore, in recent years, network alignment has become a hot spot in both academia and industry. However, there still exist some problems in currently existing works:

(i) **Topology Consistency.** Many previous works [2, 3, 10, 13, 14, 29, 41, 45] hold the assumption of topology consistency, namely the same node has a consistent connectivity structure across different networks. For example, NetAlign [3] utilizes max-product belief propagation based on the network topology. REGAL [10] proposes an embedding-based method based on the assumption that nodes with similar structural connectivity or degrees have a high probability to be aligned. Although one node may share some similar features in related networks, its local structural connections can be entirely different in each network due to the distinctiveness in network semantic meanings, such as the types of interaction between proteins in bioinformatics. Some works have proved that topology consistency can be easily violated in many multi-network scenarios. For example, in bioinformatics, different types of genetic interactions can construct diverse network structures [23]. Another similar example can also be found in online social network sites [16], such as Twitter and Facebook, where usersâĂŹ behavior may be divergent and platform dependent, making different social platforms show various connection relationships. Thereby, previous methods may lead to sub-optimal or even misleading alignments in these scenarios.

(ii) **Pair-Wise Learning.** Most previous works only consider the two-network scenarios or perform pair-wise learning in the multi-network scenario. However, if we jointly consider all related networks, we can obtain much more useful information to benefit the node matching. Figure 1 illustrates a toy example with three related networks. If we only consider each pair of networks, it is hard to infer the node v_4 in network G^3 is the counterpart of the node v_1 in network G^1 and G^2. However, if we consider the three networks together, this alignment can be easily found.

(iii) **Attributes Dependence.** Many previous works utilize the attribute information, like username or gender in social networks, to directly match nodes in different networks [26] or make use of

*Jingping Bi (bjp@ict.ac.cn) is the corresponding author

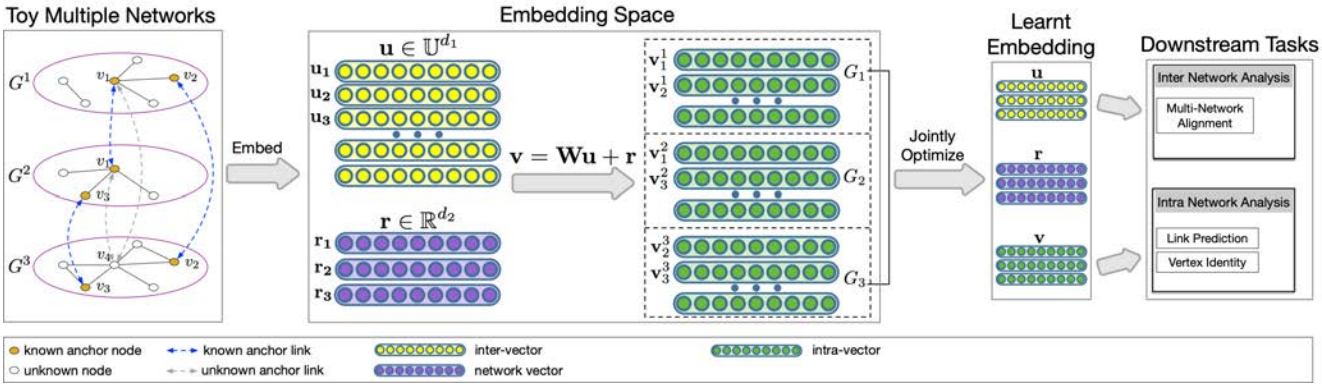

Figure 1: An illustration of a multi-network scenario. CrossMNA learns two types of embedding vectors, i.e., network vector for each network and inter-vector for each node, which is used for node matching. The intra-vector, which can be adopted for other downstream tasks, is combined by these two types of embedding vectors

the attributes to guide model learning structure information [44]. However, on the one hand, users may deliberately hide certain pieces of personal information or provide false data on their selected networks [16]. On the other hand, network data available for research is usually anonymized by the service providers for privacy concerns, where the attribute information is removed or replaced with meaningless unique identifiers [41]. Therefore, the methods based on attribute information are not general in many applications.

Considering the issues above, we intend to study the network alignment problem in a more general scenario wherein the number of networks is at least two, only topological structure available, even the networks may have different structures. In addition to the importance and novelty of this problem, we present the following challenges:

- **Semantics diversity**. The diversities in network semantics lead to the different interactional behaviors of the same node in each network, which can effect the accuracy of the node matching. Moreover, the more networks taken into consideration, the more complicated the problem is. Therefore, how to alleviate the impact of diverse network semantics on node matching is a big challenge.
- **Data imbalance**. The data imbalance has two aspects. First, the size of each network may vary considerably, including the numbers of nodes or edges in each network. Second, the number of anchor links between each pair of networks can be unequal. It is obvious that the previous pair-wise learning methods inevitably suffer from the data imbalance problem as they only consider each pair of networks. Thus how to make full use of the information across all the networks to deal with the data imbalance problem is another challenge.
- **Model Storage**. Network embedding is a practical approach to extract structural features of the node and has been applied in some network alignment methods [10, 15, 45]. However, in large-scale multi-network scenarios, it is essential to take into account the space overhead of the methods. Previous embedding-based methods need to generate the embedding vector for each node in each pair of networks in multi-network scenarios, and this takes too much storage space. Thereby, how to make overhead cheaper but not sacrifice the performance is what we should concern.

To address the challenges above, we propose a cross-network embedding based multi-network alignment method CrossMNA. It extracts an extra feature vector named *network vector* for each network, which reflects the difference of global structure among the networks. This means if the global structure of two networks is similar, their network vectors will be close in vector space. For each node in a network, we propose two types of embedding vectors: *inter-vector* and *intra-vector*. The former depicts the commonness of anchor nodes in different networks and is shared among the known anchor nodes. The latter reflects the specific structural feature of this node in its selected network but is generated through a combination of the network vector and inter-vector. By jointly training all the networks, CrossMNA can refine powerful inter-vector for network alignment tasks, and intra-vector for other downstream multi-network analysis tasks. What's more, the shared inter-vector and the combining intra-vector can significantly save space overhead without sacrificing the performance.

3 CROSSMNA: A MULTI-NETWORK ALIGNMENT APPROACH

3.1 Problem Formulation

In this work, we suppose the networks are unweighted and all the edges are directed, as an undirected edge can be divided into two directed edges. For the sake of easy understanding, we follow the definitions of network alignment as reported in [41, 42].

Definition 1 *(Multiple Aligned Networks).* We define a set of networks $\mathcal{G} = ((G^1, G^2, \cdots, G^N), (\mathcal{A}^{(1,2)}, \mathcal{A}^{(1,3)}, \cdots, \mathcal{A}^{(N-1,N)}))$ as multiple aligned networks, where $G^i, i \in \{1, 2, \cdots, N\}$ represents the i-th network in the set, N is the number of related networks, and $\mathcal{A}^{(i,j)}, i, j \in \{1, 2, \cdots, N\}$ denotes the set of anchor links between G^i and G^j. We define each network G^i as $\{V^i, E^i\}$, where V^i is the set of nodes in G^i and E^i is the set of links.

Definition 2 *(Anchor Link).* Given each two networks G^i and G^j, we define an anchor link between them as $(v_k^i, v_k^j) \in \mathcal{A}^{(i,j)}$, where

v_k^i and v_k^j is the anchor node in networks G^i and G^j respectively. The anchor links in multiple networks following the *transitivity law* defined in [41], where if $(v_k^i, v_k^j) \in \mathcal{A}^{(i,j)}$ and $(v_k^i, v_k^h) \in \mathcal{A}^{(i,h)}$, then $(v_k^h, v_k^j) \in \mathcal{A}^{(h,j)}$. For notational convenience, the nodes in different networks with the same subscript are the known anchor nodes.

Definition 3 *(Multi-Network Alignment Problem).* Given a set of networks and part of known anchor links among the networks, this problem is to discover the unknown or potential anchor links. It is noteworthy that the networks are partially aligned [42], which means not all the nodes have counterparts in other networks, and the anchor nodes follow the one-to-one matching constraint [41].

3.2 Cross-Network Embedding

As stated before, the different network semantic meanings lead to diverse interactional behaviors of the anchor nodes, which influences the global structure of the networks. For instance, in Figure 1 the anchor node v_1 shows different connection relationships in G^1 and G^2. However, as the same entity, the anchor node should also display some common features across the networks. For example, suppose that we have known that node v_4 in G^3 is the counterpart of node v_1, we can observe that the anchor node v_1 tends to interact with nodes v_2 or v_3 in each network. Therefore, we propose CrossMNA in multi-network scenarios under the assumption that an anchor node in a selected network can both show some similar structural features with its counterparts and distinctive connection relationships due to its network semantic meaning. It is noteworthy that if the related networks have the same semantic meaning, the anchor nodes will display consistent connection relationships among these networks, which is the topology consistent assumption as previous works hold.

It is obvious that the common features among the anchor nodes are what we need for network alignment. To this end, we propose an *inter-vector* $\mathbf{u}$ to preserve the common features among the anchor nodes. Through training, we hope the inter-vector of an unknown anchor node can be close to its counterparts in vector space. Nevertheless, this inter-vector is hard to be learnt directly, as there is no direct correlation between the unknown anchor nodes. For example, there is no direct relationship between the node v_1 in G^1 and the node v_4 in G^3. Therefore, we have to learn the inter-vector indirectly.

On the other side, it is straightforward to extract structural features of nodes in a network via network embedding methods, which named *intra-vector* $\mathbf{v}$ in CrossMNA. This type of vector contains both the commonness among counterparts and the specific local connections in its selected network due to the semantics, so it cannot be applied for node matching unless we can divestiture the impact of network semantic. Thus, we are motivated to present the following equation to build a correlation among intra-vector, inter-vector, and network semantics:

$$\mathbf{v}_i^k = \mathbf{u}_i + \mathbf{r}^k, \tag{1}$$

where $\mathbf{v}_i^k$ is the intra-vector of node v_i in network G^k which can be easily learnt, $\mathbf{u}_i$ is the inter-vector of node v_i and its known counterparts are shared this vector, $\mathbf{r}^k$ is the *network vector* which can extract the unique characteristics of G^k and reflects the global difference among the networks. Thus, we can refine the inter-vector of the anchor nodes indirectly by training the combining-based intra-vectors.

We take the toy multi-network in Figure 1 as example for further explanation. Considering the anchor node v_1, it should share some common features among the networks and this commonness is what the inter-vector should represent. Meanwhile, as G^1 and G^2 are two different networks, the local connections of v_1 can also be distinct because of the diverse network semantic meanings. Following Equation (1), we can give the intra-vector of node v_1 in G^1 and G^2 as:

$$\begin{aligned} \mathbf{v}_1^1 &= \mathbf{u}_1 + \mathbf{r}^1, \\ \mathbf{v}_1^2 &= \mathbf{u}_1 + \mathbf{r}^2. \end{aligned} \tag{2}$$

On the one hand, through jointly training the intra-vectors, the shared $\mathbf{u}_1$ can store the complementary information between the two networks: for example v_1 can be connected to v_2 and v_3 at the same time. On the other hand, $\mathbf{r}^1$ and $\mathbf{r}^2$ can reflect the global differences between the two networks owing to the common information transmitting in $\mathbf{u}_1$.

Then we consider the node v_4 in G^3. Its intra-vector can be writen as:

$$\mathbf{v}_4^3 = \mathbf{u}_4 + \mathbf{r}^3. \tag{3}$$

By learning the structural information in G^3, $\mathbf{v}_4^3$ can contain some common features similar to $\mathbf{v}_1^1$ or $\mathbf{v}_1^2$, for example v_4 also tends to interact with v_2 and v_3. Owing to to other known anchor links between G^3 and the other networks, the network vector $\mathbf{r}^3$ can preserve the specific semantic features of G^3. Therefore, by peeling off the impact of network semantic difference via $\mathbf{u}_4 = \mathbf{v}_4^3 - \mathbf{r}^3$, the inter-vector $\mathbf{u}_4$ can reflect much more similar features with $\mathbf{u}_1$, by which we can infer that v_4 is the counterpart of v_1.

The meanings of the inter-vector and intra-vector are different, they can be in different vector spaces. Therefore, we propose a transformation matrix $\mathbf{W}$ to align them with different dimensions and rewrite the Equation (1) as:

$$\mathbf{v}_i^k = \mathbf{W}\mathbf{u}_i + \mathbf{r}^k, \mathbf{u}_i \in \mathbb{U}^{d_1}, \mathbf{v}_i^k \in \mathbb{R}^{d_2}, \tag{4}$$

where $\mathbb{U}^{d_1}$ and $\mathbb{R}^{d_2}$ are two different vector spaces with dimension d_1 and d_2 respectively. $\mathbf{W}$, $\mathbf{u}_i$ and $\mathbf{r}^k$ are the parameters need to learned in CrossMNA.

From the above discussion, we can find that theoretically the more related networks we considered, the more accurate the node matching is. Therefore, CrossMNA needs to jointly train all the related work, and we thus propose the total objective function as:

$$\mathcal{J} = \sum_k \mathcal{J}^k, \tag{5}$$

where $\mathcal{J}^k$ is the objective function of each G^k, which tries to preserve the structural information of each node in G^k. Following [31], for each directed edge (v_i^k, v_j^k) in G^k, we define the conditional

probability of v_j^k generated by v_i^k as:

$$p(v_j^k|v_i^k) = \frac{exp(\mathbf{v}_i^k \cdot \mathbf{v}_j^k)}{\sum_{v_z^k \in V^k} exp(\mathbf{v}_i^k \cdot \mathbf{v}_z^k)} = \frac{exp((\mathbf{W}\mathbf{u}_i + \mathbf{r}^k) \cdot (\mathbf{W}\mathbf{u}_j + \mathbf{r}^k))}{\sum_{v_z^k \in V^k} exp((\mathbf{W}\mathbf{u}_i + \mathbf{r}^k) \cdot (\mathbf{W}\mathbf{u}_z + \mathbf{r}^k))}, \quad (6)$$

and the objective of each network G^k can be defined as:

$$\mathcal{J}^k = \sum_{(v_i^k, v_j^k) \in E^k} p(v_j^k|v_i^k). \quad (7)$$

By jointly optimizing, the known anchor nodes will play their roles as much as possible to transmit the structural information through the shared inter-vector $\mathbf{u}$, making this vector contain the commonness among the anchor nodes. At the same time, through Equation (6), the intra-vector of each anchor node can preserve the diverse structural features in different networks, which makes the network vector $\mathbf{r}^k$ extract the specific feature of its own global structure.

For each unknown anchor nodes v_i^k, although we cannot directly make connections to its counterparts, its combining-based intra-vector can preserve some similar features as its counterparts in other networks. By peeling off the impact of the network semantic meaning $\mathbf{r}^k$, the inter-vector $\mathbf{u}_i$ will display the characteristic features as its anchor nodes do, which can be effectively used for node matching.

To speed up the training process, following word2vec [21], we perform negative sampling to approximate the objective function (6) as:

$$E_{(v_i^k, v_j^k)} = -log\sigma(\mathbf{v}_i^k \cdot \mathbf{v}_j^k) - \sum_{v_z^k \in P(z)} log\sigma(-\mathbf{v}_i^k \cdot \mathbf{v}_z^k), \quad (8)$$

where $\sigma(x) = 1/(1 + exp(-x))$ is the sigmoid function and the distribution $P(v) \propto d_v^{3/4}$, where d_v is the degree of node v in the given network. Therefore, we rewrite the objective function of (5) as the total loss function of the whole multi-network:

$$\mathcal{L} = \sum_{k \in [1,N]} \sum_{(v_i^k, v_j^k) \in E^k} -log\sigma(\mathbf{v}_i^k \cdot \mathbf{v}_j^k) - \sum_z log\sigma(-\mathbf{v}_i^k \cdot \mathbf{v}_z^k). \quad (9)$$

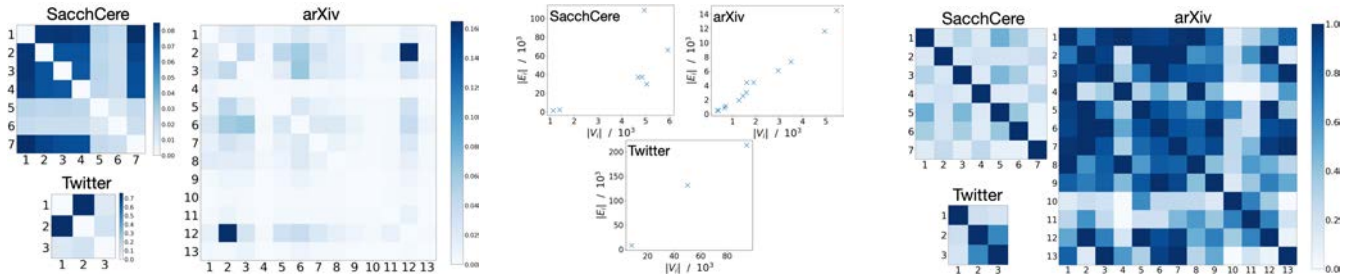
We adopt Adam[11] to minimize the total loss function.

As we know, in real-world, it is ubiquitous to meet the data imbalance problem among multiple networks. Previous methods can easily suffer from the data imbalance problem as they under the pair-wise learning scheme. However, our CrossMNA can make up this problem, because CrossMNA jointly trains all the networks and transmits the complementary information among the known anchor nodes through the shared inter-vectors, which can alleviate the influence of the data imbalance problem. What's more, compared to existing embedding-based methods, CrossMNA is much more lightweight. Instead of generating embedding vector for each node in each pair of networks, CrossMNA shares the common intra-vector across the networks and uses a more flexible combining-based vector generation strategy as defined in Equation (4) to generate the intra-vector for each node in each network. No matter compared to the embedding-based network alignment methods or the existing multi-network embedding methods, CrossMNA can always significantly reduce the memory overhead, and we will compare the size of CrossMNA with other models in Section 4.7.

3.3 Multi-Network Mining

After training, we can get two types of embedding vectors for each node: the intra-vector reflects the structural information of a node in a selected network, which is suitable for the intra-network analysis tasks, while the inter-vector interprets the commonness of the anchor nodes in different networks, which can be effectively applied to multi-network alignment task.

A naive way to find the alignments for a node is to compute all pairs of similarities between the inter-vectors, which is time-consuming. However, in practice, we usually only need to find the soft alignments for each node by returning its top-α most likely nodes in other networks. So following [10], we use the k-d tree data structure to accelerate similarity search [4] in the matching process. We here use cosine similarity to define the distance of two nodes in vector space.



In some applications, we can get the complete groundtruth among multiple networks beforehand, which means all the aligned links are known. As our CrossMNA is a cross-network embedding approach, it can be easily exploited in these applications to make the data mining tasks on multiple networks more actionable. During training, the inter-vector takes the role of transmitting the structural information among the anchor nodes. Therefore, CrossMNA can preserve the complementary information across multiple networks. At the same time, because we extract the specific features of each network into its network vector, the intra-vector which is combined by the inter-vector and the specific network vector, can both keep the complementary information of its counterparts in other networks and the distinctive properties of its selected network. This can be effective in many downstream multi-network analysis tasks, such as link prediction and vertex identity.

4 EXPERIMENTAL EVALUATION

In this section, we perform a set of experiments to validate our proposed CrossMNA. We first compare our method with several state-of-the-art methods on the multi-network alignment task. Then, to verify the effectiveness of CrossMNA in extracting useful features of the nodes, we also compare our CrossMNA with several multi-network embedding methods on link prediction tasks.

4.1 Dataset Description

We employ three real-world multi-network datasets from different fields, e.g., social platform, bioinformatics, and academics. To reflect the data imbalance problem in each dataset, we present the distribution of anchor links between each pair of networks in Figure 2(a) and size of each network in Figure 2(b). We can find that the scale of each network vary greatly in all datasets and distribution of anchor links can be uneven, especially in Twitter and SacchCere. We also present the global structural similarities between each pair of networks, by comparing the common neighbors reachable in three steps of the anchor nodes. From Figure 2(c) we can find that the related networks have quite diversity structures, especially in Twitter and SacchCere. We detail the datasets as follows:

(a) Distribution of anchor links. (b) Size of networks. (c) Global similarity between networks.

Figure 2: Detailed information of the datasets. (a) Each grid represents $|A^{(i,j)}|/|A|$. (b) Each dot is a network, the abscissa/ordinate represents the number of nodes/edges. (c) Each grid reflects the global similarity between two networks.

arXiv[1] [6] consists of various networks in terms of different arXiv categories. There are 14,489 nodes, 59,026 coauthorship connections, and 13 networks. The number of anchor links among the networks is 23,626.

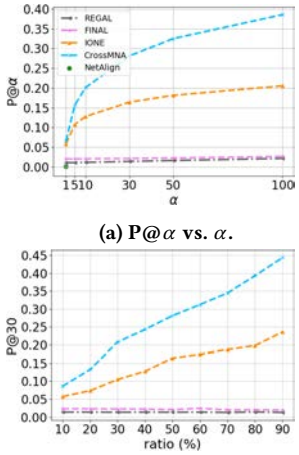
Twitter[1] [24] This dataset is a specific Twitter dataset which focused on People's Climate March in 2014. It makes use of 3 networks, corresponding to retweet, mentions, and replies. 102,439 nodes, 353,495 edges and 55,600 anchor links are included.

SacchCere[1] [7, 30] is a subset of BioGRID, which is a public database that archives and disseminates genetic and protein interaction data from humans and model organisms. It contains 6,570 nodes, 282,755 connections and 7 networks, each represents one type of genetic interaction. There are a total of 55,831 anchor links.

4.2 Baseline Methods

Multi-Network Alignment. To show the effectiveness of our method in addressing the multi-network alignment problem, we compare with four different baseline methods through only using network structure information.

NetAlign [3] proposes the message passing algorithms to match networks under unsupervised schemas.



FINAL [43] proposes a family of algorithms to align attributed networks. It formulates network alignment from an optimization perspective referring to the alignment consistency principle.

REGAL [10] is an unsupervised multi-network alignment method, which extracts similarity-based representations among graphs and infers the soft alignments by comparing the learnt embedding vectors.

IONE [15] is a state-of-the-art network embedding based method under semi-supervised schemes, which solves both the network embedding problem and the user alignment problem simultaneously with a unified optimization framework.

As NetAlign and FINAL both require the prior alignment information, following previous work we construct a degree similarity matrix and take the top-$log|V|$ entries for each node.

Intra-Link Prediction. To verify the ability of CrossMNA on extracting effective features of the nodes among the networks. We also compare our proposed CrossMNA with five network embedding methods on link prediction task, which are divided into two

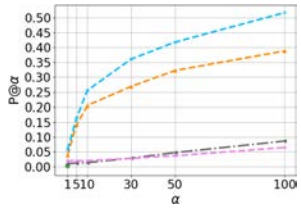
(a) P@α vs. α.

(b) P@30 vs. Training ratio.

Figure 3: Performance with Twitter.

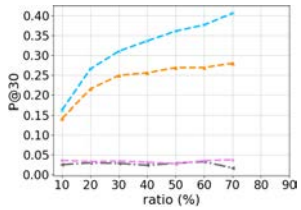
categories in terms of single-network embedding or multi-network embedding:

DeepWalk [27] is a typical network embedding method that learns vertex representations based on single network structures. It performs a random walk on the network to obtain vertex sequences and conducts Skip-Gram model to train the sequences.



LINE [31] is another network embedding model which aims at learning node embeddings in a large-scale network. It minimizes a loss function to preserve both first-order and second-order proximity between nodes.

node2vec [8] defines a flexible notion of a nodeâĂŹs neighborhood and propose a biased random walk, which is a trade-off between Breadth First Search and Depth First Search.



PMNE [17] is a multi-network embedding method which proposes two simply merged approaches and a Co-analysis method to obtain one overall embedding for each node. In our experiments, we compare with its final Co-analysis method. The Co-analysis PMNE performs a biased random-walk across each network and conducts Skip-Gram model to train the node sequences.

MELL [19] is a multi-network embedding method which simultaneously learns the embedding vector of each node and a layer

embedding of each single network, using all of the network structures.

4.3 Experiment Configuration

The parameters of the compared methods are set as follows: For FINAL, we follow the default setting, i.e. $\{\alpha, t_{max}\} = \{0.3, 30\}$. For REGAL we set the maximum hop distance $K = 2$; For Deepwalk, we set walks per vertex as 20, window size as 5 and walk length as 80; For LINE, we employ both first-order and second-order proximity and obtain representations via concatenation, and we set the negative samples $k = 5$; For node2vec, we empirically set $p = 2$ and $q = 0.5$. For PMNE and MELL, we follow their default settings, i.e., $\{\alpha, p, q\} = \{0.5, 0.5, 0.5\}$, $\{k, \lambda, \beta, \gamma\} = \{4, 1, 1, 1\}$. For fair comparisons, we set the same node dimension $d = 200$ for all embedding-based methods in network alignment, and $d = 100$ for each network embedding model in link prediction. For our method CrossMNA, we thus set $d_1 = 200$, $d_2 = 100$ and the number of negative samples as 1 to speed up the training process. We use the inter-vector $\mathbf{u}$ for network alignment task and the intra-vector $\mathbf{v}$ for link prediction task.

For multi-network alignment task, we randomly remove part of the anchor links as the test set and the rest as the training set. We compare the precision of the soft alignment for each method. We first introduce the $Precision^{(i,j)}@\alpha$ as the evaluation metric of mapping nodes from G^i to G^j:

$$Precision^{(i,j)}@\alpha = \frac{|CorrectNodes^{(i,j)}@\alpha|}{|UnMappedAnchors^{(i,j)}|}, \tag{10}$$

where $|UnMappedAnchors^{(i,j)}|$ is the number of unknown anchor links between G^i and G^j and $|CorrectNodes^{(i,j)}@\alpha|$ is the number of the correct alignments from G^i to G^j in top-α choices. Therefore, the evaluation metric on multi-network alignment can be defined as:

$$Precision@\alpha = \frac{1}{N(N-1)} \sum_i \sum_{j \neq i} Precision^{(i,j)}@\alpha, \tag{11}$$

where N is the number of networks.

For intra-link prediction task, we randomly split all edges into two sets for training and testing respectively. We also randomly sample an unconnected node pair as a negative edge for each positive edge in the test set and use both the positive and negative edges for testing. We here adopt a standard evaluation metric ROC-AUC [9] in our experiments.

4.4 Performance Evaluation

Multi-Network Alignment. The experimental results are presented in Figure 3-5. We first keep the training ratios to 0.5 and give the results of different @α settings, which is the subfigure (a) for each dataset. Then we vary the training ratio from 0.1 to 0.9 with an interval of 0.1 and evaluate the *Precision*@30 of each method, which is the subfigure (b) for each dataset. We remove the results of training ratio 0.8 and 0.9 on SacchCere, because most networks have few anchor nodes in the test set, leading to the unstable performance of each method. We only give *P*@1 for NetAlign as it aims to find the hard matching for the node. From the results, we have the following observations:

(i) CrossMNA can outperform all the baselines in each dataset on almost all training ratios. We can gain 10% to 20% improvement on Twitter dataset than the state-of-the-art method IONE, and 5% to 12% improvement on SacchCere. In arXiv dataset, CrossMNA can also achieve about 10% improvement on different training ratios. Furtherly, even when the training ratio is very small, such as 10% and 20%, CrossMNA can still achieve the best performance and get 5% to 10% improvement. This result demonstrates that our method is still effective when the known anchor links are rare, which is a very common problem in many real-world applications.

(ii) The unsupervised methods NetAlign, REGAL, and FINAL show poor performance on all datasets, because the structures of each network do not follow the topology consistent assumption they hold, which leads to the misleading alignments in all datasets. The state-of-the-art embedding-based method IONE, however, can achieve good performance on each dataset. However, it only considers the pair-wise learning, thus it ignores many useful complementary information across different networks. What's more, it does not explicitly consider the problems of distinctive network structures, resulting in the mismatching of some anchor nodes with different local structures. Therefore, it is hard to achieve better performance when the networks have quite different structures.

(iii) Combined with Figure 2, we can find that most networks in arXiv dataset tend to have similar global structure, and the anchor nodes are more evenly distributed across networks. Therefore, IONE can achieve good performance on this dataset, e.g., IONE

Table 1: Results of alignment between each pair of networks in Twitter dataset. The training ratio is 50% and 1→2 denotes matching nodes from the 1st network to the 2nd network.

$P^{(i,j)}$@30	1→2	2→1	1→3	3→1	2→3	3→2
IONE	0.056	0.054	0.035	0.032	0.4601	0.4589
CrossMNA	**0.1327**	**0.1106**	**0.2817**	**0.1676**	**0.5863**	0.4210

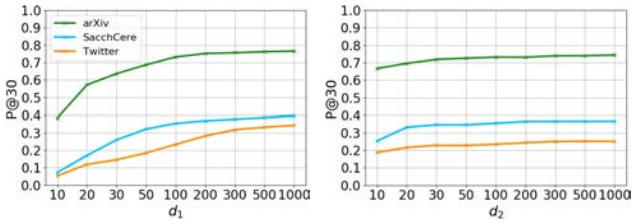

Figure 6: Parameter study on multi-network alignment.

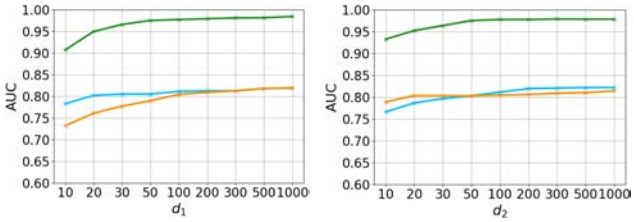

Figure 7: Parameter study on link prediction.

can even gain better performance on $P@1$ when the training ratio is 50% than CrossMNA. However, CrossMNA can take advantage of the jointly learning all the networks, so our CrossMNA can have a stable improvement of about 10% on different ratios. For SacchCere dataset, as the semantic meanings are different among the networks, the structure of each network is diverse, which prevents the baselines from achieving good results. However, as we jointly learn from all the networks, the abundant complementary information among the networks can improve the quality of learnt embeddings, alleviating the problem above. For Twitter dataset, the state-of-the-art method IONE cannot achieve satisfactory result due to two reasons: (i) the sizes of networks vary a lot and the distribution of anchor nodes is uneven in this dataset, e.g., the 1st network has nearly 100,000 nodes but 3nd network has only about 8,000 nodes and most anchor links are between the 1st and 2nd networks; (ii) the networks show diverse structures, e.g., the 1st network shows quite different topology structure compared to the other two networks. For better understanding, we present the performance of alignment between each pair of networks on Twitter in Table 1. We can observe that IONE can gain a comparable result with our CrossMNA in alignment between the 2nd and 3rd networks, which have the similar topology structure. However, for alignment between the 1st-2nd networks and the 1st-3rd networks, IONE cannot achieve satisfactory results because the size of the networks vary a lot and they show quite diversity global structures, which we can find in Figure 2(c). However, as our CrossMNA extracts an extra network vector to peel off the influences of network semantic on node's local connections, the inter-vector can preserve the common features among the anchor nodes as much as possible, which shows significant improvement on this dataset.

To summarize, the above observations illustrate our method is significantly effective and appropriate to address multi-network alignment problem.

Intra-Link Prediction. Besides applied on network alignment, the node embedding learnt by our CrossMNA can also be adopted in other downstream network analysis tasks, e.g., link prediction and vertex identity. We take the link prediction task as an example to evaluate the quality of the learnt features. We compare with five state-of-the-art methods, three for the single-layer network and two for multiple networks. For the models designed for the single-layer network, we train a separate embedding for each network and use that to predict the links of the corresponding networks. We evaluate the AUC values of different models with the training ratio 30%, 50%, and 80% and propose the results in Table 2.

Upon the experimental results, we find that for all the datasets, our CrossMNA can achieve comparable performance or even significantly outperform all the baselines. What calls for special attention is that CrossMNA can achieve a nearly 5% improvement on Twitter dataset on all the training ratios. This is because the inter-vector in CrossMNA plays a role to transmit the complementary information across the networks while the network vectors can store the distinctive properties of each network, which make the combining-based intra-vector integrate the cross-network information without sacrificing the distinctive properties in its selected network. To summarize, the above results indicate the effectiveness of features refined by our method in multi-network mining tasks.

4.5 Parameter Sensitivity

There are two parameters in our method: the dimension of inter-vector d_1 and intra-vector d_2. To explore the influence of the parameters on the model performance, we set $d_1 = d_2 = 100$ as default, pick up one parameter each time and vary that parameter while fixing another to check this parameter's impact on the tasks of network alignment and link prediction. For network alignment task, we keep the training ratio to 50% and use the $P@30$ as the metric. For link prediction task, we also keep the training ratio to 50%.

From Figures 6 and 7, we can observe that d_1 has a great influence on both tasks, and as d_1 grows the performance is significantly improved. While d_1 is larger than a threshold, the performance will be stable, and the threshold is related to the size of the network. When d_1 is larger than 200 on arXiv and SacchCere, the performance will shift towards a steady distribution. However, $d_1 = 300$ has a significant improvement than $d_1 = 200$ on Twitter dataset in alignment task, as the scale of this dataset is very large. We also find that d_2 has a relatively smaller effect on the performance if d_1 chooses a suitable number. Upon these observations, we are motivated to set a relative larger d_1, such as 200, 300 and a very small d_2, such as 30, 50 to save the memory in practice.

Table 2: AUC score of link prediction task.

Dataset	arXiv			SacchCere			Twitter		
	30%	50%	80%	30%	50%	80%	30%	50%	80%

4.6 Case Study

In this section, we perform a set of experiments to explore whether CrossMNA can gain better performance with more related networks taken into account. To make the experimental results more convincing, we choose the arXiv dataset which has the most number of networks. This means the relationships among the networks are very complicated.

We vary the number of networks from 2 to 13 and set the training ratio to 50%. We perform this experiment 10 times, and at each time we shuffle the order of the networks which are taken into consideration. We calculate the average score and present the result of $P@30$ in Figure 8. We can observe that as the number of networks increases, the overall trend of precision also goes up. These results indicate that the complementary information among the networks benefits the result of alignment, and the more related networks considered, the better performance our CrossMNA can achieve.

Table 3: Space complexity analysis among embedding-based network alignment methods.

model	number of parameters	p=0	p=0.1	p=0.2
IONE	$d \cdot (N-1)N\|V\|$	3051.75 (MB)		
REGAL	$d \cdot N\|V\|$	762.93		
CrossMNA	$d_1 \cdot \|V\|\,(N - Np + p) + d_2 \cdot N + d_1 \cdot d_2$	763.01	701.21	640.94

Notes:

In practice, we usually set $d_2 \ll d_1 \approx d$.
p denotes the ratio of known anchor links.

4.7 Scalability

In this section, we explore the scalability of our CrossMNA. Concretely, we analyze the space complexity and time complexity of our method respectively.

4.7.1 Space Complexity Analysis. As we know, in real life the networks could be very huge. In large-scale multi-network analysis tasks, if we learn embeddings for all nodes in each network, the storage issue could be a big challenge. Therefore, we ought to analyze the space complexity of the embedding-based models. We first analyze the number of parameters in each model. Then we perform a set of experiments to show the actual space overhead with regard to the size of the network. For convenience, we assume that each network shares the same set of nodes. We here use a subgraph of Youtube [32] and adopt randomized permutation to generate multiple networks. We analyze the embedding-based network alignment methods and the multi-network embedding methods respectively.

From Table 3, we observe that IONE inevitably takes too much memory especially when many related networks exist. Given IONE belongs to pair-wise learning, it needs to generate embeddings for each pair of networks. Unlike IONE, REGAL saves much space as it can directly train multiple networks together owing to the randomly sampling landmarks strategy to approximate the similarities among nodes. For our CrossMNA, because of jointly training multiple networks and the combination strategy, it only generates the inter-vector for the node and the network vector for each network. It is noteworthy that the inter-vector is shared among the known anchor nodes, so the more the known anchor nodes, the less space our CrossMNA takes. For easy understanding, we give an example with five networks and 100,000 nodes and present the space overhead with different ratios of the known anchor links. We set $d = d_1 =$

Table 4: Space complexity analysis among multi-network embedding methods.

model	number of parameters
DeepWalk/LINE	$d \cdot N\|V\|$
PMNE	$d \cdot \|V\|$
MELL	$d \cdot N(\|V\| + 1)$
MTNE [35]	$d \cdot (N + 1)\|V\|$
SMNE [38]	$d \cdot \|V\| + s \cdot N\|V\| + d \cdot s \cdot N$
CrossMNA	$d_1 \cdot \|V\| + d_2 \cdot N + d_1 \cdot d_2$
Notes:	
s is the dimension of typed relation vector in SMNE and $s \ll d$.	

$200, d_2 = 50$. We can find that even in the extreme case where there is no known anchor link, our method can still take up nearly the same amount of space compared to REGAL. When there are a few known anchor links, our CrossMNA can take advantage of its combination strategy and show less space overhead.

Then we compare CrossMNA with existing multi-network embedding methods. From Table 4, we can find that PMNE has the least number of parameters among all the methods. Compared to other methods, the size of SMNE is relatively smaller as its hyper-parameter s can be set as a small number. However, our CrossMNA can take the smallest memory overhead in most cases, because we do not need to generate the embedding vector for each node in each network, which requires $dN|V|$ parameters. We use the strategy of combining the common inter-vector and the network vector via a transformation matrix to generate the vector for each node in each network. Therefore CrossMNA only generates $d_1|V| + d_2N + d_1d_2$ parameters, where $d_1 \approx d$ and d_2 can be a very small number. To show the difference more clearly, we extend the size of a multi-network in the number of networks and nodes respectively, and present the memory overhead of each model in Figure 9. We can observe that CrossMNA and PMNE are significantly lighter than other models, and as the size of the network increases, the space overhead of CrossMNA and PMNE grows very slowly. However, as PMNE merges the information from all networks into one type of embedding, it inevitably loses the distinctive information in each network as shown in our previous experiments. Thus our CrossMNA is dramatically space efficient for large-scale multi-network applications compared to existing methods.

4.7.2 Time Complexity Analysis. The runtime of CrossMNA is in two parts: learning cross-network embedding and matching nodes through vectors comparison. The total time complexity of learning embeddings is approximately $O(tN\,(d_1d_2|V| + d_2|E|))$, where t is the number of iterations, N denotes the number of networks, and $|V|, |E|$ denote the number of nodes and edges in each network respectively. The time complexity of finding soft alignment between each two networks is $O(|V|log|V|)$.

5 RELATED WORK

5.1 Network Alignment

Network alignment is a fundamental problem for cross-network mining and many pieces of literature have been proposed to handle this problem. Most previous works make full use of the attribute information of nodes, e.g., username, gender, etc. The username is the most commonly used feature in almost all these works. Perito et al. [26] employ binary classifiers to determine if the cross-platform user with the same name is the same person. Vosecky et al. [34] extracts distance-based profile features and build classifiers to match users in multiple networks, and similar works can also be found in [18, 25]. In some scenarios, we can get some special contents information of the nodes. Therefore, there also exist some methods to take account of these useful contents for more precision node matching. Riederer et al. [28] links users by considering their trajectory-based content features. Almishari et al. [22] aligns users by exploiting their writing style.

The connection relationship between the nodes is another common and vital feature. Thus many works have been proposed to consider both the content information and the network structure. COSNET [44] uses an energy-based model to link users by considering both local and global consistency. HYDRA [16] presents a multi-objective framework to model heterogeneous behaviors and structure consistency simultaneously.

However, as the attribute information of the nodes is usually missing, unreliable or even unavailable in real-life applications, some methods have been proposed to align nodes only based on the structural information. BigAlign [13] proposes to align two bipartite graphs with a fast alignment algorithm. UMA [41] jointly optimizes multiple anonymized social networks in unsupervised schemes, under the constraints of transitivity law and one-to-one property. IONE [15] learns the follower-ship/followee-ship of each user under the framework of network embeddings and utilizes the embedding vectors to match unknown anchor users.

People nowadays usually participate in multiple diversities of networks simultaneously, and jointly learning from these related networks can get much more useful complementary information for alignment. UMA [41] and REGAL [10] have been proposed to optimize multiple networks together only considering structural information. However, the assumption of topology consistency makes them fail to deal with networks with distinct structures. Considering the problems above, we propose CrossMNA, a light-weight cross-network embedding based network alignment method, to jointly learn structural information across diversities of networks.

5.2 Network Embedding

Network embedding has been emerged as an effective and efficient approach for learning low-dimension distributed representations for the nodes in networks and is researched intensively. Previous works can be roughly divided into two categories: single-network embedding and multi-network embedding.

Most of the previous works focus on the single-layer network. Inspired by the distributed representation learning of words in NLP [20], DeepWalk [27] performs random walk over networks to generate vertex sequences and conducts Skip-Gram to obtain node

embeddings. On top of DeepWalk, Node2vec [8] modifies the random walk strategy into a biased random walk to explore network structure more efficiently. Unlike the random walk based methods above, LINE [31] optimizes two objective functions to separately approximate first-order and second-order proximity in the large-scale networks. Another general approach for obtaining node embeddings is matrix factorization. GreRap [5] proposed a matrix factorization based methods to encode k-step representations, where each step reflects different local information. TADW [36] incorporates text contents into network embedding under the framework of matrix factorization. Although these methods have achieved satisfactory performance on many single-layer network mining tasks, they ignore the multiple networks scenario.

To make the data mining task on the multiple networks more actionable, recently several works have been proposed to transform the multiple networks into low-dimension vector space. PMNE [17] proposes two simple merge-based methods which only consider inter-layer edges or intra-layer edges, and one cross-layer method which performs a biased random-walk across each layer, to obtain one overall embedding for each node. MTNE [35] and SMNE [38] builds a bridge among different layers by sharing a common embedding across each layer of the multiple networks. MELL [19] proposes the method of simultaneously learning node embeddings and layer embeddings using all of the network structures.

However, most of these multi-network embedding models ignore the problem of space overhead, which makes them hard to be applied in large-scale multi-network applications. Unlike these methods, our CrossMNA occupies much less physical without sacrificing the performance, owing to the shared inter-vectors and the flexible combination strategy.

6 CONCLUSION

We have studied the problem of multi-network alignment and propose CrossMNA, a light-weight cross-network embedding based network alignment method for tackling today's large-scale multi-network applications. CrossMNA novelly defines two categories of embedding vectors for each node, i.e. inter-vector and intra-vector. The commonness of anchor nodes in different networks is represented by the inter-vector, while the specific structural feature is interpreted by the intra-vector. In addition, the coordination of inter-vector and intra-vector dramatically decline the space overhead while reserving the adequate performance. Extensive experiments showed analytically our CrossMNA can significantly outperform other currently existing baselines and multi-network embedding methods.

ABSTRACT

We present a method for implementing shrinkage of treatment effect estimators, and hence improving their precision, via experiment splitting. Experiment splitting reduces shrinkage to a standard prediction problem. The method makes minimal distributional assumptions, and allows for the degree of shrinkage in one metric to depend on other metrics. Using a dataset of 226 Facebook News Feed A/B tests, we show that a lasso estimator based on repeated experiment splitting has a 44% lower mean squared predictive error than the conventional, unshrunk treatment effect estimator, a 18% lower mean squared predictive error than the James-Stein shrinkage estimator, and would lead to substantially improved launch decisions over both.

1 INTRODUCTION

As the cost of experimentation decreases, researchers are increasingly able to collect data on multiple, related experiments, which test similar kinds of changes [6, 8, 15, 27, 30]. Technology companies may test multiple versions of the machine learning models determining what content is shown to users, where models may differ in their features, architecture, hyperparameter values, or the optimization algorithm used. This raises the prospect of being able to improve inferences for any given experiment, by using the information contained in the other, related experiments. In Bayesian terms, estimating a prior for treatment effect sizes based on previous experiments, and updating it given the data from the current experiment, may yield a better estimate of the true treatment effect than would be possible given the current experiment's data alone. This kind of *empirical Bayes* analysis has a rich history in statistics [11, 12, 19, 22, 31]. With the proliferation of A/B testing, it is increasingly relevant to the modern analysis of experimental data.

We propose a methodology for performing nonparametric, multivariate empirical Bayes shrinkage, which turns the shrinkage problem into a standard prediction problem. The basic idea is as follows: we split each experiment randomly into two subexperiments, each with their own test and control group. We regress the estimated treatment effect in the first subexperiment on the estimated treatment effect in the second subexperiment. Because the dependent variable is unbiased, this regression also estimates the conditional mean of the true treatment effect, given the data in the second subexperiment. In other words, it is an empirical Bayes estimator of the parameter of interest. Other variables likely to be predictive of the treatment effect can be added as covariates into this regression, including estimated treatment effects on auxiliary metrics in the second subexperiment. The prediction algorithm used may be a simple linear regression, but could also be more flexible and nonparametric, allowing for nonlinearities, interactions, and regularization of covariates.

In this methodology, the prior distribution of treatment effects is not explicitly estimated.[1] Instead, we directly estimate the conditional mean of the treatment effect given the observed data, using the experiment splits. Other experiments implicitly determine the prior, and hence the degree of shrinkage implied by this conditional mean. This raises the question of how to choose the fraction of data allocated to the first and the second subexperiments. We derive an expression for the mean squared error of the experiment splitting estimator with univariate least squares shrinkage, and characterize the limiting behavior of the optimal experiment splitting fraction as a function of the number of experiments and the variance of treatment effects and sampling error.

Using a dataset of 226 Facebook News Feed A/B tests, we evaluate the performance of experiment splitting estimators relative to the leading alternatives, including other empirical Bayes shrinkage estimators. We find that experiment splitting reduces mean squared prediction error by 44% compared to the conventional, unshrunk estimator, by 18% compared to James-Stein shrinkage, and by 13% compared to the "Tweedie" estimator. Launching all experiments with positive estimates results in a 40% higher estimated cumulative lift for the lasso than the unshrunk estimator. While experiment splitting generates some performance improvements from flexible,

[1] Other empirical Bayes methods which avoid estimating priors are surveyed in [18], including Robbins' formula [31], the local false-discovery rate [17], and Tweedie's formula [16].

nonparametric shrinkage and appropriate regularization of treatment effect predictors, we find the main gains are attributable to the multivariate shrinkage that experiment splitting straightforwardly enables. Estimated treatment effects in one metric may reveal information about the true treatment effect in another metric, and experiment splitting makes it easy to incorporate this covariance information.

We focus on shrinkage of treatment effect estimators across experiments, but the idea of using split sample regressions to generate better estimators applies more broadly. If the heterogeneity in treatment effects across user subgroups within an experiment is of interest, experiment splitting can be applied at the level of user subgroups within a single experiment. In non-experimental settings where multiple means from separate samples are being estimated, sample splitting can be used to determine the appropriate degree of shrinkage for each sample mean.

Relative to existing work on empirical Bayesian shrinkage, which we discuss in Section 2, our contribution is to formulate the shrinkage problem as a prediction problem to which standard machine learning algorithms can be applied. This leads to easy-to-implement algorithms for very general forms of shrinkage, which do not require parametric assumptions on the treatment effect or sampling error distributions, and which allow for incorporating information from a potentially high-dimensional vector of auxiliary metrics.

While using split sample regressions to shrink treatment effect estimates appears to be new to the literature, other applications of sample splitting for causal inference abound. Sample splitting has been proposed as a means for constructing valid confidence intervals for heterogeneous treatment effect estimates [3, 37], making the statistical analysis of random forests more tractable [4, 7], and reducing false positives from specification searches [2, 23]. A fast-growing body of work analyzes the properties of semiparametric "cross-fitting" estimators, in which high-dimensional nuisance parameters are estimated by machine learning algorithms on a subsample of the data, and their out-of-sample predictions used to estimate the causal parameters of interest [5, 13, 14, 29, 36, 38].

2 EMPIRICAL BAYESIAN SHRINKAGE

For each of N_E experiments, we have a test group and a control group, each made up of N_P people.[2] In experiment i, we observe test and control group participant outcomes, $(Y^t_{i,k})_{k=1}^{N_P}$ and $(Y^c_{i,k})_{k=1}^{N_P}$. Within each experiment, test and control outcomes are iid across people. The treatment effect in experiment i is defined as $\theta_i = E(Y^t_{i,k}) - E(Y^c_{i,k})$, and the θ_i are themselves iid across experiments. We denote by $\widehat{\theta}_i$ the difference of sample means treatment effect estimator: $\widehat{\theta}_i = \frac{1}{N_P}\sum_{i=k}^{N_P}(Y^t_{i,k} - Y^c_{i,k}) = \theta_i + \varepsilon_i$, where ε_i is sampling error, assumed independent of θ_i. We wish to compute the conditional mean of the treatment effects given the observed data. Of particular interest is the Bayes estimator $E(\theta_i|\widehat{\theta}_i)$, which minimizes mean squared error [31]. We briefly review existing approaches to this problem under various distributional assumptions on $(\theta_i, \varepsilon_i)$.

[2]The assumption that the test and control groups are of equal size is made only to simplify the exposition, and is inessential in what follows.

2.1 Normal Treatments, Normal Errors

Known variances. Consider the case where $\theta_i \sim N(0, \sigma^2_\theta)$, $Y^c_{i,k} \mid \theta_i \sim N(0, \sigma^2_Y)$ and $Y^t_{i,k} \mid \theta_i \sim N(\theta_i, \sigma^2_Y)$, for known variances σ^2_θ and σ^2_Y. The difference of sample means estimator has distribution $\widehat{\theta}_i \mid \theta_i \sim N(\theta_i, \sigma^2_\varepsilon)$, where $\sigma^2_\varepsilon = 2\sigma^2_Y/N_P$. By Bayes' rule the posterior distribution of the treatment effect given the data is $\theta_i \mid \widehat{\theta}_i \sim N(\alpha\widehat{\theta}_i, \alpha\sigma^2_\varepsilon)$, where $\alpha = \sigma^2_\theta/(\sigma^2_\theta + \sigma^2_\varepsilon)$. The Bayes estimator of θ_i is $E(\theta_i \mid \widehat{\theta}_i) = \alpha\widehat{\theta}_i$. This shrinks the difference of sample means estimator, $\widehat{\theta}_i$, towards the prior mean of the treatment effects, zero, by the coefficient α.[3] Thus with normal treatment effects and sampling error, optimal shrinkage is linear in the estimate $\widehat{\theta}_i$. The Bayes risk with squared loss for the difference of sample means $\widehat{\theta}_i$ is $\sum_{i=1}^{N_E} E(\widehat{\theta}_i - \theta_i)^2 = \sigma^2_\varepsilon N_E$, whereas for the Bayesian shrinkage estimator $\alpha\widehat{\theta}_i$, it is $\sum_{i=1}^{N_E} E(\alpha\widehat{\theta}_i - \theta_i)^2 = \alpha\sigma^2_\varepsilon N_E$ [17]. The gains from optimal shrinkage are large if the signal-to-noise ratio $\sigma^2_\theta/\sigma^2_\varepsilon$, and hence α, is small. When the sampling error variance σ^2_ε is very large, almost all of the variation in $\widehat{\theta}_i$ reflects sampling error, rather than variation in the underlying treatment effect θ_i, and the Bayes estimator offsets the effect of sampling error by aggressively shrinking $\widehat{\theta}_i$ towards the prior mean.

Unknown treatment effect variance. In practice σ^2_θ, and hence the desired shrinkage factor α, may be unknown. One may specify a prior distribution over σ^2_θ and conduct full Bayesian inference, computing the posterior of θ_i given the data and priors [34, 35]. An alternative is empirical Bayes, in which the shrinkage factor is estimated from the data. The celebrated James-Stein estimator is

$$\widehat{\theta}^{JS}_i = \left(1 - \frac{(N_E - 2)\sigma^2_\varepsilon}{\sum_{i=1}^{N_E}\widehat{\theta}^2_i}\right)\widehat{\theta}_i.$$

Although originally studied in a frequentist setting with fixed $\theta_i's$ [26, 32], it can be viewed as an empirical Bayes estimator, where $1 - (N_E - 2)\sigma^2_\varepsilon/\sum_{i=1}^{N_E}\widehat{\theta}^2_{i,2}$ is an unbiased estimator of the Bayes optimal shrinkage factor [17, 20, 33].

Unknown sampling error variance or prior mean. In experimental settings the sampling error variance σ^2_ε is typically unknown, but can be readily estimated. Letting $\widehat{\sigma}^2_Y$ denote the sample variance of all test and control outcomes across all people and experiments, we use the estimator $\widehat{\sigma}^2_\varepsilon = 2\widehat{\sigma}^2_Y/N_P$. When the prior mean is non-zero, the same shrinkage logic as above applies, with estimates being linearly shrunk towards the prior mean instead of towards zero. When this prior mean is unknown, it can be estimated as the sample mean across experiments of the observed $\widehat{\theta}_i$.

2.2 General Treatments, Normal Errors

The treatment effects θ_i need not be normally distributed, and are significantly non-normal in the data we study in Section 5. This implies that $E(\theta_i \mid \widehat{\theta}_i)$ need not be linear in $\widehat{\theta}_i$, unlike in the normal case. Let f denote the marginal density of $\widehat{\theta}_i$. Then *Tweedie's formula* ([10, 16]) for the posterior mean of θ_i is:

[3]The fact that the Bayes optimal estimator of θ_i involves shrinking $\widehat{\theta}_i$ towards zero is consistent with $\widehat{\theta}_i$ being unbiased for θ. The former observation is that $E(\theta_i \mid \widehat{\theta}_i) \leq \widehat{\theta}_i$; the latter that $E(\widehat{\theta}_i \mid \theta_i) = \theta_i$.

$$E(\theta_i \mid \widehat{\theta}_i) = \theta_i + \sigma_\varepsilon^2 \frac{d \log f(\widehat{\theta}_i)}{d\theta_i}. \quad (1)$$

Because the $\widehat{\theta}_i$ are observed, unlike the θ_i, we can directly estimate the density f from the data, and use this estimate in equation (1) to construct an estimator of $E(\theta_i \mid \widehat{\theta}_i)$. Even if the treatment effects are non-normal, normality may still be a reasonable assumption for the sampling error. If N_P is large and the assumptions of the central limit theorem hold, ε_i will be close to normal.

3 EXPERIMENT SPLITTING

Experiment splitting takes a different approach to estimating treatment effects. The main observation is that multiple independent estimates of the same treatment effect can be obtained from a single experiment, by simply partitioning the experiment into subexperiments. In brief, by randomly splitting each experiment into two subexperiments, we can estimate the conditional mean of the treatment effect estimate in the second subexperiment given the treatment effect estimate in the first. This conditional mean is what is required for optimally shrinking our estimates from the second subexperiment.

In more detail, we split both the test group and the control group into two subgroups, with a fraction γ of people selected uniformly at random for the first subexperiment (up to integer constraints), and the remainder assigned to the second subexperiment. Without loss of generality, let $(Y^t_{i,k})_{k=1}^{\lfloor \gamma N_P \rfloor}$ and $(Y^c_{i,k})_{k=1}^{\lfloor \gamma N_P \rfloor}$ be the test and control outcomes of the people in the first subexperiment, and similarly $(Y^t_{i,k})_{k=\lfloor \gamma N_P \rfloor+1}^{N_P}$ and $(Y^c_{i,k})_{k=\lfloor \gamma N_P \rfloor+1}^{N_P}$ for people in the second subexperiment. In each subexperiment, we construct the difference of means treatment effect estimator: $\widehat{\theta}_{i,1} = \frac{1}{\lfloor \gamma N_P \rfloor} \sum_{k=1}^{\lfloor \gamma N_P \rfloor} (Y^t_{i,k} - Y^c_{i,k})$ and $\widehat{\theta}_{i,2} = \frac{1}{N_P - \lfloor \gamma N_P \rfloor} \sum_{k=\lfloor \gamma N_P \rfloor+1}^{N_P} (Y^t_{i,k} - Y^c_{i,k})$. It follows that $E(\widehat{\theta}_{i,2} \mid \widehat{\theta}_{i,1}) = E(\theta_i \mid \widehat{\theta}_{i,1})$, as $\widehat{\theta}_{i,2}$ equals θ_i plus a mean zero error term independent of $\widehat{\theta}_{i,1}$. Moreover, $E(\widehat{\theta}_{i,2} \mid \widehat{\theta}_{i,1})$, and hence $E(\theta_i \mid \widehat{\theta}_{i,1})$, can be estimated by standard regression or prediction techniques. This conditional mean is the Bayes estimator of θ_i given the data in the first subexperiment. Thus by having a set of "hold-out" subexperiments, we can estimate the optimal level of shrinkage. This requires no assumptions on the marginal distributions of θ_i or ε_i, beyond the mild regularity conditions for estimating a conditional mean.

Experiment splitting yields an estimate of $E(\theta_i \mid \widehat{\theta}_{i,1})$, not $E(\theta_i \mid \widehat{\theta}_i)$. The conditioning is on the difference in means in only the first subexperiment, not the entire data. In principle not conditioning on all data might impair estimator performance, to the extent that more conventional estimators dominate experiment splitting. The results of Section 5 indicate to the contrary that experiment splitting estimators can substantially outperform unshrunk, James-Stein and Tweedie estimators, in real-world A/B tests.

This framework also naturally extends to accommodate covariates. Letting X denote a vector of variables available based on data from the first subexperiment, we can estimate $E(\widehat{\theta}_{i,2} \mid X_i)$. In contrast to conventional experiment meta-analysis, X_i includes an estimate of the outcome of interest formed from the data in experiment i, $\widehat{\theta}_{i,1}$. In addition, the covariate vector X_i may include treatment effects on other metrics in the same experiment, or experimental metadata, all of which may be useful for predicting θ_i. Thus the experiment splitting estimator's performance may be improved, if auxiliary metrics or experiment metadata are available that are predictive of the outcome of interest. The conditional expectation can be estimated by standard prediction algorithms like the lasso, gradient boosted decision trees, or neural nets. Thus experiment splitting allows us to treat nonparametric multivariate shrinkage as a simple prediction problem. Unlike classical approaches to the problem of multivariate shrinkage (e.g. [21]), it is unnecessary to estimate the full covariance matrix of all metrics' treatment effects.[4] The covariate vector may even be high-dimensional, as this can be accommodated by common supervised learning algorithms.

Generating confidence intervals around the estimate of $E(\theta_i \mid X_i)$ poses no special difficulty for the experiment splitting estimator. The only requirement is that valid confidence intervals can be calculated for whatever statistical procedure is applied for estimating the conditional mean.

3.1 Selecting the Experiment Splitting Fraction

Because of the relation between experiment splitting and cross-validation described in Section 3.4, we also call the first subexperiment (used to construct the covariates in the experiment splitting regression) the "training" subexperiment, and the second subexperiment (used to construct the outcomes) the "validation" subexperiment. The relative amount of data in training and validation subexperiments affects the properties of the experiment splitting estimator. If most of the data is assigned to the training subexperiment, then the sampling error in $\widehat{\theta}_{i,1}$ is relatively small; if most of the data is assigned to the validation subexperiment, then the sampling error in $\widehat{\theta}_{i,2}$ is relatively small. The optimal splitting fraction strikes a balance so that $\widehat{E}(\theta_i \mid \widehat{\theta}_{i,1})$, the estimator of the conditional mean $E(\theta_i \mid \widehat{\theta}_{i,1})$, is as close as possible on average to θ_i.

We present two strategies for estimating the out-of-sample error rate for selecting the optimal experiment splitting fraction. The first is cross-validation. This requires splitting the original experiment into *three*: two subexperiments corresponding to the training and validation data, and a third, "test" subexperiment, which is used as a out-of-sample, independent measure of the truth. The difference between a model's predictions—which are a function of the training and validation data—and the estimates of the true effect from the test data, can be used to estimate the model's performance. We perform the random assignment of data into training, validation and tests sets $S > 1$ times and average the results, to reduce the variance in the estimated performance metric due to the choice of splits. This entire procedure can be performed for various choices of γ (which determines the relative sizes of the training and validation subexperiments), and the γ yielding the lowest prediction error can be selected. Algorithm 1 summarizes this procedure, given $\gamma \in \{\gamma_1, \gamma_2 \ldots, \gamma_G\}$, and with half of the overall data allocated to the test subexperiment.

[4] In addition [21] assume that the metrics' sampling error is independent across metrics and homoskedastic. These assumptions—especially independence across metrics—are hard to justify in typical A/B tests.

Algorithm 1 Cross-Validation for Optimal Splitting

(1) For splitting fraction indices $g = 1$ to G:
  (a) For splitting simulations $s = 1$ to S:
    (i) For experiments $i = 1$ to N_E, randomly split experiment i into the training, validation and test subexperiments, each with a proportion $0.5\gamma_g, 0.5(1-\gamma_g)$ and 0.5 of the data, respectively.
    (ii) Apply the experiment splitting estimator to the training and validation subexperiments, and obtain predictions of the true effect in each experiment.
    (iii) Calculate the mean squared difference between these predictions and the estimated effects in the test subexperiment. Denote this err_{gs}.
  (b) Calculate the mean squared prediction error over splitting simulations s, $\text{MSPE}_g := \frac{1}{S}\sum_{s=1}^{S}\text{err}_{gs}$.
(2) Return γ_{g^*}, where $g^* \in \arg\min_g \text{MSPE}_g$.

The second strategy for selecting the experiment splitting fraction involves minimizing an unbiased risk estimate. This is analogous to covariance penalty approaches to estimating prediction error, including Mallows' C_p [28], the Akaike Information Criterion (AIC) [1], and Stein's unbiased risk estimate [34]. Unlike cross-validation, the unbiased risk estimate we develop applies only to multivariate OLS shrinkage, but does not require holding out a test subexperiment, is computationally simpler, and yields insight into how the optimal splitting fraction depends on sample sizes and variance parameters. Given a vector of experiment covariates X_i of length l, the treatment effect estimator for experiment i is $X_i'\widehat{\beta}$, where $\widehat{\beta} = \arg\min_\beta \sum_i(\widehat{\theta}_{i,2} - X_i'\widehat{\beta})^2$. The unshrunk subexperiment treatment effect estimates are written as $\widehat{\theta}_{i,j} = \theta_i + \varepsilon_{i,j}$, for $j = 1, 2$. We assume that the error $\varepsilon_{i,j}$ is independent across i and j, and that $\varepsilon_{i,2}$ is independent of X_i. Let $\sigma^2_{\varepsilon_j}$ denote the variance of $\varepsilon_{i,j}$. We also assume that the $N_E \times l$ regressor matrix $X = (X_1, X_2, \ldots, X_{N_E})'$ has rank l with probability 1. The following proposition forms the basis of our unbiased risk estimator. All proofs are in the appendix.

Proposition 1. *The mean squared error of the multivariate linear shrinkage estimators* $(X_i'\widehat{\beta})_{i=1}^{N_E}$ *is*

$$\sum_{i=1}^{N_E} E(\theta_i - X_i'\widehat{\beta})^2 = \left(\sum_{i=1}^{N_E} E(\widehat{\theta}_{i,2} - X_i'\widehat{\beta})^2\right) - (N_E - 2l)\sigma^2_{\varepsilon_2}.$$

Proposition 1 shows that to estimate risk, we simply adjust the sum of squared residuals by a term which depends on N_E, the number of experiments, and l, the number of regressors. As l increases, the in-sample model fit, measured by the sum of squared residuals, increasingly understates the true error. Let $\widehat{\sigma}^2_{\varepsilon_2}$ denote an unbiased estimator of $\sigma^2_{\varepsilon_2}$, which can be easily calculated from the individual-level outcomes in the second subexperiment. Then $\left(\sum_{i=1}^{N_E}(\widehat{\theta}_{i,2} - X_i'\widehat{\beta})^2\right) - (N_E - 2l)\widehat{\sigma}^2_{\varepsilon_2}$ is unbiased for the risk of the experiment splitting estimator. This risk estimate can be calculated for different experiment splitting fractions, in order to select the estimated risk-minimizing fraction.

3.2 Determinants of the Optimal Split

In the case of univariate OLS, we regress the estimated treatment effect in the validation subexperiment on a constant and the estimated treatment effect in the training subexperiment. Our shrinkage estimator for experiment i is $\widehat{\beta}_0 + \widehat{\beta}_1\widehat{\theta}_{i,1}$, where $(\widehat{\beta}_0, \widehat{\beta}_1) = \arg\min_{\beta_0,\beta_1}\sum_i(\widehat{\theta}_{i,2} - \beta_0 - \beta_1\widehat{\theta}_{i,1})^2$. With relatively more data in the training subexperiment, the variance of $\widehat{\theta}_{i,1}$ decreases. But little data in the validation subexperiment means that the $\widehat{\theta}_{i,2}$ are imprecisely estimated, increasing the variance of $(\widehat{\beta}_0, \widehat{\beta}_1)$. We show how the optimal splitting fraction that balances these two effects depends on the number of experiments, and the variance of treatment effects and sampling error. The following result gives an explicit expression for risk of univariate OLS shrinkage in terms of the sample size and variance parameters.

Corollary 1. *The mean squared error of the univariate linear shrinkage estimators* $(\widehat{\beta}_0 + \widehat{\beta}_1\widehat{\theta}_{i,1})_{i=1}^{N_E}$ *is*

$$\sum_{i=1}^{N_E} E(\theta_i - \widehat{\beta}_0 - \widehat{\beta}_1\widehat{\theta}_{i,1})^2 = \frac{(N_E - 2)\sigma^2_\theta\sigma^2_{\varepsilon_1}}{\sigma^2_\theta + \sigma^2_{\varepsilon_1}} + \sigma^2_{\varepsilon_2}.$$

The next result derives the limiting behavior of the optimal split. For simplicity we treat the sample sizes and the experiment splitting fraction as real-valued variables, so the necessary derivatives are defined. We require $0 < \underline{\gamma} \le \gamma \le \overline{\gamma} < 1$ for some $\underline{\gamma}$ and $\overline{\gamma}$ close to zero and one, so that no subexperiment has zero observations.

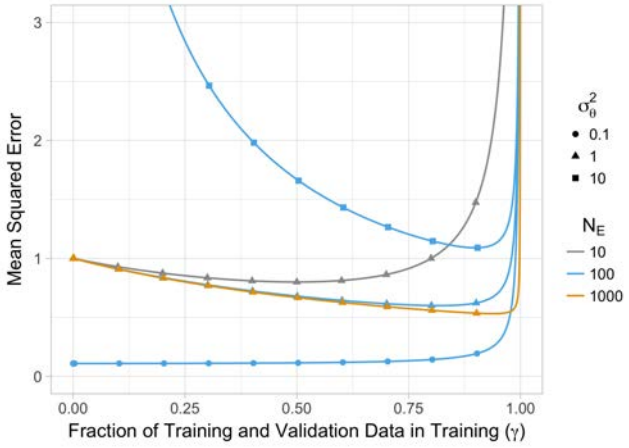
Proposition 2. *Assume* $Var(Y_i^t|\theta_i) = Var(Y_i^c|\theta_i) = \sigma^2_Y$ *for all experiments* i, *and* $N_E \ge 3$. *Define* $\sigma^2_\varepsilon = \frac{2\sigma^2_Y}{N_P}$, *and let* $\gamma^* \in [\underline{\gamma}, \overline{\gamma}]$ *minimize mean squared error from univariate linear shrinkage. Then* $\lim_{N_E\to\infty}\gamma^* = \overline{\gamma}$, $\lim_{\sigma^2_\theta\to 0}\gamma^* = \lim_{\sigma^2_\varepsilon\to\infty}\gamma^* = \underline{\gamma}$, *and* $\lim_{\sigma^2_\theta\to\infty}\gamma^* = \lim_{\sigma^2_\varepsilon\to 0}\gamma^* = \frac{\sqrt{N_E-2}}{1+\sqrt{N_E-2}}$.

Of particular note is the limiting behavior of γ^* as N_E grows. The optimal split puts increasingly more data in the training subexperiment, as any noise in the dependent variable of the splitting regression can be compensated for with a sufficiently large number of experiments N_E. Figure 1 shows the mean squared error from univariate linear shrinkage, for varying values of σ^2_θ and N_E, for σ^2_ε fixed at 1, and normal treatment effects and sampling errors. Consistent with Proposition 2, the optimal γ is increasing in σ^2_θ and N_E. The figure illustrates the asymmetry in risk caused by very small vs. very large values of γ. As γ approaches 0, the signal in $\widehat{\theta}_{i,1}$ vanishes, $\widehat{\beta}_1$ approaches 0, and experiment splitting approaches the bounded risk of the complete shrinkage case. As γ approaches 1, risk is unbounded: extreme imprecision in the dependent variable can cause extreme errors in the shrinkage estimator.

When $\sigma^2_\theta = 0.1$ and $N_E = 100$, there is no interior solution for γ^*, and risk is strictly increasing in γ. This implies that experiment splitting is futile if the signal-to-noise ratio is too small. For large enough sampling error variance, complete shrinkage—the limiting case as γ approaches 0—is always superior to experiment splitting. The suboptimality involved in performing experiment splitting nonetheless is small, however, even for moderate values of γ.

Figure 2 shows γ^*, the optimal fraction of data to allocate to the training subexperiment, as a function of the variance of treatment

Figure 1: Experiment Splitting Fractions and RMSE



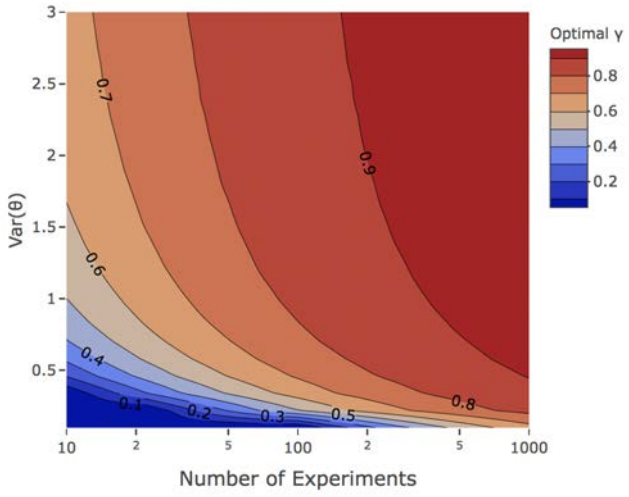


Figure 2: Optimal Experiment Splitting Fraction

effects, σ^2_θ, and the number of experiments, N_E. The sampling error σ^2_ε is again fixed at one. With N_E between 100 and 200 and a signal-to-noise ratio between around one and three, the training subexperiment should contain about 80% to 90% of the data.

3.3 Repeated Experiment Splitting

Our focus until now has been on generating predictions from datasets in which each experiment is split *once*.[5] An alternative is repeated splitting, where we randomly split each experiment into training and validation subexperiments $R > 1$ times. This is appealing, as averaging over repeated splits reduces the "excess" variance due to the random choice of user assignments to subexperiments. This averaging can be understood as a form of Rao-Blackwellization. The experiment splitting estimator is a function of the training and validation assignment, and the individual-level data. Conditioning on the individual-level data—a sufficient statistic—by averaging possible training and validation splits will improve the mean-squared error of the experiment splitting estimator. In the empirical results of Section 5, we verify that this is indeed the case.

[5]This is true even in the cross-validation procedure of Algorithm 1: the additional split there is used to evaluate the quality of the model predictions, not to generate the predictions themselves.

Algorithm 2 Repeated Experiment Splitting

(1) For experiment splitting repetitions $r = 1$ to R:
  (a) For $i = 1$ to N_E, randomly split experiment i into two subexperiments, with a fraction γ of data in the training subexperiment and $1 - \gamma$ in the validation subexperiment. Let $\widehat{\theta}^{(r)}_{i,1}$ and $\widehat{\theta}^{(r)}_{i,2}$ denote the unshrunk estimated treatment effects in those subexperiments.
  (b) Given the set of N_E pairs $\left(\widehat{\theta}^{(r)}_{i,1}, \widehat{\theta}^{(r)}_{i,2}\right)_{i=1}^{N_E}$, estimate the conditional mean $E\left(\widehat{\theta}^{(r)}_{i,2} \mid \widehat{\theta}^{(r)}_{i,1}\right)$. Denote this estimator by $\widehat{m}^{(r)}(\cdot)$.
  (c) For $i = 1$ to N_E, compute the shrinkage estimates $s^{(r)}_{i,1} := \widehat{m}^{(r)}\left(\widehat{\theta}^{(r)}_{i,1}\right)$.
(2) For $i = 1$ to N_E, return the repeated experiment splitting shrinkage estimator for experiment i, given by $\frac{1}{R}\sum_{r=1}^{R} s^{(r)}_{i,1}$.

Algorithm 2 describes the repeated experiment splitting algorithm. The case of $R = 1$ reduces to the original, single repetition experiment splitting estimator. The validity of this procedure for $R > 1$ follows immediately from the validity of the $R = 1$ case. The conditional mean $E\left(\widehat{\theta}^{(r)}_{i,2} \mid \widehat{\theta}^{(r)}_{i,1}\right)$ does not depend on the repetition r, since the data is identically distributed across repetitions. Denote this conditional mean function by $m(\cdot)$. For each repetition r, as long as our estimator $\widehat{m}^{(r)}(\cdot)$ is consistent for $m(\cdot)$, the average of these estimators over r will also be consistent. If the estimates $\widehat{m}^{(r)}(\cdot)$ were independent across r, setting the number of repetitions R to be sufficiently high would ensure arbitrarily precise estimates of m. In practice the $\widehat{m}^{(r)}(\cdot)$ are correlated as they are all functions of the same dataset, and this will not be the case.

For cross-validation of the splitting fraction, we nest this algorithm in the cross-validation meta-algorithm, Algorithm 1. The inner loop of Algorithm 1 calls for applying an experiment splitting estimator given a splitting fraction γ_g. In this setting, implementing that step itself requires splitting the data R times.

3.4 Connection with Cross-Validation

Experiment splitting may appear similar to the practice of cross-validating predictive models. The researcher splits experiments and estimates the optimal degree of shrinkage, based on predicting outcomes in the "held-out" subexperiments. Similarly, in cross-validation, the researcher splits data and estimates the optimal degree of regularization based on predicted outcomes in the held-out data. This is more than an analogy. Experiment splitting with univariate OLS shrinkage and a prior treatment effects mean of zero

is equivalent to cross-validation of a particular ridge regression. This connection holds for any fixed splitting fraction γ, and is unrelated to the use of cross-validation for selecting the splitting fraction as described in Section 3.1.

In experiment splitting with a prior treatment effect mean of zero, the univariate linear regression problem is $\min_\beta \sum_i (\widehat{\theta}_{i,2} - \beta\widehat{\theta}_{i,1})^2$. Define $\Delta_{i,k} = Y^t_{i,k} - Y^c_{i,k}$. That is, we arbitrarily pair up test and control participants into N_P pairs, and denote each pair's difference in outcomes by $\Delta_{i,k}$. Note that $E(\Delta_{i,k}) = \theta_i$ for all i. Regress $\Delta_{i,k}$ on N_E indicator variables, one corresponding to each experiment, on the sample of people in the first subexperiment:

$$\Delta_{i,k} = \sum_{j=1}^{N_E} \alpha_j \mathbb{I}(i = j) + \epsilon_{i,k},$$

for $i = 1, 2, \ldots, N_E$ and $k = 1, 2, \ldots \lfloor \gamma N_P \rfloor$. Let $\widehat{\alpha}_{OLS,j}$ denote the OLS estimates of the α_j. Each $\widehat{\alpha}_{OLS,j}$ will simply be the average of the dependent variable for observations corresponding to that experiment, and so we recover the difference in sample means estimator: $\widehat{\alpha}_{OLS,j} = \widehat{\theta}_{j,1}$ for all experiments j. Letting $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_{N_E})'$, the ridge regression problem for a given regularization parameter λ is

$$\min_\alpha \left\{ \left(\Delta_{i,k} - \sum_{j=1}^{N_E} \alpha_j \mathbb{I}(i = j) \right)^2 + \lambda \alpha' \alpha \right\}. \tag{2}$$

Denoting the design matrix for this problem by X and the dependent variable by y, the solution is $\widehat{\alpha}_{Ridge} = (X'X + \lambda I)^{-1} X'y$. Since X is orthogonal, this implies $\widehat{\alpha}_{Ridge,j} = \frac{\lfloor \gamma N_P \rfloor}{\lfloor \gamma N_P \rfloor + \lambda} \widehat{\theta}_{j,1}$ for all j. Thus ridge regression shrinks all the raw estimates to zero by the same relative amount, where the shrinkage factor depends on λ.

Choosing λ by cross-validation, i.e. minimizing out-of-sample squared error in predictions on the data from the second subexperiments, amounts to solving:

$$\min_\lambda \sum_{i=1}^{N_E} \sum_{k=\lfloor \gamma N_P \rfloor + 1}^{N_P} \left(\Delta_{i,k} - \frac{\lfloor \gamma N_P \rfloor}{\lfloor \gamma N_P \rfloor + \lambda} \widehat{\theta}_{i,1} \right)^2.$$

Because $\widehat{\theta}_{i,2} = \frac{1}{N_P - \lfloor \gamma N_P \rfloor} \sum_{k=\lfloor \gamma N_P \rfloor + 1}^{N_P} \Delta_{i,k}$, this is equivalent to

$$\min_\lambda \sum_{i=1}^{N_E} \left(\widehat{\theta}_{i,2} - \frac{\lfloor \gamma N_P \rfloor}{\lfloor \gamma N_P \rfloor + \lambda} \widehat{\theta}_{i,1} \right)^2,$$

which in turn is equivalent to the original experiment splitting problem, $\min_\beta \sum_{i=1}^{N_E} (\widehat{\theta}_{i,2} - \beta\widehat{\theta}_{i,1})^2$. It follows that the experiment splitting gives the same estimators as cross-validated ridge regression. Similarly, the repeated experiment splitting procedure described in Algorithm 2 is equivalent to a variant of k-fold cross-validation, where for each fold, each experiment is randomly split into training and validation datasets. This connection motivates the naming convention of calling the first subexperiment the training subexperiment and the second the validation subexperiment, as equation (2) is estimated on the first dataset, and its tuning parameter λ is chosen by cross-validation against the second dataset.

Section 2.1 notes that with normal sampling error and treatment effects, the optimal shrinkage is linear. The Bayesian interpretation of ridge regression makes the same assumptions of normality on the treatment effects and the sampling error, so it is natural that it also implies linear shrinkage. Other penalties on the α parameter in equation (2) correspond to non-normal priors on treatment effects, and hence to fitting different, nonlinear regression models in the experiment splitting problem. The L_1 lasso penalty, for example, is equivalent to solving the experiment splitting problem with the soft-thresholding operator $\min_\alpha \sum_{i=1}^{N_E} \left(\widehat{\theta}_{i,2} - \text{sign}(\widehat{\theta}_{i,1})(|\widehat{\theta}_{i,1}| - \alpha)^+ \right)^2$ (see [24] for discussion of the relation between the lasso and the soft-thresholding operator).

Relative to the experiment-level regression of $\widehat{\theta}_{i,2}$ on $\widehat{\theta}_{i,1}$, the individual-level regression in equation (2) requires specifying the form of regularization term (and implicitly, the prior distribution of treatment effects). Inappropriate choices of regularization could lead to suboptimal forms of shrinkage. The L_2 penalty in ridge regression, implying linear shrinkage, may be inappropriate when the distribution of treatment effects is highly non-normal. The experiment-level regression of $\widehat{\theta}_{i,2}$ on $\widehat{\theta}_{i,1}$ requires no such assumptions, and will asymptotically recover the optimal shrinkage with any consistent nonparametric regression technique.

4 EXTENSIONS

4.1 Shrinkage Across Subgroups

Our focus has been on experiment splitting regressions where each data point in the regression corresponds to a separate experiment. We may also wish to perform shrinkage across non-overlapping subgroups of people within an experiment, either instead of, or in addition to, shrinkage across experiments. The experiment splitting methodology extends directly to this setting: instead of i indexing experiments, let i index subgroups (or subgroup by experiment pairs), and the same methodology applies without modification. Subgroup metrics which may be correlated with the magnitude of treatment effects or their sampling error variance, including demographics and subgroup size, are natural covariates to include in the experiment splitting regression.

4.2 Predicting Using Pooled Estimates

A variation on experiment splitting is to estimate $E(\theta_i \mid \widehat{\theta}_{i,1})$ as usual, but to generate predictions of θ_i by evaluating this conditional mean estimate $\widehat{m}$ at the *pooled* estimate $\widehat{\theta}_i$, instead of the subexperiment estimate $\widehat{\theta}_{i,1}$. Intuitively, evaluating $\widehat{m}$ at an estimator with the same mean and a lower variance should improve performance. We find this indeed results in a non-trivial decrease in prediction error in our data, but only if repeated experiment splitting is not already being used. A heuristic explanation can be given in the case of univariate OLS experiment splitting. For simplicity of exposition we assume the prior mean of θ_i to be zero. Let $\mathcal{D}$ denote all experimental data, and $\mathcal{A}$ the random assignments of people to subexperiments. Conditional on the data and averaging over repeated splits, the prediction from repeated experiment splitting as described in Algorithm 2 is $E_{\mathcal{A}}(\widehat{\beta}_1 \widehat{\theta}_{i,1} \mid \mathcal{D}) + O(1/R)$. The average prediction from repeated experiment splitting, evaluating the estimated conditional mean at the pooled mean $\widehat{\theta}_i$, is $E_{\mathcal{A}}(\widehat{\beta}_1 \mid \mathcal{D})\widehat{\theta}_i$. Under standard regularity conditions, for any fixed experiment i, $E_{\mathcal{A}}(\widehat{\beta}_1 \widehat{\theta}_{i,1} \mid \mathcal{D}) = E_{\mathcal{A}}(\widehat{\beta}_1 \mid \mathcal{D}) E_{\mathcal{A}}(\widehat{\theta}_{i,1} \mid \mathcal{D}) + O(1/N_E)$, as the

influence any single experiment has on the estimated regression parameter $\widehat{\beta}_1$ is $O(1/N_E)$. But $E_{\mathcal{A}}(\widehat{\theta}_{i,1} \mid \mathcal{D}) = \widehat{\theta}_i$, so with repeated experiment splitting, the difference between predictions using pooled estimates and predictions using subexperiment estimates must be of order $O(1/R) + O(1/N_E)$.

It may appear that the reason for this lack of performance improvement is that the function $\widehat{m}$, designed as it is for optimally shrinking the subexperiment estimate $\widehat{\theta}_{i,1}$, results in "overshrinking" the more accurate, pooled estimate $\widehat{\theta}_i$. A feasible procedure for transforming an estimate of $E(\theta_i \mid \widehat{\theta}_{i,1})$ into an estimate of $E(\theta_i \mid \widehat{\theta}_i)$ would help avoid this issue. One could estimate the former function by experiment splitting, transform it to an estimate of the latter function, and evaluate the latter function at the pooled estimate, $\widehat{\theta}_i$. It appears that performing this transformation in the general, multi-metric, non-normal case would effectively require estimating the full joint distribution of treatment effects and sampling error.[6] This would void the benefits that shrinkage via experiment splitting has in simplicity and ease of implementation, so we do not pursue this extension here.

5 EMPIRICAL RESULTS

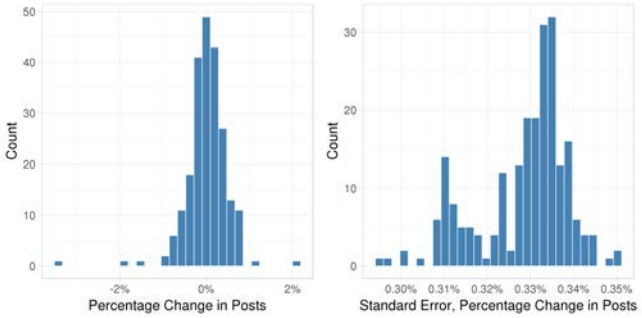
5.1 Data

We study a set of 226 Facebook News Feed A/B tests conducted in 2018.[7] Each A/B test caused a change in the order in which stories appear in News Feed, with the goal of showing users more relevant content first. We analyze a single day's worth of data from each test. The outcome metric we study is the percentage change in posts per person to News Feed in the test group relative to the control group. In addition, for each test we track the percentage change in 23 auxiliary metrics, including likes, comments and link clicks. These will be used as covariates in our regressions, allowing us to make more precise inferences about the percentage change in posts per person. People in each test are randomly assigned with equal probability to the test and control groups. The sample size in each test varies between 10.0 and 10.9 million people.[8]

Figure 3 shows the distributions across experiments of the percentage change in posts, and its standard error. We calculate standard errors using the delta method. The percentage change in posts is non-normal: the Shapiro-Wilk test rejects the null hypothesis of normality with a p-value below 0.01%. This remains true after removing the experiments with a greater than 2% change in absolute value. This suggests that linear shrinkage, as implied by normal treatment effects and normal sampling error (and hence normal observed outcomes), is likely suboptimal.

Figure 4 shows the scatterplot of the percentage change in posts, for the training and validation subexperiments. There are two sets of points. The first is for $\gamma = 0.2$ (a 20%-80% split of data into

Figure 3: Distributions of Estimates and Standard Errors



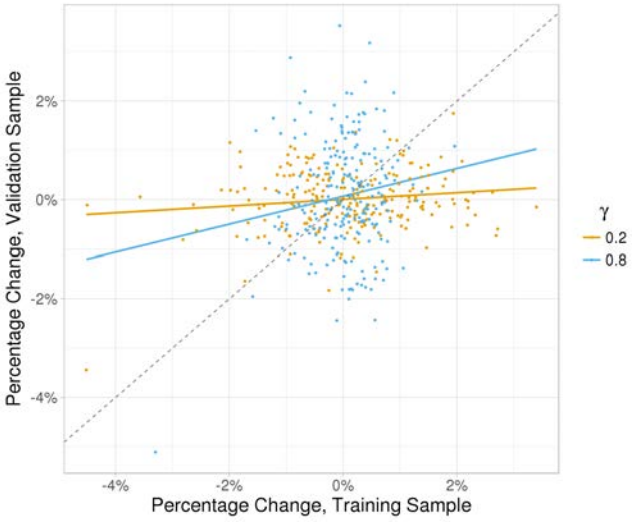


Figure 4: Percentage Change in Posts, $\gamma = 0.2, 0.8$

training and validation sets), and the second is for $\gamma = 0.8$. For each set of points, we plot the OLS line of best fit. The dashed gray line is the 45-degree line. For large N_E, the OLS slope coefficient is approximately $Cov(\widehat{\theta}_{i,2}, \widehat{\theta}_{i,1})/Var(\widehat{\theta}_{i,1}) = \sigma_\theta^2/(\sigma_\theta^2 + \sigma_{\varepsilon_1}^2)$, which is decreasing in $\sigma_{\varepsilon_1}^2$ and less than one.[9] Consistent with this, in Figure 4, increasing γ from 0.2 to 0.8 increases the slope of the line of best fit, but the slope remains less than than one.

5.2 Estimators

The estimators we consider fall into two classes. The first are the experiment splitting estimators, which fit predictive models for the percentage change in posts in the validation subexperiments, given the data from the training subexperiments. The second are the pooling estimators, which combine the data from the training

[6] The special case of a single metric with normal treatment effects and sampling error is straightforward. With a fraction γ of data in the training subexperiment, if $E(\theta_i \mid \widehat{\theta}_{i,1}) = \beta_1 \widehat{\theta}_{i,1}$, then it can be shown that $E(\theta_i \mid \widehat{\theta}_i) = \frac{\beta_1}{\lambda(1-\beta_1)+\beta_1} \widehat{\theta}_i$.

[7] This is a convenience sample, and is not intended to give a representative picture of the effects of News Feed tests generally.

[8] Estimates from smaller experiments should be shrunk more than estimates from larger experiments, all else equal. In practice the variation in sample sizes in this dataset is relatively small, and the gains from including sample size as an additional covariate in our predictive models were minimal.

[9] If $\gamma = 0.5$, the training and validation datasets have the same distributions, and it might be supposed that, by symmetry, the line of best fit through the scatterplot must have a slope of approximately one. This intuition is incorrect, as the formula for the slope coefficient shows.

and validation experiments. In either case we measure estimator performance by calculating the squared distance between estimator predictions and the percentage change in posts in the test subexperiments, on average across all experiments, as in Algorithm 1.

Experiment Splitting Estimators. The experiment splitting estimators all predict the percentage change in posts for the validation subexperiments. The estimators differ in the prediction algorithm used, and the covariates included. The covariates are either the percentage change in posts for the training subexperiments, or the percentage changes in all metrics in the training subexperiments. The predicted values from the estimated models provide the estimated treatment effect for each experiment. We study the following experiment splitting estimators.[10]

- *Univariate OLS*: Linear regression on a constant and the percentage change in posts in the training subexperiments.
- *Univariate Loess*: Locally quadratic regression, using the same regressors as univariate OLS.
- *Multivariate OLS*: Linear regression, using the percentage change in all metrics (posts, and all 23 auxiliary metrics) in the training subexperiments as predictors.
- *Lasso*: Lasso, using the same predictors as multivariate OLS.

In addition, we study the repeated experiment splitting versions of the above estimators, with R, the number of times the training and validation data is repeatedly split, equal to 10. Larger values of R result in only minimal improvements in estimator performance. The tuning parameters required for the loess and lasso models are selected by experiment-level cross-validation on the union of the training and validation data.

Pooling Estimators. The pooling estimators combine training and validation data. Unlike experiment splitting, which uses the validation observations to construct the outcomes and the training observations to construct the predictors, the pooling estimators make no distinction in which sample an observation is from.

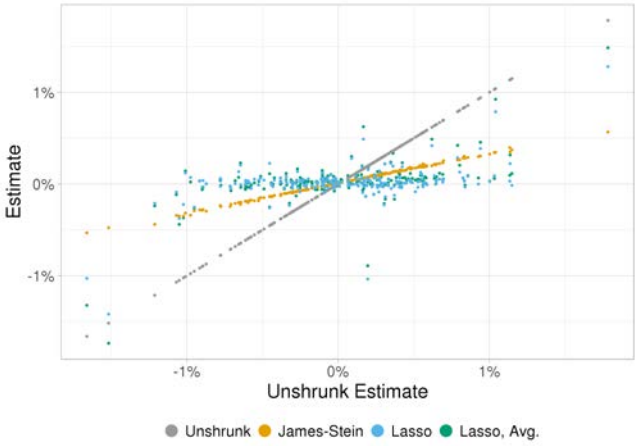
- *Unshrunk*: The percentage change in posts in the combined training and validation test group, relative to the combined training and validation control group.
- *James-Stein*: The James-Stein type method of moments estimator described in [9], which allows for heteroskedastic sampling error.
- *Tweedie*: The nonparametric estimator based on equation (1), using Lindsey's method to estimate the density, as in [16].

Figure 5 plots the unshrunk treatment effect estimates against the unshrunk, James-Stein, lasso without repeated splits, and lasso with repeated splits estimators. The splitting estimators are calculated with $\gamma = 0.2$. By construction, the unshrunk points lie on the 45-degree line. The other estimators tend to shrink the unshrunk estimates towards the overall mean, but do so in different ways. James-Stein is an almost linear function of the unshrunk estimates, with a slope of less than one.[11] The lasso estimators are not smooth functions of the unshrunk estimator, reflecting the influence of auxiliary metrics. They sometimes shrink more and sometimes less

[10] Random forests and gradient boosted decision trees perform worse than multivariate OLS and lasso, and are omitted from the results.

[11] The James-Stein estimates are not exactly linear in the unshrunk estimates, because of the adjustment for heteroskedasticity, as in [9].

Figure 5: Unshrunk vs. Other Estimators, $\gamma = 0.2$



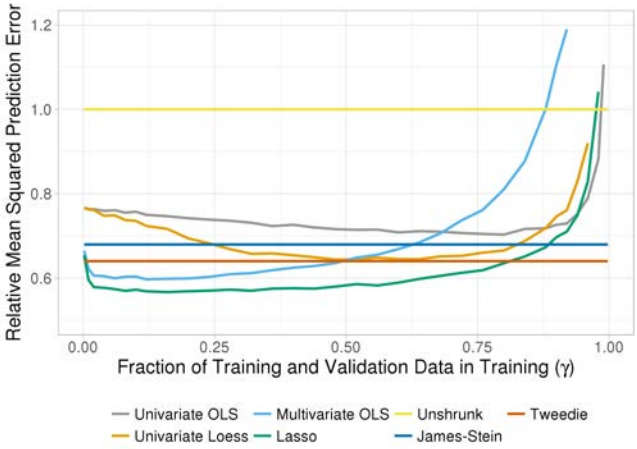


Figure 6: Pooled and Single Split Estimators, Error

than the James-Stein estimates, but on average both have larger variance than James-Stein.

Figure 6 shows the prediction errors for the basic experiment splitting estimators, and Figure 7 shows the prediction errors for the experiment splitting estimators with averaging over repeated splits. Both figures also show the three pooling estimators. The prediction errors are calculated as in Algorithm 1, with the number of splitting simulations S set to 100. The unshrunk estimator performs quite poorly. James-Stein shrinkage reduces mean squared prediction error (MSPE) by 32% relative to the unshrunk case. The non-normal distribution of effect sizes in Figure 3 suggests that Tweedie's estimator, which can adapt to a non-normal distribution of the truth, θ_i, should outperform James-Stein. This is indeed the case, with Tweedie having a 6% lower MSPE than James-Stein.

The unaveraged estimators, with the exception of univariate OLS, all perform better than James-Stein for an appropriately chosen

Figure 7: Pooled and Repeated Split Estimators, Error

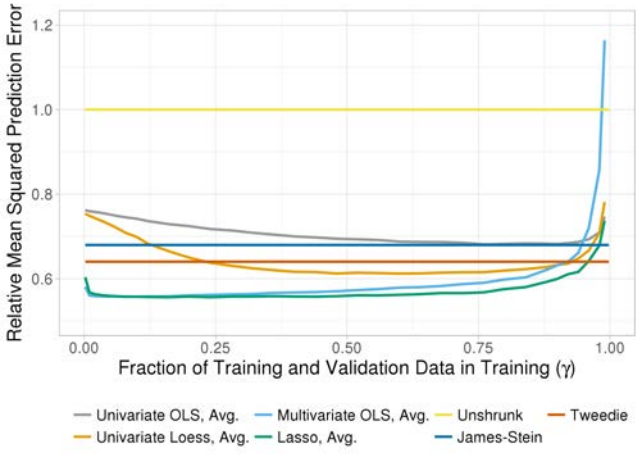

Table 1: Relative MSPE and Standard Errors, $\gamma = 0.24$

Estimator	Relative MSPE	Std. Error
Unshrunk	1.000	0.009
James-Stein	0.680	0.006
Tweedie	0.640	0.006
Univariate OLS	0.739	0.006
Univariate OLS, Avg.	0.717	0.006
Univariate Loess	0.682	0.006
Univariate Loess, Avg.	0.638	0.006
Multivariate OLS	0.603	0.006
Multivariate OLS, Avg.	0.562	0.005
Lasso	0.570	0.005
Lasso, Avg.	0.556	0.005

value of γ. Of particular note are the multivariate models, multivariate OLS and lasso. One might expect the comovements in auxiliary metrics to be informative: intuitively, if a experiment shows a large movement on the metric of interest, but not on auxiliary metrics which tend to covary with the metric of interest, we might infer that the large movement is likely a false positive due to sampling error. Indeed, the multivariate OLS and lasso estimators perform well. At their optimal splitting fractions they improve on the unshrunk estimator by 40% and 43%, and on Tweedie by 7% and 11%. This implies that our inferences about changes in posts can be much improved by taking into account how *other* metrics have changed, because of the correlation between the true treatment effects for posts and for other metrics. Thus experimental analyses which analyze one metric in isolation, without taking into account the comovements in other, related metrics may be quite suboptimal.

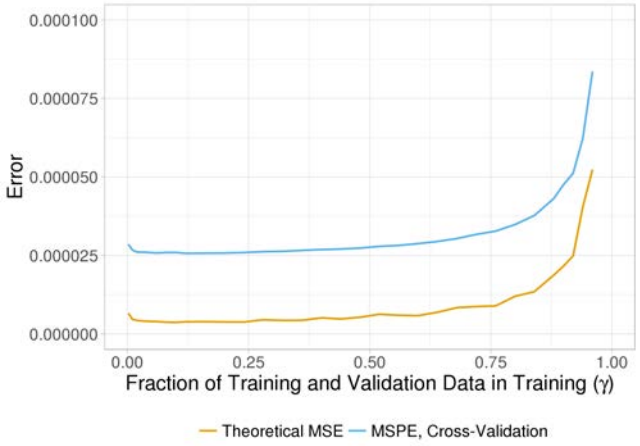
The MSPEs of the estimators which average over repeated splits are uniformly lower than their unaveraged counterparts. Repeated splitting reduces the minimum MSPE of multivariate OLS and lasso by 7% and 2%. The best performing estimator is the lasso averaged over repeated splits. It improves on the unshrunk estimator's MSPE by 44%, on James-Stein by 18%, and on Tweedie by 13%, and its minimum MSPE is reached at $\gamma = 0.24$. Table 1 shows all estimators' MSPE relative to the unshrunk estimator at $\gamma = 0.24$, along with standard errors summarizing statistical uncertainty caused by the finite number of splitting simulations, $S = 100$.

Table 2: Cumulative Treatment Effects, $\gamma = 0.24$

Estimator	Top 1%	Top 5%	Top 10%	All Positive
Unshrunk	0.81%	2.63%	4.36%	11.20%
Lasso, Avg.	2.34%	6.27%	6.83%	15.66%

Figure 6 also shows that choosing precisely the right γ for the multivariate repeated experiment splitting estimators is not necessary in order to obtain large performance improvements relative to the pooling estimators. This is especially true for the repeated lasso splitting estimator, as both averaging and the regularization of the lasso penalty have the effect of reducing the sensitivity of MSPE to the splitting fraction, γ. The repeated splitting lasso estimator has a roughly constant error for $\gamma \in [0.05, 0.75]$. By contrast the performance of the univariate OLS and loess estimators are considerably more sensitive with respect to γ, and their optimal γ is larger.

Some distinctive patterns in Figures 6 and 7 are the relatively flat MSPE curves for the lasso, and the observation that repeated splitting does not much decrease the lasso's minimal RMPSE. These features are consistent with a data generating process in which lifts in the most important covariates are precisely estimated, for any reasonable sample size. This implies that for γ above a small threshold, those covariate values will change little. If the error in the outcome variable is not too large (γ is not too close to one), the lasso gives high quality predictions, which will vary little both as a function of γ, and across repeated experiment splits.



The purpose of A/B tests is typically to identify and launch the best performing treatments. Consequently MSPE may not be the most relevant evaluation criterion for practitioners. Instead, the key desideratum for an estimator may be whether the experiments it ranks highest do indeed have relatively large treatment effects. We can assess this by selecting the most promising experiments, as ranked by a given estimator, and evaluating their performance on the out-of-sample, test subexperiments. Table 2 shows that repeated lasso, the best performing estimator by MSPE, also performs well according to this criterion. The top 10% of experiments, as ranked by the unshrunk estimator, have a cumulative treatment effect of 4.36%.[12] The corresponding figure for the lasso is 57% higher, at 6.83%. The relative difference between the lasso and unshrunk estimators are even more pronounced in the far right tail, as the columns for the top 5% and top 1% of experiments show. Launching all estimates with a positive estimated treatment effect gives an estimated cumulative lift of 11.20% for the unshrunk estimator, while the figure for the lasso is 40% higher, at 15.66%.[13]

Proposition 1 allows us to estimate the mean squared error of the multivariate OLS experiment splitting estimator as a function of γ.

[12]The James-Stein estimator performs very similarly to the unshrunk estimator, as it results in almost the same ordering of experiments.

[13]The repeated lasso outperforms all other experiment splitting estimates according to all criteria in Table 2 except "Top 10%", where it is second to repeated multivariate OLS, which has a marginally higher cumulative treatment effect of 6.84%.

Figure 8: Multivariate OLS Error Estimates

This can be compared to the prediction error of multivariate OLS as computed by the cross-validation procedure of Algorithm 1. The latter is larger than the former for all γ, as it measures prediction error relative to the *estimated effects* in the test subexperiments, rather than error relative to the truth. However, Figure 8 indicates that estimating the optimal γ according to Proposition 1 performs comparably to cross-validation.

6 CONCLUSION

Inference on a particular metric and experiment can generally be improved by borrowing strength both across other experiments and other metrics. Experiment splitting provides a easily implementable methodology for realizing these performance gains, by transforming the problem of developing an appropriate shrinkage estimator into a simple prediction problem. In our sample of Facebook News Feed A/B tests, experiment splitting outperforms unshrunk estimators and conventional shrinkage estimators, especially after incorporating information from comovements in other metrics related to the outcome of interest. While our focus has been on average treatment effects in the context of experimentation, analogous "shrinkage via sample splitting" techniques are likely to be useful in causal inference more generally, with potential applications to estimating quantile treatment effects, local average treatment effects given instrumental variables, and average treatment effects under unconfoundedness.

APPENDIX

Proof of Proposition 1.

We have $\sum_{i=1}^{N_E} E(\theta_i - X_i'\widehat{\beta})^2 = N_E\sigma_{\varepsilon_2}^2 + \sum_{i=1}^{N_E} E(\widehat{\theta}_{i,2} - X_i'\widehat{\beta})^2 - 2\sum_{i=1}^{N_E} E\left(\varepsilon_{i,2}(\widehat{\theta}_{i,2} - X_i'\widehat{\beta})\right)$. Collect the $\widehat{\theta}_{i,2}$ and $\varepsilon_{i,2}$ observations across experiments i into the N_E-vectors $\widehat{\boldsymbol{\theta}}_2$ and $\boldsymbol{\varepsilon}_2$. Define the matrix $M = I - X(X'X)^{-1}X'$, with elements m_{ij}. Then

$$\begin{aligned} E\sum_{i=1}^{N_E} \varepsilon_{i,2}(\widehat{\theta}_{i,2} - X_i'\widehat{\beta}) &= E(\boldsymbol{\varepsilon}_2' M \widehat{\boldsymbol{\theta}}_2) \\ &= E\left\{E\left(\sum_i m_{ii}\varepsilon_{i,2}\widehat{\theta}_{i,2} \mid M\right)\right\} \\ &= E\left\{\sum_i m_{ii}\sigma_{\varepsilon_2}^2\right\} \\ &= \sigma_{\varepsilon_2}^2 E(\mathrm{tr}(M)) \\ &= (N_E - l)\sigma_{\varepsilon_2}^2. \end{aligned}$$

Hence $\sum_{i=1}^{N_E} E(\theta_i - X_i'\widehat{\beta})^2 = \left(\sum_{i=1}^{N_E} E(\widehat{\theta}_{i,2} - X_i'\widehat{\beta})^2\right) - (N_E - 2l)\sigma_{\varepsilon_2}^2$.

Proof of Corollary 1.

From standard results on the relation between the variance of regression residuals and the variance of regression errors (e.g. [25]),

$$\sum_{i=1}^{N_E} E(\widehat{\theta}_{i,2} - \widehat{\beta}_0 - \widehat{\beta}_1\widehat{\theta}_{i,1})^2 = (N_E - 2)E(\widehat{\theta}_{i,2} - \beta_0 - \beta_1\widehat{\theta}_{i,1})^2.$$

Further,

$$\begin{aligned} E(\widehat{\theta}_{i,2} - \beta_0 - \beta_1\widehat{\theta}_{i,1})^2 &= Var(\widehat{\theta}_{i,2}) - \frac{Cov^2(\widehat{\theta}_{i,2}, \widehat{\theta}_{i,1})}{Var(\widehat{\theta}_{i,1})} \\ &= \sigma_\theta^2 + \sigma_{\varepsilon_2}^2 - \frac{\sigma_\theta^4}{\sigma_\theta^2 + \sigma_{\varepsilon_1}^2}. \end{aligned} \tag{3}$$

The first equality follows from $\beta_1 = Cov(\widehat{\theta}_{i,2}, \widehat{\theta}_{i,1})Var(\widehat{\theta}_{i,1})^{-1}$, and the second from independence of sampling errors and treatment effects. Combining equation (3) and Proposition 1 gives the result.

Proof of Proposition 2.

With fractions γ and $1-\gamma$ of data in the training and validation subexperiments, we have $\sigma_{\varepsilon_1}^2 = \sigma_\varepsilon^2/\gamma$ and $\sigma_{\varepsilon_2}^2 = \sigma_\varepsilon^2/(1-\gamma)$. Define

$$h(\gamma, \sigma_\varepsilon^2, \sigma_\theta^2, N_E) = \frac{(N_E - 2)\sigma_\theta^2\sigma_\varepsilon^2/\gamma}{\sigma_\theta^2 + \sigma_\varepsilon^2/\gamma} + \frac{\sigma_\varepsilon^2}{(1-\gamma)}.$$

By Corollary 1, the problem of minimizing the mean squared error is $\min_{\gamma\in[\underline{\gamma},\overline{\gamma}]} h(\gamma, \sigma_\varepsilon^2, \sigma_\theta^2, N_E)$. Some calculations show

$$\frac{\partial h}{\partial \gamma} = \sigma_\varepsilon^2\left(\frac{1}{(1-\gamma)^2} - \frac{(N_E - 2)\sigma_\theta^4}{(\sigma_\varepsilon^2 + \gamma\sigma_\theta^2)^2}\right), \tag{4}$$

$$\frac{\partial^2 h}{\partial \gamma^2} = 2\sigma_\varepsilon^2\left(\frac{(N_E - 2)\sigma_\theta^6}{\left(\sigma_\varepsilon^2 + \gamma\sigma_\theta^2\right)^3} + \frac{1}{1-\gamma^3}\right). \tag{5}$$

From equation (5), $\frac{\partial^2 h}{\partial \gamma^2} > 0$. By convexity of h in γ, if $\left.\frac{\partial h}{\partial \gamma}\right|_{\gamma=\overline{\gamma}} < 0$ then $\gamma^* = \overline{\gamma}$, and if $\left.\frac{\partial h}{\partial \gamma}\right|_{\gamma=\underline{\gamma}} > 0$ then $\gamma^* = \underline{\gamma}$. Otherwise γ^* solves $\left.\frac{\partial h}{\partial \gamma}\right|_{\gamma=\gamma^*} = 0$. The limiting behavior of γ^* follows from these observations and equation (4). For large N_E, $\left.\frac{\partial h}{\partial \gamma}\right|_{\gamma=\overline{\gamma}} < 0$ and so $\lim_{N_E\to\infty} \gamma^* = \overline{\gamma}$. Arguments for limits wrt σ_θ^2 and σ_ε^2 are similar.

ABSTRACT

This paper introduces an active-learning-based truth estimator for social networks, such as Twitter, that enhances estimation accuracy significantly by requesting a well-selected (small) fraction of data to be labeled. Data assessment and truth discovery from arbitrary open online sources are a hard problem due to uncertainty regarding source reliability. Multiple truth finding systems were developed to solve this problem. Their accuracy is limited by the noisy nature of the data, where distortions, fabrications, omissions, and duplication are introduced. This paper presents a semi-supervised truth estimator for social networks, in which a portion of inputs are carefully selected to be reliably verified. The challenge is to find the subset of observations to verify that would maximally enhance the overall fact-finding accuracy. This work extends previous passive approaches to recursive truth estimation, as well as semi-supervised approaches where the estimator has no control over the choice of data to be labeled. Results show that by optimally selecting claims to be verified, we improve estimated accuracy by 12% over unsupervised baseline, and by 5% over previous semi-supervised approaches.

1 INTRODUCTION

This paper presents an active-learning based truth estimator for data collected on social media. We envision scenarios, such as disaster response, where a large number of unvetted local sources make claims about the state of events, possibly combining fact with rumor. A claim, in this paper, refers to the statement of a tweet, or a similar expression of fact (on social media) that may be correct or not. A major challenge in consuming such social media feeds lies in uncertainty regarding source reliability and thus difficulty assessing correctness of claims. Online sources who contribute the information are often unknown or have little prior reputation to consider. The problem becomes: is it possible to correctly filter true observations from the collective output of online sources of unknown reliability?

Our estimator computes, for each reported claim, the probability that the claim is correct. The estimator is novel in that it selects some well-chosen small subsets of claims for verification. We assume that another mechanism is available to verify the selected claims (i.e., give the estimator their ground-truth true/false label). Presumably, this external mechanism is costly and so has to be applied with care, which motivates the problem of selecting the best claims to verify from the perspective of maximally improving the overall accuracy of our estimator.

We extend a large body of work on fact-finding [5, 12, 14, 15, 19, 20] that estimates the reliability of sources iteratively with assessing the veracity of claims over the *entire* data set. We build on a state of the art estimator [3] that considers sources with significant error correlations. Those correlations arise from the *open* nature of online data. That is to say, sources are not independent. They can see each other's outputs and may occasionally copy others. Source non-independence creates opportunities for the spread of data contamination, as bad data (e.g., rumors) can be copied from one source to another. The non-independence of online open sources calls for estimators, such as the one used in this paper, that explicitly take source dependencies into account.

Finally, our estimator is unique in finding pivot observations whose true/false values, if verified, would maximally improve overall fact-finding accuracy. It selects a small set of pivot observations from the large volume of inputs for an external party (e.g., a human) to label. These labeled observations are then reinserted into the estimator to maximally improve its accuracy. The size of the pivot set can be either pre-defined or adjusted on the run. As shown in the evaluation, the above active selection of best observations to verify improves over semi-supervised approaches that do not have control over which claims are verified, or that use uncertainty in truth value alone as the basis for selection. To the authors' knowledge, ours is the first *semi-supervised* truth estimator for social media that *actively learns* the most judicious data claims to label (while accommodating non-independent sources).

We evaluate our truth estimator using both simulations and real data. We show that our approach significantly outperforms several baselines in a wide range of experimental conditions.

The rest of this paper is organized as follows. Section 2 describes the data model and problem statement. Section 3 presents the active-learning-based truth estimation algorithm. Section 4 evaluates the accuracy of estimation results using simulations. Section 5 presents empirical evaluation results. Observations and limitations are discussed in Section 6. Section 7 summarizes related work.

2 MODEL AND PROBLEM STATEMENT

Our active-learning truth estimator integrates social sensing data with human supervision to estimate the probability of correctness of individual claims. Unsupervised truth estimators of social network posts are constrained by uncertainty in reliability of arbitrary online sources. To improve accuracy over previous work, we allow for verifying a small faction ($< 5\%$) of social media posts. Our algorithm adopts an active learning structure that automatically determines the best set of posts to verify.

Let the set of all data sources be denoted by $\mathcal{S}$, where $|\mathcal{S}| = n$. The observations they make constitute the set of assertions, denoted by C, where $|C| = m$. The ith source and the jth assertion are referred to as $S_i \in \mathcal{S}$ and $C_j \in C$, where $i \in \{1, 2, \cdots, n\}$ and $j \in \{1, 2, \cdots, m\}$. The act of making an assertion by a specific source is called a *claim*. If source S_i makes an assertion C_j, we say logically that S_i claims $C_j = True$, denoted by claim $S_iC_j = 1$. The same assertion can be made by multiple sources at different times. The set of all claims made by all sources is represented by source claim matrix $\mathcal{SC}$, where each element is of the form $S_iC_j = value$, where $value = 1$ if source S_i makes claim $C_j = 1$ and $value = 0$ otherwise. Note that, the only natural language processing needed in this paper is to identity similar claims made by multiple sources and cluster them into one assertion. In this paper, we use simple cosine similarity between tweets as a distance metric. Previous work suggested that cosine similarity is sufficient for Twitter data[18]. Hence, clusters of tweets that are sufficiently close by this metric are considered to make the same assertion.

Our active-learning truth estimator selects a set of assertions to label by an external (accurate) entity in order to improve accuracy. Note that, we only verify a small ratio ($< 5\%$) of total assertions. Verification can incur human labor and cost, which should be kept as low as possible. Let us denote the set of labeled assertions as set $\bar{C}$, the size of labeled assertions as V, verification result as $\mathcal{V}$, in which $\mathcal{V}_j = 1$ and 0 means the verification result of assertion j is *True* and *False*, respectively. In this paper, we assume that human participants who verify $\bar{C}$ have full access to ground truth, such that all the labeled data are accurate. Our algorithm automatically estimates the best set of assertions to verify, which means the set $\bar{C}$ is not preset and is derived on the run.

Since we assume that sources are open (and hence their outputs can be seen by other sources), in general, a source may report something original or may copy an observation posted by others. This copying behavior is very common today on social media, causing fast spread of rumors and misinformation. If source S_a occasionally copies from source S_b, we say that S_a is *influenced* by S_b. Prior literature described algorithms for empirically detecting the existence of influence (manifesting in copying behavior) among sources [9]. Intuitively, these algorithms infer influence from unusual correlations among source outputs much in the same way cheating can be detected from correlated answers on exams. Since data are time-stamped, the direction of influence can be estimated, assuming that data published earlier influences data published later.

Table 1: List of Parameters

$\mathcal{S}$	Set of all sources
C	Set of all assertions
n	# sources
m	# claims
$\mathcal{SC}$	Source-claim matrix
$\bar{C}$	Set of labeled assertions
$\tilde{C}$	Set of unlabeled assertions
$\mathcal{V}$	Set of verification results
V	Number of labeled assertions
$\mathcal{Z}$	Estimated values of assertions
$\mathbf{A}$	Source original claim probability matrix
$\mathbf{P}$	Source dependent claim probability matrix
G	Influence network
$\mathbf{D}$	Dependency matrix
θ	Set of unknown parameters

We therefore assume the existence of an observed influence network, G, where nodes represent individual sources and directional edges denote the direction of influence between them. Note that, the existence of an edge in G between a parent node and a child node does not mean that the child always copies from the parent. It merely means that *some* claims of the child may be copied from the parent.

A claim S_iC_j is called original if no ancestors of S_i in the influence network, G, made the same claim with an earlier timestamp. Otherwise, we say the claim is dependent (meaning it might have been copied because an ancestor of node S_i in the influence graph made the same claim earlier). We use the indicator D_{ij} to denote claim dependencies. Specifically, $D_{ij} = 0$ indicates that claim S_iC_j is original. $D_{ij} = 1$ means the claim is dependent.

We use $\tau(C_j)$ to denote the actual truth value of assertion C_j. The goal is to identify the truth value of all observed assertions and select the best set of assertions to verify, given the source claim matrix $\mathcal{SC}$ and influence graph G.

3 EXPECTATION MAXIMIZATION FRAMEWORK OVERVIEW

3.1 Solution Overview

The estimator uses an expectation maximization framework that maximizes a pre-defined likelihood function. The algorithm jointly estimates source reliability and claim correctness, then uses estimates to select a set of assertions for human participants to verify. The labeled assertions are then combined with unlabeled data to compute improved estimates via EM framework.

Let $\mathcal{SC}$ denote the set of claims made in the interested interval. $\mathcal{S}$ and C are the corresponding sets of sources (who reported observations) and measured assertions (for which values were reported

in time-slot), respectively. Our goal is to estimate the truth value $\tau(C_j)$ for every assertion C_j, as well as to update the reliability of each source. We introduce two sets of parameters to characterize the behavior of sources. Specifically, for each source i:

- Let $\mathbf{A}^i$ denotes the *original claim probability* matrix, in which the entry $\mathbf{A}^i_{pq} = P(S_iC_j = p|\tau(C_j) = q, \mathbf{D}_{ij} = 0)$ denotes the probability that source S_i claims that assertion C_j has value p, when the ground truth value is q and the claim is original.
- Let $\mathbf{P}^i$ denotes the *dependent claim probability* matrix, in which the entry $\mathbf{P}^i_{pq} = P(S_iC_j = p|\tau(C_j) = q, \mathbf{D}_{ij} = 1)$ denotes the probability that source S_i claims that assertion C_j has value p, when the ground truth is q, and given that some ancestor of S_i in the influence graph, G, claimed $C_j = p$ earlier.

The estimated value of assertion C_j is denoted by the vector $\mathcal{Z}_j$. For a binary assertion, $\mathcal{Z}_j = \{z_{j,0}, z_{j,1}\}$, where $z_{j,q} = P(\tau(C_j) = q)$, is the probability that C_j has value q. The active-learning truth estimator proceeds in three stages:

- Estimating the true value of each assertion C_j and the reliability of each source S_i by EM framework: the estimator adapts an expectation maximization (EM) algorithm to jointly estimate reliability parameters of sources and truth values of variables from data. Given the claims made by sources, denoted by matrix $\mathcal{SC}$, and the source dependency matrix $\mathbf{D}$, the EM algorithm outputs the reliability for each source $S_i \in \mathcal{S}$ and the estimated truth value of each assertion $C_j \in C$. Note that, those estimates are unsupervised (No verification is involved in this step). They remain to be fused with a set of verified assertions, which are selected in next step.
- Selecting a set of assertions of size V to verify: Our truth estimator is blinded to ground truth (We do not have access to ground truth until we output the verification set). To estimate the optimal set of assertions to verify, we use the likelihood function as metric: the set which maximizes the likelihood function is selected. Note that, we do not have access to ground truth in this step, which means we have no information on verification results. Thus, for each assertion to verify, we need to estimate the effect of both *True* and *False*. Expected likelihood is then computed by averaging over all verification results. The probability of verification results is derived from truth estimates in step 1. The algorithm iterates through every possible sets of assertions to derive the optimal set. In later section, we also propose an heuristic approximation to dramatically reduce computation cost.
- Re-estimating truth value of assertions and reliability of sources with labeled data. After obtaining verification results from human participants, we combine labeled assertion with unlabeled ones to update our estimation via semi-supervised EM framework.

The above three steps are discussed in the following three subsections respectively.

3.2 Estimating Truth Value and Source Reliability via EM Framework[14]

Let us define the concatenation of source parameter matrices, $\mathbf{A}^i$ and $\mathbf{P}^i$, as the unknown parameter set $\boldsymbol{\theta}$ to be estimated. We adapt an expectation maximization algorithm to estimate these parameters based on matrix $\mathcal{SC}$ collected in the interested interval. The expectation maximization likelihood is formulated as log likelihood of observation matrix:

$$\theta_{MAX} = argmax_{\boldsymbol{\theta}}\{\log(\mathbb{P}(\mathcal{SC}|\boldsymbol{\theta}, \mathbf{D}))\} \tag{1}$$

The expected likelihood of observation matrix is formulated as multiplication of assertions:

$$\mathcal{L} = \mathbb{E}_{\boldsymbol{\theta}}[\mathbb{P}(\mathcal{SC}|\boldsymbol{\theta}, \mathbf{D})] = \prod_{C_j \in C} \sum_{q=0}^{v} \mathbb{P}(SC_j, C_j = q|\boldsymbol{\theta}, \mathbf{D})$$

$$= \prod_{C_j \in C} \sum_{q=0}^{v} \mathbb{P}(SC_j|C_j = q, \boldsymbol{\theta}, \mathbf{D})\mathbb{P}(C_j = q|\boldsymbol{\theta}, \mathbf{D}) \tag{2}$$

where v is the largest value for an assertion. For example, in the binary case, an assertion can take either the value 0 or 1. Hence, $v = 1$. SC_j is the jth column of SC, representing all the claims made on assertion j. $\mathbb{P}(SC_j|C_j = q, \boldsymbol{\theta}, \mathbf{D})$ represents the collective probability of all claims that said assertion $C_j = q$. It can be expressed as multiplication of all sources who made claims to assertion j:

$$\mathbb{P}(SC_j|C_j = q, \boldsymbol{\theta}, \mathbf{D}) = \prod_{S_i \in \mathcal{S}_j} \mathbb{P}(S_iC_j|C_j = q, \boldsymbol{\theta}, \mathbf{D}_{ij}) \tag{3}$$

where

$$\mathbb{P}(S_iC_j|C_j, \boldsymbol{\theta}, \mathbf{D}_{ij}) = \begin{cases} \mathbf{A}^i_{pq} & C_j = q, S_iC_j = p, \mathbf{D}_{ij} = 0 \\ \mathbf{P}^i_{pq} & C_j = q, S_iC_j = p, \mathbf{D}_{ij} = 1 \end{cases} \tag{4}$$

are the source reliability parameters.

Using E-step and M-step of standard EM-algorithm, we get the following iterative updates:

$$\mathcal{Z}_{j,p} = \frac{B_p}{\sum_{q=1}^{v} B_q}$$

$$\mathbf{A}^i_{pq} = \frac{\sum_{S_iC_j=p, \mathbf{D}_{ij}=0} z_{j,q}}{\sum_{S_iC_j, \mathbf{D}_{ij}=0} z_{j,q}}$$

$$\mathbf{P}^i_{pq} = \frac{\sum_{S_iC_j=p, \mathbf{D}_{ij}=1} z_{j,q}}{\sum_{S_iC_j, \mathbf{D}_{ij}=1} z_{j,q}} \tag{5}$$

where

$$B_p = \prod_{q=1}^{v} \prod_{S_iC_j=q} \mathbb{P}(S_iC_j|C_j = p) \tag{6}$$

The EM framework then iteratively updates the above formula until they converge.

3.3 Selecting Set of Assertions to Verify

Providing the estimated truth values via expectation maximization framework, we derive the set of verified assertions that maximize the expectation maximization likelihood. Let $\tilde{C}$ denote the set of labeled claims, $\bar{C}$ be the set of unlabeled claims, $\bar{C} = C - \tilde{C}$. $\mathcal{V}$ denotes the set of verification result, in which $\mathcal{V}_j \in \mathcal{V}$ is the verified

Algorithm 1 Semi-supervised Expectation Maximization

Input: Source-Claim matrix SC
Initialize $\boldsymbol{\theta}^{(0)}$, $\mathcal{Z}^{(0)}$, $\tilde{\boldsymbol{\theta}}^{(0)}$, $\mathcal{L}$ and $\tilde{C}$
while $\boldsymbol{\theta}^{(r)}$ does not converge **do**
  for C_j in C **do**
    Compute probability: $\mathbb{P}(S_iC_j|C_j, \boldsymbol{\theta}^{(r+1)}, \mathbf{D})$ according to (3)
  end for
  for S_i in S **do**
    Estimate parameters: $\mathbf{A}_{pq}^{i,(r+1)}$, $\mathbf{P}_{pq}^{i,(r+1)}$ and $\mathcal{Z}_j^{(r+1)}$ according to (5)
  end for
end while
Update EM likelihood $\mathcal{L}$ according to (2)
for $C' \subset C, |C'| = V$ **do**
  Compute expected likelihood estimation $\mathcal{L}_{C'}$ according to (12)
  if $\mathcal{L}_{C'} > \mathcal{L}$ **then**
    $\mathcal{L} = \mathcal{L}_{C'}$
    $\tilde{C} = C'$
  end if
end for
Label $\tilde{C}$ by human participants
while $\tilde{\boldsymbol{\theta}}^{(r)}$ does not converge **do**
  for C_j in C **do**
    Update parameters $\mathbf{A}_{pq}^{i,(r+1)}$, $\mathbf{P}_{pq}^{i,(r+1)}$ and $\mathcal{Z}_j^{(r+1)}$ according to (13)(14)
  end for
end while
Output: $\mathbf{A}_{pq}^{i}$, $\mathbf{P}_{pq}^{i,(r+1)}$ and $\mathcal{Z}_j^{k}$
END

result of assertion j. The expected complete data log likelihood conditioning on verification result $\mathcal{V}$ can be written as:

$$\begin{aligned} Q_{\mathcal{V}} &= \mathbb{E}_{\boldsymbol{\theta}_{\mathcal{V}}}[\log \mathbb{P}(SC|\boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V})] \\ &= \sum_{C_j \in \tilde{C}} \sum_{q=0}^{v} \mathbb{P}(C_j = q|\boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \log \mathbb{P}(SC_j|C_j = q, \boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \\ &= \sum_{C_j \in \tilde{C}} \sum_{q=0}^{v} \mathbb{P}(C_j = q|\boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \log \mathbb{P}(SC_j|C_j = q, \boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \\ &+ \sum_{C_j \in \bar{\tilde{C}}} \sum_{q=0}^{v} \mathbb{P}(C_j = q|\boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \log \mathbb{P}(SC_j|C_j = q, \boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \end{aligned} \tag{7}$$

in which first term is the log likelihood of labeled assertions, the probability of assertion j of value q is

$$\mathbb{P}(C_j = q|\boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) = \begin{cases} 1 & q = \mathcal{V}_j \\ 0 & q \neq \mathcal{V}_j \end{cases} \tag{8}$$

The second term is the log likelihood of unlabeled assertions, it is derived according to EM algorithm described in section 3.2. The semi-supervised expectation maximization likelihood is then formulated as:

$$\begin{aligned} Q_{\mathcal{V}} = &\sum_{C_j \in \tilde{C}} \sum_{q=0}^{v} \mathbb{P}(C_j = q|\boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \log \mathbb{P}(SC_j|C_j = q, \boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \\ &+ \sum_{C_j \in \bar{\tilde{C}}} \mathbb{P}(C_j = \mathcal{V}_j|\boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \log \mathbb{P}(SC_j|C_j = \mathcal{V}_j, \boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \end{aligned} \tag{9}$$

Our goal is to estimate the set of labeled assertions that achieve best semi-supervision results. To maximize the above likelihood over all possible combinations of labeled assertions, we adopt linear programming to estimate semi-supervised EM. The main observation is: Given the bipartite $\mathcal{SC}$ graph, as we verify an assertion (change from estimated truth value to ground truth), the reliability estimates of sources that make claims on the verified assertion are explicitly influenced: those sources gain higher reliability estimates since they correctly claim the verified assertion, while other sources slightly lose reliability estimates depending on their speak rates. As source reliability estimates change, other assertions are indirectly influenced. It can in turn affects more sources, however the changes are minimal. Thus in verification selection, we assume the estimated truth of non-verified assertions remain unchanged, which enables linear programming to simplify the above EM likelihood. The simplified log likelihood conditioning on $\mathcal{V}$ is:

$$\begin{aligned} Q_{\mathcal{V}} = &\sum_{C_j \in \tilde{C}} \sum_{q=0}^{v} \mathbb{P}(C_j = q) \log \mathbb{P}(SC_j|C_j = q, \boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \\ &+ \sum_{C_j \in \bar{\tilde{C}}} \mathbb{P}(C_j = \mathcal{V}_j|\boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \log \mathbb{P}(SC_j|C_j = \mathcal{V}_j, \boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \\ = &\sum_{C_j \in \tilde{C}} \sum_{S_i \in \mathcal{SC}_j} \sum_{q=0}^{v} \mathbb{P}(C_j = q) \log \mathbb{P}(S_iC_j|C_j = q, \boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \\ &+ \sum_{C_j \in \bar{\tilde{C}}} \sum_{S_i \in \mathcal{S}_j} \mathbb{P}(C_j = \mathcal{V}_j|\boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \log \mathbb{P}(S_iC_j|C_j = \mathcal{V}_j, \boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) \end{aligned} \tag{10}$$

where $\mathbb{P}(C_j = q)$ is estimated in previous section 3.2, and

$$\mathbb{P}(S_iC_j|C_j, \boldsymbol{\theta}_{\mathcal{V}}, \mathbf{D}, \mathcal{V}) = \begin{cases} \mathbf{A}^i_{pq|\mathcal{V}} & C_j = q, S_iC_j = p, \mathbf{D}_{ij} = 0 \\ \mathbf{P}^i_{pq|\mathcal{V}} & C_j = q, S_iC_j = p, \mathbf{D}_{ij} = 1 \end{cases} \tag{11}$$

$\mathbf{P}^i_{pq|\mathcal{V}}$ describes dependent behaviours between two sources (follow or retweet) given verification result $\mathcal{V}$. $\mathbf{A}^i_{pq|\mathcal{V}}$ is the probability of making independent assertions providing the verification result is $\mathcal{V}$. Note that, the verification result $\mathcal{V}$ is unknown in this section. We hence need to compute the expected likelihood by averaging over all possible verification results. The probability of $\mathcal{V}$ is derived from truth estimation $\mathcal{Z}$ in previous section 3.2, such that $\mathbb{P}(\mathcal{V}) = \prod_{v_j \in \mathcal{V}} z_{j,v_j}$. The expected likelihood is then formulated as:

$$Q = \sum_{\mathcal{V}} \mathbb{P}(\mathcal{V}) Q_{\mathcal{V}} \tag{12}$$

The simplified EM likelihood can be maximized as a linear programming, with constraint $\sum_q \mathbf{A}^i_{pq|\mathcal{V}} = 1$, $\sum_q \mathbf{P}^i_{pq|\mathcal{V}} = 1$ and $|\bar{C}| = V$, where V is the number of assertions to be verified.

3.4 Re-estimating Truth Value and Source Reliability with Labeled Assertions

The optimal set of assertions is then verified by human participants. After obtaining the verification results, we re-compute truth estimates from semi-supervised EM likelihood formulated in (9). Using E-step and M-step described in section 3.2, we can derive iterative updates:

$$\mathcal{Z}_{j,p} = \begin{cases} \frac{B_p}{\sum_{q=1}^{v} B_q} & j \notin \bar{C} \\ 1 & j \in \bar{C}, q = v_j \\ 0 & j \in \bar{C}, q \neq v_j \end{cases}$$
$$\mathbf{A}^i_{pq} = \frac{\sum_{S_iC_j=p, \mathbf{D}_{ij}=0} z_{j,q}}{\sum_{S_iC_j, \mathbf{D}_{ij}=0} z_{j,q}}$$
$$\mathbf{P}^i_{pq} = \frac{\sum_{S_iC_j=p, \mathbf{D}_{ij}=1} z_{j,q}}{\sum_{S_iC_j, \mathbf{D}_{ij}=1} z_{j,q}} \tag{13}$$

where

$$B_p = \prod_{q=1}^{v} \prod_{S_iC_j=q} \mathbb{P}(S_iC_j|C_j = p) \tag{14}$$

Algorithm 2 Greedy Approximation

```
Input: Source-Claim matrix SC and Number of assertions to label V
Initialize C̄ = ∅, C̃ = C, L and d
Compute EM estimation according to (5)(6)
while |C̄| < V do
    for C_j ∈ C̃ do
        Compute expected likelihood L_j according to (16)
        if L_j > L then
            L = L_j
            Set j to be the verification index d
        end if
    end for
    Add C_j to C̄
end while
Re-Compute EM estimations according to (13)(14)
END
```

3.5 A Greedy Approach

The above verification algorithm takes V^d set of parameters to cover all d possible verification results of V assertions. Although each verification estimation takes minimal computation cost, the number of combinations can grow exponentially as the dataset. In this section, we describe a greedy approach to significantly reduce number of parameters on such large dataset. Start with $\bar{C} = \emptyset$, the approach adds one assertion to $\bar{C}$ via greedy approach (select the assertion that maximizes expected likelihood). We run the above iteration V times, getting one verified claim in each iteration. We may also redo expectation maximization to update source reliability and truth after certain number of verifications.

In this section, we analyze the greedy approach to demonstrate it is a good estimation. We study the effect of verifying one assertion. Denote the verified assertion as C_{ve}, estimated correctness before verification is z_{ve}. $\bar{C}$ is the set of labeled assertions (not including C_{ve}), $\tilde{C}$ is the set of unlabeled assertions. The likelihood before verifying C_{ve} is:

$$\begin{aligned} Q &= \sum_{C_j \in \bar{C}} \sum_{q=0}^{v} \mathbb{P}(C_j = q|\boldsymbol{\theta}_{ve}, \mathbf{D}) \log \mathbb{P}(SC_j|C_j = q, \boldsymbol{\theta}_{ve}, \mathbf{D}) \\ &+ \sum_{C_j \in \tilde{C}} \sum_{q=0}^{v} \mathbb{P}(C_j = q) \log \mathbb{P}(SC_j|C_j = q, \boldsymbol{\theta}_{ve}, \mathbf{D}) \\ &= \sum_{C_j \in \bar{C}} \sum_{q=0}^{v} \mathbb{P}(C_j = q|\boldsymbol{\theta}_{ve}, \mathbf{D}) \log \mathbb{P}(SC_j|C_j = q, \boldsymbol{\theta}_{ve}, \mathbf{D}) \\ &+ \sum_{C_j \in \tilde{C} - C_{ve}} \sum_{q=0}^{v} \mathbb{P}(C_j = q) \log \mathbb{P}(SC_j|C_j = q, \boldsymbol{\theta}_{ve}, \mathbf{D}) \\ &+ \sum_{q=0}^{v} \mathbb{P}(C_{ve} = q) \log \mathbb{P}(SC_j|C_{ve} = q, \boldsymbol{\theta}_{ve}, \mathbf{D}) \end{aligned} \tag{15}$$

On verifying C_{ve}, with probability $\mathbb{P}(C_{ve} = q_{ve})$, the result is $C_{ve} = q_{ve}$. The expected likelihood after verifying C_{ve} is:

$$\begin{aligned} Q' &= \sum_{q_{ve}=0}^{v} \mathbb{P}(C_{ve} = q_{ve}) \times \\ &\{ \sum_{C_j \in \bar{C}} \sum_{q=0}^{v} \mathbb{P}(C_j = q|\boldsymbol{\theta}_{q_{ve}}, C_{ve}, \mathbf{D}) \log \mathbb{P}(SC_j|C_j = q, C_{ve}, \boldsymbol{\theta}_{q_{ve}}, \mathbf{D}) \\ &+ \sum_{C_j \in \tilde{C} - C_{ve}} \sum_{q=0}^{v} \mathbb{P}(C_j = q) \log \mathbb{P}(SC_j|C_j = q, C_{ve}, \boldsymbol{\theta}_{q_{ve}}, \mathbf{D}) \\ &+ \log \mathbb{P}(SC_j|C_{ve}, \boldsymbol{\theta}_{q_{ve}}, \mathbf{D}) \} \end{aligned} \tag{16}$$

Since we assume the estimated truth of non-verified assertions remain unchanged, thus for any assertion $j \in \tilde{C}, j \neq ve$, we have:

$$\mathbb{P}(C_j = q|\boldsymbol{\theta}_{C_{ve}, q_{ve}}, \mathbf{D}) = \mathbb{P}(C_j = q) \tag{17}$$

The effect of verifying an assertion is two-fold: Change on estimated correctness of verified assertion and change on estimated reliability scores of related sources.

Change on estimated correctness of verified assertion

First, we study the effect on estimated correctness of verified assertion C_{ve}. Estimates of C_{ve} changes from z_{ve} before verification, to 1 with probability z_{ve} and 0 with probability $1 - z_{ve}$. This part of likelihood is represented as the last item of (15) and (16). We can see the overall expected likelihood does not change, since the probability of verified results follows the correctness estimation of C_{ve}. Thus, multiple verified assertions are independent in terms of influence of estimated correctness.

Change on estimated reliability scores of related sources
Verifying an assertion changes source reliability scores, which implicitly affects estimated truth value of unlabeled assertions. Original claim probability matrix of sources are estimated as:

$$\mathbf{A}^i_{pq} = \frac{\sum_{S_iC_j=p} z_{j,q}}{\sum_{S_iC_j} z_{j,q}} \tag{18}$$

After verification, estimated reliability matrices become:

$$\mathbf{A}^i_{pq} = \begin{cases} \frac{\sum_{j\in C-C_{ve}, S_iC_j=p} z_{j,q}+1}{\sum_{j\in C-C_{ve}, S_iC_j} z_{j,q}+1} & \mathbb{P} = z_{ve} \\ \frac{\sum_{j\in C-C_{ve}, S_iC_j=p} z_{j,q}}{\sum_{j\in C-C_{ve}, S_iC_j} z_{j,q}} & \mathbb{P} = 1 - z_{ve} \end{cases}$$

Same applies to dependent claim probability matrix. Since verification affects both nominator and denominator in reliability estimates, it does change the expected likelihood. Multiple verifications interact dependently on source reliability scores. Providing we are only verifying a small set of assertions, we can make a further approximation that the changes on source reliability are positive (With high probability, a verification overall improves source reliability estimation). With this assumption, the problem becomes submodular and monotone, and thus greedy algorithm gives a $(1-1/e)$-approximation solution to our problem. However, in sparse networks, the above assumption does not hold and will cause slight performance drop.

4 EVALUATION USING SYNTHETIC DATA

We evaluate our algorithm using both real and synthetic data sets. This section describes evaluation using synthetic data. Evaluation using real-world data is presented in the next section.

Our use of synthetic data admittedly misses realistic qualities of target applications. The advantage, however, lies in exercising full control over ground truth, nature of assertions, and nature of sources, hence allowing evaluation under a broad set of conditions. By changing parameters of synthetic data generation, we are able to comment on general trends and on robustness of our results across a wide range of conditions. This broader picture complements our more localized (if accurate) understanding derived from the point cases represented by the specific collected data sets (in the next section).

We develop a synthetic data generator that creates n sources $\{S_1, S_2, \cdots, S_n\}$, of which some fraction are not reliable. Each source makes a subset of assertion selected from some larger set maintained by the generator. The generator works as follows:

- First, it generates m assertions $\{C_1, C_2, \cdots, C_m\}$ to choose from, and chooses source reliability and speak rates for each of the n sources. Reliability matrices and speak rates are generated as Gaussian distributions of preset parameters. A control parameter P_{true} determines the percentage of true assertions in the overall set. Hence, turning that parameter down would increase the fraction of "rumors" compared to true statements among the data reported.
- Second, the generator generates claims in accordance with the chosen source parameters and populates the set $\mathcal{SC}$ for the period of simulation. It loops over all sources. In each round, the speak rate of a source, P_{speak}, decides if the source will make a claim. If so, another probability, P_{depend}, decides whether or not this claim will be a repeat of a previous one (e.g., retweet). A repeat is generated in accordance with the dependency graph by repeating some claim of an ancestor in the graph. If P_{depend} decides that the claim is an original claim, then either a true or a false assertion is chosen according to reliability parameters of this source.
- The generated claims using the above method are given to our set of algorithms to analyze.

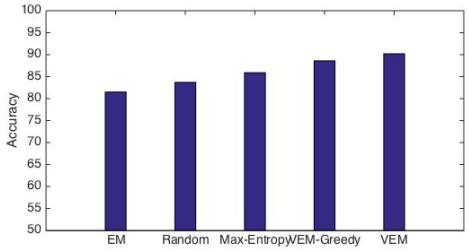

Figure 1: Simulation accuracy

In the simulation, reliable sources have expected 70% chance of making correct claims, while unreliable sources have expected 40%. We evaluate five different methods:

- EM: The pure *EM* uses expectation maximization but without any verification. It jointly estimates source reliability and assertion truth values from source claim matrix *SC* and dependency graph *G*. The original algorithm was published in [14].
- Random: It augments *EM* by randomly selecting the assertions to verify.
- Max-Entropy: The *Max-Entropy* algorithm picks the assertions that have the closest probability of true and false values (i.e., the most uncertainty in estimated value).
- VEM: *VEM* is the active-learning algorithm described in section 3.2 - 3.4.
- VEM-Greedy: It is the Greedy approximation of *VEM*, described in 3.5.

We conduct 50 independent experiments for each data point. For data generation, unless mentioned otherwise, we use number of sources $n = 50$, speak rate $P_{speak} = 0.2$, expected reliability of good sources = 0.7 and expected reliability of bad sources = 0.4. A total of $m = 250$ claims are generated in each simulation. We limit the assertions to verify to 5%. In general, we expect our algorithm to work better when sources are more predictable (e.g., good sources are nearly 100% accurate, and bad sources are always inaccurate). The above settings (of 70% and 40% reliability) were meant to increase entropy in order to stress test the algorithm.

4.1 Simulation Accuracy

We compare the simulation results of the five algorithms to ground truth. From Fig. 1, we see that our *VEM* algorithm outperforms all other algorithms. The *Random* selection of assertions to verify can occasionally correct a claim but is inferior to others. The *Max-Entropy* algorithm selects more uncertain assertions, but it is not the best choice, since it does not take into account the global

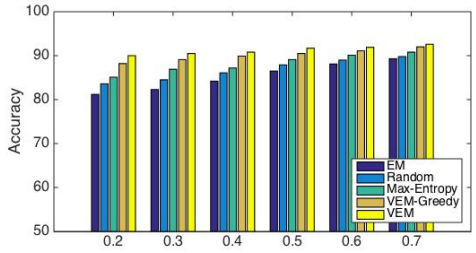

Figure 2: Vary Claim Prob.

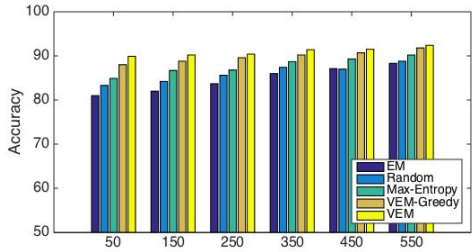

Figure 3: Vary # of Sources

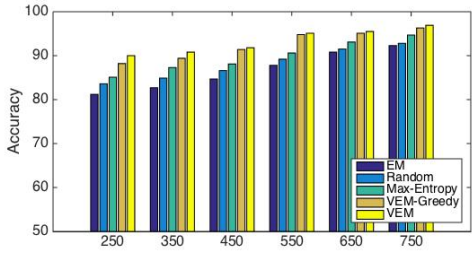

Figure 4: Vary # of Assertions

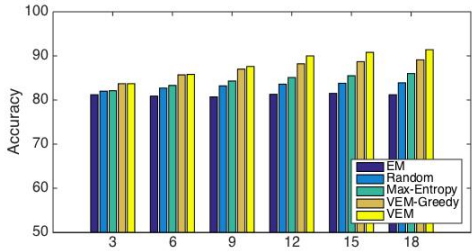

Figure 5: Vary # of verified assertions

interaction between assertions. Our algorithm achieves better accuracy than the above two methods. The reason is two-fold. First, *VEM* jointly considers an assertion's value uncertainty and its interactions with other assertions. For example, if only one unknown source made this assertion then knowing its true value has a more limited effect (on understanding source reliability) than if several unknown sources made this assertion (in which case the verification will yield information pertinent to several sources at once). Second, *VEM* selects the best set of assertions to verify by iteratively estimating verification outcome. *VEM-Greedy* provides a low cost approximation to our *VEM* algorithm to reduce computational complexity. It achieves comparable accuracy but is much lighter. Next, we study the effect of varying data set generation parameters. In each experiment, we vary one parameter while keeping others unchanged. The simulator generates a new dataset of each set of parameters. First, we vary the parameter P_{speak}, the probability of a source making claim, from 0.2 to 0.7 with increments of 0.1. This has the effect of modulating the density of the source claim matrix. In Fig. 2, our *VEM* achieves the best accuracy for every speak rate setting. *VEM-Greedy* has comparable performance to *VEM* and still beats the other three algorithms. Note that, although *VEM* has better accuracy than *VEM-Greedy*, it iterates through all possible combinations of assertions, which is computationally expensive in a large dataset. Another observation is that, at low speak rates, our algorithm significantly outperforms *EM*, *Random* and *Max-Entropy*. The reason is, in a sparse source claim matrix, *EM* produces more uncertain results: more truth estimations fall close to 0.5 than 0 or 1. *VEM* provides better improvements over baselines on such sparse graphs. In the second experiment, we change the number of sources n from 50 to 550 in increments of 100. In Fig. 3, our algorithm outperforms the others over the entire range. Adding sources has a similar effect on accuracy as increasing speak rate. In our default setting, with $P_{speak} = 0.2$, the graph is sparse, which impairs the performance of the *EM* algorithm. When we increase the number of sources, the number of edges connecting to each assertion is increased. This leads to an improvement in performance. Again, our algorithm outperforms others for every setting of parameters. In third experiment, we vary the number of assertions from 250 to 750 in increments of 100. The speak rate P_{speak} and the number of sources are unchanged. In Fig. 4, the baseline *EM*, *Random* and *Max-Entropy* have similar trends as in the previous two simulations. Our *VEM* and *VEM-Greedy* improve slightly more when increasing the number of assertions. The reason is: since we always verify 5% of the total number of assertions, having more assertions allows us to verify more as well, deriving better value due to their judicious selection of claims to verify. The immediate implication is that our algorithm fits well with larger data sets.

In the next simulation, we study the effect of varying number of verified assertions. We change the this number from from 3 to 18 with increment of 3, keeping the total at 250 (i.e., roughly 1.2% to 7.5%). In Fig. 5, our algorithm is shown to outperform the others in all 6 scenarios. There are two observations:

- We observe an increasing performance gap between *VEM* (*VEM-Greedy*) and other algorithms as we increase number of verified assertions. *Random* and *Max-Entropy* use a passive learning approach, which has no control over labeled data. Thus, they are susceptible to selecting less advantageous assertions. Our *VEM* algorithm determines the best assertions to verify offering a better advantage as the number of verified assertions increases.
- The improvements in total accuracy achieved slow down after 12 assertions. This demonstrates 5% is a good fraction for pivot assertions.

4.2 Compare Computation Time

Here we compare the computation overheads of different algorithms. We increase the size of the source claim matrix by increasing the number of sources and assertions as indicated on the horizontal axis. We then average the time needed to process the data sets over

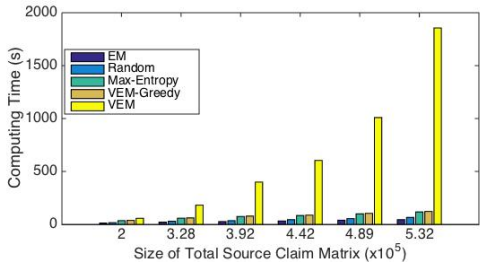

Figure 6: Computation Time Comparison

20 independent runs. The result is shown in Fig. 6. *Random*, *Max-Entropy* and *VEM-Greedy* have slight overheads over baseline *EM*. Our *VEM*, however, grows exponentially with the number of claims. The simulation indicates that *VEM* is good for smaller datasets but does not scale well to larger ones. However, *VEM-Greedy*, its greedy approximation, has a roughly similar overhead as *Random* and *Max-Entropy*, yet still achieves better results than other methods.

Results in this section confirm two main observations. First, the accuracy improvement attributed to the new algorithm holds true across a broad set of conditions on sources, assertions, percentage of verified assertions, and overall sparsity of the Source-Claim matrix. Overall, better advantages are seen in larger experiments. Second, the quality of the results is fairly robust to changes in synthetic data generation. Hence, when discussing specific data sets in the next section, we have reason to believe that the observed performance advantages are not coincidental to only those specific data sets and configurations. With that, we turn to results obtained when experimenting with real data.

5 EMPIRICAL EVALUATION

In this section, we evaluate our algorithm on four empirical data sets collected on Twitter in 2018 and 2015. The data were collected using Twitter API. Each data set was collected by specifying event keywords or a geographic location. The data collection tool would then collect tweets that contain the indicated keywords or originate from the indicated location. Four datasets were created, labeled: (1) Hurricane, (2) Facebook, (3) Kirkuk, (4) LA Marathon, representing the events of: (1) Hurricane Florence in 2018, (2) Facebook under federal investigation, (3) Battle with ISIS in Kirkuk city, and (4) A marathon in LA:

- Hurricane Florence: In September 2018, Hurricane Florence hit the US East Coast, including North Carolina, South Carolina and Maryland. The disaster caused 53 deaths and over 38 *billion* USD dollars in damage over its course.
- Facebook Federal Investigation: In 2018, Facebook faced a federal investigation into its sharing of user data with the political consulting firm Cambridge Analytica. Some 87 million facebook users' data were claimed to be improperly shared.
- Kirkuk: On March 10th 2015, Kurdish forces in Northern Iraq attacked the self proclaimed "Islamic State" (ISIS) outpost, west of the city of Kirkuk. Battles raged and a lot of commentary followed on social media about state of affairs on the ground.
- LA Marathon: This data set collects tweets about the Los Angeles Marathon on March 15th, 2015. The runners started from Dodger Stadium and ran a course to the coastline in Santa Monica, passing through downtown Los Angeles, Hollywood, the Sunset Strip, Santa Monica Blvd, and Ocean Avenue, among other landmarks. Much Twitter activity followed the event as it unfolded.

Table 2: Information Summary of Twitter Dataset

	#Assertions	#Sources	#Claims
Hurricane Florence	9052	7645	9378
Facebook	10238	8236	11395
Kirkuk	6172	4816	6188
LA Marathon	7072	5174	7148

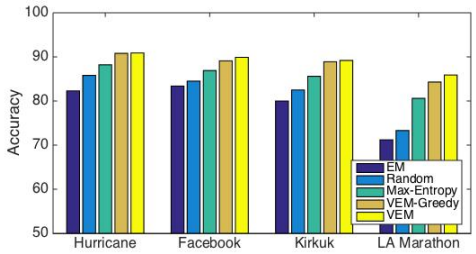

Figure 7: Empirical evaluation

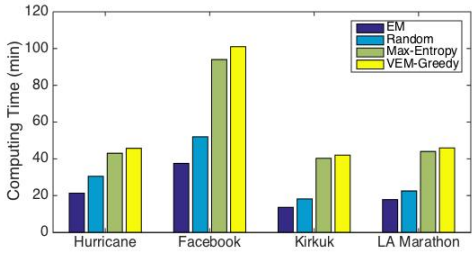

Figure 8: Computation Time

Our intent was to use data sets that differ significantly in time (e.g., today versus three years ago), and differ significantly in topic (e.g., social event, political event, or natural disaster). To evaluate our algorithm, the most popular 1000 assertions were selected (i.e., those supported by the highest number of claims from sources). Each algorithm then computes the probability of each of these 1000 assertions to be true. To avoid variations in the number of assertions returned, the highest-probability 200 assertions (ranked true) by each algorithm are computed. We then manually grade the correctness of those tweets by human graders. To prevent bias, the graders have no information on which algorithm generated which output. Each tweet is marked as "True", "False", or "Unconfirmed" by the grader. An "Uncomfirmed" tweet is either non-verifiable or is an opinion (a subjective assessment, such as 'Facebook is user-friendly'). We then compute accuracy as the percentage of assertions labeled "True" by the grader in the top 200 returned by each algorithm: $\#True/(\#True+\#False+\#Unconfirmed)$. Note that our accuracy analysis presents a pessimistic performance evaluation, since we count unconfirmed assertions as "False".

The results of this evaluation are shown in Fig. 7. Consistently with simulations, our algorithm outperforms all baselines. The

reason is: *VEM* iterates through every combination of assertions to estimate the semi-supervised EM likelihood, which is theoretically more accurate than other heuristic methods. *Random* selection and *Max-Entropy* fail to select the best assertions to verify.

Our algorithm improves accuracy by 8.6%, 6.5%, 9.2%, 12.7% respectively over baseline *EM* when only 5% of the total assertions are verified. Said differently, it reduces error roughly in half (from the neighborhood of 20% to the neighborhood of 10%). Thus, it does significantly improve truth finding quality in social sensing systems. In addition, the lighter version, *VEM-Greedy*, has comparable performance in all four datasets.

Lets take a deeper look at those algorithms. *EM* is the baseline approach. It allows us to understand the benefits of active learning. Prior work shows that *EM* outperforms traditional iterative algorithms (i.e., Sum, Average Log, Truth Finder, in social sensing system) [18]. The main sources of inaccuracy in the unsupervised *EM* are: (1) It requires relatively dense data to have better accuracy. (2) Our evaluation counts subjective opinions as False. Subjective assessments made by reliable sources get high credibility scores, which reduces accuracy in our evaluation.

Random reflects performance of semi-supervision if the set of labeled assertions was not controlled (i.e., when labeled data are arbitrarily chosen). It allows us to assess the performance improvement due to a good choice of assertions to verify. Similarly, the original *Max-Entropy* shows that a good choice depends on more than just the uncertainty in the value of the assertion. *Max-Entropy* improves accuracy over *Random* by verifying the most uncertain assertions. Our algorithm does better because it succeeds in finding assertions that are connected in the source claim graph in such a way that their verification potentially benefits other estimated values. Hence, by verifying a small set of assertions, we also improve the estimation of source reliability, which influences the estimation of other assertions. *VEM* uses linear programming to find the best assertions to verify. It does incur a high computational cost. Thus, the lighter version of *VEM*, *VEM-Greedy* is derived. Empirical results show that it still outperforms *Random* and *Max-Entropy*.

Finally, Fig. 8 gives a comparasion of computation time on real datasets. *Random* has similar execution time as baseline *EM* since the algorithm only does one round of EM estimation. *Max-Entropy* and *VEM-Greedy* does two rounds of EM because those two algorithms select assertions to verify based on EM estimates then re-estimate with labeled assertions. *VEM* takes 2276, 3365, 350 and 564 minutes to execute due to its high combinatorial computation cost. Note that, *VEM* does not need to iterate over every combinations in real datasets, since some subsets of assertions can be eliminated by heuristics.

The evaluation shows that across a diverse selection of Twitter data sets from different times and topics, our algorithm, *VEM*, improves accuracy, compared to the baselines in a manner largely consistent with simulation results. Moreover, *VEM-Greedy* offers nearly the same performance at a much lower overhead.

6 DISCUSSION AND FUTURE WORK

The work presented in this paper can be extended in several ways.

Errors and imperfections: The accuracy of our approach is contingent on the accuracy of several underlying components. For example, we group claims by cosine similarity, but semantically-aware clustering methods may yield better results. We assume an "oracle" that allows the selected claims to be reliably verified, but the oracle itself might be wrong. Not all assertions might be verifiable by an oracle. In some scenarios, only a subset can be verified. Our model relaxation that enables the greedy algorithm to perform well does not hold when networks are sparse. This deficiency partially explains the performance gap between the expensive form of inference and the greedy form. A more thorough analysis is needed in order to assess the sensitivity of our approach to these and other sources of error.

One-hot constraints: Our approach as discussed evaluates the truth values of individual assertions independently. In reality, there may be "one-hot" constraints on the value that is true. For example, different assertions might describe a suspect in a street shooting differently, but if the descriptions are conflicting, only one description is true. Our algorithm can be easily extended to accommodate such constraints in scenarios where it is possible to identify claims that are mutually conflicting. This might be easier to do for more structured data, such as crowdsensing data, where users report multiple-choice observations via an app.

Scalability: One important feature of crowdsourcing systems is scalability. Our algorithm runs under a batch setting, which means all data are considered at the same time in the estimation. In practice, this is not always a concern. Often one desires to verify information on specific claims or topics, which allows pre-filtering of larger datasets to the issue of concern. However, should one decide to run the algorithm on larger data, one possibility is to use an incremental form. Specifically, previous work presented online recursive truth estimators based on an EM framework that allow propagating information from one window to the next as priors [18] to be undated incrementally in the current window. This allows the algorithm to work on one slice of data at a time, making it more scalable.

Two changes must be made to support such an online extension. First, time should be slotted into intervals. The EM framework would only be applied to claims collected in the current time-slot. Posterior beliefs are then computed from EM estimates of current and previous time-slots, summarizing source reliability and claim correctness probabilities from previous history. Posterior beliefs then become prior beliefs in the next time-slot and are included in online EM estimation [18]. Second, since user queries can be made at any time-slot, an interesting challenge is whether the labeling overhead can be distributed more judiciously over time. For example, if no significant uncertainty exists, maybe spare some verification budget for the next window.

Collusion: As with many fact-finding and reputation systems, one challenge is malicious attacks. A group of collaborators or multiple replicas generated by a single user can attempt to fool the system to boost correctness of false assertions. This can be done by gradually gaining trust from providing true observations, then coordinating on delivering the same false message(s). While it is virtually impossible to detect a single such manipulation, repeated manipulation over time is detectable. Previous literature proposed mechanisms to detect such collaborations based on several observations on social networks. For example, collaborating groups tend to coincidentally make observations on the same set assertions repeatedly [10] and

tend to have more friend/follow links among themselves than external links to honest users [8]. Our assertion selection can combine those features to better assess source reliability in the presence of malicious attacks.

Verification cost: We implicitly assume that every verification attempt has the same cost, leading to a formulation where only the total fraction of verified assertions is bounded. Our algorithm can be further extended to the settings where verification of different assertions has a different cost. The problem becomes to select an optimal set of assertions while keeping cost below a preset value. Extending *VEM* algorithm is straight-forward, since it iterates through every possible set of assertions and estimates their verification effect. *VEM-Greedy*, however, has to consider verification cost in some appropriate manner since it selects assertions greedily one at a time. A simple solution is to select the assertion which has highest approximate improvement per unit cost.

Natural language processing: Our approach minimizes the use of natural language processing and does not interpret the content of tweets, which makes it easily applicable to any language, dialect, or topic with no prior language training. If tools for natural language processing were to be used, they would improve our truth estimator in several ways. For example, the same observation can be expressed in multiple ways or languages, which we shall fail to recognize as the same assertion. Some natural language processing could mitigate this problem.

Applicability and real world scenarios: We are currently working on integrating our algorithm into our Apollo social sensing toolkit (http://apollo2.cs.illinois.edu). Apollo extracts tweets hourly using the Twitter API and processes them to discover real-world events related to a given broad topic, such as disasters, world conflicts, local traffic, or other categories, supplied by the user as query terms. It further filters descriptions of these events, retaining only what it believes to be the most trustworthy claims (tweets). Using the approach described in this paper, the tool can be extended by selecting a very small subset of tweets and asking the user to assess their veracity. In return, our algorithm will improve the quality of assessment and filtering of the majority of claims. This capability can be applied in many contexts. For example, in post-disaster scenarios, rumors often proliferate about the extent of damage, availability of help, and instructions for survivors. Apollo can help mitigate the confusion. More recently, actors on social media were blamed for misinformation campaigns, for purposes ranging from intimidation to political manipulation. Apollo may offer a countermeasure that reduces information contamination. Finally, in the absence of disasters and conflicts, the tool can be used simply as an online (near) real-time news source, distilling myriads of evolving events, on a topic of user choice, into a much smaller amount of higher-quality newsworthy headlines. In the authors' own lab, Apollo is being used by graduate students to catch up on the most salient events in their home countries, especially those that do not receive much coverage in the local news. This is an anecdotal proof of value of the tool as a new personalizable medium to keep up with evolving real-time events worldwide.

7 RELATED WORK

This paper builds on advances in social sensing, which evolved from participatory sensing, initially introduced in [2]. Recent applications include BigRoad[6], RST[7], and Nutrilyzer[13].

Reliability and data quality are among the key problems of social sensing. To eliminate conflicts among multi-source data, the topic of truth-discovery has been studied extensively in machine learning/data mining [5, 19, 20] and social network literature [1, 15–17].

Early truth finders were based on the concepts of hubs and authority, in which the source reliability and claim trustworthiness updates each other in an iterative fashion. Yin et al. utilized interdependencies between source trustworthiness and fact confidence, introducing TruthFinder as an unsupervised fact finder. Later work extended TruthFinder by introducing heuristics into the analysis, including: small set of pre-labeled truth [20], incorporating prior knowledge [11], similarity between claim values [4] and extra parameters to source reliability [12]. Wang et al. [15] first formulated fact finding into a maximum likelihood estimation problem and jointly estimated source reliability and claim correctness using an expectation maximization approach. Subsequent work [14, 16] extended the original EM by taking into account dependencies.

The above work assumed a batch setting in which all data have to be available at once. However, the amount of data can grow exponentially over time, and the gap between staring and finishing of data collection can be large, which leads to high computation cost and slow response to queries. Yao et al. proposed a recursive estimator for streaming social media data[17]. The online recursive estimator adapted a batch EM framework by passing posterior belief across time windows. We are the first extension of the maximum-likelihood estimation approach for social media truth discovery to the case of active learning that investigates the selection of data to label for maximum improvement in results.

8 CONCLUSIONS

In this paper, we presented an active-learning based truth estimator that discovers truth values of observations made in social networks. Our algorithm achieves significantly higher accuracy compared with existing methods. We evaluated our approach in simulation as well as on real data collected from Twitter. Our algorithms significantly outperformed existing work. A light-weight version of the original approach was developed that offered the best compromise between quality of results and computation efforts. The paper is a first example of applying an active learning approach to improve the performane of truth discovery on social media.

ABSTRACT

With the rapid development of fashion market, the customers' demands of customers for fashion recommendation are rising. In this paper, we aim to investigate a practical problem of fashion recommendation by answering the question "which item should we select to match with the given fashion items and form a compatible outfit". The key to this problem is to estimate the outfit compatibility. Previous works which focus on the compatibility of two items or represent an outfit as a sequence fail to make full use of the complex relations among items in an outfit. To remedy this, we propose to represent an outfit as a graph. In particular, we construct a *Fashion Graph*, where each node represents a category and each edge represents interaction between two categories. Accordingly, each outfit can be represented as a subgraph by putting items into their corresponding category nodes. To infer the outfit compatibility from such a graph, we propose *Node-wise Graph Neural Networks* (NGNN) which can better model node interactions and learn better node representations. In NGNN, the node interaction on each edge is different, which is determined by parameters correlated to the two connected nodes. An attention mechanism is utilized to calculate the outfit compatibility score with learned node representations. NGNN can not only be used to model outfit compatibility from visual or textual modality but also from multiple modalities. We conduct experiments on two tasks: (1) Fill-in-the-blank: suggesting an item that matches with existing components of outfit; (2) Compatibility prediction: predicting the compatibility scores of given outfits. Experimental results demonstrate the great superiority of our proposed method over others.

The first two authors Zeyu Cui and Zekun Li contribute to this work equally and are listed as joint first authors. Shu Wu and Xiaoyu Zhang are both corresponding authors.

1 INTRODUCTION

Clothing plays an increasingly significant role in human's social life, as a proper outfit can enhance one's beauty and display the personality. However, not everyone has a strong fashion sensitivity. "How to make a suitable and beautiful outfit?" has become a daily headache for many people. Solving this problem requires modeling human notions of the compatibility. Here we aim to propose an effective method to predict the compatibility of outfits and thus help people make proper outfits.

Previous works on compatibility learning mainly focused on the compatibility of two items. These works followed the idea to map the items into a style space and estimate the distance between style vectors of items. Veit *et.al* used SiameseCNNs [1, 38] to transform items from the image space to the style space. Mcauley *et.al* [23] proposed to use Low-rank Mahalanobis Transformation to map items into the style space. Lately, some works proposed to model the compatibility of items by mapping items into several style spaces [11, 31]. Recently, there appear a few works directly measure the compatibility of outfit. Li *et.al* [17] proposed to represent an outfit as a sequence and adopt Recurrent Neural Network (RNN) [3, 6, 12, 21, 24, 25, 33] to model the compatibility. Similarly, another work [9] further represented an outfit as a bidirectional sequence with a specific order (i.e., top to bottom and then to accessories), and used Bidirectional Long Short Term Memories (Bi-LSTMs) to predict the next item in an outfit.

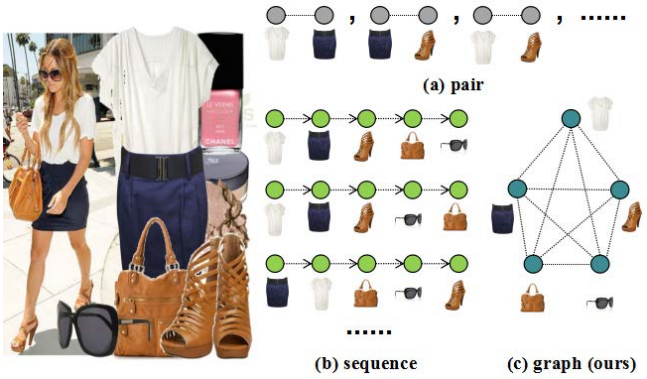

Figure 1: Different representations of an outfit. Left is the outfit. (a), (b) and (c) in the right are its pair, sequence and graph representations respectively. Circles represent the items and links represent the relations.

Solving the task of modeling outfit compatibility relies on an appropriate outfit representation. The previous works take advantage of two kinds of outfit representations: *pair representation* [11, 23, 31, 38] and *sequence representation* [9]. We show different outfit representations in Figure 1. From (a) we can see that representing the outfit as pairs separately cannot reflect the complex relations among multiple items. In term of *sequence representation* in (b), there doesn't exist a fixed order of items. More importantly, the relations among items in an outfit are not ordered since an item has relations with not only its prior or rear item in the sequence. To remedy this, we propose a new outfit representation: *graph representation*. As shown in (c), it can better reflect the dense and complex relations among multiple items in an outfit.

In particular, we construct a *Fashion Graph* based on Polyvore dataset, where each node represents a category and each edge represents the interaction between two nodes. If two categories have matching relation (i.e., they appear in the same outfit), there should be interactions between them. We have two directed edges between them in *Fashion Graph* since the interactions in two directions ought to be different. For example, one may select a pair of socks to match the shoes but not select shoes for socks in particular. A compatible outfit should have a key property: the categories of items in it are not overlapped (e.g., there won't be two pairs of shoes in an outfit). Thus, by putting each item into its corresponding node, an outfit can be represented as a subgraph of *Fashion Graph*. The task of modeling outfit compatibility can be accordingly converted to a graph inference problem.

A possible method is using Graph Neural Networks (GNN) to model the node interactions and infer compatibility from the graph. GNN is an approach to applying neural networks to graph-structured data, first proposed by Gori *et al.* [7]. It can be applied on most kinds of graphs, including directed, undirected and cyclic graphs. However, it has trouble in propagating information across a long range in a graph. To address this, Li *et al.* [18] proposed Gated Graph Neural Network (GGNN) by introducing a Gated Recurrent Units (GRU) for updating. Nevertheless, in GGNN, the nodes interact with others by communicating their state information on the edges in a fixed way, which leads to a limitation that it has difficulty in modeling flexible and complex node interactions.

To address this limitation, we propose a novel model NGNN to better model node interactions and better infer the compatibility from graph. In NGNN, the communication of state information on each edge is different. Specifically, when two nodes communicate state information on the edge, the state information will first be transformed by a transformation function determined by parameters correlated to the two nodes. In this way, NGNN can model edge-wise interactions with node-wise parameters. Since the parameters are correlated to nodes instead of numerous edges, it can greatly reduce the parameter space. During training process, NGNN only deals with the nodes in the subgraph each time, which reduces the time complexity as well. Moreover, when there are more data to train the model, we only need to update the parameters of these concerned nodes without changing the edges or other nodes, which is effective in real applications. With the learned node representations, we utilize an attention mechanism to calculate a graph-level output to serve as the outfit compatibility score.

The framework of our proposed method is shown in Figure 2. We first construct a *Fashion Graph* where an outfit can be represented as a subgraph. Then we use the proposed novel model NGNN to model node interactions and learn the node representations. Finally, we predict the compatibility score by calculating a graph-level output using an attention layer. This proposed method can model outfit compatibility from visual, textual or any single modality with a channel of input features. By using two channels of input to NGNN, it can also be used to jointly model the outfit compatibility from visual and textual modality.

We conduct experiments on two tasks: (1) Fill-in-the-blank: suggesting an item that matches with existing components of outfit; (2) Compatibility prediction: predicting the compatibility scores of given outfits. Experiment results on the Polyvore dataset demonstrate the great superiority of our method over others. The code and dataset of our work have been released[1].

Our main contributions can be summarized in threefold:

- To the best of our knowledge, this is the first attempt to represent an outfit as a graph, which can better capture the complex relations among multiple items in an outfit.
- We propose a novel model NGNN which can better model node interactions in the graph and learn better node representations. Taking advantage of NGNN, we can not only model outfit compatibility from visual or textual modality, but also from multiple modalities.
- Experimental results on a real-world dataset (Polyvore dataset) demonstrate the great superiority of our method over others.

2 RELATED WORK

2.1 Fashion Compatibility Modeling

There have been many studies focusing on modeling the compatibility of clothing recently, since it is the key to fashion recommendation. McAuley *et al.* assumed that there existed a latent style space where compatible items stayed close. They used Low-rank Mahalanobis Transformation (LMT) to map items into a latent space and

[1] https://github.com/CRIPAC-DIG/NGNN

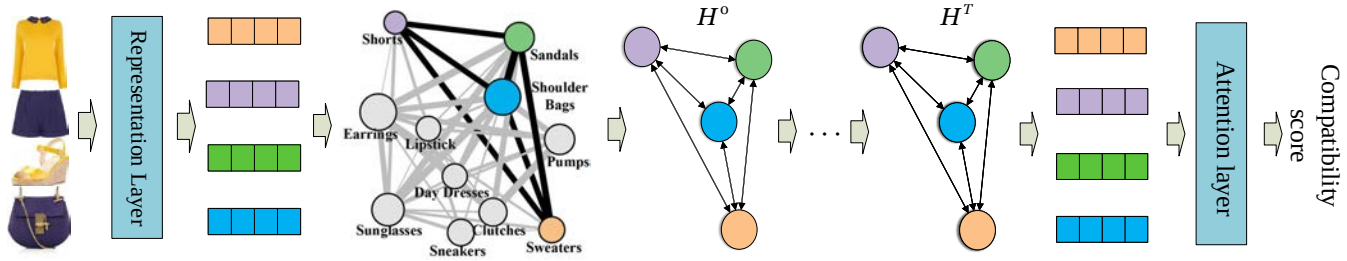

Figure 2: Overview of the proposed method. Based on the dataset, we first construct a *Fashion Graph*, where each node represents a category and each edge represents the interaction between two nodes. An outfit (e.g. sweater, short, sandals, shoulder bag) can be represented as a subgraph. We then design NGNN to model the node interactions and learn node representations. An attention layer is finally utilized to calculate the compatibility score.

measured the distance there [23]. Following that, Veit *et al.* proposed to learn the distance metric with an end-to-end SiameseCNNs [38]. Some other works mapped items into several latent spaces and jointly modeled the distances in these latent spaces, which can measure the compatibility of items in different aspects [2, 11, 31]. However, these works only focus on the compatibility of two items instead of a whole outfit.

Recently, some studies have been trying to model the compatibility of a whole outfit directly. Li *et al.* extracted multi-modal information from items and evaluated the outfit compatibility with an Recurrent Neural Network (RNN) [17]. Then they constructed an outfit recommendation by selecting the items which achieve the highest compatibility scores along with the given items. Han *et al.* represented an outfit as a sequence with a specific order. Then they used bidirectional LSTMs to predict the next item given a set of items and also the compatibility scores of outfits [9]. Modeling outfit compatibility relies on a proper representation of the outfit, which can reflect the complex relations among multiple items. In this work, we represent an outfit as a graph, which is proved to be more effective than pairs and sequence in the later experiments.

Categorical information plays a dominant role in the representation of an item. In the above conventional methods modeling items in a common visual latent space, the items of same categories tends to be close, which makes it harder to reflect the style information. For example, in the common visual latent space, the similarity between suit pants and leather shoes is much smaller than the similarity between suit pants and jeans. In Sherlock [10], the embedding matrices for transferring visual features to style features vary among different categories. Liu *et al.* proposed that items consist of two components: style and category [20]. In this work, we utilize the categorical information directly by putting items into its corresponding category nodes in the *Fashion Graph*.

2.2 Graph Neural Networks

There have been various ways to deal with graph-structured data. Some works convert graph-structured data into sequence-structured data to deal with. Inspired by word2vec [26], Perozzi *et al.* proposed an unsupervised DeepWalk algorithm to learn node embedding in graph based on random walks [27]. After that, Tang *et al.* proposed a network embedding algorithm LINE [36], followed by node2vec [8]. Some works apply neural networks on the graph-structured data directly. Duvenaud *et al.* designed a special hashing function so that Convolutional Neural Network (CNN) can be used on the graphs [5]. Kipf *et al.* proposed a semi-supervised method on graphs based on an efficient variant of CNN [14].

Gori *et al.* first proposed Graph Neural Networks (GNN) [7], another approach to applying neural networks directly to graph-structured data. GNN can be applied on most kinds of graphs, including directed, undirected and cyclic graphs. Feed-forward neural networks are applied to every node in the graph recurrently. The nodes interact with others by communicating their state information. Thus, the hidden state of nodes will update dynamically. Scarselli *et al.* utilized multi-layer perceptions (MLP) to update the hidden state of nodes [29]. However, there exists problem in propagating information across a long range in a graph. To remedy this, Li *et al.* proposed Gated Graph Neural Network (GGNN) by introducing a Gated Recurrent Units (GRU) for updating [18]. GGNN has been utilized for various tasks, such as image classification [22], situation recognition [16], recommendation [39] and script event prediction [19]. Nevertheless, it has difficulty in modeling complex node interactions since the communication of state information on the edges are in a fixed way. To address this limitation, we propose a novel model NGNN, which can better model node interactions so as to better infer outfit compatibility from the graph. In NGNN, the communication of state information on each edge is different. It can model edge-wise interactions with node-wise parameters.

3 DATASET AND FEATURES

In this section, we introduce the dataset we use and how we extract the visual and textual features of items, which are used as input of our proposed method.

3.1 Polyvore Dataset

Polyvore dataset released by [9] was collected from a popular fashion website Polyvore.com[2], where fashion stylists can share the outfits they created to the public. As shown in Figure 3, items in the outfits have rich information including clear images, category information, titles, numbers of likes, etc. We only use the images, titles and category information of items in this paper. The dataset has been utilized by several works on fashion analysis [13, 17, 32].

[2]http://www.polyvore.com/.

Category	Image	Title
Coats		Irregular lapel blue trench coat
Knee Length Skirts		Beautiful cotton lace skirt yellow
Sandals		Mcq alexander mcqueen mirrored leather sandals
Necklaces		Navy blue yellow statement bib necklace earrings set

Figure 3: Examples of outfit composition on Polyvore.com. Each item has a clear image, titles and category information.

There are totally 21889 outfits covering 380 categories in the Polyvore dataset, which was split into three non-overlapping sets, 17316 for training, 1497 for validation and 3076 for testing. Following [32], there are many categories appearing too few times in the dataset such as *Toys*, *Furniture* and *Cleaning*, which are not actually fashion categories. To ensure the training quality, we keep categories which appear more than 100 times in the dataset and 120 categories remain. To ensure the integrity of outfits, we filtered out the outfits consisting of less than 3 items. Finally, there remain 16983 outfits in the training set, 1497 in the validation set and 2697 in the test set, with totally 126054 items covering 120 categories. The maximum size of outfits is 8 and the average size is 6.2.

3.2 Features

We extract the visual features using the images of items and textual features using titles. We will model the outfit compatibility using these features of items as described in the following.

3.2.1 Visual Feature. We utilize the advanced deep convolutional neural network GoogleNet InceptionV3 model [34] to extract the visual features, which has been proved to be effective in image representation learning [4, 9, 15, 30]. In particular, we feed the images of items into the model and adopted the linear layer output as the visual feature. The visual feature of each item is a 2048-dimensional vector.

3.2.2 Textual Feature. Following [32], we first construct a vocabulary based on the words of the titles in the dataset. Due to the noise of these user-generated titles, we first filter out the words which appear in less than 5 items. Since there are many meaningless words such as 'a', 'an' and 'de', we then filter out words with less than 3 characters. Finally we obtain a vocabulary with 2757 words and therefore we represented the textual feature of each item as a 2757-dimensional Boolean vector.

4 PROPOSED METHOD

We first formulate the problem. Then we introduce how to construct the *Fashion Graph* and model outfit compatibility from the graph with NGNN. We also introduce how to jointly model outfit compatibility from multiple modalities with NGNN. Finally, we describe the training strategy and analyze our model.

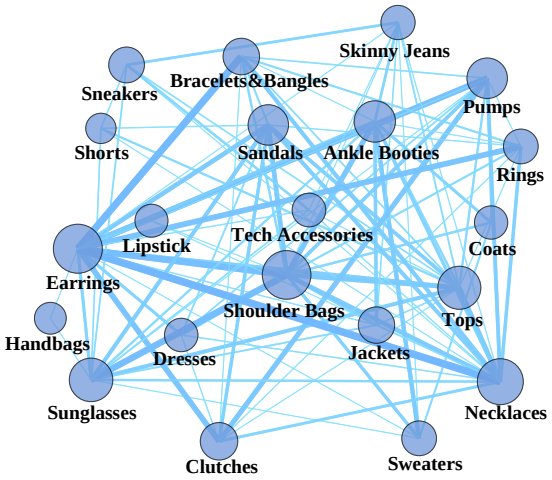

Figure 4: Illustration of the most popular categories in Polyvore dataset. Each circle denotes a category, and each link denotes the matching relation between two categories (i.e., they have appeared in the same outfit). The areas of circles and the widths of the links are proportional to the number of fashion items in the corresponding categories and the co-occurrence frequency between categories.

4.1 Problem Formulation

In this paper, we aim to model the compatibility of outfits. We have a set of outfits $\mathcal{S} = \{s_1, s_2, s_3, ...\}$ in the training set. The total item set is $\mathcal{V}$. Given an outfit s consisting of $|s|$ items (each item has an image and textual description), we aim to predict the compatibility score x_s of the outfit. The score can be used for various tasks of fashion recommendation.

We introduce some notations which will be used in the following. For each item $v_i \in \mathcal{V}$, its feature is f_i and the representation of f_i in the latent space is r_i. The category of v_i is c_i. The corresponding node of c_i in the *Fashion Graph* is n_i, while the state of node n_i in NGNN is h_i.

4.2 Graph Construction
