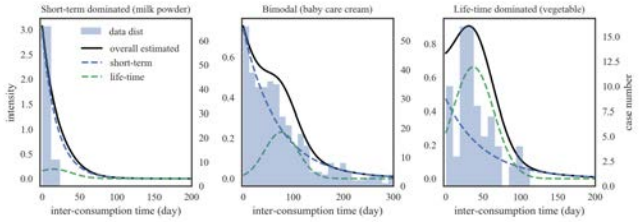

Figure 5: Some examples to validate the parametric modeling assumptions. For different types of items, overall intensity (black) closely approximates real distributions of inter-consumption gap (bar). Moreover, Exponential (blue) and Gaussian (green) distribution fit short-term and life-time effects well, respectively.

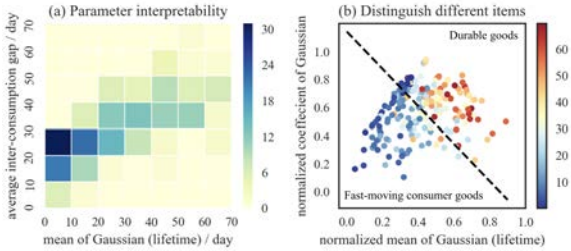

Figure 6: Correlation between item's inter-consumption gap and the learned lifetime parameter μ^i in Gaussian distribution (left), where color represents the number of items. And joint distribution of parameter μ^i and π^i (right), where red and blue stand for longer and shorter inter-consumption gap in average, respectively.

lower repeat consumption ratio (e.g. *Order*), due to the lack of collaborative filtering information, mainly modeling repeat consumption results in bad performance.

Second, although collaborative filtering and Hawkes Process methods gain encouraging results in different datasets, SLRC performs consistently better than other baselines in all datasets (the best combination with collaborative filtering method may be different in distinct datasets). This shows the proposed model is capable of utilizing both the strengths of collaborative filtering and temporal dynamics of repeat consumption in Hawkes Process, leading to great overall performance improvement consequently. Aside from the performance improvement over models about repeat consumption (i.e. FPMC, UtilitySVD, HCM), SLRC outperforms methods based on Hawkes Process without concern about item-specific temporal dynamics of repeat consumption (i.e. TSR-Hawkes, Neu-Hawkes and LS-Hawkes), which indicates the importance of modeling both short-term and life-time effects in kernel function. The integration of collaborative filtering methods also plays an important role, which estimates users' inherent preference for items more accurately and helps to better recommend novel items that meet users' interests.

Third, the experimental results demonstrate that the incorporation of SLRC leads to a big gap of improvement (up to 35.0%) compared to the original collaborative filtering baselines. This shows the information of repeat consumption and its item-specific temporal dynamics are critical to recommender systems. Notice that the improvement for traditional method BPRMF is extremely large in most datasets. SLRC introduces history sequence information and temporal factors into the model, so BPRMF may attentively model inherent preference more accurately. For other baselines that take more information into consideration themselves, SLRC also brings consistent performance gain on all datasets. Besides, the encouraging results on all the datasets in different scenarios show the scalability and flexibility of our model.

5.3 Parametric Assumptions Validating

Here we want to validate whether the learned parameters have interpretable meaning as we assume when designing the model.

First, we study how well the learned intensity function fits real data. Figure 5 gives some examples from different datasets. We draw both the distribution of inter-consumption gap in real data and how estimated intensity drifting with time[6]. The results show that the overall intensity (black) closely approximates real distribution of inter-consumption gap. Moreover, the *short-term effect* (blue) and *life-time effect* (green) capture the temporal characteristics of repeat consumption well, respectively. Take vegetable as an example (the right figure), we find there are numerous repurchasing behavior for vegetables around 30 days after previous consumption in Section 3.3. As expected, the Gaussian distribution for vegetable learned in SLRC shows around 30 days mean ($\mu^i = 36$ days) and the importance of *life-time effect* is high ($\pi^i = 0.65$), indicating *life-time effect* is in dominated position.

Next, remind that the mean (μ^i) and the coefficient (π^i) of life-time effect in Eq. 7 are item-specific. μ^i can be seen as item's expected lifetime and π^i is the importance of life-time effect. Figure 6 (a)[7] shows the correlation between item's inter-consumption gap in average and corresponding parameter μ^i. Parameters are trained in *Baby* dataset with $\text{SLRC}_{\text{BPRMF}}$ model. Other combinations in other datasets yield similar results. Note that the information of inter-consumption gap is not introduced in SLRC explicitly, but μ^i is reasonably in direct proportion to average inter-consumption gap (Pearson Correlation Coefficient: 0.7468), showing that items that are often consumed again after a long period of time (long lifetime) get larger μ^i just as assumed.

Further, we show the joint distribution of μ^i and π^i in Figure 6 (b), which demonstrates that items with higher average inter-consumption gap (red in color) almost have larger μ^i and π^i. The dashed line in figure obviously divides items into two kinds: fast-moving consumer goods (below) and durable goods (above). Some representative items above the dashed line are toys, baby walkers, beds and so on, while fast- moving consumer goods like paper diaper and milk powder are mostly under the dashed line. Another convincing and interesting observation is that most feeding bottles appear above the dashed line while nipples only appear below the dashed line, for the reason that users often change nipples but seldom change feeding bottles.

[6]Here we assume previous consumption happens at the origin of coordinates and show the temporal trend of self-excitation.

[7]We discard items that are never repeatedly consumed. And items with extremely high or low number of average inter-consumption gap are also removed.

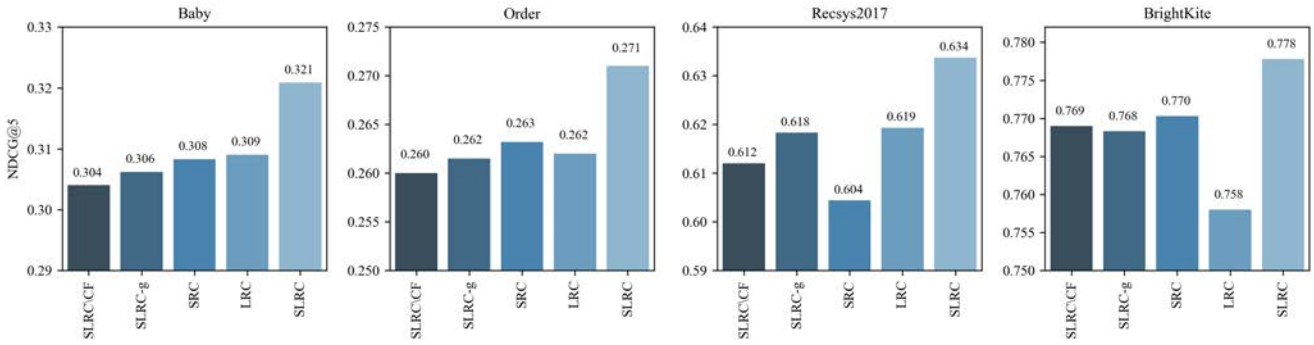

Figure 7: Performance comparison between SLRC and methods with no consideration for CF or variety of temporal dynamics. SLRC performs the best again various variations. All improvements are statically significant ($p < 0.05$).

Table 3: Difference comparison between variants of SLRC.

Variants	CF	Item-specific	Life-time	Short-term
SLRC\CF		✓	✓	✓
SLRC-g	✓		✓	✓
SRC	✓	✓		✓
LRC	✓	✓	✓	
SLRC	✓	✓	✓	✓

To sum up, SLRC gains remarkable performance improvement and the estimated parameters can further explain various temporal patterns of repeat consumption across different items perfectly.

6 FURTHER ANALYSIS

6.1 Ablation Study

To verify the effect of CF part and the two item-specific temporal dynamics (short-term and life-time effects) addressed in the model, we compare SLRC to a series of baselines without consideration for variety of temporal characteristics of repeat consumption.

- **SLRC\CF**. This model removes the CF part of SLRC and uses an item-specific parameter to estimate the base intensity.
- **SLRC-g**. This model does not concern the variety across different items. Parameters related to self-excitation are not item-specific (parameters in $\Theta_s = \{\boldsymbol{\alpha}, \boldsymbol{\pi}, \boldsymbol{\beta}, \boldsymbol{\mu}, \boldsymbol{\sigma}\}$ are global values).
- **SRC**. This model only consider short-term effect without life-time effect, where the triggering kernel in intensity function is an item-specific Exponential distribution.
- **LRC**. Similar with SRC, LRC only takes life-time effect into consideration, where an item-specific Gaussian distribution acts as the triggering kernel in intensity function.

Table 3 intuitively shows the difference between SLRC and its variants. Combinations with different baselines yield similar results, so here we only show results when combined with BPRMF (i.e. base intensity is calculated by BPRMF for SRC, LRC, SLRC-g). The results shown in Figure 7 indicate that although variants of SLRC achieve consistently better performance than BPRMF, none of them can outperform the full SLRC model.

Without the integration of CF, SLRC\CF leads to loss of performance, which demonstrates that the CF part of SLRC plays an important role for holistic recommendation task. As for SLRC-g, it neglects inherent properties (like lifetime) of distinct items. The short-term and life-time effects estimated over all items can be inaccurate when evaluating some specific items. Therefore the difference in temporal dynamics across items are critical to model repeat consumption behavior.

On the other hand, SRC and LRC do not take both temporal factors into consideration and hence get worse results, which demonstrates that the lack of variety of temporal factors can lead to lower predictive ability (e.g. continuous recommendation for mobiles shortly after purchasing one and mobiles could not be recommended when it is the time to change a new one). It is noteworthy that the performances of SRC and LRC vary across datasets. The results are similar in *Baby* and *Order* for the reason that both short-term and life-time effects are common in item purchasing scenario. But LRC is better than SRC in *Recsys2017*, which may be the result of obvious life-time effect in this dataset as shown in Section 3.3. The short-term effect is weaker compared with other datasets because users seldom click a job posting again in a short time. While in *BrightKite*, SRC outperforms LRC greatly. It is also reasonable because users often revisit hotels they appreciate recently but seldom go to the one visited long time ago. The short-term effect is much stronger than life-time effect in such scenario.

Further, dynamically modeling short-term and life-time effects for different items, our SLRC model is able to utilize strengths of CF and capture complex patterns of repeat consumption, achieving the best performance in all the datasets.

6.2 Discussion on Exploration and Exploitation

Besides the great performance improvement, we want to figure out how well our model balances the recommendation of novel items and consumed items. The self-excitation addressed in the model should not result in recommending more consumed items under all circumstances. Therefore, we construct a series of subsets (the same size) from the test dataset with different ratios of repeat consumption to simulate exploration dominated and exploitation dominated scenarios. This can be done by randomly sampling a certain ratio (namely, repeat ratio r) of cases from repeat consumption set and filling the rest with cases randomly sampled from the other part

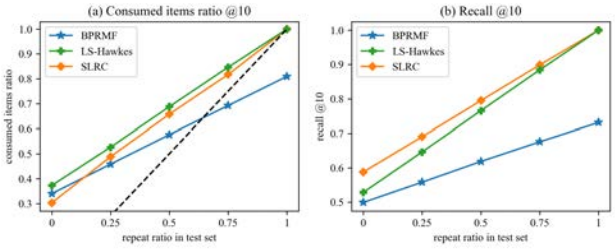

Figure 8: Results on test subsets with different ratios of repeat consumption case. In the left figure, the dashed line shows expected trend of consumed items ratio. SLRC shows a better balance of exploration and exploitation, and gains better result all the time.

containing no repeat consumptions. When repeat ratio r is small, exploration cases are in dominant position (if $r = 0$, all cases in the subset are consumptions for novel items), otherwise exploitation cases dominate the subset.

Figure 8 shows consumed items ratio and Recall@10 on subsets with different repeat ratio r. Consumed items ratio means the proportion of test cases whose corresponding recommendation list contains consumed items. Ideally, model should recommend less consumed items when repeat ratio r is small (i.e. users tend to seek novel items) but to retrieve more consumed items when r is large (i.e. users want to purchase items consumed before). In the left figure, the dashed line shows expected trend of consumed items ratio. We conduct top-10 recommendation in *Recsys2017* dataset and use BPRMF as the base method. Several observations from these results are worth highlighting:

- All the models recommend more consumed items when repeat ratio gets larger (i.e. users express more needs for consumed items) and yield better performance.
- SLRC recommends less items when repeat ratio is small, while recommends more consumed items otherwise, leading to a better balance of exploration and exploitation compared with BPRMF and LS-Hawkes.
- SLRC achieves better results under all circumstances. The improvement gap compared to BPRMF gets larger as repeat ratio increases. And only when all test cases are repeat consumption, LS-Hawkes can achieve similar performance with SLRC.

The main conclusion is that addressing both short-term and lifetime effects helps SLRC to well balance exploration and exploitation. SLRC will not recommend extra consumed items when users do not need. While in the cases when users express demands for consumed items, our model properly recommends more consumed items. Notice that the performance of LS-Hawkes gets closer to SLRC's when repeat ratio increases, the reason may be that LS-Hawkes wrongly gives higher scores to some consumed items without considering various temporal dynamics and CF information, so novel items cannot be recommended for some exploration cases. As a result, only when there are all repeat consumption cases, LS-Hawkes can achieve similar performance with SLRC.

In summary, the results demonstrate that SLRC clearly captures users' need for consumed items, achieving a good balance of exploration and exploitation. Furthermore, in real-world scenarios where repeat consumption takes a moderate part, SLRC model performs significantly better than other methods.

7 CONCLUSION AND FUTURE WORK

Repeat consumption comes to be increasingly important recently. It is necessary to model repeat consumption behavior so that recommender system can recommend items user consumed before at proper time. In this work, we focus to build a holistic model that can recommend novel items and consumed items simultaneously. Two factors are revealed for modeling various time-varying patterns of repeat consumption: *short-term effect* and *life-time effect*. To address this variety, we propose a novel model, **S**hort-Term and **L**ife-Time **R**epeat **C**onsumption (SLRC), which explicitly takes the two factors into consideration with combination of two techniques: Collaborative Filtering (CF) and Hawkes Process. According to extensive experiments, significant performance improvement is achieved in four real-world datasets compared to state-of-the-art baselines. Besides, with high interpretability, SLRC is able to discover distinct items' lifetimes. And different types of items such as fast-moving consumer goods and durable goods can even be distinguished by the learned parameters, showing the model can perfectly captures various item-specific dynamics of repeat consumption. Generally, our model is able to be leveraged as a framework that utilize repeat consumption information to enhance existing recommender systems based on collaborative filtering and hence achieve better recommendation results in real-work applications.

In the future, we will turn to category level and consider mutual-excitation of similar items. Intuitively, a previous consumption not only has influence on the item itself, but also influences purchase tendency of similar items. The item-specific modeling method in SLRC may suffer from data sparsity greatly. Further, simultaneous consumption has some inherent relationship with repeat consumption. How to combine these two together is an interesting but seldom explored problem.

ABSTRACT

The continuing expansion of mobile app ecosystems has attracted lots of efforts from the research community. However, although a large number of research studies have focused on analyzing the corpus of mobile apps and app markets, little is known at a comprehensive level on the evolution of mobile app ecosystems. Because the mobile app ecosystem is continuously evolving over time, understanding the dynamics of app ecosystems could provide unique insights that cannot be achieved through studying a single static snapshot. In this paper, we seek to shed light on the dynamics of mobile app ecosystems. Based on 5.3 million app records (with both app metadata and apks) collected from three snapshots of Google Play over more than three years, we conduct the first study on the evolution of app ecosystems from different aspects. Our results suggest that although the overall ecosystem shows promising progress in regard of app popularity, user ratings, permission usage and privacy policy declaration, there still exists a considerable number of unsolved issues including malicious apps, update issues, third-party tracking threats, improper app promotion behaviors, and spamming/malicious developers. Our study shows that understanding the evolution of mobile app ecosystems can help developers make better decision on developing and releasing apps, provide insights for app markets to identifying misbehaviors, and help mobile users to choose desired apps.

1 INTRODUCTION

It has been over 10 years since the first Android-based smartphone was announced in 2008 [18, 27]. Android has evolved significantly in the past decade, and has become the most popular mobile operating system with 85.9% market share as of 2017 [55]. Google reported that there were over 2 billion monthly active devices using Android as of May 2017 [48]. Millions of mobile apps with myriad features have become the key to boost the evolution of smartphones and Android. Google Play, the official Android app market, was first introduced in 2008 [72]. Since its launch, (Android) mobile apps have impacted our society at an astounding pace and scale. It is now one of the largest app stores in the world, with over 2.5 million apps available for download in October 2018[1]. The total number of app downloads in Google Play has surpassed 200 billion by 2017 [70].

Billions of mobile users, millions of mobile apps and app developers, thousands of devices manufacturers, and hundreds of app markets have formed a symbiotic relationship, which we refer to as the ***mobile app ecosystem***. The global app economy is also poised to explode, which is estimated to worth 6.3 trillion dollars by 2021 [45]. As a result, the continuing evolution of mobile app ecosystems has increased the complexity and myth of the whole ecosystem, which itself needs considerable efforts to understand its characteristics and working mechanism.

The mobile app ecosystem has attracted a lot of efforts from the research community. A large number of studies have focused on analyzing the mobile apps and app markets, including exploring the characteristics of mobile apps [11, 32, 35, 43, 59], understanding and comparing app markets [7, 14, 60, 67, 69, 70], security and privacy analysis of mobile apps [10, 25, 26, 41], understanding app developers and mobile users [16, 22, 33, 40, 74], etc.

However, little is known at a comprehensive level on the **evolution of mobile app ecosystems**. Although several previous work have performed large-scale measurement studies on the app ecosystem and analyzed millions of apps [60, 70], they only studied the ecosystem based on a static snapshot collected in a given time slot. For example, PlayDrone [60] performed the characterization of 1.1 million Google Play apps crawled in 2013, and Wang *et al.* [69] studied the ecosystem from the perspective of app developers on over 1.2 million Google Play apps and 320,000 developers collected in 2015. To the best of our knowledge, no previous work have studied the evolution of app ecosystems comprehensively at a large scale.

Because the Android ecosystem is evolving over time, studying the dynamics of the app ecosystem could gain unique insights

[1]It is reported that the number of apps in Google Play has surpassed 3 million in 2017. However, Google has been removing a significant number of apps from time to time.

that cannot be achieved by studying static app market snapshots. From app developers' perspective, understanding the evolution of app ecosystems could help them make better decision on developing and releasing apps, e.g., realizing which app categories are most competitive and the trend, and understanding the impact that developer actions will likely have on the success of their apps. From the view of app markets, studying the evolution of the app ecosystem could help them with monitoring and further improving the app market, as the number of apps keeps increasing. Previous studies suggest that malicious apps and fraudulent developers are prevalent in app markets [60, 70], thus lessons learned from a longitudinal analysis can provide insights into identifying fraudulent app promotion and malicious behaviors. Besides, a longitudinal measurement study of the ecosystem is a valuable indicator of understanding the real threats and challenges. From mobile users' perspective, understanding the dynamics of app markets could help them make better decision when choosing desired apps with similar functionality, e.g., avoiding the apps that have not been updated for years, which may contain vulnerabilities and have compatibility issues.

This Study. In this paper, we make the first effort towards understanding the evolution of mobile app ecosystems. Specifically, we seek to shed light on the evolution of Google Play, the official and the most popular Android app market. To this end, we have collected three snapshots of Google Play, which were crawled in March 2014, March 2015 and September 2017, respectively (Section 3). This dataset includes 5.3 million Android app entities in total, with all the metadata and apks. We first use this dataset to provide a high-level characterization of all the apps and analyze the evolving trends, including the distribution of free and paid apps, the evolution of app downloads and app rating, the ranking and competitiveness of app categories, the evolution of permission usage and privacy policy declaration, and the presence of third-party tracking and advertising libraries (Section 4). Next, for the 743,530 long-lasting apps (appeared in all three snapshots) in our dataset, we further investigate their growth rate, app updates, and permission changes (Section 5). Third, we provide an in-depth analysis of malicious and deceptive behaviors across the three snapshots, discussing the presence of malicious apps and aggressive app promotion behaviors (Section 6). At last, we analyze the evolution from the developers' perspective. We have classified the developers into different groups based on the number of apps they released and analyzed their evolution, and further pinpoint the spamming and malicious developers (Section 7). Among many interesting results and observations, the following are the most prominent:

- The app monetization scheme evolves during the evolution of the mobile app ecosystem. The number of paid apps has decreased significantly in Google Play, while mobile advertising is getting more popular.
- Although the popularity and overall quality of apps published in Google Play are getting better, the overall ecosystem shows a typical Pareto effect all the time, i.e., dominated by a small number of apps and developers.
- There exists a trend that the percentage of apps that request sensitive permissions are on the decline. Google's regulation on privacy policy has greatly improved the privacy protection of mobile users, e.g., the percentage of apps declaring privacy policies in 2017 is four times of the number in 2014.
- Over 61% of the long-lasting apps have not received any updates for three years, which indicates that these apps cannot utilize new features introduced by new Android versions, and may have compatibility issues and vulnerabilities.
- The proportion of potentially malicious apps in Google Play is decreasing. However, spamming apps that use misleading references to other apps are always prevalent in Google Play, many using more sophistic methods to insert keywords.
- Although Google Play removes spamming developers and malicious developers regularly, the number of developers with misbehaviors is nonetheless increasing.

To the best of our knowledge, this is the first comprehensive longitudinal study of the mobile app ecosystem at scale. Our dataset is by far one of the largest Google Play app repositories in the research community, with all the metadata and apks. We believe that our efforts and the revealed insights can benefit the research community, as well as various stakeholders of the mobile app ecosystem.

2 RELATED WORK

2.1 Mobile App Ecosystem Analysis

A number of research efforts have focused on analyzing the mobile app ecosystem [7, 28, 29, 31, 34, 38, 46, 60, 69, 70]. They usually first collect a large number of apps from Google Play or alternative markets, and then measure the app ecosystem from various dimensions. We have summarized the most related work on app ecosystem analysis, as shown in Table 1. Two representative studies are AndroidZoo [38] and the work of Wang *et al.* [70]. AndroZoo focused on crawling a large-scale dataset of APKs, which has enabled a number of studies focusing on malware analysis and app repository mining [31]. Wang *et al.* [70] performed a large-scale comparative study that covers more than 6 million Android apps downloaded from 16 alternative markets and Google Play to understand the catalog similarity across app stores and malicious behaviors. Although these studies have measured the mobile app ecosystem in large scale, they only captured a single snapshot of the ecosystem and did not consider the longitudinal evolution.

2.2 App Evolution Analysis

One line of research is analyzing the app evolution. Potharaju *et al.* [49] performed a longitudinal study of 160K apps, however, they only studied the evolution of metadata (e.g., price and downloads) and only covered 10% of apps in Google Play. Calciati *et al.* [13] and Taylor *et al.* [56, 57] analyzed the evolution of apps' permission requests, and found that apps tend to request more permissions in their evolution. Taylor and Martinovic [56] studied the evolution of financial apps from permission usage and vulnerabilities. Gao *et al.* [23] analyzed the vulnerability evolution of Android apps based on a set of Android app lineages in large scale, and found that apps do not get safer as they get updated. Wang *et al.* [67] found that a large portion of apps in Google Play are removed from time to time. They presented a large-scale study of 791,138 removed Google Play apps to identify potential reasons for app removal. Although these studies have analyzed app evolution from specific

Table 1: Related work on mobile app ecosystem analysis.

perspectives, these studies lack of a comprehensive understanding on the evolution of the app ecosystem.

2.3 Mobile App Analysis

A large number of studies focus on mobile app analysis, including security and privacy analysis [10, 25, 30, 39, 41, 42, 65, 66, 68], app repackaging detection [15, 63], app quality analysis [37, 50, 54, 58], third-party library detection [12, 44, 53, 62, 64] and mobile ad network analysis [17, 20], etc. Most of these studies focus on one specific issue and lack of the measurement study of the app ecosystem, although similar approaches could be used to understand the evolution of specific issues in the mobile app ecosystem.

3 STUDY DESIGN

3.1 Data Collection

We have created three snapshots of Google Play, which were crawled in 2014, 2015 and 2017, respectively. Note that we use the term **snapshot** to refer to the entire state of the market, i.e., it contains meta-information of (almost) all the apps and the corresponding apks. This dataset is representative enough to study the evolution of app ecosystem, as the timeline in our study period covers three major Android system updates (version 5.0, 6.0 and 7.0).

First Snapshot. It was created in March 2014. Our crawling strategy started from top 500 Google Play apps in each category (considered as seeds), and 12,500 apps that belong to 25 general categories in total. Then, we use a breadth-first-search approach to crawl (1) "Similar Apps" shown on the app web pages recommended by Google Play and (2) other apps released by the same developer by retrieving the developers' Google Play web pages. Note that we downloaded all the apk files of free apps through the Google Play API. Furthermore, We have taken efforts to crawl all the app metadata (e.g., app names, descriptions, version names, developer names, user ratings, app installs, the privacy policy links, etc). We have crawled over 1.5 million apps, which represent almost all the apps that can be crawled from Google Play at that time [60].

Second Snapshot. In March 2015 (1 year after the first snapshot), we repeated the same process as described above to crawl Google Play apps, except that we take the previous 1.5 million crawled apps as our searching seeds. It could ensure that we check all the 1.5 million apps crawled in 2014. Overall, we are able to collect more than 1.6 million Android apps in this snapshot.

Third Snapshot. We repeated the same process in September 2017 (2.5 years after the second snapshot), and we take the 1.6 million apps crawled in the second snapshot as searching seeds. At last, we have crawled 2.1 million apps in total.

Table 2: Summary of our dataset.

	# Apps	# Free	#Paid	Installs	# Developers
Google Play 2014	1,522,730	1,292,064	230,666	55.1B	413,933
Google Play 2015	1,650,895	1,408,593	242,302	90.2B	398,855
Google Play 2017	2,144,733	2,012,904	131,829	193.5B	541,105

We launched crawlers in parallel via Aliyun Cloud servers that were located in North America. In order to avoid potential regional/language bias, we instrumented our crawlers in the default mode that supports English. This is the largest longitudinal Android app dataset in our research community that has collected the detailed information of both apks and app metadata.

3.2 Dataset Characteristics

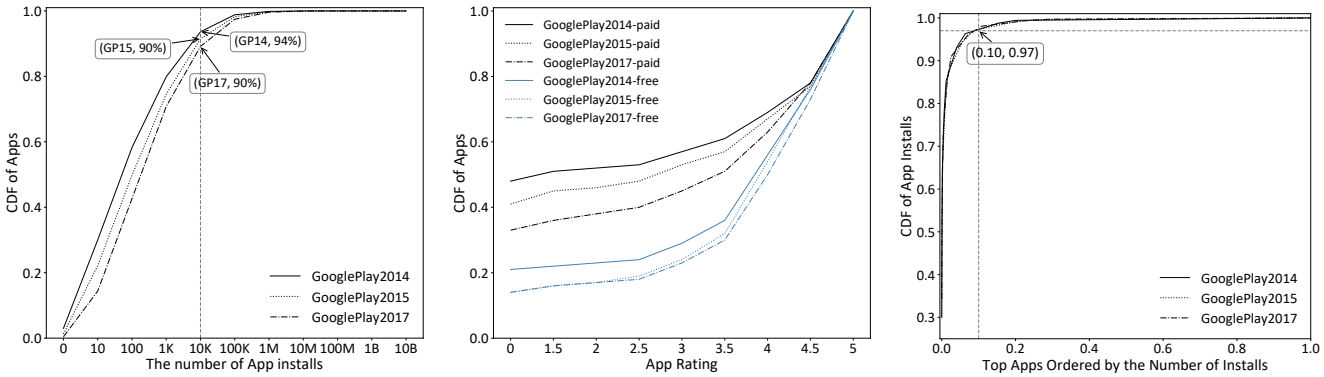

Table 2 reports the number of apps we harvested in the three snapshots. We could observe some general trends here: (1) From 2014 to 2017, the number of free apps in Google Play increases greatly, from roughly 1.3 million to the 2 million mark. In contrast, the number of paid apps decreases rapidly since 2015. The number of paid apps in 2017 is roughly half of the number in 2015. (2) The overall number of app installs in Google Play grows steadily. The number of app installs in 2015 is twice the number of 2014, while in 2017 the number has doubled compared to the 2015 snapshot. (3) The number of app developers in Google Play has not seen significant increase, which remains stable in the range of 400K to 500K. It is interesting to see that the number of app developers decrease in the 2015 snapshot compared to 2014.

4 OVERALL TREND OF APP EVOLUTION

4.1 Free vs. Paid Apps

It is a trend that the number of paid apps has decreased significantly in Google Play. The percentage of paid apps dropped by more than 60% (from 15.2% in 2014 to 6.1% in 2017). As to app installs, the proportion of paid apps is nearly negligible. Free apps occupy more than 99.7% of total app installs across snapshots.

There is a sharp decrease in the number of available paid apps from 2015 to 2017. To further investigate the reason, we analyzed the catalog similarity of paid apps between the three snapshots, and get two main observations: (1) More than 95% of the paid apps in 2017 are originated from 2015, while only 6,252 new paid apps have emerged in the two-year period. More than 99.5% of new apps crawled in the 2017 (1.28 million) snapshot are free apps. (2) Only 52% of paid apps (125,577) in 2015 remained as paid apps in 2017. For the remaining 116,725 apps, 6,989 of them (6%) became free apps (with the same app name and package name) in 2017, and roughly 94% of them had been removed/discontinued/renamed, so that we cannot locate them by searching the names in Google Play.

(a) The distribution of app installs. (b) The distribution of app ratings. (c) A few apps account for most of the downloads.

Figure 1: The evolution of app installs and app ratings.

Implication. One possible reason is that mobile ads and in-purchase become the most popular monetization schemes in Go play apps (cf. Section 4.7). As a result, new developers should ret their app releasing and monetization strategies.

4.2 App Installs

We further investigate the distribution of app installs across three snapshots. Figure 1(a) reports the cumulative distribu of app installs, which suggests that ***the popularity and qua of apps published in Google Play is getting better***. Over of apps have less than 10K installs by 2014, while the numb reduced to 89% by 2017. The average number of app installs raised from 36,183 (2014) to 90,209 (2017).

Then we characterize the app popularity distribution for all apps ordered by the number of installs, as illustrated in Figure Our results highlight a typical **Pareto effect**, with top 0.1% of a in Google Play represent roughly 60% of total installs, while the 1% of apps account for 80% of total installs. This observation is sistent across all the three snapshots. It suggests that although overall market shows a promising trend in regard of app popula the market is still dominated by a small percentage of apps.

4.3 App Ratings

We then investigate the distribution of app ratings in Google P across the snapshots, as shown in Figure 1(b). In general, the distribution of app ratings for free apps is better than paid apps. The app ratings are getting better for both free and paid apps, i.e., more apps are getting higher user ratings. This trend is more obvious for paid apps. For the 2017 dataset, over 55% of paid apps received app ratings higher than 3-star, while the number in the 2014 dataset is 43%. For the free apps, the distribution of app ratings in the 2015 and 2017 dataset are almost the same, which are slightly better than in 2014.

4.4 App Categories

For the 2014 and 2015 snapshots, there are generally 25 categories, as listed in Figure 2. While, in 2017, 8 new categories were introduced, including "Beauty" and "Dating". As the distribution of apps and developers is fairly diverse for different categories, we examined the differences between each category in order to understand

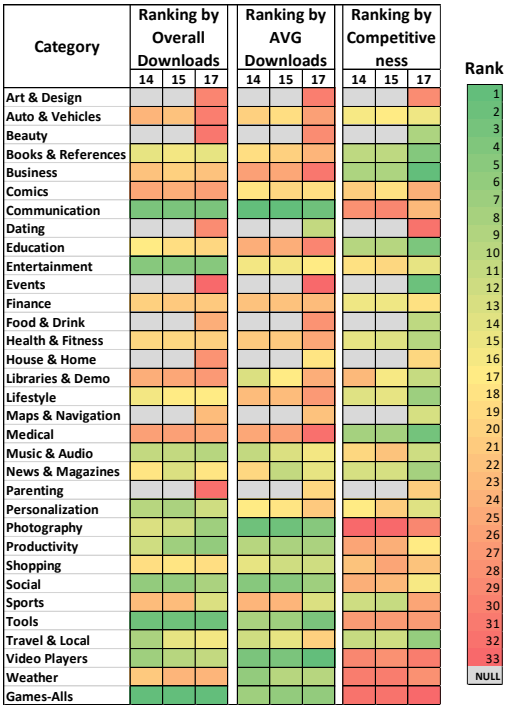

Figure 2: Distribution of app categories.

which categories are more popular and more competitive over time. This is also important to understand the trend of popular apps.

To this end, we compare the app categories based on (1) the total number of app installs, (2) the average number of app installs, and (3) the percentage of popular apps in each category, which can be regarded as an indicator of category competitiveness. Note that we regarded the apps that belong to the top 1% of the most downloaded apps as **popular apps**. The result is shown in Figure 2.

Category Ranking by Total Installs. Besides the "Games" Category, "Tools" received the most number of app installs (e.g., 25 billion till 2017) across the three years. The ranking of most categories does not vary significantly during the period. Five out of the 33 categories have received higher ranking from 2014 to 2017, for

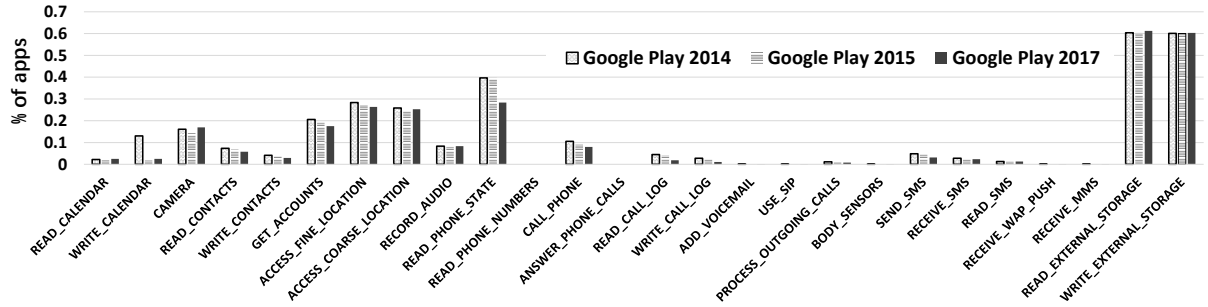

Figure 3: Evolution of requested sensitive permissions.

example, the ranking of category "Sports" went up to 11 from 21. Six categories (e.g., "Travel & Local") have received lower rankings.

Category Ranking by Average Downloads. We then compare app categories based on the average app installs, which is an indicator of app quality and user adoption. As shown in Figure 2, the general trend is stable, except for a few categories. Although category "Entertainment" receives quite high number of overall installs (rank-4 across the period), it only ranks No. 14 on average app downloads. Although the "Weather" category only ranks 19 to 22 in regard of total installs, the average app installs in this category are quite high, which ranks 5 to 8 during the evolution.

Ranking by Competitiveness. We then rank app categories based on the percentage of popular apps in each category. "Business" and "Medical" are the most competitive categories, while the total installs and average installs of these two categories rank low among the 33 categories. "Video Player" and "Communication" categories are the least competitive categories, while they have the most number of average app installs. This result could offer insights to new app developers on their developing and releasing strategies.

4.5 Permission Usage

We then investigate how sensitive permission usage by Google Play apps has evolved over time. Permission requests protect sensitive information available from a device, while Google requires developers to use sensitive permissions only when it is necessary for the functioning of the app. We seek to investigate how the permission usage in the whole ecosystem has evolved. For each app, we extract its requested permissions. Note that we only focus on the so-called *dangerous permissions* as listed by Android [8], i.e., the 26 system permissions used to guard accesses to sensitive data.

Figure 3 shows the overall result. The trend is that the number of apps requesting sensitive permissions are on the decline. More than 13% of apps requested the WRITE_CALENDER permission in 2014, while the numbers in 2015 and 2017 are only 1.7% and 2.5%, respectively. As another example, roughly 40% of apps requested the READ_PHONE_STATE permission in 2014 and 2015, while the number went down to 28% in 2017. Note that we will discuss the evolution of per-app permission request in Section 5.

One possible reason leading to this result is that Google Play requires all developers to provide a privacy policy since 2017 when an app requests sensitive permissions, which may in turn help apps respect users' privacy (i.e., eliminate unnecessary permissions).

4.6 Privacy Policies

Since 2017, Google Play requires developers to provide a valid privacy policy when an app requests or handles sensitive information [47]. It is reported that Google Play will remove apps with no privacy policies [1]. Thus, we can compare the developers' practices on privacy policy declaration along with the timeline. Note that the dataset we crawled in 2014 does not contain the privacy policy URL of the corresponding app, thus we only compare the apps in the 2015 and 2017 snapshots.

Our empirical analysis suggests that Google Play apps may declare privacy policy in either the app description or in the field of privacy policy shown on web pages. Thus, for the apps that request sensitive permissions, we check whether it declares privacy policies in its app description by (1) searching keywords "Privacy Policy" or (2) inspecting the privacy policy field shown on app pages. Note that we only consider whether the privacy policy exists, i.e., it should declare a privacy policy as long as it requests sensitive information, as required by Google Play. We did not check whether the privacy policy is consistent with its actual behaviors, which is another interesting topic that is out of the scope of this paper [73].

Figure 4 shows the analysis result for each sensitive permission. For the apps that request a specific permission, we calculate the percentage of apps with privacy policies. The results show that, in 2015, less than 20% of apps (11% on average) declared privacy policies even if they have requested dangerous permissions. For example, 216,160 apps requested the "CAMERA" permission in 2015, while only 31,814 of them (14.7%) declared privacy policies. This scenario has been greatly improved in 2017. For most permissions, more than half of the apps that used these permissions have declared privacy policies. The percentage is generally four times higher than that in 2015. For example, more than 62.8% of apps that use the "CAMERA" permission now have declared privacy policies.

Implication. This result suggests that the guidelines of Google Play on privacy policies have greatly improved the privacy protection of mobile users. Nevertheless, we should notice that a considerable number of apps still have not declared privacy policies, even if they request access to users' sensitive data, which indicates that they may violate Google Play's policy but are not removed.

4.7 Mobile Advertisement Services

Third-party libraries form an integral part of the mobile ecosystem, helping ease app development and enable features such as

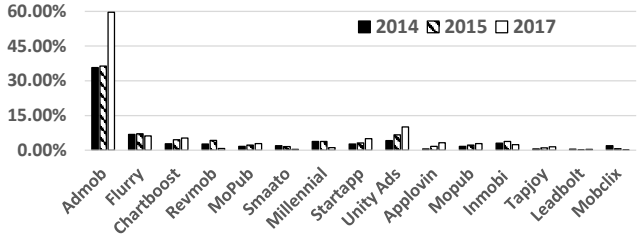

Figure 5: Top 15 mobile advertisement libraries.

analytics, social networking, and app monetization through advertisements. However, previous work suggested that third-party tracking services, especially the mobile advertisement services, may bring security and privacy issues to mobile users.

One important question here we want to explore is *whether more Google Play apps have embedded advertisement services during our investigation period.* Thus, we first need to identify third-party libraries in the apps we crawled. Here we extend a state-of-the-art clustering-based approach [43] to the millions of apps we crawled, and build a complete list of third-party libraries used in Google Play apps. The key idea is that, code that belongs to third-party libraries would be grouped in a large cluster. Then we manually labelled ad libraries based on several existing classifications, including AppBrain library classification [9], PrivacyGrade classification [6], and Common Library classification [36]. At last, we have manually labeled over 100 ad libraries.

Overall, 43.8% of apps in 2014 used at least one ad library, while over 68% of apps in 2017 embedded ad libraries. It means that more and more Google Play apps tend to use advertisement libraries, which is consistent with our findings in Section 4.1 that the app monetization schemes have changed over time, i.e., the number of paid apps is decreasing and most free apps rely on mobile advertisement to make money. Figure 5 further shows the top 15 mobile advertisement libraries used in Google Play apps. It is no doubt that Admob is dominating Google Play all the time. Over 35% of apps in the 2014 snapshot use the Admob library, while the percentage has raised to roughly 60% in our 2017 dataset.

5 LONG-LASTING APPS

In this section, we focus on the life cycle of apps. We define "**long-lasting apps**" as those available in all three Google Play snapshots, and we define "**removed**" apps as those apps that were removed from Google Play in either the 2015 or 2017 snapshot. In our dataset, 743,530 apps are flagged as "long-lasting apps", i.e., we have crawled three snapshots of them. It indicates that over 50% of the apps released in 2014 have been removed during the four-year period. We will next investigate them from different perspectives, including *app growth rate*, *app updates* and *permission evolution.*

5.1 Growth Rate

It is important to study the growth rate of app installs for the long-lasting apps, which could offer insights on how to develop successful apps. Thus, we first classify the number of app installs into 10 ranges, e.g., $[1, 10)$, $[10, 100)$, $[100, 1K)$, etc. Then, we analyze how many of them keep staying in the original ranges, and how many of them have evolved to higher install ranges.

Figure 6(a) presents the results. Overall, more than 57% of apps did not move ahead to a higher install ranges, especially for the apps with installs higher than 10K. For the apps with less than 1K downloads in the 2014 snapshot, roughly 40% of them have moved into a higher range during our study period. Interestingly, very few unpopular apps (roughly 0.04%) would become popular (with more than 1 million installs) later, as almost all of them would remain unpopular and with relative low downloads. This result suggests that the *initial status of the app would determine whether this app could be successful to a great extent.*

5.2 App Updates

We then study the statistics on app updates, which form a critical part of the app life cycle and would greatly affect app quality. It is important to understand how apps update over time, especially as several new Android versions was introduced during the period of our snapshots. For example, Lollipop (version 5.0) was released in October 2014, Marshmallow (version 6.0) was introduced in May 2015, and Nougat (version 7.0) was announced in August 2016.

Percentage of Updated Apps. For each long-lasting app, we have analyzed its three snapshots by comparing the hash values of the apks and the extracted version names and version code. To our surprise, **roughly 61% of apps have not received any update within our observation period**. Only 11.44% of them have been updated at least twice[2]. This means that more than 60% apps did not release new versions for almost four years, even if the Android system has evolved over several versions, and introduced several key features such as runtime permission enforcement [2].

App Updates across Categories. We then investigate whether there is a correlation between app updates and app categories, as

[2]Our sampling only covered 3 snapshots, while the apps may update more than twice.

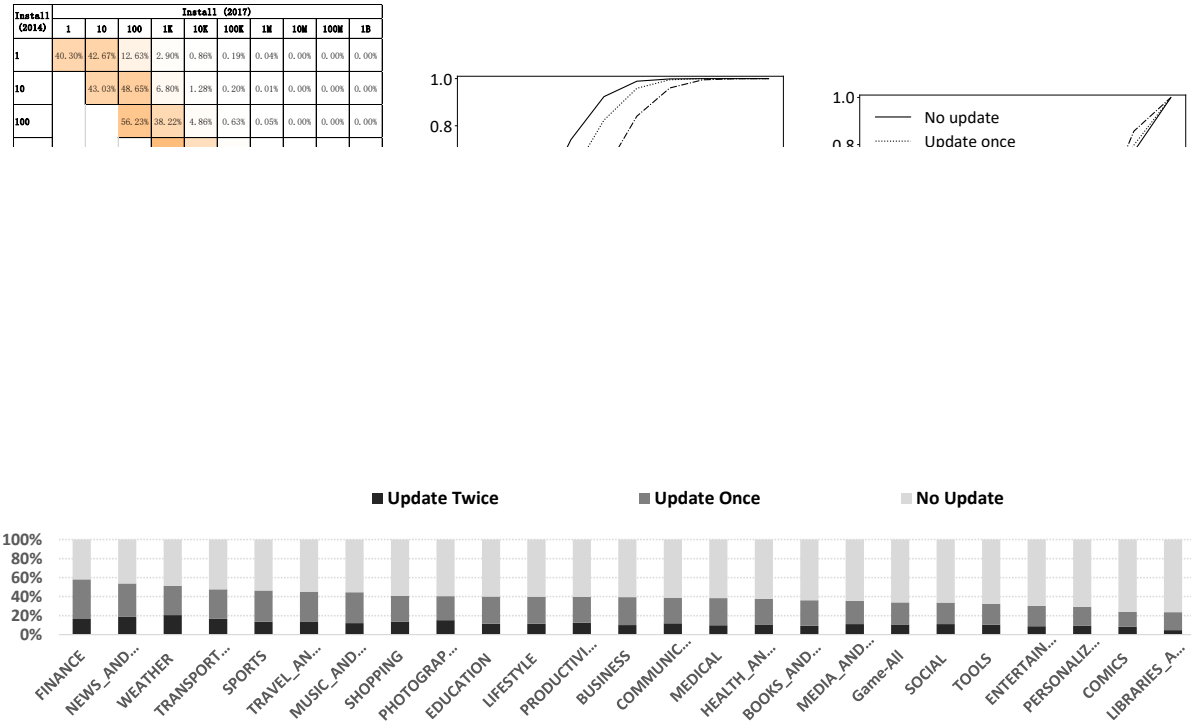

Figure 7: The distribution of app updates across categories.

shown in Figure 7. Apps in "Finance" and "News and Magazine" categories have received the highest number of updates, with roughly 60% of them have been updated at least once. In contrast, categories "Comics" and "Libraries and Demo" are the most inactive, with roughly only a quarter of apps in these categories have been updated at least once. One possible reason is that apps in categories like "Libraries and Demo" contain mostly static content that do not need to be updated, while apps in categories like "Finance" contain mostly dynamic content and they need to be updated frequently in order to provide new features. Nevertheless, the percentage of apps that received frequent updates is relatively low.

App Updates vs. App Popularity We then investigate whether popular apps received more updates than the unpopular ones, or whether app updates have positive effects on app installs. Figure 6(b) shows the distribution of app installs at different "update frequency levels". It is obvious that there is a positive correlation between app updates and app popularity. Over 40% of apps in the "update twice" group have received more than 10K installs, while the percentage in the "no update" group is only 7%. We further analyze the user ratings of long-lasting apps, in order to investigate whether users are more satisfied with apps that received more updates. As shown in Figure 6(c), there is no strong correlation between app rating and app update, although the distribution of app ratings for apps updated twice is slightly better.

5.3 Permission Evolution

We also analyzed permission changes at the per-app level to understand how many permissions each individual app had added or removed during the evolution. For a given app, its permission usage between snapshots falls into the four categories: (1) new permissions, (2) removed permissions, (3) both new and removed permissions, (4) permissions unchanged. Between the three snapshots we created, there are two intervals where we could study permission evolution.

Table 3: The distribution of permission evolution patterns.

		15-17			
		new	removed	both	unchanged
14-15	new	1.03%	1.76%	1.50%	1.70%
	removed	4.12%	1.17%	1.66%	0.97%
	both	0.50%	0.53%	1.16%	0.36%
	unchanged	21.21%	38.95%	20.49%	2.90%

Changes in Permission Usage. We first investigate how many long-lasting apps changed their permission usage during the evolution. Note that our previous observation suggests that over 60% of apps did not received any updates, thus we eliminate these apps when studying the changes in permission usage. As shown in the Table 3, each cell has two corresponding values, which represent the permission evolution states from 2014 to 2015 and from 2015 to 2017, respectively. Roughly 2.9% of the apps have no permission changes during the period, while only 0.4% of apps have requested more permissions all the time. Note that over 80% of apps do not have permission changes from 2014 to 2015, while roughly 95% of apps changed their permissions from 2015 to 2017. Over 42% of apps removed sensitive permissions and did not introduce new permissions from the year 2015 to 2017.

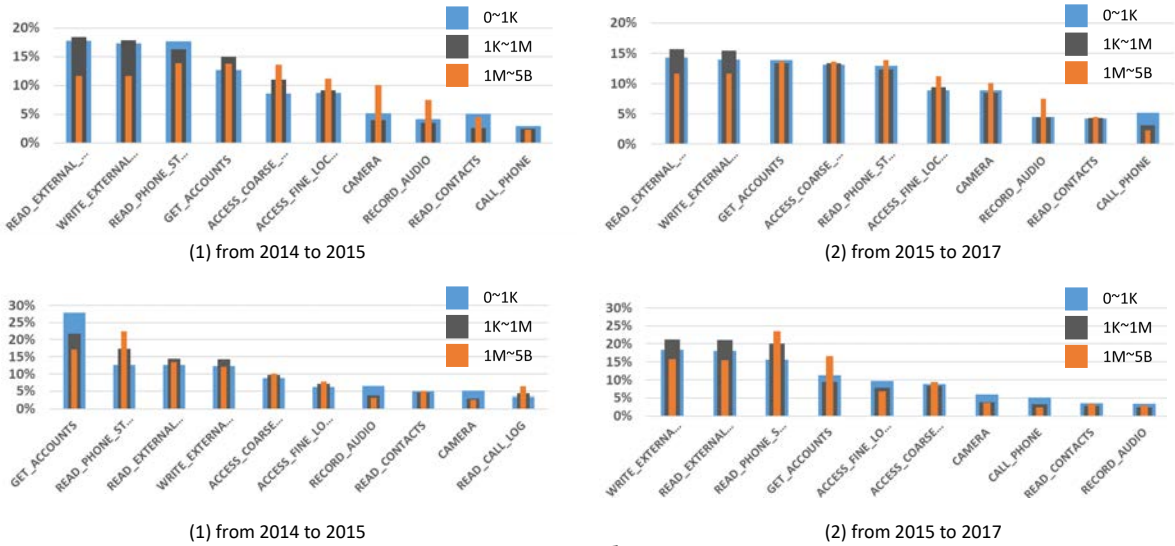

Figure 9: Removed permissions.

Changed Permissions We then analyze the permissions that were added to apps when they were updated, to understand the potential privacy risks. Figure 8 shows the breakdown of the most commonly added permissions for apps with different download levels. The top 2 permissions added are "READ_EXTERNAL_ STORAGE" and "WRITE_EXTERNAL_STORAGE", especially for the apps with low installs. Many apps added the "READ_EXTERNAL_STORAGE" permission while they have already declared the corresponding write permission. What is apparently unclear to these developers is that, apps granted with the write permission have implicitly obtained the read access as well, so there is no need to ask for the read permission. Besides, popular apps tend to request more sensitive permissions such as "CAMERA" and "RECORD_AUDIO" during the evolution than the apps with lower app installs. Figure 9 shows which permissions were removed the most. "GET_ACCOUNTS" is the most commonly removed permission from 2014 to 2015, and the external storage permissions are the most frequently added and removed permissions from 2015 to 2017.

6 THE EVOLUTION OF SECURITY RISKS

In this section, we study the evolution of security risks and developing misbehaviors, i.e., the presence of malicious apps, and the spamming apps using ranking fraud techniques.

6.1 Malicious Apps

As a measure to eliminate malicious apps, Google Play has adopted some vetting process to keep malware from entering the market, e.g., the Bouncer service [52] and machine-learning based approaches [19]. However, it is reported that malicious apps are recurrently found in Google Play [4, 5, 21, 61], especially for new malware variants [3]. As Google Play is removing malware from time to time, we want to investigate whether Google Play is moving towards higher security levels during its evolution.

Table 4: Distribution of potential malware over time.

Year	AV-rank (# apps, % apps)		
	≥ 1	≥ 10	≥ 20
Google Play 2014	261,480 (17.17%)	44,664 (2.93%)	9,324 (0.61%)
Google Play 2015	250,484 (15.17%)	37,111 (2.25%)	8,716 (0.53%)
Google Play 2017	179,184 (8.35%)	19,459 (0.91%)	3,854 (0.18%)

To this end, we upload all the apps we collected from the three snapshots to VirusTotal, a popular online malware analysis service that aggregates more than 60 anti-virus engines. Note that, some anti-virus engines on VirusTotal may not always report reliable results [10, 71]. To reduce false positives, we use "AV-Score" to represent how many engines flag an app as malware. We empirically select the threshold of "$AV - Score = 10$" as a robust choice for identifying malware, as suggested by previous studies [10, 70].

Distribution of Malicious Apps We first analyze the presence of malicious apps in the three snapshots, as reported in Table 4. We are glad to report that *the proportion of potentially malicious apps in Google Play is decreasing year by year.* Roughly 50% of the apps in snapshot 2014 are flagged at least by one anti-virus engine, while the percentage for snapshot 2017 is significantly lower (8.35%). According to the threshold of "$AV - Score = 10$", around 0.91% of the apps in snapshot 2017 are labeled as malware, while the percentage in snapshot 2014 is three times higher.

Evolution of Malware Families We also analyzed the malware families that are prevalent on Google Play. We resort to AVClass [51], a widely used malware labeling tool to obtain the family name of each identified malware, and Figure 10 shows the results. The top malware families are relatively stable across the three years. "revmob" and "airpush" are the most popular malware families, which are well-known aggressive adware.

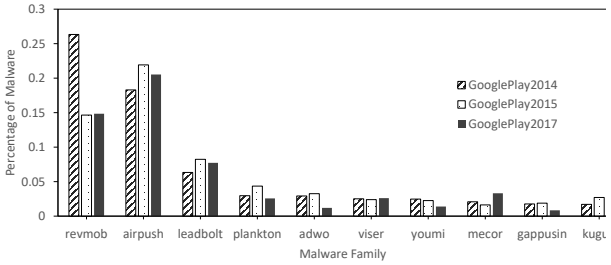

Figure 10: The distribution of the top 10 malware famili

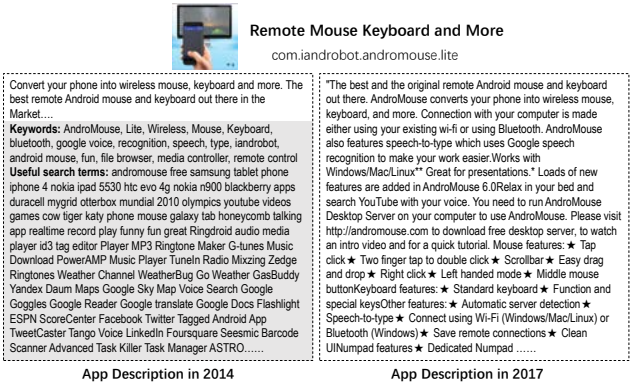

Figure 11: An example of misleading references to popular apps (left). The description has been improved later (right).

6.2 Spamming Apps

Google Play has updated its developer policy on metadata to make app listing accurate and relevant in October 2016 [24]. Google asked the developers to avoid user testimonials, excessive details, misleading references to other apps and repetitive, excessive or irrelevant keywords. The motivation is that some developers would like to insert irrelevant keywords (e.g., the names of popular apps and popular searching words) in their app descriptions, so that their apps would appear popular (highly ranked) in the search results, which is a common spamming technique and even used by some app store optimization (ASO) providers.

Approach. Therefore, it is important to investigate whether the situation of spamming apps has been improved with the evolution. To this end, we resort to the most straightforward strategy to identify spamming apps with irrelevant descriptions, which is to identify apps that insert names of popular apps in their descriptions. This strategy proposed by Seneviratne *et al.* [54] is of interest to spamming developers. As a result, we first collect the top 100 popular app names, then we count the number of popular app names mentioned in the descriptions of all the apps we harvested. Note that popular app names could be common words, such as "Video Player", "Weather" and "Music", thus we also excluded 10 such common words from this study.

Result. Table 5 summarizes the result. In general, during the evolution, more apps embed these popular app names in their descriptions. Since mobile apps may communicate with Facebook and Twitter to provide social networking functionalities, having those keywords in the app descriptions does not directly mean that these apps are spamming apps. By manually inspecting some cases, we believe that incorporating more than 10 popular app names in the description are mostly spamming apps.

The result suggests that the 2017 snapshot contains more possible spamming apps, while the aggressive level is not as serious as that in snapshot 2014 and 2015. For example, there are 56 apps in snapshot 2015 that have listed more than 40 keywords in their app descriptions (the most aggressive one has 80 keywords), while the most aggressive one in 2017 only has 25 keywords. We further explore the evolution of these spamming app candidates. About 62% of these apps identified in 2014 and 2015 snapshots were removed in 2017, and for the remaining apps, all of their app descriptions have been improved. For example, as shown in Figure 11, the app "com.iandrobot.andromouse.lite" has inserted more than 200 search keywords (named "Useful search terms") related to other popular

Table 5: The distribution of the number of misleading references to other popular apps.

Year	References (# apps)				
	≥ 1	≥ 5	≥ 10	≥ 15	≥ 20
Google Play 2014	489,795	18,479	593	122	68
Google Play 2015	792,130	39,827	1,232	261	96
Google Play 2017	1,261,613	86,730	3,013	148	20

apps in the description we crawled in 2015 (left), while the description has been improved as in 2017 (right). Nevertheless, there are still over 3,000 possible spamming apps in the 2017 snapshot. We manually examined some of them, and found that they tend to use some sophistic methods to insert keywords. Rather than listing keywords without logic, they seek to embed the keywords into real sentences. For example, "com.aditya.hexawhite" is an icon replacement app, which has incorporated lots of popular app names and keywords in its description using statements such as "compatible with [A list of App Names]" and "Icon List: [A list of App Names]"

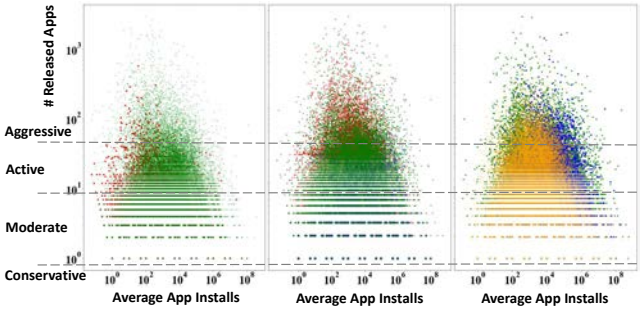

Figure 12: The distribution of app developers in Google Play over time. Green, Blue and Yellow dots represent new developers in 2014, 2015 and 2017 respectively. Red dot represents the developers removed in the next snapshot.

7 THE EVOLUTION OF APP DEVELOPERS

This section investigates the dynamics of app developers. Table 2 shows that there are roughly 400K to 500K developers in Google

Table 6: Developer groups.

Snapshot	Category (# developers, % Percentage)			
	Conservative	Moderate	Active	Aggressive
GP2014	239,331 (57.8%)	151,541 (36.6%)	20,219 (4.9%)	2,869 (0.7%)
GP2015	211,029 (52.9%)	156,961 (39.4%)	27,737 (7.0%)	3,128 (0.8%)
GP2017	306,996 (56.7%)	194,544 (36.0%)	35,066 (6.5%)	4,499 (0.8%)

Play during the span of our study. However, as we plotted in Figure 12, developers change greatly during the evolution, as a considerable number of developers have disappeared, while new developers have emerged. Only 42% of developers in the 2017 snapshot are originated from 2014. Next, we first study the developer popularity, then we classify developer into different groups, and further characterize spamming and malicious developers.

7.1 Top Developers

We characterize the developer popularity distribution for all the developers ordered by the number of accumulated installs, as illustrated in Figure 13(a). This result suggests that the distribution of developer installs also follows the Pareto effect. Top 1% of developers have occupied roughly 83% of total installs across the three snapshots. We further compare the catalog similarity of the top 1% of developers, and found that more than 80% of them are the same. Thus, although the active developers change greatly across snapshots, the most popular ones are relative stable, so that Google Play is dominated by a small number of developers all the time.

7.2 Developer Categorization

Previous work [69] proposed to classify developers into four groups based on the number of apps they released, including Conservative (1 app), Moderate (2 to 9 apps), Active (10 to 49 apps) and Aggressive (more than 50 apps). In this work, we follow this classification to study the evolution of app developers.

Table 6 and Figure 12 shows the distribution of different developer groups. The developer distribution follows the similar pattern. Conservative developers account for more than half of the community, while less than 1% of the developers are aggressive developers.

Spamming Developers. Previous work identified the prevalence of spamming developers in Google Play, who have released a large number of low-quality apps (mostly are clones) with almost no downloads. This study tries to study the evolution of spamming developers, i.e., whether spamming developers left or are removed. Following the same criteria (aggressive developers with no popular apps and with an average install number lower than 10,000), we flag each developer as spamming or not. We have identified the number of spamming developers in these three snapshots, with numbers at 2,378, 2,474 and 3,299 respectively.

Removal of Spamming Developers. Figure 12 indicates that a large number of developers in the 2014 and 2015 snapshots are removed. We are interested in whether spamming developers were removed or not, because many of them released hundreds of low-quality and least popular apps, which should be removed. Thus we analyze the percentage of removed apps for spamming developers we found in the the 2014 and 2015 snapshots, as shown in Figure 13(b). We can see that, more than 40% of the spamming developers are removed from Google Play, with some of them having released hundreds of apps. More than 40% of the released apps have been removed for roughly 60% of the spamming developers. For example, developer "ReverbNation Artists" had released 2,634 apps in total (with average installs of 226) in the snapshot 2015, while it was removed along with all its 2,634 apps in 2017.

7.3 Malicious Developers

We are also interested in the malicious developers who have released malware to Google Play. Thus, we regard the developers who have created at least one malicious app (with AV-Score >=10) as a malicious developer. The number of malicious developers is 13,488 (3.26%), 12,894 (3.23%) and 8,621 (1.59%), respectively. The most aggressive developers have released hundreds of malware. For example, "Apps Ministry LLC" has distributed 611 malware, and "AppShareNI" released 448 malware. We further analyze whether these malicious apps are dominated by malicious developers, as shown in Figure 13(c). We can see that, top 10% malicious developers account for roughly 50% to 60% of the malicious apps.

8 DISCUSSION

We believe that our efforts and the revealed insights can contribute to different stakeholders of the mobile app ecosystem.

App Markets. For market maintainers, because Google Play may remove low-quality and policy-violation apps regularly, the lessons learned from this longitudinal study could help app markets understand real threats and challenges, and help them further improve the markets. For example, market maintainers should pay more attention to the fraudulent app promotion activities mentioned in this paper. Besides, although the percentage of malicious apps and malicious developers in Google Play are decreasing year by year, there still exist new emerging malicious apps, while aggressive developers may still be able to release a large number of malware to the market.

App Developers and App Users. From the perspective of app developers, various findings revealed in this paper could help them make better decision on how to develop and release apps, e.g., app categories, app monetization schemes, and app growth rate, etc. For mobile users, it is better to avoid apps that have not been updated for years, and avoid the potentially risk/low-quality apps that were released by malicious and spamming developers.

9 CONCLUDING REMARKS

We conduct a large-scale longitudinal study to understand the evolution of mobile app ecosystems. Specifically, our analysis covers over 5 million app records collected from three different snapshots of Google Play over a period of more than three years. Overall, our findings suggest that the overall ecosystem shows a promising progress in regard of app popularity, user ratings and privacy respecting. However, there still exists a considerable number of unsolved issues including malware, app update issues, aggressive app promotion behaviors, and spamming/malicious developers. We believe that our research efforts can positively contribute to benefiting app users and developers, attracting the focus of the research community and regulators, and advocating best operational practices across app market operators.

ABSTRACT

Collaborative filtering often suffers from sparsity and cold start problems in real recommendation scenarios, therefore, researchers and engineers usually use side information to address the issues and improve the performance of recommender systems. In this paper, we consider knowledge graphs as the source of side information. We propose **MKR**, a **M**ulti-task feature learning approach for **K**nowledge graph enhanced **R**ecommendation. MKR is a deep end-to-end framework that utilizes knowledge graph embedding task to assist recommendation task. The two tasks are associated by cross&compress units, which automatically share latent features and learn high-order interactions between items in recommender systems and entities in the knowledge graph. We prove that cross&compress units have sufficient capability of polynomial approximation, and show that MKR is a generalized framework over several representative methods of recommender systems and multi-task learning. Through extensive experiments on real-world datasets, we demonstrate that MKR achieves substantial gains in movie, book, music, and news recommendation, over state-of-the-art baselines. MKR is also shown to be able to maintain satisfactory performance even if user-item interactions are sparse.

1 INTRODUCTION

Recommender systems (RS) aims to address the information explosion and meet users personalized interests. One of the most popular recommendation techniques is collaborative filtering (CF) [11], which utilizes users' historical interactions and makes recommendations based on their common preferences. However, CF-based methods usually suffer from the sparsity of user-item interactions and the cold start problem. Therefore, researchers propose using *side information* in recommender systems, including social networks [10], attributes [30], and multimedia (e.g., texts [29], images [40]). *Knowledge graphs* (KGs) are one type of side information for RS, which usually contain fruitful facts and connections about items. Recently, researchers have proposed several academic and commercial KGs, such as NELL[1], DBpedia[2], Google Knowledge Graph[3] and Microsoft Satori[4]. Due to its high dimensionality and heterogeneity, a KG is usually pre-processed by *knowledge graph embedding* (KGE) methods [27], which embeds entities and relations into low-dimensional vector spaces while preserving its inherent structure.

Existing KG-aware methods

Inspired by the success of applying KG in a wide variety of tasks, researchers have recently tried to utilize KG to improve the performance of recommender systems [31, 32, 39, 40, 45]. Personalized Entity Recommendation (PER) [39] and Factorization Machine with Group lasso (FMG) [45] treat KG as a heterogeneous information network, and extract meta-path/meta-graph based latent features to represent the connectivity between users and items along different types of relation paths/graphs. It should be noted that PER and FMG rely heavily on manually designed meta-paths/meta-graphs, which limits its application in generic recommendation scenarios. Deep Knowledge-aware Network (DKN) [32] designs a CNN framework to combine entity embeddings with word embeddings for news recommendation. However, the entity embeddings are required in advance of using DKN, causing DKN to lack an end-to-end way of training. Another concern about DKN is that it can hardly incorporate side information other than texts. RippleNet [31] is a memory-network-like model that propagates users' potential preferences in the KG and explores their hierarchical interests. But the importance of relations is weakly characterized in RippleNet, because the embedding matrix of a relation $\mathbf{R}$ can hardly be trained to capture the sense of importance in the quadratic form $\mathbf{v}^\top\mathbf{R}\mathbf{h}$ ($\mathbf{v}$ and $\mathbf{h}$ are embedding vectors of two entities). Collaborative Knowledge base Embedding (CKE) [40] combines CF with structural knowledge, textual knowledge, and visual knowledge in a unified framework. However, the KGE module in CKE (i.e., TransR [13]) is more suitable for in-graph applications (such as KG

completion and link prediction) rather than recommendation. In addition, the CF module and the KGE module are loosely coupled in CKE under a Bayesian framework, making the supervision from KG less obvious for recommender systems.

The proposed approach

To address the limitations of previous work, we propose MKR, a multi-task learning (MTL) approach for knowledge graph enhanced recommendation. MKR is a generic, end-to-end deep recommendation framework, which aims to utilize KGE task to assist recommendation task[5]. Note that the two tasks are not mutually independent, but are highly correlated since an item in RS may associate with one or more entities in KG. Therefore, an item and its corresponding entity are likely to have a similar proximity structure in RS and KG, and share similar features in low-level and non-task-specific latent feature spaces [15]. We will further validate the similarity in the experiments section. To model the shared features between items and entities, we design a *cross&compress unit* in MKR. The cross&compress unit explicitly models high-order interactions between item and entity features, and automatically control the cross knowledge transfer for both tasks. Through cross&compress units, representations of items and entities can complement each other, assisting both tasks in avoiding fitting noises and improving generalization. The whole framework can be trained by alternately optimizing the two tasks with different frequencies, which endows MKR with high flexibility and adaptability in real recommendation scenarios.

We probe the expressive capability of MKR and show, through theoretical analysis, that the cross&compress unit is capable of approximating sufficiently high order feature interactions between items and entities. We also show that MKR is a generalized framework over several representative methods of recommender systems and multi-task learning, including factorization machines [22, 23], deep&cross network [34], and cross-stitch network [18]. Empirically, we evaluate our method in four recommendation scenarios, i.e., movie, book, music, and news recommendations. The results demonstrate that MKR achieves substantial gains over state-of-the-art baselines in both click-through rate (CTR) prediction (e.g., 11.6% *AUC* improvements on average for movies) and top-K recommendation (e.g., 66.4% *Recall*@10 improvements on average for books). MKR is also shown to maintain satisfactory performance even when user-item interactions are sparse.

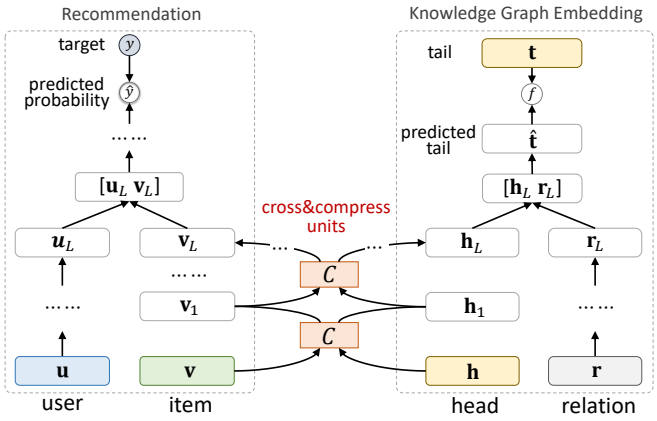
Contribution

It is worth noticing that the problem studied in this paper can also be modelled as *cross-domain recommendation* [26] or *transfer learning* [21], since we care more about the performance of recommendation task. However, the key observation is that though cross-domain recommendation and transfer learning have single objective for the target domain, their loss functions still contain constraint terms for measuring data distribution in the source domain or similarity between two domains. In our proposed MKR, the KGE task serves as the constraint term *explicitly* to provide regularization for recommender systems. We would like to emphasize that the major contribution of this paper is exactly modeling the problem as multi-task learning: We go a step further than cross-domain recommendation and transfer learning by finding that the inter-task similarity is helpful to not only recommender systems but also knowledge graph embedding, as shown in theoretical analysis and experiment results.

[5]KGE task can also benefit from recommendation task empirically as shown in the experiments section.

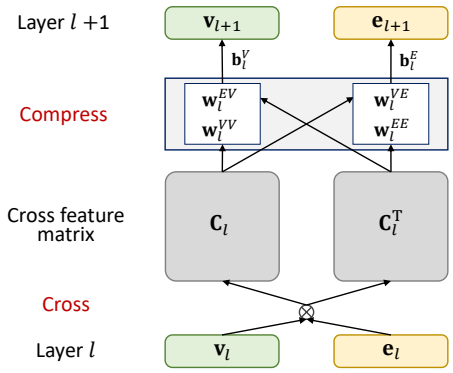
2 OUR APPROACH

In this section, we first formulate the knowledge graph enhanced recommendation problem, then introduce the framework of MKR and present the design of the cross&compress unit, recommendation module and KGE module in detail. We lastly discuss the learning algorithm for MKR.



2.1 Problem Formulation

We formulate the knowledge graph enhanced recommendation problem in this paper as follows. In a typical recommendation scenario, we have a set of M users $\mathcal{U} = \{u_1, u_2, ..., u_M\}$ and a set of N items $\mathcal{V} = \{v_1, v_2, ..., v_N\}$. The user-item interaction matrix $\mathbf{Y} \in \mathbb{R}^{M \times N}$ is defined according to users' implicit feedback, where $y_{uv} = 1$ indicates that user u engaged with item v, such as behaviors of clicking, watching, browsing, or purchasing; otherwise $y_{uv} = 0$. Additionally, we also have access to a knowledge graph $\mathcal{G}$, which is comprised of entity-relation-entity triples (h, r, t). Here h, r, and t denote the head, relation, and tail of a knowledge triple, respectively. For example, the triple (*Quentin Tarantino*, *film.director.film*, *Pulp Fiction*) states the fact that Quentin Tarantino directs the film Pulp Fiction. In many recommendation scenarios, an item $v \in \mathcal{V}$ may associate with one or more entities in $\mathcal{G}$. For example, in movie recommendation, the item "Pulp Fiction" is linked with its namesake in a knowledge graph, while in news recommendation, news with the title "Trump pledges aid to Silicon Valley during tech meeting" is linked with entities "Donald Trump" and "Silicon Valley" in a knowledge graph.



Given the user-item interaction matrix $\mathbf{Y}$ as well as the knowledge graph $\mathcal{G}$, we aim to predict whether user u has potential interest in item v with which he has had no interaction before. Our goal is to learn a prediction function $\hat{y}_{uv} = \mathcal{F}(u, v|\Theta, \mathbf{Y}, \mathcal{G})$, where $\hat{y}_{uv}$ denotes the probability that user u will engage with item v, and Θ is the model parameters of function $\mathcal{F}$.

2.2 Framework

The framework of MKR is illustrated in Figure 1a. MKR consists of three main components: recommendation module, KGE module, and cross&compress units. (1) The recommendation module on the left takes a user and an item as input, and uses a multi-layer perceptron (MLP) and cross&compress units to extract short and dense features for the user and the item, respectively. The extracted features are then fed into another MLP together to output the predicted probability. (2) Similar to the left part, the KGE module in the right part also uses multiple layers to extract features from the head and relation of a knowledge triple, and outputs the representation of the predicted tail under the supervision of a score function f and the real tail. (3) The recommendation module and the KGE module are bridged by specially designed cross&compress units. The proposed unit can automatically learn high-order feature interactions of items in recommender systems and entities in the knowledge graph.

(a) Framework of MKR

(b) Cross&compress unit

Figure 1: (a) The framework of MKR. The left and right part illustrate the recommendation module and the KGE module, respectively, which are bridged by the cross&compress units. (b) Illustration of a cross&compress unit. The cross&compress unit generates a cross feature matrix from item and entity vectors by *cross* operation, and outputs their vectors for the next layer by *compress* operation.

2.3 Cross&compress Unit

To model feature interactions between items and entities, we design a cross&compress unit in MKR framework. As shown in Figure 1b, for item v and one of its associated entities e, we first construct $d \times d$ pairwise interactions of their latent feature $\mathbf{v}_l \in \mathbb{R}^d$ and $\mathbf{e}_l \in \mathbb{R}^d$ from layer l:

$$\mathbf{C}_l = \mathbf{v}_l \mathbf{e}_l^\top = \begin{bmatrix} v_l^{(1)} e_l^{(1)} & \cdots & v_l^{(1)} e_l^{(d)} \\ \cdots & & \cdots \\ v_l^{(d)} e_l^{(1)} & \cdots & v_l^{(d)} e_l^{(d)} \end{bmatrix}, \tag{1}$$

where $\mathbf{C}_l \in \mathbb{R}^{d \times d}$ is the cross feature matrix of layer l, and d is the dimension of hidden layers. This is called the *cross* operation, since each possible feature interaction $v_l^{(i)} e_l^{(j)}, \forall (i,j) \in \{1, ..., d\}^2$ between item v and its associated entity e is modeled explicitly in the cross feature matrix. We then output the feature vectors of items and entities for the next layer by projecting the cross feature matrix into their latent representation spaces:

$$\begin{aligned} \mathbf{v}_{l+1} &= \mathbf{C}_l \mathbf{w}_l^{VV} + \mathbf{C}_l^\top \mathbf{w}_l^{EV} + \mathbf{b}_l^V = \mathbf{v}_l \mathbf{e}_l^\top \mathbf{w}_l^{VV} + \mathbf{e}_l \mathbf{v}_l^\top \mathbf{w}_l^{EV} + \mathbf{b}_l^V, \\ \mathbf{e}_{l+1} &= \mathbf{C}_l \mathbf{w}_l^{VE} + \mathbf{C}_l^\top \mathbf{w}_l^{EE} + \mathbf{b}_l^E = \mathbf{v}_l \mathbf{e}_l^\top \mathbf{w}_l^{VE} + \mathbf{e}_l \mathbf{v}_l^\top \mathbf{w}_l^{EE} + \mathbf{b}_l^E, \end{aligned} \tag{2}$$

where $\mathbf{w}_l^{\cdot\cdot} \in \mathbb{R}^d$ and $\mathbf{b}_l^{\cdot} \in \mathbb{R}^d$ are trainable weight and bias vectors. This is called the *compress* operation, since the weight vectors project the cross feature matrix from $\mathbb{R}^{d \times d}$ space back to the feature spaces $\mathbb{R}^d$. Note that in Eq. (2), the cross feature matrix is compressed along both horizontal and vertical directions (by operating on $\mathbf{C}_l$ and $\mathbf{C}_l^\top$) for the sake of symmetry, but we will provide more insights of the design in Section 3.2. For simplicity, the cross&compress unit is denoted as:

$$[\mathbf{v}_{l+1}, \mathbf{e}_{l+1}] = C(\mathbf{v}_l, \mathbf{e}_l), \tag{3}$$

and we use a suffix [v] or [e] to distinguish its two outputs in the following of this paper. Through cross&compress units, MKR can adaptively adjust the weights of knowledge transfer and learn the relevance between the two tasks.

It should be noted that cross&compress units should only exist in low-level layers of MKR, as shown in Figure 1a. This is because: (1) In deep architectures, features usually transform from general to specific along the network, and feature transferability drops significantly in higher layers with increasing task dissimilarity [38]. Therefore, sharing high-level layers risks to possible negative transfer, especially for the heterogeneous tasks in MKR. (2) In high-level layers of MKR, item features are mixed with user features, and entity features are mixed with relation features. The mixed features are not suitable for sharing since they have no explicit association.

2.4 Recommendation Module

The input of the recommendation module in MKR consists of two raw feature vectors $\mathbf{u}$ and $\mathbf{v}$ that describe user u and item v, respectively. $\mathbf{u}$ and $\mathbf{v}$ can be customized as one-hot ID [8], attributes [30], bag-of-words [29], or their combinations, based on the application scenario. Given user u's raw feature vector $\mathbf{u}$, we use an L-layer MLP to extract his latent condensed feature[6]:

$$\mathbf{u}_L = \mathcal{M}(\mathcal{M}(\cdots \mathcal{M}(\mathbf{u}))) = \mathcal{M}^L(\mathbf{u}), \tag{4}$$

where $\mathcal{M}(\mathbf{x}) = \sigma(\mathbf{W}\mathbf{x}+\mathbf{b})$ is a fully-connected neural network layer[7] with weight $\mathbf{W}$, bias $\mathbf{b}$, and nonlinear activation function $\sigma(\cdot)$. For item v, we use L cross&compress units to extract its feature:

$$\mathbf{v}_L = \mathbb{E}_{e \sim \mathcal{S}(v)} \left[C^L(\mathbf{v}, \mathbf{e})[\mathbf{v}] \right], \tag{5}$$

where $\mathcal{S}(v)$ is the set of associated entities of item v.

After having user u's latent feature $\mathbf{u}_L$ and item v's latent feature $\mathbf{v}_L$, we combine the two pathways by a predicting function f_{RS},

[6] We use the exponent notation L in Eq. (4) and following equations in the rest of this paper for simplicity, but note that the parameters of L layers are actually different.
[7] Exploring a more elaborate design of layers in the recommendation module is an important direction of future work.

for example, inner product or an H-layer MLP. The final predicted probability of user u engaging item v is:

$$\hat{y}_{uv} = \sigma\big(f_{RS}(\mathbf{u}_L, \mathbf{v}_L)\big). \tag{6}$$

2.5 Knowledge Graph Embedding Module

Knowledge graph embedding is to embed entities and relations into continuous vector spaces while preserving their structure. Recently, researchers have proposed a great many KGE methods, including translational distance models [2, 13] and semantic matching models [14, 19]. In MKR, we propose a deep semantic matching architecture for KGE module. Similar to the recommendation module, for a given knowledge triple (h, r, t), we first utilize multiple cross&compress units and nonlinear layers to process the raw feature vectors of head h and relation r (including ID [13], types [36], textual description [35], etc.), respectively. Their latent features are then concatenated together, followed by a K-layer MLP for predicting tail t:

$$\begin{aligned} \mathbf{h}_L &= \mathbb{E}_{v \sim \mathcal{S}(h)} \Big[C^L(\mathbf{v}, \mathbf{h})[\mathbf{e}] \Big], \\ \mathbf{r}_L &= \mathcal{M}^L(\mathbf{r}), \\ \hat{\mathbf{t}} &= \mathcal{M}^K \left(\begin{bmatrix} \mathbf{h}_L \\ \mathbf{r}_L \end{bmatrix} \right), \end{aligned} \tag{7}$$

where $\mathcal{S}(h)$ is the set of associated items of entity h, and $\hat{\mathbf{t}}$ is the predicted vector of tail t. Finally, the score of the triple (h, r, t) is calculated using a score (similarity) function f_{KG}:

$$score(h, r, t) = f_{KG}(\mathbf{t}, \hat{\mathbf{t}}), \tag{8}$$

where $\mathbf{t}$ is the real feature vector of t. In this paper, we use the normalized inner product $f_{KG}(\mathbf{t}, \hat{\mathbf{t}}) = \sigma(\mathbf{t}^\top \hat{\mathbf{t}})$ as the choice of score function [18], but other forms of (dis)similarity metrics can also be applied here such as KullbackâĂŞLeibler divergence.

2.6 Learning Algorithm

The complete loss function of MKR is as follows:

$$\begin{aligned} \mathcal{L} =& \mathcal{L}_{RS} + \mathcal{L}_{KG} + \mathcal{L}_{REG} \\ =& \sum_{u \in \mathcal{U}, v \in \mathcal{V}} \mathcal{J}(\hat{y}_{uv}, y_{uv}) \\ & - \lambda_1 \Big(\sum_{(h,r,t) \in \mathcal{G}} score(h, r, t) - \sum_{(h', r, t') \notin \mathcal{G}} score(h', r, t') \Big) \\ & + \lambda_2 \|\mathbf{W}\|_2^2. \end{aligned} \tag{9}$$

In Eq. (9), the first term measures loss in the recommendation module, where u and v traverse the set of users and the items, respectively, and $\mathcal{J}$ is the cross-entropy function. The second term calculates the loss in the KGE module, in which we aim to increase the score for all true triples while reducing the score for all false triples. The last item is the regularization term for preventing overfitting, λ_1 and λ_2 are the balancing parameters.[8]

Note that the loss function in Eq. (9) traverses all possible user-item pairs and knowledge triples. To make computation more efficient, following [17], we use a negative sampling strategy during training.

The learning algorithm of MKR is presented in Algorithm 1, in which a training epoch consists of two stages: recommendation task (line 3-7) and KGE task (line 8-10). In each iteration, we repeat training on recommendation task for t times (t is a hyper-parameter and normally $t > 1$) before training on KGE task once in each epoch, since we are more focused on improving recommendation performance. We will discuss the choice of t in the experiments section.

[8] λ_1 can be seen as the ratio of two learning rates for the two tasks.

Algorithm 1 Multi-Task Training for MKR

Require: Interaction matrix $\mathbf{Y}$, knowledge graph $\mathcal{G}$
Ensure: Prediction function $\mathcal{F}(u, v|\Theta, \mathbf{Y}, \mathcal{G})$

1: Initialize all parameters

6: Update parameters of $\mathcal{F}$ by gradient descent on Eq. (1)-(6), (9);
7: **end for**
   // *knowledge graph embedding task*
8: Sample minibatch of true and false triples from $\mathcal{G}$;
9: Sample $v \sim \mathcal{S}(h)$ for each head h in the minibatch;
10: Update parameters of $\mathcal{F}$ by gradient descent on Eq. (1)-(3), (7)-(9);
11: **end for**

3 THEORETICAL ANALYSIS

In this section, we prove that cross&compress units have sufficient capability of polynomial approximation. We also show that MKR is a generalized framework over several representative methods of recommender systems and multi-task learning.

3.1 Polynomial Approximation

According to the Weierstrass approximation theorem [25], any function under certain smoothness assumption can be approximated by a polynomial to an arbitrary accuracy. Therefore, we examine the ability of high-order interaction approximation of the cross&compress unit. We show that cross&compress units can model the order of item-entity feature interaction up to exponential degree:

Theorem 1. *Denote the input of item and entity in MKR network as* $\mathbf{v} = [v_1 \cdots v_d]^\top$ *and* $\mathbf{e} = [e_1 \cdots e_d]^\top$*, respectively. Then the cross terms about* $\mathbf{v}$ *and* $\mathbf{e}$ *in* $\|\mathbf{v}_L\|_1$ *and* $\|\mathbf{e}_L\|_1$ *(the L1-norm of* $\mathbf{v}_L$ *and* $\mathbf{e}_L$*) with maximal degree is* $k_{\boldsymbol{\alpha},\boldsymbol{\beta}} v_1^{\alpha_1} \cdots v_d^{\alpha_d} e_1^{\beta_1} \cdots e_d^{\beta_d}$*, where* $k_{\boldsymbol{\alpha},\boldsymbol{\beta}} \in \mathbb{R}$*,* $\alpha_i, \beta_i \in \mathbb{N}$ *for* $i \in \{1, \cdots, d\}$*,* $\alpha_1 + \cdots + \alpha_d = 2^{L-1}$*, and* $\beta_1 + \cdots + \beta_d = 2^{L-1}$ *(*$L \geq 1, \mathbf{v}_0 = \mathbf{v}, \mathbf{e}_0 = \mathbf{e}$*).*

In recommender systems, $\prod_{i=1}^d v_i^{\alpha_i} e_i^{\beta_i}$ is also called *combinatorial* feature, as it measures the interactions of multiple original features. Theorem 1 states that cross&compress units can automatically model the combinatorial features of items and entities for sufficiently high order, which demonstrates the superior approximation capacity of MKR as compared with existing work such as Wide&Deep [3], factorization machines [22, 23] and DCN [34]. The

proof of Theorem 1 is provided in the Appendix. Note that Theorem 1 gives a theoretical view of the polynomial approximation ability of the cross&compress unit rather than providing guarantees on its actual performance. We will empirically evaluate the cross&compress unit in the experiments section.

3.2 Unified View of Representative Methods

In the following we provide a unified view of several representative models in recommender systems and multi-task learning, by showing that they are restricted versions of or theoretically related to MKR. This justifies the design of cross&compress unit and conceptually explains its strong empirical performance as compared to baselines.

3.2.1 Factorization machines. Factorization machines [22, 23] are a generic method for recommender systems. Given an input feature vector, FMs model all interactions between variables in the input vector using factorized parameters, thus being able to estimate interactions in problems with huge sparsity such as recommender systems. The model equation for a 2-degree factorization machine is defined as

$$\hat{y}(\mathbf{x}) = w_0 + \sum_{i=1}^{d} w_i x_i + \sum_{i=1}^{d} \sum_{j=i+1}^{d} \langle \mathbf{v}_i, \mathbf{v}_j \rangle x_i x_j, \qquad (10)$$

where x_i is the i-th unit of input vector $\mathbf{x}$, $w_\cdot$ is weight scalar, $\mathbf{v}_\cdot$ is weight vector, and $\langle \cdot, \cdot \rangle$ is dot product of two vectors. We show that the essence of FM is conceptually similar to an 1-layer cross&compress unit:

Proposition 1. *The L1-norm of $\mathbf{v}_1$ and $\mathbf{e}_1$ can be written as the following form:*

$$\|\mathbf{v}_1\|_1 \ (or \ \|\mathbf{e}_1\|_1) = \left| b + \sum_{i=1}^{d} \sum_{j=1}^{d} \langle w_i, w_j \rangle v_i e_j \right|, \qquad (11)$$

where $\langle w_i, w_j \rangle = w_i + w_j$ is the sum of two scalars.

It is interesting to notice that, instead of factorizing the weight parameter of $x_i x_j$ into the dot product of two vectors as in FM, the weight of term $v_i e_j$ is factorized into the sum of two scalars in cross&compress unit to reduce the number of parameters and increase robustness of the model.

3.2.2 Deep&Cross Network. DCN [34] learns explicit and high-order cross features by introducing the layers:

$$\mathbf{x}_{l+1} = \mathbf{x}_0 \mathbf{x}_l^\top \mathbf{w}_l + \mathbf{x}_l + \mathbf{b}_l, \qquad (12)$$

where $\mathbf{x}_l$, $\mathbf{w}_l$, and $\mathbf{b}_l$ are representation, weight, and bias of the l-th layer. We demonstrate the link between DCN and MKR by the following proposition:

Proposition 2. *In the formula of $\mathbf{v}_{l+1}$ in Eq. (2), if we restrict $\mathbf{w}_l^{VV}$ in the first term to satisfy $\mathbf{e}_l^\top \mathbf{w}_l^{VV} = 1$ and restrict $\mathbf{e}_l$ in the second term to be $\mathbf{e}_0$ (and impose similar restrictions on $\mathbf{e}_{l+1}$), the cross&compress unit is then conceptually equivalent to DCN layer in the sense of multi-task learning:*

$$\begin{aligned} \mathbf{v}_{l+1} &= \mathbf{e}_0 \mathbf{v}_l^\top \mathbf{w}_l^{EV} + \mathbf{v}_l + \mathbf{b}_l^V, \\ \mathbf{e}_{l+1} &= \mathbf{v}_0 \mathbf{e}_l^\top \mathbf{w}_l^{VE} + \mathbf{e}_l + \mathbf{b}_l^E. \end{aligned} \qquad (13)$$

It can be proven that the polynomial approximation ability of the above DCN-equivalent version (i.e., the maximal degree of cross terms in $\mathbf{v}_l$ and $\mathbf{e}_l$) is $O(l)$, which is weaker than original cross&compress units with $O(2^l)$ approximation ability.

3.2.3 Cross-stitch Networks. Cross-stitch networks [18] is a multi-task learning model in convolutional networks, in which the designed cross-stitch unit can learn a combination of shared and task-specific representations between two tasks. Specifically, given two activation maps x_A and x_B from layer l for both the tasks, cross-stitch networks learn linear combinations $\tilde{x}_A$ and $\tilde{x}_B$ of both the input activations and feed these combinations as input to the next layers' filters. The formula at location (i, j) in the activation map is

$$\begin{bmatrix} \tilde{x}_A^{ij} \\ \tilde{x}_B^{ij} \end{bmatrix} = \begin{bmatrix} \alpha_{AA} & \alpha_{AB} \\ \alpha_{BA} & \alpha_{BB} \end{bmatrix} \begin{bmatrix} x_A^{ij} \\ x_B^{ij} \end{bmatrix}, \qquad (14)$$

where α's are trainable transfer weights of representations between task A and task B. We show that the cross-stitch unit in Eq. (14) is a simplified version of our cross&compress unit by the following proposition:

Proposition 3. *If we omit all biases in Eq. (2), the cross&compress unit can be written as*

$$\begin{bmatrix} \mathbf{v}_{l+1} \\ \mathbf{e}_{l+1} \end{bmatrix} = \begin{bmatrix} \mathbf{e}_l^\top \mathbf{w}_l^{VV} & \mathbf{v}_l^\top \mathbf{w}_l^{EV} \\ \mathbf{e}_l^\top \mathbf{w}_l^{VE} & \mathbf{v}_l^\top \mathbf{w}_l^{EE} \end{bmatrix} \begin{bmatrix} \mathbf{v}_l \\ \mathbf{e}_l \end{bmatrix}. \qquad (15)$$

The transfer matrix in Eq. (15) serves as the cross-stitch unit $[\alpha_{AA}\ \alpha_{AB};\ \alpha_{BA}\ \alpha_{BB}]$ in Eq. (14). Like cross-stitch networks, MKR network can decide to make certain layers task specific by setting $\mathbf{v}_l^\top \mathbf{w}_l^{EV}$ (α_{AB}) or $\mathbf{e}_l^\top \mathbf{w}_l^{VE}$ (α_{BA}) to zero, or choose a more shared representation by assigning a higher value to them. But the transfer matrix is more fine-grained in cross&compress unit, because the transfer weights are replaced from scalars to dot products of two vectors. It is rather interesting to notice that Eq. (15) can also be regarded as an *attention mechanism* [1], as the computation of transfer weights involves the feature vectors $\mathbf{v}_l$ and $\mathbf{e}_l$ themselves.

4 EXPERIMENTS

In this section, we evaluate the performance of MKR in four real-world recommendation scenarios: movie, book, music, and news[9].

4.1 Datasets

We utilize the following four datasets in our experiments:

- **MovieLens-1M**[10] is a widely used benchmark dataset in movie recommendations, which consists of approximately 1 million explicit ratings (ranging from 1 to 5) on the MovieLens website.
- **Book-Crossing**[11] dataset contains 1,149,780 explicit ratings (ranging from 0 to 10) of books in the Book-Crossing community.
- **Last.FM**[12] dataset contains musician listening information from a set of 2 thousand users from Last.fm online music system.

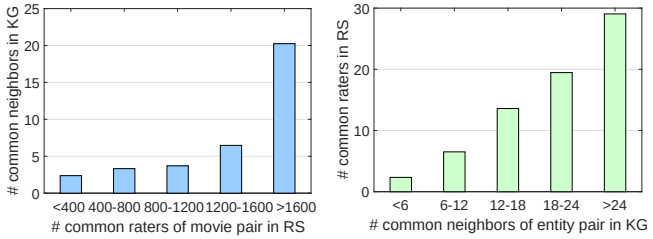
[9]The source code is available at https://github.com/hwwang55/MKR.
[10]https://grouplens.org/datasets/movielens/1m/
[11]http://www2.informatik.uni-freiburg.de/~cziegler/BX/
[12]https://grouplens.org/datasets/hetrec-2011/

Table 1: Basic statistics and hyper-parameter settings for the four datasets.

Dataset	# users	# items	# interactions	# KG triples	Hyper-parameters
MovieLens-1M	6,036	2,347	753,772	20,195	$L = 1$, $d = 8$, $t = 3$, $\lambda_1 = 0.5$
Book-Crossing	17,860	14,910	139,746	19,793	$L = 1$, $d = 8$, $t = 2$, $\lambda_1 = 0.1$
Last.FM	1,872	3,846	42,346	15,518	$L = 2$, $d = 4$, $t = 2$, $\lambda_1 = 0.1$
Bing-News	141,487	535,145	1,025,192	1,545,217	$L = 3$, $d = 16$, $t = 5$, $\lambda_1 = 0.2$

- **Bing-News** dataset contains 1,025,192 pieces of implicit feedback collected from the server logs of Bing News[13] from October 16, 2016 to August 11, 2017. Each piece of news has a title and a snippet.

Since MovieLens-1M, Book-Crossing, and Last.FM are explicit feedback data (Last.FM provides the listening count as weight for each user-item interaction), we transform them into implicit feedback where each entry is marked with 1 indicating that the user has rated the item positively, and sample an unwatched set marked as 0 for each user. The threshold of positive rating is 4 for MovieLens-1M, while no threshold is set for Book-Crossing and Last.FM due to their sparsity.



We use Microsoft Satori to construct the KG for each dataset. We first select a subset of triples from the whole KG with a confidence level greater than 0.9. For MovieLens-1M and Book-Crossing, we additionally select a subset of triples from the sub-KG whose relation name contains "film" or "book" respectively to further reduce KG size.

Given the sub-KGs, for MovieLens-1M, Book-Crossing, and Last.FM, we collect IDs of all valid movies, books, or musicians by matching their names with tail of triples (*head, film.film.name, tail*), *(head, book.book.title, tail)*, or *(head, type.object.name, tail)*, respectively. For simplicity, items with no matched or multiple matched entities are excluded. We then match the IDs with the head and tail of all KG triples and select all well-matched triples from the sub-KG. The constructing process is similar for Bing-News except that: (1) we use entity linking tools to extract entities in news titles; (2) we do not impose restrictions on the names of relations since the entities in news titles are not within one particular domain. The basic statistics of the four datasets are presented in Table 1. Note that the number of users, items, and interactions are smaller than original datasets since we filtered out items with no corresponding entity in the KG.

4.2 Baselines

We compare our proposed MKR with the following baselines. Unless otherwise specified, the hyper-parameter settings of baselines are the same as reported in their original papers or as default in their codes.

- **PER** [39] treats the KG as heterogeneous information networks and extracts meta-path based features to represent the connectivity between users and items. In this paper, we use manually designed user-item-attribute-item paths as features, i.e., "user-movie-director-movie", "user-movie-genre-movie", and "user-movie-star-movie" for MovieLens-20M; "user-book-author-book" and "user-book-genre-book" for Book-Crossing; "user-musician-genre-musician", "user-musician-country-musician", and "user-musician-age-musician" (age is discretized) for Last.FM. Note that PER cannot be applied to news recommendation because it's hard to pre-define meta-paths for entities in news.
- **CKE** [40] combines CF with structural, textual, and visual knowledge in a unified framework for recommendation. We implement CKE as CF plus structural knowledge module in this paper. The dimension of user and item embeddings for the four datasets are set as 64, 128, 32, 64, respectively. The dimension of entity embeddings is 32.
- **DKN** [32] treats entity embedding and word embedding as multiple channels and combines them together in CNN for CTR prediction. In this paper, we use movie/book names and news titles as textual input for DKN. The dimension of word embedding and entity embedding is 64, and the number of filters is 128 for each window size 1, 2, 3.
- **RippleNet** [31] is a memory-network-like approach that propagates usersâĂŹ preferences on the knowledge graph for recommendation. The hyper-parameter settings for Last.FM are $d = 8$, $H = 2$, $\lambda_1 = 10^{-6}$, $\lambda_2 = 0.01$, $\eta = 0.02$.
- **LibFM** [23] is a widely used feature-based factorization model. We concatenate the raw features of users and items as well as the corresponding averaged entity embeddings learned from TransR [13] as input for LibFM. The dimension is {1, 1, 8} and the number of training epochs is 50. The dimension of TransR is 32.
- **Wide&Deep** [3] is a deep recommendation model combining a (wide) linear channel with a (deep) nonlinear channel. The input for Wide&Deep is the same as in LibFM. The dimension of user, item, and entity is 64, and we use a two-layer deep channel with dimension of 100 and 50 as well as a wide channel.

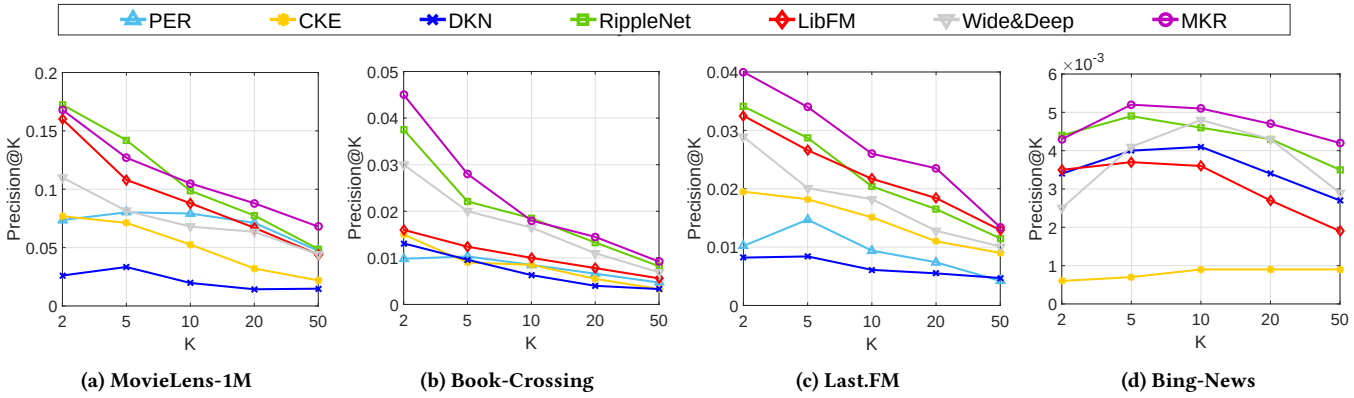
4.3 Experiments setup

In MKR, we set the number of high-level layers $K = 1$, f_{RS} as inner product, and $\lambda_2 = 10^{-6}$ for all three datasets, and other hyper-parameter are given in Table 1. The settings of hyper-parameters are determined by optimizing *AUC* on a validation set. For each dataset, the ratio of training, validation, and test set is $6:2:2$. Each experiment is repeated 3 times, and the average performance is reported. We evaluate our method in two experiment scenarios: (1) In click-through rate (CTR) prediction, we apply the trained model to each piece of interactions in the test set and output the predicted click probability. We use *AUC* and *Accuracy* to evaluate the performance of CTR prediction. (2) In top-K recommendation, we use the trained model to select K items with highest predicted click probability for each user in the test set, and choose *Precision@K* and *Recall@K* to evaluate the recommended sets.

4.4 Empirical study

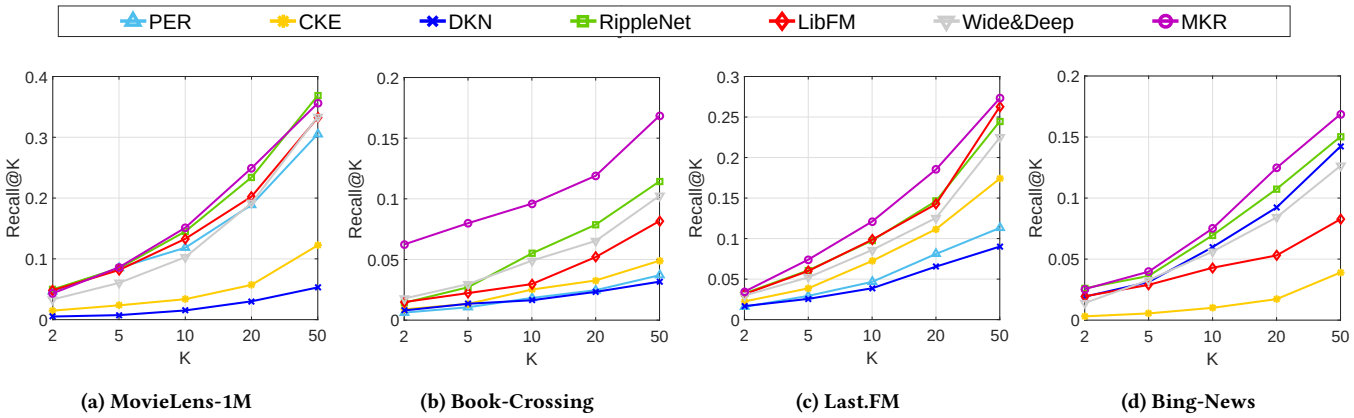
We conduct an empirical study to investigate the correlation of items in RS and their corresponding entities in KG. Specifically, we aim to reveal how the number of common neighbors of an item pair in KG changes with their number of common raters in RS. To this end, we first randomly sample 1 million item pairs from MovieLens-1M. We then classify each pair into 5 categories based on the number of their common raters in RS, and count their average number of common neighbors in KG for each category. The result is presented in Figure 2a, which clearly shows that *if two items have more common raters in RS, they are likely to share more common neighbors in KG*. Figure 2b shows the positive correlation from an opposite direction. The above findings empirically demonstrate that *items share the similar structure of proximity in KG and RS*, thus the cross knowledge transfer of items benefits both recommendation and KGE tasks in MKR.



4.5 Results

4.5.1 Comparison with baselines. The results of all methods in CTR prediction and top-K recommendation are presented in Table 2 and Figure 3, 4, respectively, from which we have the following observations:

- PER performs poor on movie, book, and music recommendation because the user-defined meta-paths can hardly be optimal in reality. Moreover, PER cannot be applied to news recommendation since entities in news titles are not within one particular domain.
- CKE performs better in movie, book, and music recommendation than news. This may be because MovieLens-1M, Book-Crossing, and Last.FM are much denser than Bing-News, which is more favorable for the collaborative filtering part in CKE.
- DKN performs best in news recommendation compared with other baselines, but performs worst in other scenarios. This is because movie, book, and musician names are too short and ambiguous to provide useful information.
- RippleNet performs best among all baselines, and even outperforms MKR on MovieLens-1M. This demonstrates that RippleNet can precisely capture user interests, especially in the case where user-item interactions are dense. However, RippleNet is more sensitive to the density of datasets, as it performs worse than MKR in Book-Crossing, Last.FM, and Bing-News. We will further study their performance in sparse scenarios in Section 4.5.3.
- In general, our MKR performs best among all methods on the four datasets. Specifically, MKR achieves average *Accuracy* gains of 11.6%, 11.5%, 12.7%, and 8.7% in movie, book, music, and news recommendation, respectively, which demonstrates the efficacy of the multi-task learning framework in MKR. Note that the top-K metrics are much lower for Bing-News because the number of news is significantly larger than movies, books, and musicians.



4.5.2 Comparison with MKR variants. We further compare MKR with its three variants to demonstrate the efficacy of cross&compress unit:

- MKR-1L is MKR with one layer of cross&compress unit, which corresponds to FM model according to Proposition 1. Note that MKR-1L is actually MKR in the experiments for MovieLens-1M.
- MKR-DCN is a variant of MKR based on Eq. (13), which corresponds to DCN model.
- MKR-stitch is another variant of MKR corresponding to the cross-stitch network, in which the transfer weights in Eq. (15) are replaced by four trainable scalars.

Table 3: Results of *AUC* on MovieLens-1M in CTR prediction with different ratios of training set *r*.

Model	*r*									
	10%	20%	30%	40%	50%	60%	70%	80%	90%	100%
PER	0.598	0.607	0.621	0.638	0.647	0.662	0.675	0.688	0.697	0.710
CKE	0.674	0.692	0.705	0.716	0.739	0.754	0.768	0.775	0.797	0.801
DKN	0.579	0.582	0.589	0.601	0.612	0.620	0.631	0.638	0.646	0.655
RippleNet	0.843	0.851	0.859	0.862	0.870	0.878	0.890	0.901	0.912	**0.920**
LibFM	0.801	0.810	0.816	0.829	0.837	0.850	0.864	0.875	0.886	0.892
Wide&Deep	0.788	0.802	0.809	0.815	0.821	0.840	0.858	0.876	0.884	0.898
MKR	**0.868**	**0.874**	**0.881**	**0.882**	**0.889**	**0.897**	**0.903**	**0.908**	**0.913**	0.917

From Table 2 we observe that MKR outperforms MKR-1L and MKR-DCN, which shows that modeling high-order interactions between item and entity features is helpful for maintaining decent performance. MKR also achieves better scores than MKR-stitch. This validates the efficacy of fine-grained control on knowledge transfer in MKR compared with the simple cross-stitch units.

4.5.3 Results in sparse scenarios. One major goal of using knowledge graph in MKR is to alleviate the sparsity and the cold start problem of recommender systems. To investigate the efficacy of the KGE module in sparse scenarios, we vary the ratio of training set of MovieLens-1M from 100% to 10% (while the validation and test set are kept fixed), and report the results of *AUC* in CTR prediction for all methods. The results are shown in Table 3. We observe that the performance of all methods deteriorates with the reduce of the training set. When $r = 10\%$, the *AUC* score decreases by 15.8%, 15.9%, 11.6%, 8.4%, 10.2%, 12.2% for PER, CKE, DKN, RippleNet, LibFM, and Wide&Deep, respectively, compared with

(a) KG size (b) Training frequency (c) Dimension of embeddings

Figure 5: Parameter sensitivity of MKR on Bing-News w.r.t. (a) the size of the knowledge graph; (b) training frequency of the RS module t; and (c) dimension of embeddings d.

Table 4: The results of *RMSE* on the KGE module for the three datasets. "KGE" means only KGE module is trained, while "KGE + RS" means KGE module and RS module are trained together.

dataset	KGE	KGE + RS
MovieLens-1M	0.319	**0.302**
Book-Crossing	0.596	**0.558**
Last.FM	0.480	**0.471**
Bing-News	0.488	**0.459**

the case when full training set is used ($r = 100\%$). In contrast, the *AUC* score of MKR only decreases by 5.3%, which demonstrates that MKR can still maintain a decent performance even when the user-item interaction is sparse. We also notice that MKR performs better than RippleNet in sparse scenarios, which is accordance with our observation in Section 4.5.1 that RippleNet is more sensitive to the density of user-item interactions.

4.5.4 Results on KGE side. Although the goal of MKR is to utilize KG to assist with recommendation, it is still interesting to investigate whether the RS task benefits the KGE task, since the principle of multi-task learning is to leverage shared information to help improve the performance of all tasks [42]. We present the result of *RMSE* (rooted mean square error) between predicted and real vectors of tails in the KGE task in Table 4. Fortunately, we find that the existence of RS module can indeed reduce the prediction error by 1.9% $\sim$ 6.4%. The results show that the cross&compress units are able to learn general and shared features that mutually benefit both sides of MKR.

4.6 Parameter Sensitivity

4.6.1 Impact of KG size. We vary the size of KG to further investigate the efficacy of usage of KG. The results of *AUC* on Bing-News are plotted in Figure 5a. Specifically, the *AUC* and *Accuracy* is enhanced by 13.6% and 11.8% with the KG ratio increasing from 0.1 to 1.0 in three scenarios, respectively. This is because the Bing-News dataset is extremely sparse, making the effect of KG usage rather obvious.

4.6.2 Impact of RS training frequency. We investigate the influence of parameters t in MKR by varying t from 1 to 10, while keeping other parameters fixed. The results are presented in Figure 5b. We observe that MKR achieves the best performance when $t = 5$. This is because a high training frequency of the KGE module will mislead the objective function of MKR, while too small of a training frequency of KGE cannot make full use of the transferred knowledge from the KG.

4.6.3 Impact of embedding dimension. We also show how the dimension of users, items, and entities affects the performance of MKR in Figure 5c. We find that the performance is initially improved with the increase of dimension, because more bits in embedding layer can encode more useful information. However, the performance drops when the dimension further increases, as too large number of dimensions may introduce noises which mislead the subsequent prediction.

5 RELATED WORK

5.1 Knowledge Graph Embedding

The KGE module in MKR connects to a large body of work in KGE methods. KGE is used to embed entities and relations in a knowledge into low-dimensional vector spaces while still preserving the structural information [33]. KGE methods can be classified into the following two categories: (1) Translational distance models exploit distance-based scoring functions when learning representations of entities and relations, such as TransE [2], TransH [35], and TransR [13]; (2) Semantic matching models measure plausibility of knowledge triples by matching latent semantics of entities and relations, such as RESCAL [20], ANALOGY [19], and HolE [14]. Recently, researchers also propose incorporating auxiliary information, such as entity types [36], logic rules [24], and textual descriptions [46] to assist KGE. The above KGE methods can also be incorporated into MKR as the implementation of the KGE module, but note that the cross&compress unit in MKR needs to be redesigned accordingly. Exploring other designs of KGE module as well as the corresponding bridging unit is also an important direction of future work.

5.2 Multi-Task Learning

Multi-task learning is a learning paradigm in machine learning and its aim is to leverage useful information contained in multiple related tasks to help improve the generalization performance of all the tasks [42]. All of the learning tasks are assumed to be related to

each other, and it is found that learning these tasks jointly can lead to performance improvement compared with learning them individually. In general, MTL algorithms can be classified into several categories, including feature learning approach [34, 41], low-rank approach [7, 16], task clustering approach [47], task relation learning approach [12], and decomposition approach [6]. For example, the cross-stitch network [41] determines the inputs of hidden layers in different tasks by a knowledge transfer matrix; Zhou et. al [47] aims to cluster tasks by identifying representative tasks which are a subset of the given m tasks, i.e., if task T_i is selected by task T_j as a representative task, then it is expected that model parameters for T_j are similar to those of T_i. MTL can also be combined with other learning paradigms to improve the performance of learning tasks further, including semi-supervised learning, active learning, unsupervised learning,and reinforcement learning.

Our work can be seen as an asymmetric multi-task learning framework [37, 43, 44], in which we aim to utilize the connection between RS and KG to help improve their performance, and the two tasks are trained with different frequencies.

5.3 Deep Recommender Systems

Recently, deep learning has been revolutionizing recommender systems and achieves better performance in many recommendation scenarios. Roughly speaking, deep recommender systems can be classified into two categories: (1) Using deep neural networks to process the raw features of users or items [5, 28–30, 40]; For example, Collaborative Deep Learning [29] designs autoencoders to extract short and dense features from textual input and feeds the features into a collaborative filtering module; DeepFM [5] combines factorization machines for recommendation and deep learning for feature learning in a neural network architecture. (2) Using deep neural networks to model the interaction among users and items [3, 4, 8, 9]. For example, Neural Collaborative Filtering [8] replaces the inner product with a neural architecture to model the user-item interaction. The major difference between these methods and ours is that MKR deploys a multi-task learning framework that utilizes the knowledge from a KG to assist recommendation.

6 CONCLUSIONS AND FUTURE WORK

This paper proposes MKR, a multi-task learning approach for knowledge graph enhanced recommendation. MKR is a deep and end-to-end framework that consists of two parts: the recommendation module and the KGE module. Both modules adopt multiple nonlinear layers to extract latent features from inputs and fit the complicated interactions of user-item and head-relation pairs. Since the two tasks are not independent but connected by items and entities, we design a cross&compress unit in MKR to associate the two tasks, which can automatically learn high-order interactions of item and entity features and transfer knowledge between the two tasks. We conduct extensive experiments in four recommendation scenarios. The results demonstrate the significant superiority of MKR over strong baselines and the efficacy of the usage of KG.

For future work, we plan to investigate other types of neural networks (such as CNN) in MKR framework. We will also incorporate other KGE methods as the implementation of KGE module in MKR by redesigning the cross&compress unit.

APPENDIX

A Proof of Theorem 1

Proof. We prove the theorem by induction:

Base case: When $l = 1$,

$$\begin{aligned}\mathbf{v}_1 =& \mathbf{v}\mathbf{e}^\top \mathbf{w}_0^{VV} + \mathbf{e}\mathbf{v}^\top \mathbf{w}_0^{EV} + \mathbf{b}_0^V \\ =& \left[v_1 \sum_{i=1}^{d} e_i w_0^{VV(i)} \ \cdots \ v_d \sum_{i=1}^{d} e_i w_0^{VV(i)} \right]^\top \\ &+ \left[e_1 \sum_{i=1}^{d} v_i w_0^{EV(i)} \ \cdots \ e_d \sum_{i=1}^{d} v_i w_0^{EV(i)} \right]^\top \\ &+ \left[b_0^{V(0)} \ \cdots \ b_0^{V(d)} \right]^\top .\end{aligned}$$

Therefore, we have

$$\begin{aligned}\|\mathbf{v}_1\|_1 &= \left| \sum_{j=1}^{d} v_j \sum_{i=1}^{d} e_i w_0^{VV(i)} + \sum_{j=1}^{d} e_j \sum_{i=1}^{d} v_i w_0^{EV(i)} + \sum_{i=1}^{d} b_0^{V(d)} \right| \\ &= \left| \sum_{i=1}^{d} \sum_{j=1}^{d} (w_0^{EV(i)} + w_0^{VV(j)}) v_i e_j + \sum_{i=1}^{d} b_0^{V(d)} \right|.\end{aligned}$$

It is clear that the cross terms about $\mathbf{v}$ and $\mathbf{e}$ with maximal degree is $k_{\boldsymbol{\alpha},\boldsymbol{\beta}} v_i e_j$, so we have $\alpha_1 + \cdots + \alpha_d = 1 = 2^{1-1}$, and $\beta_1 + \cdots + \beta_d = 1 = 2^{1-1}$ for $\mathbf{v}_1$. The proof for $\mathbf{e}_1$ is similar.

Induction step: Suppose $\alpha_1 + \cdots + \alpha_d = 2^{l-1}$ and $\beta_1 + \cdots + \beta_d = 2^{l-1}$ hold for the maximal-degree term x and y in $\|\mathbf{v}_l\|_1$ and $\|\mathbf{e}_l\|_1$. Since $\|\mathbf{v}_l\|_1 = \left|\sum_{i=1}^{d} v_l^{(i)}\right|$ and $\|\mathbf{e}_l\|_1 = \left|\sum_{i=1}^{d} e_l^{(i)}\right|$, without loss of generosity, we assume that x and y exist in $v_l^{(a)}$ and $e_l^{(b)}$, respectively. Then for $l + 1$, we have

$$\|\mathbf{v}_{l+1}\|_1 = \sum_{i=1}^{d} \sum_{j=1}^{d} (w_l^{EV(i)} + w_l^{VV(j)}) v_l^{(i)} e_l^{(j)} + \sum_{i=1}^{d} b_l^{V(d)}.$$

Obviously, the maximal-degree term in $\|\mathbf{v}_{l+1}\|_1$ is the cross term xy in $v_l^{(a)} e_l^{(b)}$. Since we have $\alpha_1 + \cdots + \alpha_d = 2^{l-1}$ and $\beta_1 + \cdots + \beta_d = 2^{l-1}$ for both x and y, the degree of cross term xy therefore satisfies $\alpha_1 + \cdots + \alpha_d = 2^{(l+1)-1}$ and $\beta_1 + \cdots + \beta_d = 2^{(l+1)-1}$. The proof for $\|\mathbf{e}_{l+1}\|_1$ is similar. □

B Proof of Proposition 1

Proof. In the proof of Theorem 1 in Appendix A, we have shown that

$$\|\mathbf{v}_1\|_1 = \left| \sum_{i=1}^{d} \sum_{j=1}^{d} (w_0^{EV(i)} + w_0^{VV(j)}) v_i e_j + \sum_{i=1}^{d} b_0^{V(d)} \right|.$$

It is easy to see that $w_i = w_0^{EV(i)}$, $w_j = w_0^{VV(j)}$, and $b = \sum_{i=1}^{d} b_0^{V(d)}$. The proof is similar for $\|\mathbf{e}_1\|_1$. □

We omit the proofs for Proposition 2 and Proposition 3 as they are straightforward.

ABSTRACT

With the rapid development of sharing economy, massive sharing systems such as Uber, Airbnb, and bikeshare have percolated into people's daily life. The sharing economy, at its core, is to achieve efficient use of resources. The actual usage of shared resources, however, is unclear to us. Little measurement or analysis, if any, has been conducted to investigate the resource usage status with the large-scale data collected from these sharing systems. In this paper, we analyze the bike usage status in three typical bikeshare systems based on 140-month multi-event data. Our analysis shows that the most used 20% of bikes account for 45% of usage, while the least used 20% of bikes account for less than 1% of usage. To efficiently utilize shared bikes, we propose a usage balancing design called eShare which has three components: (i) a statistical model based on archived data to infer historical usage; (ii) an entropy-based prediction model based on both real-time and archived data to infer future usage; (iii) a model-driven optimal calibration engine for bike selection to dynamically balance usage. We develop an ID swapping based evaluation methodology and measure the efficiency of eShare with data from three systems including the world's largest bikeshare system with 84,000 bikes and 3,300 stations. Our results show that eShare not only fully utilizes shared bikes but also improves service quality.

1 INTRODUCTION

Bike sharing is widely adopted in major cities around the world as a new way of travel [7]. In a bikeshare system, people pick up a bike from one station and drop off it at another station, providing great convenience to people's daily commute. As of June 2014, bikeshare systems have been launched in 712 cities, operating approximately 806,200 bicycles at 37,500 stations [22].

As a sharing platform, one of the key concerns is to efficiently utilize the shared bike resources. However, our data analysis on three representative bikeshare systems shows that inefficient bike usage is a common phenomenon in existing bikeshare systems. For example, the statistic results on NiceRide bikeshare system show that the most used 20% of bikes account for 45% of the total rentals, while the least used 20% of bikes account for less than 1% of the total rentals. This is because bikes in current systems are arbitrarily assigned to users, ignoring both cumulative service time of bikes and potential rental duration of users.

The current bike sharing mechanism has several drawbacks. First, a large amount of bikes in the system are rarely utilized but continually introducing maintenance costs while the unsatisfied status of the frequently used bikes leads to complaints on service quality. Second, the irregular or excessive bike usage contributes to bike depreciation, leading to a huge amount of damaged bikes. Per the statistics of Capital bikeshare system, 9,284 bikes are damaged because of heavy riding from Nov 2014 to Oct 2015, which costs about 3 million US dollars in inspecting/repairing those bikes [5]. In addition, massive damaged bikes appear in busy seasons (e.g., from May to August in Capital bikeshare) and operators are too busy to inspect/repair them, which further reduce the service quality.

To overcome these drawbacks, a straightforward strategy is to manage bikes to be balanced used. This strategy helps existing bikeshare systems make full use of all bikes. In addition, while bikes are balanced used, we should avoid the situation that all bikes wear out at the same time which overwhelms system operators. We thus propose *batch balancing* which gracefully degrades bikes in batches so that (i) shared bikes are fully utilized and (ii) the usage

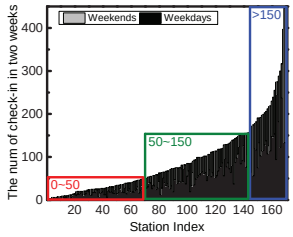

Figure 1: Demand Dist.

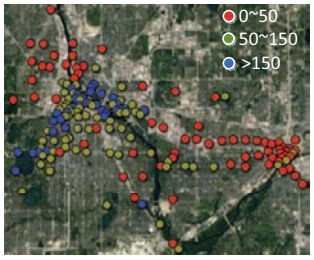

Figure 2: Demand Map

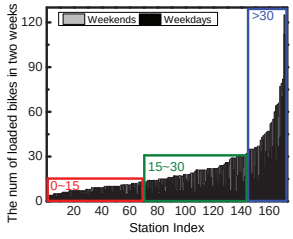

Figure 3: Service Dist.

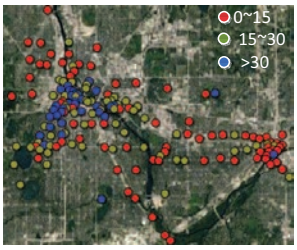

Figure 4: Service Map

status meets operators' demands (e.g., to fit the bike usage status with bike repair/upgrade schedule).

Managing shared bikes to be efficiently used seems straightforward because we can intuitively assign bikes to users based on lengths of their trips when they rent bikes. However, the key challenge is that we can only know their trip lengths when they *return* bikes, not when they *rent* bikes. As a result, naively assigning a newer bike to a passenger may increase usage unbalance because other older bikes may have to be assigned to later passengers with longer trips, and vice versa. Furthermore, it is more challenging to achieve batch balancing which has to meet operators' demands.

Although controlling the usage status is crucial in sharing platforms, most existing work is focused on demand/supply modeling *at station levels* [1, 4, 9, 15] and bike redistribution among stations [16, 17, 25]. To the best of our knowledge, little work, if any, has been conducted to investigate the usage issue *at individual bike levels*. In this paper, we present the first data-driven usage balancing mechanism called eShare to analyze, quantify and (batch) balance the shared usage status at individual bike levels based on large scale data from three bikeshare systems. Specifically, the key contributions of this paper are as follows:

• We conduct the first data analysis on usage balancing for bikeshare systems. To our knowledge, our analysis on bikeshare systems is based on the most comprehensive long-term multi-site data until now, i.e., 140-month multi-event data related to bikes (i.e., rental records, station status, rebalancing and repairs records) for 3 major cities with different system scales and population (i.e., 3.3 million, 6.1 million, and 9.1 million) in both developed and developing countries.

• Built upon the identified features, we design a data-driven usage balancing mechanism, called eShare, which consists of three technical components: (i) a statistical model based on archived data to infer historical usage; (ii) an entropy-based prediction model based on both real-time and archived data to infer future bike usage; (iii) a usage calibration engine based on these two models to select bikes for users to optimize bike usage at individual levels. The calibration engine is the core of achieving efficient usage balancing.

• We develop an ID swapping based measurement methodology and evaluate the performance of eShare through extensive data-driven experiments based on the data from three bikeshare systems including the largest bikeshare system in the world, with 84,000 bikes and 3,300 stations in Hangzhou, as well as the second largest bikeshare system in the US. with 3,700 bikes and 429 stations in Washington D.C. The evaluation results show that the standard deviation of global bike usage is reduced by 90% with our eShare design when the number of batch equals to one.

2 ANALYSIS OF SHARED USAGE

In this section, we first analyze the current usage status of shared bikes in existing systems. Then, we introduce the benefit of usage balancing in efficient sharing.

2.1 Current Bike Sharing Status

By analyzing the usage status in existing bikeshare systems, this subsection shows the need for bike usage balancing. The analysis results from three bikeshare systems in three cities show that inefficient usage is common phenomenon. The basic information about these three systems is shown in Table 1. Details of the data are in Section 3.

Unbalanced Demand: We first introduce the unbalanced demand phenomenon in existing bikeshare systems. Figure 1 plots each station's total number of rentals in two weeks in NiceRide bikeshare system. We find that (i) about 17.6% of the stations (marked as "blue " in Figure 2) are extremely busy which have more than 150 rentals in two weeks; (ii) about 40% of the stations (marked as "red" in

Table 1: Statistic of Three Bikeshare Systems

	Capital	Hangzhou	NiceRide
Launched Time	2010.9	2008.5	2010.6
Num of Stations	429	3.4×10^3	190
Num of Bikes	3,700	8.4×10^4	1,700
Ridership/Day	5.8×10^3	2.3×10^5	1.9×10^3

the demand map in Figure 2) have a low user demand, i.e., fewer than 50 rentals in two weeks. Statistically, 17.6% of the busiest stations satisfy 44.5% of the user demand. In addition, we find that the user demand at some stations varies dramatically on weekdays and weekends, e.g., the user demand at the stations near campus increases on weekdays and drops on weekends.

Unbalanced Service: To meet user demand, the operators in bikeshare systems redistribute bikes among stations. Figure 3 shows the number of bikes loaded to each station in two weeks in NiceRide bikeshare system. We find that the service level at different stations is quite different as in Figure 4: (i) some stations have a high service level with more than 30 loaded bikes (marked as "blue circle"); (ii) however, some stations have a service level with fewer than 15 loaded bikes (marked as "red circle"); (iii) most of the stations with high service levels locate in the downtown and the campus areas.

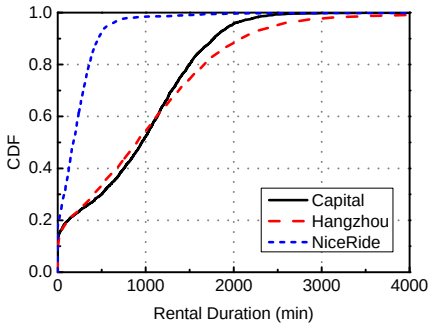

Figure 5: The CDFs of accumulated rental duration

Unbalanced Usage: We investigate the bike usage in Capital, Hangzhou, and NiceRide bikeshare systems. We find that inefficient bike usage is a common phenomenon in existing bikeshare systems. Figure 5 plots the CDF of bikes' rental durations in two weeks in the three bikeshare systems. We find that the bike usage is inefficient in all three systems. For example, in Capital bikeshare system, about 20% of bikes are used more than 1500 minutes while 20% of bikes are used less than 120 minutes in two weeks. As shown in Figure 5, similar results are found in Hangzhou and NiceRide bikeshare systems as well.

2.2 The Benefit of Bike Usage Balancing

From the above discussion, we learn that inefficient bike usage is a common phenomenon in existing bikeshare systems. Bike usage balancing helps existing bikeshare systems improve sharing efficiency. Specifically, with the help of usage balancing, users are able to use those rarely-used new bikes which improves service quality. Inefficient bike usage also causes heavy riding on a portion of bikes which leads to massive damaged bikes. In addition, compared with traditional bikes, shared bikes are designed for sharing purpose and most of them are equipped with special sensors or communication devices. These shared bikes are much more expensive than traditional bikes and need to be batch customized. Bike usage balancing has great potential to help operators achieve efficient system maintenance by letting the system-wide bike usage meet operators' repair/upgrade schedule.

Furthermore, investigating bike usage helps system operators obtain information including but not limited to (i) the current status of a bike, (ii) the residual service time of a bike, (iii) whether a bike needs to be repaired, and (iv) whether bikes are efficiently used. This information can help operators manage bikes and improve the quality of sharing service.

3 ESHARE OVERVIEW

Leveraging upon the share usage analysis results, we aim to develop a novel usage balancing mechanism for efficient sharing. In the following, we first introduce the infrastructure of bikeshare systems and the collected data. Then, we propose design objectives, followed by design overview.

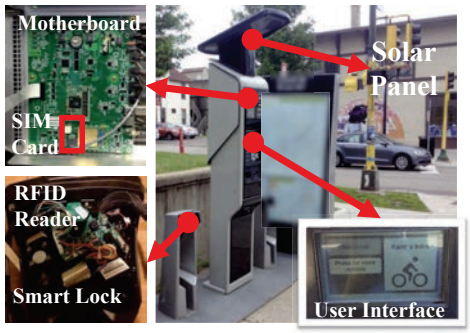

Figure 6: The infrastructure of bikeshare systems

3.1 Bikeshare Infrastructure

Leveraging experiences we gained in our project, we provide our expertise and are part of a team to design, deploy and maintain NiceRide bikeshare system as shown in Figure 6.

From the figure, we can see that passive RFID reader along with smart dock is installed in each dock in a station. When a user comes to borrow a bike, she/he needs to use her/his access key (i.e., RFID tags) to unlock a bike. Once passive RFID reads the tag, the user's information along with current timestamp is sent to central server through the communication device installed in the kiosk (as shown in Figure 6). In our bikeshare system, T-Mobile is adopted to transmit these data. Once user's information is verified by the central server, authorization message is sent back to the station. The smart lock will unlock the bike and the user thus can take the bike.

There is also a RFID tag in the head tube of each bike. When a user finishes her/his trip and returns the bike to a dock, the RFID tag

will be close enough to the passive RFID reader which will recognize the return. The real-time return information is then transmitted to the central server which will compute rental fees based on the rental duration.

3.2 Data Sets

Our infrastructure collects multi-event data as follows.

• **User Trip Data:** Each record includes user ID, borrowed bike ID, trip duration, start/end date and time, and start/end station. These data are used to infer user's habit (e.g., origin/destination and rental time) and bike's usage status.

• **Station Status Data:** Each record includes time, station ID/name, station GPS with available bikes or docks. These data help us obtain real-time station status and decide which bike should be selected for a user.

• **Operators' Rebalancing Data:** A rebalancing record includes operators' ID, bike ID, loading/unloading, station ID, time. Combined with the user trip data, these data help us obtain bikes' IDs in a station, and are also used to infer repaired bikes after operators return them.

• **Bike Repair Data:** Different from the above data sets, bike repair data cannot be extracted from the sensing data directly, but they are essential to our design. We build a new data set by manually recording each repaired bike's ID and its corresponding date from 08/03/15 to 10/05/16 in NiceRide bikeshare system. We use this data set as the ground truth for evaluation purposes. Based on the repaired bike data, we can infer (i) the current status of a bike, (ii) the residual service time of a bike, and (iii) whether a bike needs to be repaired.

The above data are typically collected by most of existing bikeshare systems in order to monitor and improve service quality. As a result, our eShare design is helpful to other bikeshare systems to improve the usage efficiency.

3.3 Design Objectives

Leveraging the multi-event data, we aim to design a data-driven usage balancing mechanism to help operators efficiently maintain the shared bikes. Specifically, eShare is designed to achieve the following two objectives:

• **Better Service Quality:** eShare should avoid excessive wearing on a small portion of bikes and fully exploit those rarely-used bikes to improve the overall service quality. In addition, some bikeshare systems impose a mandatory decommission day for operational and maintenance concerns. For example, the mandatory decommission deadline for sharing bikes is three years in China. In the US, although there is no mandatory decommission deadline, most of bikeshare systems upgrade bikes every two to four years. In these cases, eShare aims at controlling the bike usage, so that all bikes are evenly used before the decommissioning/upgrade day. Such an even usage improves overall service quality for riders.

• **Efficient Maintenance:** While bike usage is controlled to be evenly-used, eShare should avoid the situation that all bikes wear out at the same time which may overwhelm repair staff. The concept of *batch balancing* can gracefully degrade bikes in batches so that the workload of repairs is aligned with the staff capacity. To achieve this batch balancing objective, eShare needs to have the capability to statistically control the number of repairing bikes to meet operators' repair capability. Furthermore, it would be desirable to control the interval between routine repairs, so that bike parts can be purchased in batch and labors can be scheduled efficiently.

3.4 Design Overview

Keeping these design objectives in mind, we establish eShare – a usage balancing mechanism which consists of three modules. Although the description of these modules is specific to the bikeshare system, our approach is generically applicable to other sharing systems (e.g., rideshare).

• A historical usage model: It is a statistical model responsible for quantifying the bike historical usage with archived data.

• A future usage model: It is a predictive model responsible for inferring bike usage associated with future rentals from potential passengers.

• A usage calibration engine: It is based on the historical usage as well as the potential usage of the incoming rental, and chooses a bike for coming users to minimize the system-wide usage variance. The usage calibration engine is the core of achieving batch balancing.

eShare is designed to achieve batch balancing control, e.g., controlling the usage of bikes in the same batch to reach the usage threshold for routine repair. In the following, we introduce these three modules as well as how to achieve batch balancing with these modules in detail.

For the sake of clarity, in Section 4, we first introduce our basic design where we use rental duration to quantify bike usage. Thus, our historical usage model is simply to add all cumulated historical rental durations for the same bike together as its historical usage. We directly introduce the other two modules, i.e., the predictive future usage model and the system-wide usage calibration model in Section 4 to show our key idea. Then, in Section 5, we propose an advanced design to quantify bike usage by incorporating more factors (e.g., origin and destination, terrain features, etc.) in addition to rental duration.

4 BASIC DESIGN

This section introduces future usage prediction model, followed by the system-wide usage calibration model. Then, we introduce how to achieve usage balancing with these models.

4.1 Future Usage Prediction

This section describes the predictive future usage model which estimates coming users' rental duration, thus to obtain potential bike usage. Given both historical and real-time user trip data, we propose a fine-grained Bayesian model to estimate users' rental duration. In existing bikeshare systems, when users swipe their cards to rent a bike, the bikeshare system obtains users' ID, start station, and start time. Based on users' historical rental records, we use this real-time information as a condition to predict users' rental duration.

In the following, we first demonstrate that a user's rental duration between a pair of origin (i.e., start station) and destination (i.e., end station) is stable. Then we show that the entropy of a user's destination is low, especially when the start station and start time are given.

• **Property 1: Stable Rental Duration.** For a user u renting a bike at start station S_u and returning the bike at destination D_u, the rental duration R_u is stable. Moreover, if the hour of the start time t_u is given, the standard deviation of the rental duration, denoted by $\sigma(R_u)$, will be further reduced.

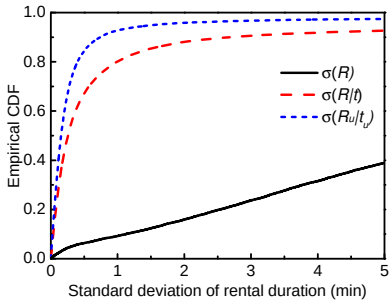

Figure 7: The CDFs of the standard deviation of rental duration with the same origin and destination given start time and user information.

Figure 7 shows the CDFs of (i) $\sigma(R)$, i.e., the standard deviation of rental duration with the same origin and destination, (ii) $\sigma(R|t)$, i.e., the standard deviation of all users' rental duration with the same origin and destination given the hour of the rental start time t, and (iii) $\sigma(R_u|t_u)$, i.e., the standard deviation of user u's rental duration with the same origin and destination pair given user u's start time t_u. The statistical result is based on 58,330 users' 483,239 rental records from 04/01/2015 to 11/01/2015 in NiceRide bikeshare system. From the figure, we can clearly see that the rental duration becomes more stable when the hour of the rental start time and the user information is given. With the start time information, 90% of $\sigma(R|t)$ are lower than three minutes. With both the start time and user information, 90% of $\sigma(R_u|t_u)$ are lower than one minute.

• **Property 2: Low Entropy Destination** The entropy of user u's destination $H(D_u)$ is low. The conditional entropy $H(D_u|S_u, t_u)$ is much lower when the start station S_u and start time t_u are given.

Figure 8 plots user u's CDFs of $H(D_u)$, $H(D_u|S_u)$, and $H(D_u|S_u, t_u)$ based on all her/his trip records during eight months, which are computed as follows,

$$H(D_u) = -\sum_{D_u \in \Psi} p(D_u) \log p(D_u),$$
$$H(D_u|S_u) = \sum_{D_u, S_u \in \Psi} p(S_u, D_u) \log \frac{p(S_u)}{p(S_u, D_u)},$$
$$H(D_u|S_u, t_u) = \sum_{\substack{D_u, S_u \in \Psi, \\ t_u \in \chi}} p(S_u, D_u, t_u) \log \frac{p(S_u, t_u)}{p(S_u, D_u, t_u)},$$

where Ψ is the set of bikeshare stations, and $\chi = \{[00:00:00, 01:00:00), [01:00:00, 02:00:00), \cdots, [23:00:00, 24:00:00)\}$ is the set of hours in a day.

Figure 8 plots the CDFs of (i) $H(D_u)$, i.e., the entropy of user u's destination, (ii) $H(D_u|S_u)$, i.e., the conditional entropy of user u's destination when the start station S_u is given, and (iii) $H(D_u|S_u, t_u)$, i.e., the conditional entropy of user u's destination when both start station S_u and start time t_u are given. The statistical result is based on 43,316 users' rental data who have at least two rental records.

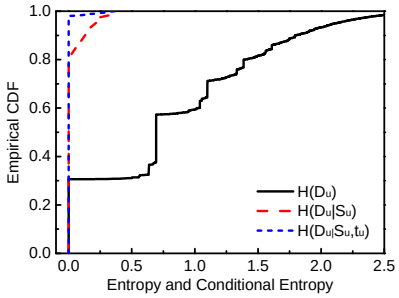

Figure 8: The CDFs of entropy & conditional entropy of destination given start station and time.

15,014 users' rental data are removed in this statistics since these users have only one rental record and thus the entropy of their destination is always zero. As shown in Figure 8, with user's start station and start time information, the values of conditional entropy $H(D_u|S_u)$ and $H(D_u|S_u, t_u)$ are greatly reduced. $H(D_u|S_u, t_u)$ is almost zero, which means user u's destination is almost fixed when his/her start station S_u and start time t_u are given. From the result in Figure 8, we find the destination distribution of a user's coming rental can be accurately predicted given historical user trip records and real-time start station and time.

With the stable duration and low-entropy destination distribution, user u's expected duration $E(R_u)$ is predicted by

$$E(R_u) = \sum_{D_u^i \in \Psi} p(D_u^i) R_u(D_u^i), \quad (1)$$

where $D_u^i \in \Psi$ is user u's possible end station given the start station S_u and start time t_u. $p(D_u^i)$ is the probability that user u will go to end station D_u^i, and $R_u(D_u^i)$ is the rental duration between start station S_u and end station D_u^i.

We use station-wide average rental duration to predict a user's rental duration when the user information is unknown. The predicted rental duration $E(R)$ is given by

$$E(R) = \frac{1}{|U_t^S|} \sum_{u_j \in U_t} E(R_{u_j}), \quad (2)$$

where $E(R_{u_j})$ is computed using Eq.(1), and U_t^S is the set of users who rent bikes in start station S at start time t.

4.2 Usage Calibration Engine

After obtaining the historical bike usage and the usage for the coming rental, this section introduces the system-wide usage calibration engine which is designed to select bikes for users to minimize system-wide usage variance. Although the usage calibration design itself only balances the system-wide usage, it can be used as an engine to achieve batch balancing by introducing weight to historical usage, which will be introduced in Section 4.3. In the following, we first propose the rationale behind our design. Then, we introduce the calibration algorithm.

4.2.1 Design Rationale. When a user u comes to a station to rent a bike, let the available bikes in this station be $\{b_1, b_2, ..., b_m\}$. We calculate the historical usage of these bikes $\{H_{b_1}, H_{b_2}, ..., H_{b_m}\}$ using the usage statistic model (i.e., the rental duration in the basic version of eShare). We then apply future usage prediction model to infer user u's future usage $E(R_u)$. For an arbitrary bike b_i in the station,

if it is selected for user u, then this bike's usage is updated to the sum of its historical usage and future usage, i.e., $R_{b_i} = H_{b_i} + E(R_u)$.

When minimizing the system-wide usage variance, it will be helpful if the usage calibration engine obtains *station-wide* usage statistics. We use an example to illustrate this idea. There are two bikes $\{b_1, b_2\}$ in the station. Bike b_1's historical usage is three hours while bike b_2's historical usage is two hours. When a user u_1 comes to a station to rent a bike, the bikeshare system obtains the user's real-time and historical usage after the user swiped his/her card. The system applies the usage prediction algorithm and obtains u_1's potential usage is one hour. On the other hand, the station-wide average usage is two hour.

Without considering the station-wide statistics, the calibration engine will select bike with minimum usage, i.e., bike b_2, and assign it to user u_1 to minimize system-wide usage variance. Bike b_2's usage is thus updated to $R_{b_2} = H_{b_2} + E_{R_{u_1}} = 2 + 1 = 3$. Since the station-wide average usage is two hour, in statistics, bike b_1's usage is given by $R_{b_1} > 3 + 2 = 5$. The usage variance is thus greater than $(3 - \frac{3+5}{2})^2 + (5 - \frac{3+5}{2})^2 = 2$.

However, if station-wide average usage is considered, the calibration engine will select the bike b_1 for user u_1. The bike usage is updated to $R_{b_1} = 3 + 1 = 4$ and $R_{b_2} > 2 + 2 = 4$, and the usage variance is greater than zero. Comparing these two cases, we find that it is better to consider station-wide usage statistics in bike selection since it helps to achieve smaller usage variance.

4.2.2 Calibration Algorithm. We now introduce how to utilize station-wide usage statistics to let the calibration engine decide the most suitable bike for a user u to minimize the system-wide usage variance. We assume that there are m bikes in the station when user u_1 comes to rent a bike. In the usage calibration design, without losing generality, we consider k potential users, i.e., $u_1, u_2, \ldots, u_k$, where $1 \le k \le m$ and $[u_2, \ldots, u_k]$ are users coming after u_1. Note that the problem formulation with a generic k is helpful for practical settings especially when coming users' reservation information is provided. Let each user u_i's expected usage be $E(R_{u_i})$, where $E(R_{u_1})$ is calculated based on Eq.(1). $E(R_{u_i})$, where $2 \le i \le k$, is estimated based on Eq.(2) when coming users' information is vacant.

Since the variety of bike selection at a station does not change the usage variance of bikes at other stations, the goal of minimizing the system-wide variance is equivalent to

$$\min \sum_{i=1}^{k} \sum_{j=1}^{m} \|(H_{b_j} + E(R_{u_i}))x_{ij} - \overline{R}\|^2, \tag{3}$$

s.t.

$$\begin{aligned} &\sum_{i=1}^{k} x_{ij} \le 1 \quad j = 1, \ldots, m, \\ &\sum_{j=1}^{m} x_{ij} = 1 \quad i = 1, \ldots, k, \\ &\sum_{i=1}^{k} \sum_{j=1}^{m} x_{ij} = k, \qquad x_{ij} = 0 \text{ or } 1, \end{aligned} \tag{4}$$

where $x_{ij} = 1$ if bike b_j for user u_i is selected, 0 if not. In the optimization target, H_{b_j} represents bike b_j's historical usage, $E(R_{u_i})$ represents the expected usage when bike b_j for user u_i is selected, and $H_{b_j} + E(R_{u_i})$ represents the total usage when bike b_j is selected for user u_i. $\overline{R}$ is the system-wide average bike usage and $\overline{R} = \frac{1}{n}(\sum_{k=1}^{n} H_{b_k} + \sum_{i=1}^{k} E_{R_i})$. Then the optimization target represents choosing bikes at station S for coming users to minimize the usage variance. The first set of constraints ensures that no more than one user is assigned to any bike. The second set of constraints ensures that one bike is selected for every user. The third constraint ensures that k of the bikes for all the k users are selected.

We find that it is difficult to solve the nonlinear usage calibration problem with the four constraints directly. In the following, we transform the above nonlinear usage calibration problem to a linear programming problem.

Lemma 4.1. ***(Problem Transformation)*** *The nonlinear usage calibration problem in formula (3)-(4) is equivalent to the linear programming problem with the optimization target* $\min \sum_{i=1}^{k} \sum_{j=1}^{m} \|H_{b_j} + E(R_{u_i}) - \overline{R}\|^2 x_{ij}$ *and the same constraints in formula (4).*

We find that this transformed problem is a variation of the classic assignment problem, named k-cardinality assignment problem, in which there are k rows and m columns, but only k rows are assigned to k columns to minimize the sum of corresponding costs. The k-cardinality assignment problem has optimal solutions that can be achieved by the rectangular assignment algorithm with time complexity $O(k^2 \log k)$.

In the usage calibration process, on the one hand, the system-wide usage variance can be further reduced when we have exact reservation information of more coming users (i.e., a larger k). The estimation of the expected usage of coming users contains prediction errors, which may lead to an inefficient calibration to increase the usage variance. When the estimated user information is adopted, we run the usage calibration algorithm with all possible k, where k is an integer and $k \in [1, m]$, to choose the k which achieves the minimal system-wide variance. By solving the usage calibration problem in formula (3)-(4) with the optimal k, the calibration algorithm chooses the bike which is assigned to u_1.

• **Special Case:** Note that the above usage calibration algorithm includes the special case that the algorithm has no knowledge about the coming users, i.e., $k = 1$ in the usage calibration problem formulation.

Lemma 4.2. ***(Lower Bound)*** *When the algorithm has no knowledge about the coming users, the usage calibration algorithm chooses the bike with minimum usage in the station and reaches the lower bound.*

From this lemma, the performance of the usage calibration algorithm will not be worse than the performance of the algorithm which always selects the bike with minimum usage in a station.

4.3 Batch Balancing

The above usage calibration engine minimizes the system-wide bike usage variance. This engine provides us the capability to achieve batch balancing (e.g., balancing the usage of bikes in the same batch to reach the threshold calling for repair or other maintenance

activities at the same time). With the help of the usage calibration engine, we are able to manage the number of wear-out bikes to meet the maintenance capability by simply adjusting bikes' historical usage to either accelerate or postpone bike usage.

Let the batch of controlled bikes be $\{cb_1, cb_2, \ldots, cb_i, \ldots\}$. We update these bikes' usage with $\alpha \times R(cb_i)$, where $R(cb_i)$ is bike cb_i's real usage. We then apply $\alpha R(cb_i)$ as bike cb_i's usage in the usage calibration algorithm. Recall that the calibration model minimizes the system-wide bike usage variance. When other bikes' average usage is $\overline{R}$, the batch of controlled bikes's real usage is $\frac{\overline{R}}{\alpha}$. When $0 < \alpha < 1$, the usage of the batch of controlled bikes are accelerated. These bikes' usage are postponed when $\alpha > 1$. In real-world control applications in bikeshare systems, when the expected usage after control $\{C(cb_1), C(cb_2), \ldots, C(cb_i), \ldots\}$ is provided, then the value of α for bike cb_i is given by $\alpha(cb_i) = \frac{\sum_{i=1}^{n} C(cb_i)}{n \cdot C(cb_i)}$.

5 ADVANCED DESIGN

In the basic version of eShare, we quantify bike usage using rental duration which accounts for riding time. In this section, we provide an advanced design to quantify the bike usage by exploiting the depreciation caused by each rental trip (accounting for terrain features) from user trip data and bike repair data.

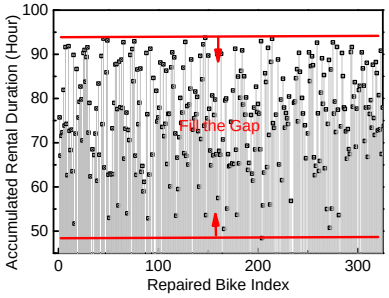

Figure 9: Accumulated Duration of Damaged Bikes

In the basic version of eShare, we use "rental duration" to quantify the bike usage. It works well under the situation that the depreciation caused by rental trips with same rental time are similar or the same. But in some scenarios, even with the same rental time, some rental trips may cause more bike depreciation than others, which leads to a higher repair cost. For example, in Bay Area bikeshare system in San Francisco, the rental trips locate in steep slopes cause more depreciation than those trips locate in flat roads. Under such a scenario, simply using "rental duration" may not accurately decide the status of a bike and the repair frequency. To provide some empirical insights, we use a repair event as an indicator of high usage for a bike. Then, we can explore the rental time distribution of repaired bikes to investigate if accumulated rental duration can be effectively used to indicate usage or not. Figure 9 shows the rental duration of the repaired bikes in NiceRide bikeshare system from 08/03/2015 to 11/01/2015. From this figure, we find that a bike that is repaired due to high usage can have a rental duration as short as 50 hours and as long as 95 hours . Thus, the rental duration alone is not enough to quantify usage.

In the following, we propose an enhanced usage quantification method by leveraging the depreciation caused by each rental trip from the large repaired bike data set. Let the differentiated source-destination pairs in the user trip records be $SD = \{sd_1, sd_2, \ldots, sd_l\}$. For each source-destination pair $sd_j \in SD$, we introduce depreciation rate w_j, where $w_j > 0$. Let the bikes in the repair records be $[rb_1, rb_2, \ldots, rb_N]$. For each repaired bike rb_i, we extract all its rental records from the user trip data within the repair-cycle. For bike rb_i's each differentiated source-destination pair $sd_j^{rb_i}$, we sum up the rental duration under this source-destination pair and obtain $A_j^{rb_i}$, which is accumulated rental duration under trip sd_j. Then, for each repaired bike rb_i, we obtain its adjusted total service duration $\sum_{j=1}^{l} w_j A_j^{rb_i}$.

Since we have a large repaired bike data set, we obtain a large observation of variables about the repaired bikes' total service duration, i.e., $X = [x_1\ x_2\ \ldots\ x_i\ \ldots]^T$, where $x_i = \sum_{j=1}^{l} w_j A_j^{rb_i}$. We assume that the total bike service duration subjects to normal (Gaussian) distribution, i.e., $X \sim N(\mu, \sigma^2)$, where μ is the expected average bike service duration. To reduce the variance of repaired bikes' total service duration, we aim to

$$\min \sum_{i=1}^{N} (\sum_{j=1}^{l} w_j A_j^{rb_i} - X'[i])^2, \tag{5}$$

where $X' = [x'_1\ x'_2\ \ldots\ x'_i\ \ldots]^T$, $X' \sim N(\mu, \sigma'^2)$ and $\sigma' \to 0$.

Lemma 5.1. *The minimum variance of repaired bikes' total service duration will be achieved when*

$$\hat{\mathbf{w}} = (\mathbf{A}^{\mathrm{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathrm{T}}\mathbf{X}'. \tag{6}$$

Eq.(6) provides an optimal solution to the problem in Eq.(5) when the total bike service duration follows normal distribution. From Lemma 5.1, we obtain the depreciation rate w_j for each differentiated trip sd_j. The depreciation rate w_j quantifies each source-destination pair's rental cost and fills the gap among repaired bikes' rental duration. The enhanced usage statistics model thus builds a connection between the usage and rental costs by inferring repaired bikes from the accumulated rental duration. Besides, this depreciation rate provides the operators the basis of a new charging scheme about rental fees with fine-grained depreciation rate.

6 EVALUATION: ID SWAPPING

This section evaluates the performance of eShare with real world data sets from three bikeshare systems. The basic information of these data sets are shown in Table 2. The format of these data sets is introduced in Section 3.2.

6.1 Evaluation Methodology

This section introduces the ID swapping based evaluation methodology which utilizes long-term multi-event data, including user trip, operator rebalancing and bike repair data, to evaluate the performance of eShare. The existing systems' bike usage information, including user ID, bike ID, time and station, can be found directly from the user trip data. Recall that eShare selects a bike from the available bikes in the station for each rent to minimize the system-wide usage variance. We first recover the available bikes (IDs) in a station at anytime. We observe that station status changes if and only if a user borrows/returns a bike or a system operator unloads/loads a bike. In other words, a bike is always in a station in the

Table 2: Basic Information of Collected Data from Three Bikeshare Systems.

Data Set Name	Accessed Periods	Data Size	Number of Records	Recording Frequency
Capital_User_Trip	10/01/10 - 12/31/15	1.4GB	11.8×10^6	Event Driven
Capital_Station_Status	08/04/14 - 12/31/15	1.9GB	269×10^6	Every 1min
Capital_Repair_Bike	01/01/11 - 09/30/15	297KB	3.14×10^3	Event Driven
HangZhou_User_Trip	01/01/13 - 12/31/13	4.2GB	103×10^6	Event Driven
HangZhou_Station_Status	01/01/13 - 12/31/13	1.2GB	248×10^3	Every 30min
HangZhou_Rebalancing	01/01/13 - 12/31/13	109MB	8.5×10^6	Event Driven
NiceRide_User_Trip	06/10/10 - 11/01/15	189MB	1.8×10^6	Event Driven
NiceRide_Rebalancing	04/01/12 - 11/01/15	31.9MB	465×10^3	Event Driven
NiceRide_Repair_Bike	08/03/15 - 10/05/16	272KB	3,724	Event Driven

duration after it is returned/loaded by the previous user/operator and before the next borrow/unload activity comes.

Based on this observation, eShare exploits the available bikes (IDs) for the bike selection of each rent. By utilizing both historical usage and real time card swiping information, eShare selects a bike for each rent in the user trip data. If the selected bike ID is different from the bike ID in the rent record in user trip data, we swap these two bikes' IDs and create a new user trip data with the bike (ID) selected by eShare. In other words, the selected bike by eShare will replace the original bike in the rent record. *Note that such a swap will not change the station status and thus will not change either user demand or service level.* Based on the newly-built user trip data, we are able to do statistics on eShare's system-wide bike usage.

•**Compared Algorithms:** To show the effectiveness of usage balancing in sharing platforms, we compare eShare with (i) the ground truth, which is the bike selection strategy extracted from the user trip data set and (ii) the algorithm which always selects the bike with minimum usage in a station, indicated as "Minimum Usage" in the figures.

•**Performance Metric:** We evaluate the bike usage efficiency from both single-bike and system-wide perspectives:

(i) **Service Timespan:** from single-bike perspective, we investigate each bike's service timespan which is defined as the time duration between the first use of a bike and the last use before a repair.

(ii) **Usage Variance:** from system-wide perspective, we investigate usage variance which is given by $\frac{1}{n}\sum_{i=1}^{n}(R_i - \overline{R})^2$, where n is the total number of bikes in the system, R_i is each bike's usage and $\overline{R}$ is the average bike usage.

The bike usage is defined as the total rental duration in service timespan multiplying by the depreciation rate. In the basic version of eShare, the depreciation rate is set to one.

6.2 Main Performance

In this subsection, we evaluate the performance of eShare by investigating bikes' service timespan and usage variance. Figure 10 shows the each bike's usage in two weeks in Capital bikeshare system with different bike selection strategies. In the figures, the bike usage of ground truth varies dramatically. The bike usage in Capital bikeshare system varies from 0 to 2000 minutes. As a comparison, Figure 10 also shows each bike's usage with eShare and "minimum usage" algorithm. From the figures, we can see that all the bikes in the systems are relatively fully utilized and the usage variance with

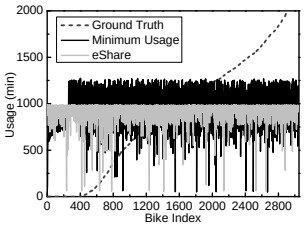

Figure 10: eShare main Performance

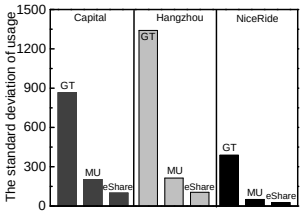

Figure 11: Bike usage Deviation

eShare is significantly reduced. In addition, eShare always achieves better performance than the "minimum usage" algorithm which is a special case of the eShare design. Figure 11 shows the standard deviation of usage with different algorithms in the three bikeshare systems. On average, the standard deviation of usage is reduced by 90% after eShare is applied to existing systems.

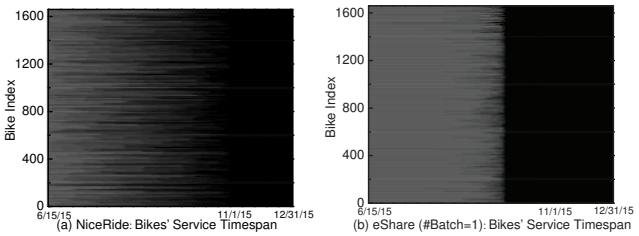

Figure 12: Service Timespan: (a) NiceRide system and (b) eShare

When bike usage is balanced, each bike's service timespan is changed accordingly. Figure 12 plots 1658 bikes' service timespan before (Figure 12(a)) and after (Figure 12(b)) eShare is applied in NiceRide bikeshare system. In the figures, when the color turns to black, it means that the bike's accumulated usage reaches the threshold for routine repair. From Figure 12(b), we find that the end of the service timespan is close when the bikes in the system are balanced used. It is helpful when the end of service time sits in a period when the bikeshare system is idle or in mandatory-decommission/bike-upgrade day.

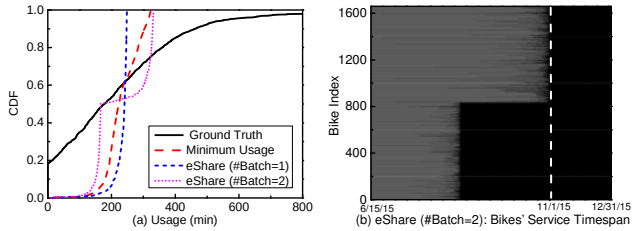

Figure 13: Capability of Batch Balancing:(a) CDFs of Usage and (b) Service Time.

•**Capability of Batch Balancing:** With eShare, we are able to achieve batch balancing. In this experiment, we accelerate the usage of half of the bikes by setting these bikes' usage to half of the real one in bike selection algorithm. Figure 13(a) shows the CDF of two-week bike usage with "Ground Truth", "Minimum Usage", "eShare ($\#Batch = 1$)", and "eShare ($\#Batch = 2$)" in NiceRide bikeshare system. From the figure, we can see that "eShare ($\#Batch = 2$)" put the 18% barely used bikes into use.

On the other hand, there is a usage gap between two portions of bikes. Figure 13(b) shows the corresponding service timespan under the bike usage with "eShare ($\#Batch = 2$)". From the figure, we can see that "eShare ($\#Batch = 2$)" makes portion of bikes' end-of-service-time sit in the idle period (e.g., November) of NiceRide bikeshare system. Figure 13 only shows eShare's capability on batch balancing while a specific control model is required to control the number of repairing bikes to fit with operators' repair capability.

6.3 Design Insight Analysis

In this subsection, we reveal design insights to illustrate why we achieve the above performance.

6.3.1 Performance of Usage Prediction. We perform the evaluation of our method with one-year user trip data from NiceRide bikeshare system which has 483,239 rental records. In this evaluation, we compare the method in eShare with the historical average (HA) method and the "HA" method with start time ("HA w/ ST"). In the "HA" method, we use the average rental duration of a source destination pair's all records to predict a new coming user's rental duration. In the "HA w/ ST" method, we use the average rental duration of a source-destination pair's records with the same hour of the start time.

The metric we adopt to measure the result is error rare which is given by $\frac{1}{N}\sum_{i=1}^{N}\frac{|\widehat{R_i}-R_i|}{R_i}$, where N is the total number of checked rental records, R_i is the ground truth of the rental duration in the i^{th} rental record and $\widehat{R_i}$ is the corresponding prediction value.

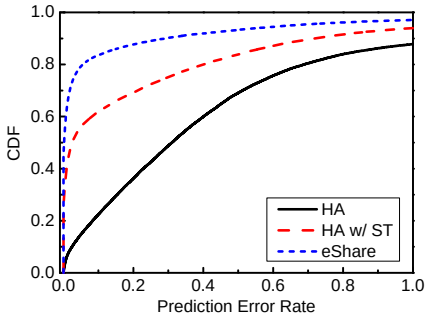

Figure 14: The CDFs of the prediction error rate

Figure 14 plots the CDFs of the prediction error rate of the "HA", "HA w/ ST", and eShare. As we can see, 80% of the predictions with our method have an error rate less than 5.5%. Compared with "HA" and "HA w/ ST", our prediction method significantly reduces the prediction error rate. The rationality behind this improvement is that our method fully exploits fine-grained user rental information from both historical and real-time user trip data in the prediction.

6.3.2 Performance of Usage Statistics. This section evaluates the performance of the enhanced usage model. In NiceRide bikeshare

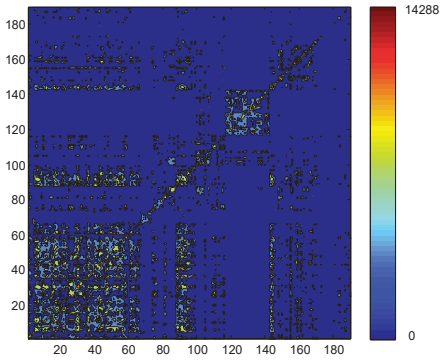

Figure 15: The four-year system-wide trip distribution with all origin-destination pairs in NiceRide bike sharing system.

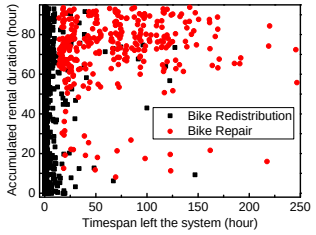

Figure 16: Timespan of Redis. and Repair

system, there are 190 stations and there are 190^2 possible origin-destination pairs. Figure 15 shows four-year system-wide trip distribution with all origin-destination pairs. There are 1,469,882 rental trips in total while the busiest origin-destination has 14,288 trips. In Figure 15, a origin-destination pair has more trips when its color is closer to red. From the figure, we can clearly see that there are many partial red dots in the diagonal. It means that there are a large number of trips which have the same origin and destination. That's the major reason why we do not adopt "mileage" as the measure of usage in this paper. Since the bikes in current bikeshare systems are not equipped with GPS, simply utilizing station distance to measure bike usage will introduce great errors in usage statistics because of the zero distance of the trips with same origin-destination.

We find that a large portion of areas are marked "blue" which means that these origin-destination pairs have almost no traffic. According to our statistics, 3,291 origin-destination pairs have more than one trip in two weeks. That's because that people normally take bike as a short-distance transport tool and only ride bikes to nearby stations.

In the following, we compute the depreciation rate $\hat{\mathbf{w}}$ for these 3,291 origin-destination pairs which requires at least 3,291 bike repair records. We manually record 3,724 bike repair logs with bike id and repair date from 08/03/15 to 10/05/16. Since the usage statistics model will be more accurate when we have more bike repair records, we use the collect repair logs as ground truth and build a model to infer repaired bikes from operator rebalancing data automatically.

For each bike unloading behavior (by operators), we compute this bike's accumulated usage from the user trip data as well as the timespan the bike left the system to classify this unloading behavior is for bike redistribution or for repair. Figure 16 plots the timespan of a bike left the system and the bike's accumulated rental duration when this bike is unload from the system. From the figure, we can see that the bike unloading for repair has long departure timespan and accumulated rental duration.

Table 3: Performance of Classification

Algorithm	TP Rate	FP Rate	Precision	Recall
KNN	0.987	0.137	0.987	0.987
Naive Bayes	0.977	0.346	0.975	0.977
Decision Trees	0.990	0.046	0.991	0.990
RandomForest	0.989	0.065	0.990	0.989
AdaBoost	0.991	0.022	0.992	0.991

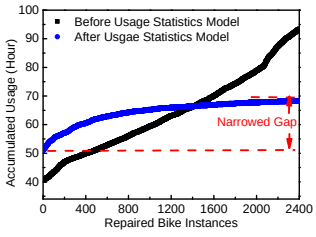

Figure 17: Model Validation

We apply classification algorithms to the data set. Table 3 reports the true positive (TP) rate, false positive (FP) rate, precision, and recall with KNN, Naive Bayes, RandomForest and AdaBoost by 10-fold cross-validation. From the experiment results, we can see that the repaired bike can be accurately predicted from user trip and operator rebalancing data. AdaBoost achieves the best performance since the data set has few outliers which can be found from Figure 16. We apply AdaBoost to four-year user trip and operator rebalancing data where we recover 12,662 bike repair records. Based on these bike repair records, we apply our usage statistics model. Its performance is shown in Figure 17 where we find that the gap of repair bikes' accumulated usage is narrowed. This is because that the usage statistics model leverages the depreciation (caused by terrain features) which reduces the variance of bikes' accumulated usage time.

7 RELATED WORK

The sharing platforms, e.g., Uber [13, 23], Airbnb [12, 20] and Bikeshare, have been on an exponential growth curve over recent years. In sharing platforms, it is crucial to investigate the usage of shared resources to provide an efficient sharing service. To the best of knowledge, most of existing research focuses on participation analysis [13, 23], incentive mechanism and benefits analysis [8, 12, 20] in the sharing economy. Little research, if any, has been conducted to study the fine-grained usage status among shared resources with large-scale data collected from these platforms.

Existing works on bike sharing systems focus on (i) demand analysis [1, 2, 9–11, 14, 15, 24–27], (ii) service analysis [3, 18, 19, 21], and (iii) redistribution scheduling [6, 16, 17]. Compared with previous studies on demand analysis, service analysis, and redistribution scheduling in bikeshare systems, this paper studies a completely new class of problem, i.e., usage balancing for efficient sharing.

8 CONCLUSION

In this paper, we design eShare to achieve usage efficient sharing. We provide a usage statistics model which quantifies (i) each bike's usage status and residual service time and (ii) each rental trip's depreciation rate. These information provides system operator valuable insights on managing bike resources and improving the quality of sharing service. We also propose a fine-grained usage prediction model for a specified user by leveraging his/her historical and real-time bike usage information collected by existing bikeshare systems. In addition, an optimal usage calibration algorithm is proposed to choose the most suitable bike to optimize the system-wide bike usage. The performance of eShare is evaluated through the data sets collected from three representative bikeshare systems. The evaluation results show that our eShare design helps existing bikeshare systems fully utilize shared bikes, improve service quality and reduce maintenance cost.

ABSTRACT

Graph neural network, as a powerful graph representation technique based on deep learning, has shown superior performance and attracted considerable research interest. However, it has not been fully considered in graph neural network for heterogeneous graph which contains different types of nodes and links. The heterogeneity and rich semantic information bring great challenges for designing a graph neural network for heterogeneous graph. Recently, one of the most exciting advancements in deep learning is the attention mechanism, whose great potential has been well demonstrated in various areas. In this paper, we first propose a novel heterogeneous graph neural network based on the hierarchical attention, including node-level and semantic-level attentions. Specifically, the node-level attention aims to learn the importance between a node and its meta-path based neighbors, while the semantic-level attention is able to learn the importance of different meta-paths. With the learned importance from both node-level and semantic-level attention, the importance of node and meta-path can be fully considered. Then the proposed model can generate node embedding by aggregating features from meta-path based neighbors in a hierarchical manner. Extensive experimental results on three real-world heterogeneous graphs not only show the superior performance of our proposed model over the state-of-the-arts, but also demonstrate its potentially good interpretability for graph analysis.

1 INTRODUCTION

The real-world data usually come together with the graph structure, such as social networks, citation networks, and the world wide web. Graph neural network (GNN), as a powerful deep representation learning method for such graph data, has shown superior performance on network analysis and aroused considerable research interest. For example, [10, 20, 24] leverage deep neural network to learn node representations based on node features and the graph structure. Some works [6, 14, 18] propose the graph convolutional networks by generalizing the convolutional operation to graph. A recent research trend in deep learning is the attention mechanism, which deals with variable sized data and encourages the model to focus on the most salient parts of data. It has demonstrated the effectiveness in deep neural network framework and is widely applied to various applications, such as text analysis [1], knowledge graph [25] and image processing [38]. Graph Attention Network (GAT) [35], a novel convolution-style graph neural network, leverages attention mechanism for the homogeneous graph which includes only one type of nodes or links.

Despite the success of attention mechanism in deep learning, it has not been considered in the graph neural network framework for heterogeneous graph. As a matter of fact, the real-world graph usually comes with multi-types of nodes and edges, also widely known as heterogeneous information network (HIN) [28]. For convenience, we uniformly call it heterogeneous graph in this paper. Because the heterogeneous graph contains more comprehensive information and rich semantics, it has been widely used in many data mining tasks. Meta-path [32], a composite relation connecting two objects, is a widely used structure to capture the semantics. Taking the movie data IMDB[1] shown in Figure 1(a) as an example, it contains three types of nodes include movie, actor and director. A relation between two movies can be revealed by meta-path Movie-Actor-Movie (*MAM*) which describes the co-actor relation, while Movie-Director-Movie (*MDM*) means that they are directed by the same director. As can be seen, depending on the meta-paths, the relation between nodes in the heterogeneous graph can have different semantics. Due to the complexity of heterogeneous graph, traditional graph neural network cannot be directly applied to heterogeneous graph.

Based on the above analysis, when designing graph neural network architecture with attention mechanism for heterogeneous graph, we need to address the following new requirements.

[1] https://www.imdb.com

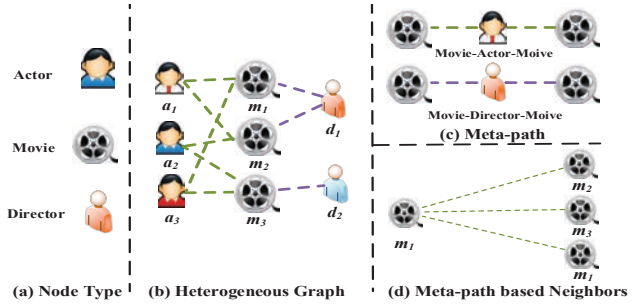

Figure 1: An illustrative example of a heterogenous graph (IMDB). (a) Three types of nodes (i.e., actor, movie, director). (b) A heterogenous graph IMDB consists three types of nodes and two types of connections. (c) Two meta-paths involved in IMDB (i.e., Moive-Actor-Moive and Movie-Director-Movie). (d) Moive m_1 and its meta-path based neighbors (i.e., m_1, m_2 and m_3).

Heterogeneity of graph. The heterogeneity is an intrinsic property of heterogeneous graph, i.e., various types of nodes and edges. For example, different types of nodes have different traits and their features may fall in different feature space. Still taking IMDB as an example, the feature of an actor may involve in sex, age and nationality. On the other hand, the feature of movie may involve in plot and actors. How to handle such complex structural information and preserve the diverse feature information simultaneously is an urgent problem that needs to be solved.

Semantic-level attention. Different meaningful and complex semantic information are involved in heterogeneous graph, which are usually reflected by meta-paths [32]. Different meta-paths in heterogeneous graph may extract diverse semantic information. How to select the most meaningful meta-paths and fuse the semantic information for the specific task is an open problem [4, 19, 26]. Semantic-level attention aims to learn the importance of each meta-path and assign proper weights to them. Still taking IMDB as an example, *The Terminator* can either connect to *The Terminator 2* via Movie-Actor-Movie (both starred by *Schwarzenegger*) or connect to *Birdy* via Movie-Year-Movie (both shot in *1984*). However, when identifying the genre of the movie *The Terminator*, *MAM* usually plays more important role, rather than *MYM*. Therefore, treating different meta-paths equally is unpractical and will weaken the semantic information provided by some useful meta-paths.

Node-level attention. In a heterogeneous graph, nodes can be connected via various types of relation, e.g., meta-path. Given a meta-path, each node has lots of meta-path based neighbors. How to distinguish the subtle difference of there neighbors and select some informative neighors is required. For each node, node-level attention aims to learn the importance of meta-path based neighbors and assign different attention values to them. Still taking IMDB as an example, when using the meta-path Movie-Director-Moive (the movies are with the same director), *The Terminator* will connect to *Titanic* and *The Terminator 2* via director *James Cameron*. To better identify the genre of *The Terminator* as sci-fi movie, the model should pay more attention to *The Terminator 2*, rather than *Titanic*. Therefore, how to design a model which can discover the subtle differences of neighbors and learn their weights properly will be desired.

In this paper, we propose a novel **H**eterogeneous graph **A**ttention **N**etwork, named HAN, which considers both of node-level and semantic-level attentions. In particular, given the node features as input, we use the type-specific transformation matrix to project different types of node features into the same space. Then the node-level attention is able to learn the attention values between the nodes and their meta-path based neighbors, while the semantic-level attention aims to learn the attention values of different meta-paths for the specific task in the heterogeneous graph. Based on the learned attention values in terms of the two levels, our model can get the optimal combination of neighbors and multiple meta-paths in a hierarchical manner, which enables the learned node embeddings to better capture the complex structure and rich semantic information in a heterogeneous graph. After that, the overall model can be optimized via backpropagation in an end-to-end manner.

The contributions of our work are summarized as follows:

• To our best knowledge, this is the first attempt to study the heterogeneous graph neural network based on attention mechanism. Our work enables the graph neural network to be directly applied to the heterogeneous graph, and further facilitates the heterogeneous graph based applications.

• We propose a novel heterogeneous graph attention network (HAN) which includes both of the node-level and semantic-level attentions. Benefitting from such hierarchical attentions, the proposed HAN can take the importance of nodes and meta-paths into consideration simultaneously. Moreover, our model is high efficiency, with the linear complexity with respect to the number of meta-path based node pairs, which can be applied to large-scale heterogeneous graph.

• We conduct extensive experiments to evaluate the performance of the proposed model. The results show the superiority of the proposed model by comparing with the state-of-the-art models. More importantly, by analysing the hierarchical attention mechanism, the proposed HAN demonstrates its potentially good interpretability for heterogeneous graph analysis.

2 RELATED WORK

2.1 Graph Neural Network

Graph neural networks (GNNs) which aim to extend the deep neural network to deal with arbitrary graph-structured data are introduced in [10, 24]. Yujia Li et al. [20] proposes a propagation model which can incorporate gated recurrent units to propagate information across all nodes. Recently, there is a surge of generalizing convolutional operation on the graph-structured data. The graph convolutional neural work generally falls into two categories, namely spectral domain and non-spectral domain. On one hand, spectral approaches work with a spectral representation of the graphs. Joan Bruna et al. [2] extends convolution to general graphs by finding the corresponding Fourier basis. Michaël et al. [6] utilizes K-order Chebyshev polynomials to approximate smooth filters in the spectral domain. Kipf et al. [18] proposes a spectral approach, named Graph Convolutional Network, which designs a graph convolutional network via a localized first-order approximation of spectral graph convolutions. On the other hand, we also have non-spectral

approaches, which define convolutions directly on the graph, operating on groups of spatially close neighbors. Hamilton et al. [14] introduces GraphSAGE which performs a neural network based aggregator over a fixed size node neighbor. It can learn a function that generates embeddings by aggregating features from a node's local neighborhood.

Attention mechanisms, e.g., self-attention [34] and soft-attention [1], have become one of the most influential mechanisms in deep learning. Some previous works introduce the attention mechanism for graph based applications, e.g., the recommendation [15, 16]. Inspired by attention mechanism, Graph Attention Network [35] is proposed to learn the importance between nodes and its neighbors and fuse the neighbors to perform node classification. However, the above graph neural network cannot deal with various types of nodes and edges and can only be applied to the homogeneous graphs.

2.2 Network Embedding

Network embedding, i.e., network representation learning (NRL), is proposed to embed network into a low dimensional space while preserving the network structure and property so that the learned embeddings can be applied to the downstream network tasks. For example, the random walk based methods [12, 23], the deep neural network based methods [36], the matrix factorization based methods [22, 37], and others, e.g., LINE [33]. However, all these algorithms are proposed for the homogeneous graphs. Some elaborate reviews can be found in [5, 11].

Heterogeneous graph embedding mainly focuses on preserving the meta-path based structural information. ESim [26] accepts user-defined meta-paths as guidance to learn vertex vectors in a user-preferred embedding space for similarity search. Even through ESim can utilize multiple meta-paths, it cannot learn the importance of meta-paths. To achieve the best performance, ESim needs to conduct grid search to find the optimal weights of hmeta-paths. It is pretty hard to find the optimal combination for specific task. Metapath2vec [7] designs a meta-path based random walk and utilizes skip-gram to perform heterogeneous graph embedding. However, metapath2vec can only utilize one meta-path and may ignore some useful information. Similar to metapath2vec, HERec [27] proposes a type constraint strategy to filter the node sequence and capture the complex semantics reflected in heterogeneous graph. HIN2Vec [9] carries out multiple prediction training tasks which learn the latent vectors of nodes and meta-paths simultaneously. Chen et al. [3] proposes a projected metric embedding model, named PME, which can preserve node proximities via Euclidian Distance. PME projects different types of node into the same relation space and conducts heterogeneous link prediction. To study the problem of comprehensive describe heterogeneous graph, Chen et al. [29] proposes HEER which can embed heterogeneous graph via edge representations. Fan et al. [8] proposes a embedding model metagraph2vec, where both the structures and semantics are maximally preserved for malware detection. Sun et al. [30] proposes meta-graph-based network embedding models, which simultaneously considers the hidden relations of all meta information of a meta-graph. In summary, all these aforementioned algorithms do not consider the attention mechanism in heterogeneous graph representation learning.

3 PRELIMINARY

A heterogeneous graph is a special kind of information network, which contains either multiple types of objects or multiple types of links.

Definition 3.1. **Heterogeneous Graph** [31]. A heterogeneous graph, denoted as $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, consists of an object set $\mathcal{V}$ and a link set $\mathcal{E}$. A heterogeneous graph is also associated with a node type mapping function $\phi : \mathcal{V} \rightarrow \mathcal{A}$ and a link type mapping function $\psi : \mathcal{E} \rightarrow \mathcal{R}$. $\mathcal{A}$ and $\mathcal{R}$ denote the sets of predefined object types and link types, where $|\mathcal{A}| + |\mathcal{R}| > 2$.

Example. As shown in Figure 1(a), we construct a heterogeneous graph to model the IMDB. It consists of multiple types of objects (Actor (A), Movie (M), Director (D)) and relations (shoot relation between movies and directors, role-play relation between actors and movies).

In heterogeneous graph, two objects can be connected via different semantic paths, which are called meta-paths.

Definition 3.2. **Meta-path** [32]. A meta-path Φ is defined as a path in the form of $A_1 \xrightarrow{R_1} A_2 \xrightarrow{R_2} \cdots \xrightarrow{R_l} A_{l+1}$ (abbreviated as $A_1A_2 \cdots A_{l+1}$), which describes a composite relation $R = R_1 \circ R_2 \circ \cdots \circ R_l$ between objects A_1 and A_{l+1}, where $\circ$ denotes the composition operator on relations.

Example. As shown in Figure 1(a), two movies can be connected via multiple meta-paths, e.g., Movie-Actor-Movie (*MAM*) and Movie-Director-Movie (*MDM*). Different meta-paths always reveal different semantics. For example, the *MAM* means the co-actor relation, while Movie-Director-Movie (*MDM*) means they are directed by the same director.

Given a meta-path Φ, there exists a set of meta-path based neighbors of each node which can reveal diverse structure information and rich semantics in a heterogeneous graph.

Definition 3.3. **Meta-path based Neighbors.** Givien a node i and a meta-path Φ in a heterogeneous graph, the meta-path based neighbors N_i^{Φ} of node i are defined as the set of nodes which connect with node i via meta-path Φ. Note that the node's neighbors includes itself.

Example. Taking Figure 1(d) as an example, given the meta-path Movie-Actor-Movie, the meta-path based neighbors of m_1 includes $m1$ (itself), m_2 and m_3. Similarly, the neighbors of m_1 based on meta-path Movie-Director-Movie includes m_1 and m_2. Obviously, meta-path based neighbors can exploit different aspects of structure information in heterogeneous graph. We can get meta-path based neighbors by the multiplication of a sequences of adjacency matrices.

Graph neural network has been proposed to deal with arbitrary graph-structured data. However, all of them are designed for homogeneous network [18, 35]. Since meta-path and meta-path based neighbors are two fundamental structures in a heterogeneous graph, next, we will present a novel graph neural network for heterogeneous graph data, which is able to exploit the subtle difference of nodes and meta-paths. The notations we will use throughout the article are summarized in Table 1.

Table 1: Notations and Explanations.

Notation	Explanation
Φ	Meta-path
$\mathbf{h}$	Initial node feature
$\mathbf{M}_{\phi}$	Type-specific transformation matrix
$\mathbf{h}'$	Projected node feature
e_{ij}^{Φ}	Importance of meta-path based node pair (i,j)
$\mathbf{a}_{\Phi}$	Node-level attention vector for meta-path Φ
α_{ij}^{Φ}	Weight of meta-path based node pair (i,j)
$\mathcal{N}_i^{\Phi}$	Meta-path based neighbors
$\mathbf{Z}_{\Phi}$	Semantic-specific node embedding
$\mathbf{q}$	Semantic-level attention vector
w_{Φ}	Importance of meta-path Φ
β_{Φ}	Weight of meta-path Φ
$\mathbf{Z}$	The final embedding

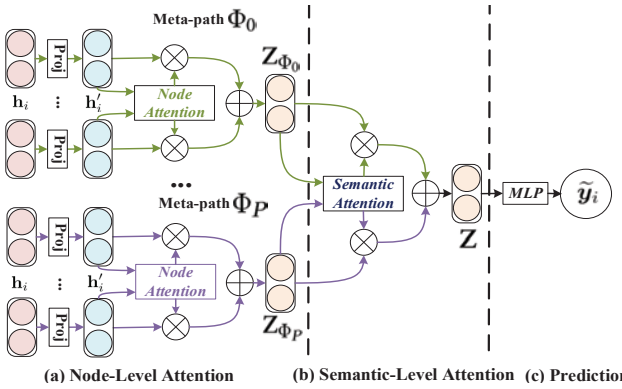

Figure 2: The overall framework of the proposed HAN. (a) All types of nodes are projected into a unified feature space and the weight of meta-path based node pair can be learned via node-level attention. (b) Joint learning the weight of each meta-path and fuse the semantic-specific node embedding via semantic-level attention. (c) Calculate the loss and end-to-end optimization for the proposed HAN.

4 THE PROPOSED MODEL

In this section, we propose a novel semi-supervised graph neural network for heterogeneous graph. Our model follows a hierarchical attention structure: node-level attention → semantic-level attention. Figure 2 presents the whole framework of HAN.

4.1 Node-level Attention

Before aggregating the information from meta-path neighbors for each node, we should notice that the meta-path based neighbors of each node play a different role and show different importance in learning node embedding for the specific task. Here we introduce node-level attention can learn the importance of meta-path based neighbors for each node in a heterogeneous graph and aggregate the representation of these meaningful neighbors to form a node embedding.

Due to the heterogeneity of nodes, different types of nodes have different feature spaces. Therefore, for each type of nodes (e.g.,node with type ϕ_i), we design the type-specific transformation matrix $\mathbf{M}_{\phi_i}$ to project the features of different types of nodes into the same feature space. Unlike [13], the type-specific transformation matrix is based on node-type rather than edge-type. The projection process can be shown as follows:

$$\mathbf{h}_i' = \mathbf{M}_{\phi_i} \cdot \mathbf{h}_i, \tag{1}$$

where $\mathbf{h}_i$ and $\mathbf{h}_i'$ are the original and projected feature of node i, respectively. By type-specific projection operation, the node-level attention can handle arbitrary types of nodes.

After that, we leverage self-attention [34] to learn the weight among various kinds of nodes. Given a node pair (i, j) which are connected via meta-path Φ, the node-level attention e_{ij}^{Φ} can learn the importance e_{ij}^{Φ} which means how important node j will be for node i. The importance of meta-path based node pair (i, j) can be formulated as follows:

$$e_{ij}^{\Phi} = att_{node}(\mathbf{h}_i', \mathbf{h}_j'; \Phi). \tag{2}$$

Here att_{node} denotes the deep neural network which performs the node-level attention. Given meta-path Φ, att_{node} is shared for all meta-path based node pairs. It is because there are some similar connection patterns under one meta-path. The above Eq. (2) shows that given meta-path Φ, the weight of meta-path based node pair (i, j) depends on their features. Please note that, e_{ij}^{Φ} is asymmetric, i.e., the importance of node i to node j and the importance of node j to node i can be quite difference. It shows node-level attention can preserve the asymmetry which is a critical property of heterogenous graph.

Then we inject the structural information into the model via masked attention which means we only calculate the e_{ij}^{Φ} for nodes $j \in \mathcal{N}_i^{\Phi}$, where $\mathcal{N}_i^{\Phi}$ denotes the meta-path based neighbors of node i (include itself). After obtaining the importance between meta-path based node pairs, we normalize them to get the weight coefficient α_{ij}^{Φ} via softmax function:

$$\alpha_{ij}^{\Phi} = softmax_j(e_{ij}^{\Phi}) = \frac{\exp\left(\sigma(\mathbf{a}_{\Phi}^{\mathrm{T}} \cdot [\mathbf{h}_i' \| \mathbf{h}_j'])\right)}{\sum_{k \in \mathcal{N}_i^{\Phi}} \exp\left(\sigma(\mathbf{a}_{\Phi}^{\mathrm{T}} \cdot [\mathbf{h}_i' \| \mathbf{h}_k'])\right)}, \tag{3}$$

where σ denotes the activation function, $\|$ denotes the concatenate operation and $\mathbf{a}_{\Phi}$ is the node-level attention vector for meta-path Φ. As we can see from Eq. (3), the weight coefficient of (i, j) depends on their features. Also please note that the weight coefficient α_{ij}^{Φ} is asymmetric which means they make different contribution to each other. Not only because the concatenate order in the numerator, but also because they have different neighbors so the normalize term (denominator) will be quite difference.

Then, the meta-path based embedding of node i can be aggregated by the neighbor's projected features with the corresponding coefficients as follows:

$$\mathbf{z}_i^{\Phi} = \sigma\left(\sum_{j \in \mathcal{N}_i^{\Phi}} \alpha_{ij}^{\Phi} \cdot \mathbf{h}_j'\right). \tag{4}$$

where $\mathbf{z}_i^{\Phi}$ is the learned embedding of node i for the meta-path Φ. To better understand the aggregating process of node-level, we

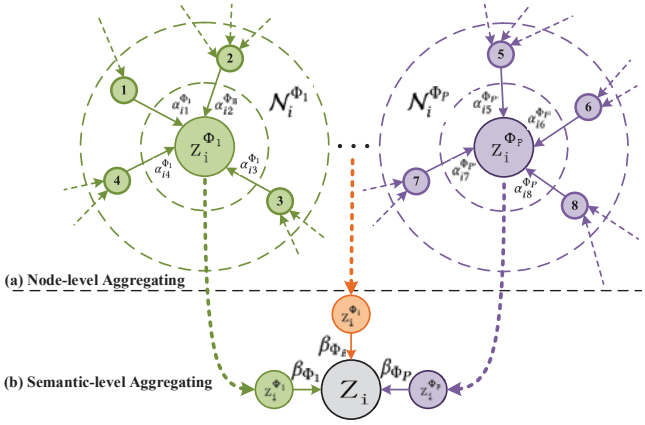

Figure 3: Explanation of aggregating process in both node-level and semantic-level.

also give a brief explanation in Figure 3 (a). Every node embedding is aggregated by its neighors. Since the attention weight α_{ij}^{Φ} is generated for single meta-path, it is semantic-specific and able to caputre one kind of semantic information.

Since heterogeneous graph present the property of scale free, the variance of graph data is quite high. To tackle the above challenge, we extend node-level attention to multihead attention so that the training process is more stable. Specifically, we repeat the node-level attention for K times and concatenate the learned embeddings as the semantic-specific embedding:

$$\mathbf{z}_i^{\Phi} = \Big\Vert_{k=1}^{K} \sigma\Big(\sum_{j\in\mathcal{N}_i^{\Phi}} \alpha_{ij}^{\Phi} \cdot \mathbf{h}_j'\Big). \tag{5}$$

Given the meta-path set $\{\Phi_0, \Phi_1, \ldots, \Phi_P\}$, after feeding node features into node-level attention, we can obtain P groups of semantic-specific node embeddings, denoted as $\{\mathbf{Z}_{\Phi_0}, \mathbf{Z}_{\Phi_1}, \ldots, \mathbf{Z}_{\Phi_P}\}$.

4.2 Semantic-level Attention

Generally, every node in a heterogeneous graph contains multiple types of semantic information and semantic-specific node embedding can only reflect node from one aspect. To learn a more comprehensive node embedding, we need to fuse multiple semantics which can be revealed by meta-paths. To address the challenge of meta-path selection and semantic fusion in a heterogeneous graph, we propose a novel semantic-level attention to automatically learn the importance of different meta-paths and fuse them for the specific task. Taking P groups of semantic-specific node embeddings learned from node-level attention as input, the learned weights of each meta-path $(\beta_{\Phi_0}, \beta_{\Phi_1}, \ldots, \beta_{\Phi_P})$ can be shown as follows:

$$(\beta_{\Phi_0}, \beta_{\Phi_1}, \ldots, \beta_{\Phi_P}) = att_{sem}(\mathbf{Z}_{\Phi_0}, \mathbf{Z}_{\Phi_1}, \ldots, \mathbf{Z}_{\Phi_P}). \tag{6}$$

Here att_{sem} denotes the deep neural network which performs the semantic-level attention. It shows that the semantic-level attention can capture various types of semantic information behind a heterogeneous graph.

To learn the importance of each meta-path, we first transform semantic-specific embedding through a nonlinear transformation (e.g., one-layer MLP). Then we measure the importance of the semantic-specific embedding as the similarity of transformed embedding with a semantic-level attention vector $\mathbf{q}$. Furthermore, we average the importance of all the semantic-specific node embedding which can be explained as the importance of each meta-path. The importance of each meta-path, denoted as w_{Φ_i}, is shown as follows:

$$w_{\Phi_i} = \frac{1}{|\mathcal{V}|} \sum_{i\in\mathcal{V}} \mathbf{q}^{\mathrm{T}} \cdot \tanh(\mathbf{W} \cdot \mathbf{z}_i^{\Phi} + \mathbf{b}), \tag{7}$$

where $\mathbf{W}$ is the weight matrix, $\mathbf{b}$ is the bias vector, $\mathbf{q}$ is the semantic-level attention vector. Note that for the meaningful comparation, all above parameters are shared for all meta-paths and semantic-specific embedding. After obtaining the importance of each meta-path, we normalize them via softmax function. The weight of meta-path Φ_i, denoted as β_{Φ_i}, can be obtained by normalizing the above importance of all meta-paths using softmax function,

$$\beta_{\Phi_i} = \frac{\exp(w_{\Phi_i})}{\sum_{i=1}^{P} \exp(w_{\Phi_i})}, \tag{8}$$

which can be interpreted as the contribution of the meta-path Φ_i for specific task. Obviously, the higher β_{Φ_i}, the more important meta-path Φ_i is. Note that for different tasks, meta-path Φ_i may has different weights. With the learned weights as coefficients, we can fuse these semantic-specific embeddings to obtain the final embedding $\mathbf{Z}$ as follows:

$$\mathbf{Z} = \sum_{i=1}^{P} \beta_{\Phi_i} \cdot \mathbf{Z}_{\Phi_i}. \tag{9}$$

To better understand the aggregating process of semantic-level, we also give a brief explanation in Figure 3 (b). The final embedding is aggregated by all semantic-specific embedding. Then we can apply the final embedding to specific tasks and design different loss fuction. For semi-supervised node classification, we can minimize the Cross-Entropy over all labeled node between the ground-truth and the prediction:

$$L = -\sum_{l\in\mathcal{Y}_L} \mathbf{Y}^l \ln(\mathbf{C} \cdot \mathbf{Z}^l), \tag{10}$$

where $\mathbf{C}$ is the parameter of the classifier, $\mathcal{Y}_L$ is the set of node indices that have labels, $\mathbf{Y}^l$ and $\mathbf{Z}^l$ are the labels and embeddings of labeled nodes. With the guide of labeled data, we can optimize the proposed model via back propagation and learn the embeddings of nodes. The overall process of HAN in shown in Algorithm 1.

4.3 Analysis of the Proposed Model

Here we give the analysis of the proposed HAN as follows:

• The proposed model can deal with various types of nodes and relations and fuse rich semantics in a heterogeneous graph. The information can transfer from one kind of nodes to another kind of nodes via diverse relation. Benefitted from such a heterogeneous graph attention network, different types of node embedding can enhance the mutual integration, mutual promotion and mutual upgrade.

• The proposed HAN is highly efficient and can be easily parallelized. The computation of attention can compute individually across all nodes and meta-paths. Given a meta-path Φ, the time

Algorithm 1: The overall process of HAN.

Input : The heterogeneous graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$,
The node feature $\{\mathbf{h}_i, \forall i \in \mathcal{V}\}$,
The meta-path set $\{\Phi_0, \Phi_1, \ldots, \Phi_P\}$.
The number of attention head K,
Output : The final embedding $\mathbf{Z}$,
The node-level attention weight α ,
The semantic-level attention weight β .

for $\Phi_i \in \{\Phi_0, \Phi_1, \ldots, \Phi_P\}$ **do**
  for $k = 1 \ldots K$ **do**
    Type-specific transformation $\mathbf{h}'_i \leftarrow \mathbf{M}_{\phi_i} \cdot \mathbf{h}_i$;
    for $i \in \mathcal{V}$ **do**
      Find the meta-path based neighbors $\mathcal{N}_i^\Phi$;
      for $j \in \mathcal{N}_i^\Phi$ **do**
        Calculate the weight coefficient α_{ij}^Φ ;
      end
      Calculate the semantic-specific node embedding $\mathbf{z}_i^\Phi \leftarrow \sigma\left(\sum_{j \in \mathcal{N}_i^\Phi} \alpha_{ij}^\Phi \cdot \mathbf{h}'_j\right)$;
    end
    Concatenate the learned embeddings from all attention head $\mathbf{z}_i^\Phi \leftarrow \Big\Vert_{k=1}^{K} \sigma\left(\sum_{j \in \mathcal{N}_i^\Phi} \alpha_{ij}^\Phi \cdot \mathbf{h}'_j\right)$;
  end
  Calculate the weight of meta-path β_{Φ_i} ;
  Fuse the semantic-specific embedding $\mathbf{Z} \leftarrow \sum_{i=1}^{P} \beta_{\Phi_i} \cdot \mathbf{Z}_{\Phi_i}$;
end
Calculate Cross-Entropy $L = -\sum_{l \in \mathcal{Y}_L} \mathbf{Y}_l \ln(\mathbf{C} \cdot \mathbf{Z}_l)$;
Back propagation and update parameters in HAN;
return Z, α, β.

complexity of node-level attention is $O(V_\Phi F_1 F_2 K + E_\Phi F_1 K)$, where K is the number of attention head, V_Φ is the number of nodes, E_Φ is the number of meta-path based node pairs, F_1 and F_2 are the numbers of rows and columns of the transformation matrix, respectively. The overall complexity is linear to the number of nodes and meta-path based node pairs. The proposed model can be easily parallelized, because the node-level and semantic-level attention can be parallelized across node paris and meta-paths, respectively. The overall complexity is linear to the number of nodes and meta-path based node pairs.

• The hierarchical attention is shared for the whole heterogeneous graph which means the number of parameters is not dependent on the scale of a heterogeneous graph and can be used for the inductive problems [14]. Here inductive means the model can generate node embeddings for previous unseen nodes or even unseen graph.

• The proposed model has potentionally good interpretability for the learned node embedding which is a big advantage for heterogeneous graph analysis. With the learned importance of nodes and meta-paths, the proposed model can pay more attention to some meaningful nodes or meta-paths for the specific task and give a more comprensive description of a heterogeneous graph. Based on the attention values, we can check which nodes or meta-paths make the higher (or lower) contributions for our task, which is beneficial to analyze and explain our results.

5 EXPERIMENTS

5.1 Datasets

The detailed descriptions of the heterogeneous graph used here are shown in Table 2.

• **DBLP**[2]. We extract a subset of DBLP which contains 14328 papers (P), 4057 authors (A), 20 conferences (C), 8789 terms (T). The authors are divided into four areas: *database, data mining, machine learning, information retrieval*. Also, we label each author's research area according to the conferences they submitted. Author features are the elements of a bag-of-words represented of keywords. Here we employ the meta-path set {*APA*, *APCPA*, *APTPA*} to perform experiments.

• **ACM**[3]. We extract papers published in KDD, SIGMOD, SIGCOMM, MobiCOMM, and VLDB and divide the papers into three classes (*Database, Wireless Communication, Data Mining*). Then we construct a heterogeneous graph that comprises 3025 papers (P), 5835 authors (A) and 56 subjects (S). Paper features correspond to elements of a bag-of-words represented of keywords. We employ the meta-path set {*PAP*, *PSP*} to perform experiments. Here we label the papers according to the conference they published.

• **IMDB.** Here we extract a subset of IMDB which contains 4780 movies (M), 5841 actors (A) and 2269 directors (D). The movies are divided into three classes (*Action, Comedy, Drama*) according

to their genre. Movie features correspond to elements of a bag-of-words represented of plots. We employ the meta-path set {*MAM*, *MDM*} to perform experiments.

5.2 Baselines

We compare with some state-of-art baselines, include the (heterogeneous) network embedding methods and graph neural network based methods, to verfify the effectiveness of the proposed HAN. To verify the effectiveness of our node-level attention and semantic-level attention, respectively, we also test two variants of HAN.

• DeepWalk [23]: A random walk based network embedding method which designs for the homogeneous graphs. Here we ignore the heterogeneity of nodes and perform DeepWalk on the whole heterogeneous graph.

• ESim [26]: A heterogeneous graph embedding method which can capture semantic information from multiple meta-paths. Because it is difficult to search the weights of a set of meta-paths, we assign the weights learned from HAN to ESim.

• metapath2vec [7]: A heterogeneous graph embedding method which performs meta-path based random walk and utilizes skip-gram to embed the heterogeneous graphs. Here we test all the meta-paths for metapath2vec and report the best performance.

• HERec [27]: A heterogeneous graph embedding method which designs a type constraint strategy to filter the node sequence and utilizes skip-gram to embed the heterogeneous graphs. Here we test all the meta-paths for HERec and report the best performance.

• GCN [18]: It is a semi-supervised graph convolutional network that designed for the homogeneous graphs. Here we test all the meta-paths for GCN and report the best performance.

• GAT [35]: It is a semi-supervised neural network which considers the attention mechanism on the homogeneous graphs. Here we test all the meta-paths for GAT and report the best performance.

• HAN$_{nd}$: It is a variant of HAN, which removes node-level attention and assigns the same importance to each neighbor.

• HAN$_{sem}$: It is a variant of HAN, which removes the semantic-level attention and assigns the same importance to each meta-path.

• HAN: The proposed semi-supervised graph neural network which employs node-level attention and semantic-level attention simultaneously.

5.3 Implementation Details

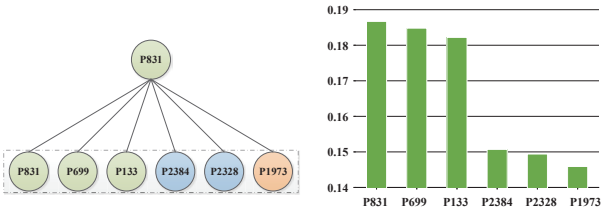
For the proposed HAN, we randomly initialize parameters and optimize the model with Adam [17]. For the proposed HAN, we set the learning rate to 0.005, the regularization parameter to 0.001, the dimension of the semantic-level attention vector $\mathbf{q}$ to 128, the number of attention head K to 8, the dropout of attention to 0.6. And we use early stopping with a patience of 100, i.e. we stop training if the validation loss does not decrease for 100 consecutive epochs. To make our experiments repeatable, we make our dataset and codes publicly available at website[4].For GCN and GAT, we optimize their parameters using the validation set. For semi-supervised graph neural network, including GCN, GAT and HAN, we split exactly

[4]https://github.com/Jhy1993/HAN

the same training set, validation set and test set to ensure fairness. For random walk based methods include DeepWalk, ESim, metapath2vec, and HERec, we set window size to 5, walk length to 100, walks per node to 40, the number of negative samples to 5. For a fair comparison, we set the embedding dimension to 64 for all the above algorithms.

5.4 Classification

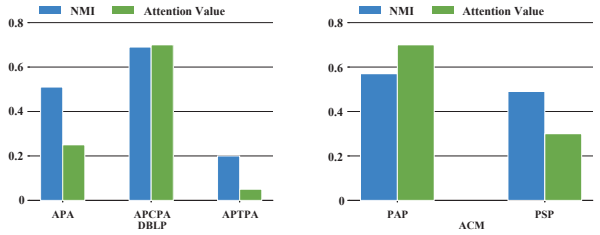
Here we employ KNN classifier with $k = 5$ to perform node classification. Since the variance of graph-structured data can be quite high, we repeat the process for 10 times and report the averaged *Macro-F1* and *Micro-F1* in Table 3.



Based on Table 3, we can see that HAN achieves the best performance. For traditional heterogeneous graph embedding method, ESim which can leverage multiple meta-paths performs better than metapath2vec. Generally, graph neural network based methods which combine the structure and feature information, e.g., GCN and GAT, usually perform better. To go deep into these methods, compared to simply average over node neighbors, e.g., GCN and HAN_{nd}, GAT and HAN can weigh the information properly and improve the performance of the learned embedding. Compared to GAT, the proposed HAN, which designs for heterogeneous graph, captures the rich semantics successfully and shows its superiority. Also, without node-level attention (HAN_{nd}) or semantic-level attention (HAN_{sem}), the performance becomes worse than HAN, which indicates the importance of modeling the attention mechanism on both of the nodes and semantics. Note that in ACM and IMDB, HAN improves classification results more significantly than in DBLP. Mainly because *APCPA* is the much more important than the rest meta-paths. We will explain this phenomenon in Section 5.7 by analyzing the semantic-level attention.

Through the above analysis, we can find that the proposed HAN achieves the best performance on all datasets. The results demonstrate that it is quite important to capture the importance of nodes and meta-paths in heterogeneous graph analysis.

5.5 Clustering



We also conduct the clustering task to evaluate the embeddings learned from the above algorithms. Once the proposed HAN trained, we can get all the node embedding via feed forward. Here we utilize the KMeans to perform node clustering and the number of clusters K is set to the number of classes. We use the same ground-truth as in node classification. And we adopt *NMI* and *ARI* to assess the quality of the clustering results. Since the performance of KMeans is affected by initial centroids, we repeat the process for 10 times and report the average results in Table 4.

As can be seen in Table 4, we can find that HAN performs consistently much better than all baselines. Also, graph neural network based algorithms usually achieve better performance. Besides, without distinguishing the importance of nodes or meta-paths, metapath2vec and GCN cannot perform well. With the guide of multiple meta-paths, HAN performs significantly better than GCN and GAT. On the other hand, without node-level attention (HAN_{nd}) or semantic-level attention (HAN_{sem}), the performance of HAN has shown various degrees of degeneration. It demonstrates that

(a) Meta-path based neighbors of P831 (b) Attention values of P831's neighbors

Figure 4: Meta-path based neighbors of node P831 and corresponding attention values (Different colors mean different classes, e.g., *green* means Data Mining, *blue* means Database, *orange* means Wireless Communication).

(a) NMI values on DBLP (b) NMI values on ACM

Figure 5: Performance of single meta-path and corresponding attention value.

via assigning the different importance to nodes and meta-paths, the proposed HAN can learn a more meaningful node embedding.

Based on the above analysis, we can find that the propsed HAN can give a comprehensive description of heterogeneous graph and achieve a significant improvements.

5.6 Analysis of Hierarchical Attention Mechanism

A salient property of HAN is the incorporation of the hierarchical mechanism, which takes the importance of node neighbors and meta-paths into consideration in learning representative embedding. Recall that we have learned the node-level attention weight α_{ij}^{Φ} and the semantic-level attention weight β_{Φ_i}. To better understand the importance of the neighbors and meta-paths, we provide a detailed analysis on the hierarchical attention mechanism.

Analysis of node-level attention. As mentioned before, given a specific task, our model can learn the attention values between nodes and its neighbors in a meta-path. Some important neighbors which are useful for the specific task tend to have larger attention values. Here we take the paper P831 [5] in ACM dataset as an illustrative example. Given a meta-path Paper-Author-Paper which describes the co-author of different papers, we enumerate the meta-path based neighbors of paper P831 and their attention values are

Table 4: Qantitative results (%) on the node clustering task.

Datasets	Metrics	DeepWalk	ESim	metapath2vec	HERec	GCN	GAT	HAN$_{nd}$	HAN$_{sem}$	HAN
ACM	NMI	41.61	39.14	21.22	40.70	51.40	57.29	60.99	61.05	**61.56**
	ARI	35.10	34.32	21.00	37.13	53.01	60.43	61.48	59.45	**64.39**
DBLP	NMI	76.53	66.32	74.30	76.73	75.01	71.50	75.30	77.31	**79.12**
	ARI	81.35	68.31	78.50	80.98	80.49	77.26	81.46	83.46	**84.76**
IMDB	NMI	1.45	0.55	1.20	1.20	5.45	8.45	9.16	10.31	**10.87**
	ARI	2.15	0.10	1.70	1.65	4.40	7.46	7.98	9.51	**10.01**

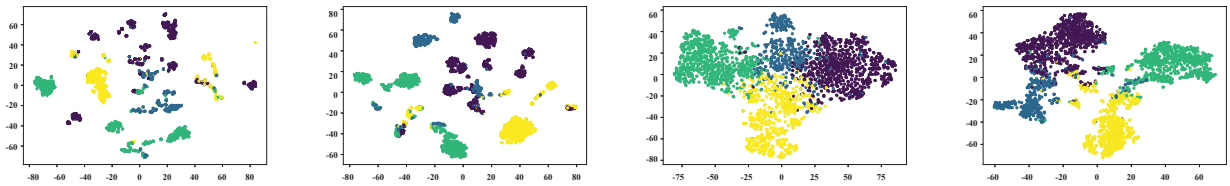
shown in Figure 4. From Figure 4(a), we can see that P831 connects to P699 [6] and P133 [7], which all belong to *Data Mining*; conects to P2384 [8] and P2328 [9] while P2384 and P2328 both belong to *Database*; connects to P1973 [10] while P1973 belongs to *Wireless Communication*. From Figure 4(b), we can see that paper P831 gets the highest attention value from node-level attention which means the node itself plays the most important role in learning its representation. It is reasonable because all information supported by neighbors are usually viewed as a kind of supplementary information. Beyond itself, P699 and P133 get the second and third largest attention values. This is because P699 and P133 also belong to *Data Mining* and they can make significant contribution to identify the class of P831. The rest neighbors get minor attention values that because they do not belong to *Data Mining* and cannot make important contribution to identify the P831's class. Based on the above analysis, we can see that the node-level attention can tell the difference among neighbors and assign higher weights to some meaningful neighbors.

Analysis of semantic-level attention. As mentioned before, the proposed HAN can learn the importance of meta-paths for the specific task. To verify the ability of semantic-level attention, taking DBLP and ACM as examples, we report the clustering results (*NMI*) of single meta-path and corresponding attention values in Figure 5. Obviously, there is a positive correlation between the performance of a single meta-path and its attention value. For DBLP, HAN gives *APCPA* the largest weight, which means that HAN considers the *APCPA* as the most critical meta-path in identifying the author's research area. It makes sense because the author's research area and the conferences they submitted are highly correlated. For example, some natural language processing researchers mainly submit their papers to ACL or EMNLP, whereas some data mining researchers may submit their papers to KDD or WWW. Meanwhile, it is difficult for *APA* to identify the author's research area well. If we treat these meta-paths equally, e.g., HAN$_{sem}$, the performance will drop significantly. Based on the attention values of each meta-path, we can find that the meta-path *APCPA* is much more useful than *APA* and *APTPA*. So even the proposed HAN can fuse them, *APCPA* still plays a leading role in identifying the author's research area while *APA* and *APTPA* do not. It also explains why the performance of HAN in DBLP may not be as significant as in ACM and IMDB. We get the similar conclusions on ACM. For ACM, the results show that HAN gives the most considerable weight to *PAP*. Since the performance of *PAP* is slightly better than *PSP*, so HAN$_{sem}$ can achieve good performance by simple average operation. We can see that semantic-level attention can reveal the difference between these meta-paths and weights them adequately.

5.7 Visualization

For a more intuitively comparation, we conduct the task of visualization, which aims to layout a heterogeneous graph on a low dimensional space. Specifically, we learn the node embedding based on the proposed model and project the learned embedding into a 2-dimensional space. Here we utilize t-SNE [21] to visualize the author embedding in DBLP and coloured the nodes based on their research areas.

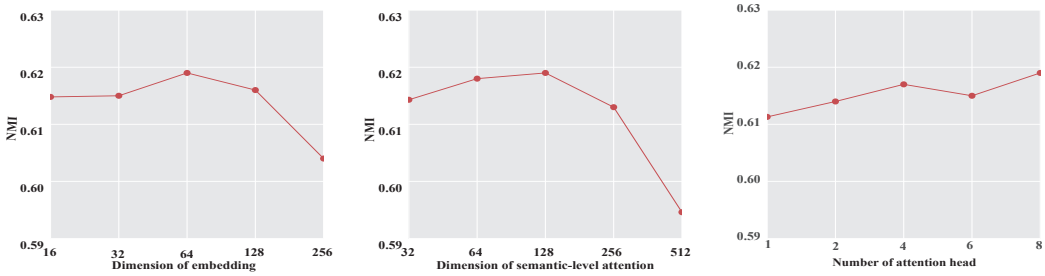
From Figure 6, we can find that GCN and GAT which design for the homogeneous graphs do not perform well. The authors belong to different research areas are mixed with each other. Metapath2vec performs much better than the above homogeneous graph neural networks. It demonstrates that the proper meta-path(e.g., *APCPA*) can make a significant contribution to heterogeneous graph analysis. However, since metapath2vec can only take only one meta-path into consideration, the boundary is still blurry. From Figure 6, we can see that the visualization of HAN peform best. With the guide of multiple meta-paths, the embedding learned by HAN has high intra-class similarity and separates the authors in different research area with distinct boundaries.



5.8 Parameters Experiments

In this section, we investigate the sensitivity of parameters and report the results of clustering (*NMI*) on ACM dataset with various parameters in Figure 7.

• **Dimension of the final embedding Z.** We first test the effect of the dimension of the final embedding $\mathbf{Z}$. The result is shown in Figure 7(a). We can see that with the growth of the embedding dimension, the performance raises first and then starts to drop slowly. The reason is that HAN needs a suitable dimension to encode the semantics information and larger dimension may introduce additional redundancies.



• **Dimension of semantic-level attention vector q.** Since the ability of semantic-level attention is affected by the dimension of the semantic-level attention vector $\mathbf{q}$, we explore the experimental results with various dimension. The result is shown in Figure 7(b). We can find that the performance of HAN grows with the

dimension of semantic-level attention vector and achieves the best performance when the dimension of $\mathbf{q}$ is set to 128. After that, the performance of HAN starts to degenerate which may because of overfitting.

• **Number of attention head** K**.** In order to check the impact of multihead attention, we explore the performance of HAN with various number of attention head. The result is shown in Figure 7(c). Note that the multihead attention is removed when the number of attention head is set to 1. Based on the results, we can find that the more number of attention head will generally improve the performance of HAN. However, with the change of attention head, the performance of HAN improve only slightly. Meanwhile, we also find that multihead attention can make the training process more stable.

6 CONCLUSION

In this paper, we tackle several fundamental problems in heterogeneous graph analysis and propose a semi-supervised heterogeneous graph neural network based solely on attention mechanism. The proposed HAN can capture complex structures and rich semantics behind heterogeneous graph. The proposed model leverages node-level attention and semantic-level attention to learn the importance of nodes and meta-paths, respectively. Meanwhile, the proposed model utilizes the structural information and the feature information in a uniform way. Experimental results include classification and clustering demonstrate the effectiveness of HAN. By analyzing the learned attention weights include both node-level and semantic-level, the proposed HAN has proven its potentially good interpretability.

ABSTRACT

Aspect-level sentiment analysis aims to provide complete and detailed view of sentiment analysis from different aspects. Existing solutions usually adopt a two-staged approach: first detecting aspect category in a document, then categorizing the polarity of opinion expressions for detected aspect(s). Inevitably, such methods lead to error accumulation. Moreover, aspect detection and aspect-level sentiment classification are highly correlated with each other. The key issue here is how to perform aspect detection and aspect-level sentiment classification jointly, and effectively. In this paper, we propose the *aspect-level sentiment capsules* model (**AS-Capsules**), which is capable of performing aspect detection and sentiment classification simultaneously, in a joint manner. AS-Capsules utilizes the correlation between aspect and sentiment through shared components including capsule embedding, shared encoders, and shared attentions. AS-Capsules is also capable of communicating with different capsules through a shared Recurrent Neural Network (RNN). More importantly, AS-Capsules model does not require any linguistic knowledge as additional input. Instead, through the attention mechanism, this model is able to attend aspect related words and sentiment words corresponding to different aspect(s). Experiments show that the AS-Capsules model achieves state-of-the-art performances on a benchmark dataset for aspect-level sentiment analysis.

1 INTRODUCTION

Sentiment analysis aims to analyze people's sentiments, opinions, evaluations, attitudes, and emotions from human languages [17, 24]. Current researches focus on document-level (*e.g.,* document, paragraph, and sentence), or in-depth aspect-level analysis. As a fine-grained task, aspect-level sentiment analysis provides complete and detailed view of sentiments from different aspects. In general, this task requires aspect detection and aspect-level sentiment classification. Most existing solutions first detect aspect category in a sentence, and then categorize the polarity of opinion expressions with respect to the detected aspect(s). In other words, the two subtasks are tackled separately. As a result, errors made in aspect detection would affect aspect-level sentiment classification. On the other hand, the two subtasks, *i.e.,* aspect detection and aspect-level sentiment classification, are highly correlated with each other.

In this paper, we propose the *aspect-level sentiment capsules* (**AS-Capsules**) model. This model utilizes the correlation between aspects and corresponding sentiments. Hence, we jointly perform the two subtasks: aspect detection and aspect-level sentiment classification.

The Research Problem. In aspect-level sentiment analysis, we have a predefined set of aspects $\mathcal{A} = \{a_1, a_2, \cdots, a_M\}$, and a predefined set of sentiment polarities $\mathcal{P} = \{o_1, o_2, \cdots, o_P\}$. Given a piece of text (*e.g.,* a sentence or a paragraph), denoted by $S = [w_1, w_2, \ldots, w_N]$, the task is to predict the aspect(s) and the corresponding sentiment(s), *i.e.,* aspect-sentiment pairs $\{\langle a_i, o_i \rangle\}$, expressed in the text.

Consider the task is to be conducted on restaurant reviews. The set of aspects $\mathcal{A}$ can be {*food, service, price, ambience, anecdote*}, and the set of sentiment polarities $\mathcal{P}$ may include {*positive*, *neutral*, *negative*}. Each restaurant review is considered a piece of text S.

Given an example review "Staffs are not that friendly, but the taste covers all.", the expected output will be aspect-sentiment pairs {⟨food, positive⟩, ⟨service, negative⟩}. Accordingly, such pairs are available for sample inputs as training data, where a supervised sentiment detection algorithm could learn from.

Recently, sentiment analysis has attracted wide attention. Aspect detection has been studied as a subtask of aspect-level sentiment analysis. The goal of aspect detection is to identify the aspect categories in sentence instead of extracting aspect terms. The aspect category set is predefined in advance. Most existing researches focus on classical machine learning models using classifiers with rich features, or deep learning models. LR and SVM are among the popular and effective classifiers. Unigram, Bigram and Lexicon features are the most important features for aspect detection. Many neural network models have been proposed for various tasks including sentiment analysis, such as Recursive Auto Encoder (RAE)[36, 37], Recurrent Neural Network (RNN) [19, 38], Convolutional Neural Network (CNN) [13, 14, 16], and more. The common solutions typically train deep learning models by using the basic models, and fine-tuning the word representations pre-trained by word2vec [20] or glove [25]. Attention-based LSTM with aspect embedding (ATAE-LSTM) [44] is shown effective to enforce the neural model to attend the related part of a sentence, with response to a specific aspect. Some variants of RNN and attention are proposed to improve the performance of aspect-level sentiment classification. However, ATAE-LSTM and its variants need aspect category as input, which limits the application. As we mentioned before, how to take advantage of the relationship between aspect detection and sentiment classification is the key.

In spite of the great success of neural network models, linguistic knowledge [30] is often required to achieve the best performance for sentiment analysis. However, linguistic knowledge is domain specific and costly to obtain. For example, the words to express positive and negative opinions in restaurant reviews will be very different from the words used in movie reviews. Further, many neural network models cannot provide explanations on how and why the predictions are made. Very recently, RNN-Capsule [45] demonstrates state-of-the-art accuracy on sentence-level sentiment classification. It does not require linguistic knowledge and is capable of outputting meaningful words with sentiment tendency. Inspired by RNN-Capsule, we propose AS-Capsules model for aspect-level sentiment analysis.

The AS-Capsules Model. The concept of "capsule" was proposed by Hinton *et al.* in 2011 [8]. A capsule is a group of neurons that "perform some quite complicated internal computations on their inputs and then encapsulate the results of these computations into a small vector of highly informative outputs" [8]. Following this high-level concept, each capsule in RNN-Capsule was designed to predict one sentiment polarity (*e.g.,* positive, negative, and neutral) [45]. In this work, we follow the same high-level concept of capsule as in RNN-Capsule, to design the AS-Capsules model for aspect-level sentiment analysis.[1]

Specifically, each individual capsule in the AS-Capsules model contains *an attribute*, *a state*, *a capsule embedding*, and *four modules*. The four modules are 'aspect representation module', 'aspect probability module', 'sentiment representation module', and 'sentiment distribution module'. For each predefined aspect, we build a capsule whose attribute is the same as the aspect category (*e.g., food* or *price*). Given a piece of text, we represent the given text by the low-level hidden vectors encoded by an encoder RNN. All capsules take the low-level hidden representations as their input, and each capsule outputs: (i) the aspect probability computed by its aspect probability module, and (ii) the sentiment distribution computed by its sentiment distribution module. All capsules utilize a shared RNN to communicate with each other to prevent capsules from attending conflict parts. The hidden representation of shared RNN is high-level because its input is the output of low-level encoder RNN. All attentions in capsule rely on the capsule embedding, which is capable of enforcing the model to focus on the correlated parts with respect to aspect. Aspect representation module and sentiment representation module share one representation generated by a component known as shared attention.

Compared with most existing neural network models for sentiment analysis, the AS-Capsules model does not heavily rely on the quality of input instance representation. The RNN layer to encode the given text input can be realized through the widely used LSTM models, GRU models or their variants. The model does not require any linguistic knowledge. Instead, each capsule is capable of outputting two kinds of attended words, one kind of words to reflect its assigned aspect category, and the other to reflect the sentiment tendency. Both sets of words are learned through the attention mechanisms. Experiments show that the words attended by each capsule well reflect the capsule's aspect category and sentiment tendency. We observe that the attended words cover a wide range of words from high frequency words to low frequency words. As low frequency words are not usually covered in sentiment lexicon, the domain-dependent aspect and sentiment words could be extremely useful sense making from the feedbacks to services or products. To summarize, the main contributions of this work are as follows:

- We propose AS-Capsules model to simultaneously perform aspect detection and aspect-level sentiment classification. A capsule is easy to build with input representations encoded by RNN. Each capsule contains an attribute, a state, a capsule embedding, and four modules known as aspect representation module, aspect probability module, sentiment representation module, and sentiment distribution module.
- The proposed AS-Capsules model does not require any linguistic knowledge to achieve state-of-the-art performance. Instead, the model is able to attend both sentiment words and aspect words reflecting the aspect knowledge of the dataset.
- We conduct experiments on a benchmark dataset (SemEval 2014 Task 4 dataset) to compare our model with strong baselines. Results show that our model is competitive and robust. We further show that our model trained on the SemEval dataset could be directly applied on Yelp reviews and output meaningful results.

2 RELATED WORK

Early approaches for sentiment analysis are mostly based on feature engineering and manually defined rules [35]. Recently, neural

[1] Our AS-Capsules model is different from the idea of Capsule Network (CapsNet) [34].

networks become the mainstream for sentiment analysis. Most current studies focus on improving the quality of vector representation of input instance using different models *e.g.,* RNN, RAE, CNN. We briefly review the related works on aspect detection, and aspect-level sentiment classification.

Aspect Detection. Aspect detection aims at identifying aspects about which users express their sentiments. A popular approach for aspect detection features a frequency-based method [10], where single nouns and compound nouns are considered possible aspects. Hence, only explicit aspects are detected. The authors in [6] then employ association rules mining to find implicit aspects. Instead of focusing on frequencies, syntax-based methods have also been used to detect aspects by means of syntactical relations [48, 49]. In general, this kind of models operates in an unsupervised manner. In [29], the authors propose a hybrid model where pointwise mutual information is used to find possible aspects, which are then fed into a Naive Bayes classifier to output a set of explicit aspects. There are also works like [11] to formulate aspect detection as a labeling problem, and a linear chain Conditional Random Field (CRF) is utilized.

Recently, relevant aspects are identified by employing word embedding techniques [32]. The method utilizes semantic and syntactic relationships in word embedding vectors in order to improve the extraction of multiple words aspects and distinguish conflict aspects. The effectiveness of word embeddings is investigated for aspect-level sentiment analysis in [1], in which both semantic and sentiment information are encoded. A semi-supervised word embedding algorithm is proposed in [50] to obtain continuous word embeddings on a large set of reviews. Then the word representations could be used to generate deeper and hybrid features to predict the aspect category.

To improve the performance of aspect detection, additional convolutional neural network features are extended in [42] besides extracting lots of features including lexicon, syntactic and cluster. Nevertheless expensive human effort and CNN operations limit its application.

Aspect-level Sentiment Analysis. Aspect-level sentiment classification deals with fine-grained classification with respect to specific aspect(s). Traditional approaches are to design a set of features manually. There are lexicon-based features built for sentiment analysis [22] with the abundance of sentiment lexicons [12, 26, 31]. Many studies focus on building sentiment classifiers with bag-of-words, sentiment lexicons, and other features, using SVM [23] or other classifiers. However, the results highly depend on the quality of features, and feature engineering is expensive.

Recently, many neural network models have been developed to tackle sentiment analysis. Transferring knowledge from existing public datasets [7] or pre-annotated information [39] improves the performance of aspect-term level sentiment classification. There are methods using memory network or linguistic knowledge to improve the performance of aspect-level sentiment classification. An innovative model named CEA is proposed in [46] using context memory, entity memory, and aspect memory.

Attention mechanism has shown to be effective in many applications including machine translation [2, 43], sentiment analysis [40, 44], summarization [33], and more. Given a sentence and the corresponding aspect(s), Attention-based LSTM with Aspect Embedding (ATAE-LSTM) [44] is able to predict the sentiment polarity at the aspect level. ATAE-LSTM is the first model to predict different sentiment tendencies with respect to different aspects in the same text. Aspect embedding and aspect based attention mechanism are designed in ATAE-LSTM to utilize aspect information effectively. The attention mechanism is well-designed to attend the different parts of a sentence when considering different aspects. To improve the performance of attention mechanism, [41] proposes a method named Aspect Fusion LSTM for incorporating aspect information for learning attentions. Motivated by similar reason, [18] proposes content attention with two enhancing attention mechanism. Multi-Head attention [43] jointly attends to information from different representation subspaces at different positions. In the proposed AS-Capsules model, we design attentions for every representation module in each capsule, which benefit from both low-level representation and high-level representation through different levels of encoder. In addition, a shared attention is able to generating shared representation as a part of both aspect and sentiment representations.

3 ASPECT-LEVEL SENTIMENT CAPSULES

The aspect-level sentiment capsules (AS-Capsules) model has its root in RNN-Capsule. Next we briefly describe RNN-Capsule, then detail the design of AS-Capsules model and its optimization method.

3.1 Preliminary: RNN-Capsule

Recurrent Neural Network. As the name suggests, RNN-Capsule is based on RNN. A recurrent neural network (RNN) is able to exhibit dynamic temporal behavior for a time sequence through connections between units. A unit can be realized by an LSTM model, a GRU model, or their variants. RNNs can be bi-directional, by using a finite sequence to predict or label each element in the sequence based on the element's past and future contexts. This is achieved by concatenating the outputs of two RNNs, one processes the sequence from left to right, and the other from right to left.

Briefly speaking, in an RNN realized by LSTM, the hidden states h_t and memory cell c_t in LSTM is a function of the previous h_{t-1} and c_{t-1}, and input vector x_t, or formally as follows:

$$c_t, h_t = \text{LSTM}(c_{t-1}, h_{t-1}, x_t) \tag{1}$$

The hidden state h_t denotes the representation of position t while encoding the preceding contexts of the position. More details about LSTM are given in [9].

RNN-Capsule. RNN-Capsule is designed to predict the sentiment category (*e.g.,* positive, negative, and neutral) of a given piece of text. The input text is encoded by RNN and the hidden vector representations are input to all capsules. One capsule is built for one sentiment category and each capsule contains an attribute, a state, and three modules. The attribute of a capsule reflects its dedicated sentiment category (*e.g.,* positive). The three modules are: (i) representation module for building capsule representation using attention mechanism, (ii) probability module for predicting the capsule's state probability based on its representation, and (iii) reconstruction module for rebuilding the representation of the input

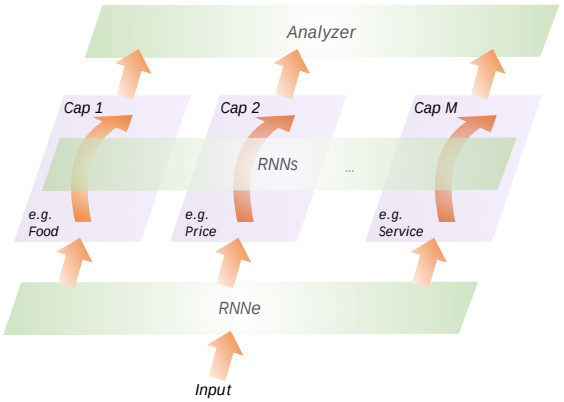

Figure 1: Architecture of AS-Capsules Model. Number of capsules equals the number of aspect categories. The hidden vectors H_1 are encoded by RNN_e, which encodes the input text. All capsules take H_1 as input and each capsule outputs its aspect probability p and sentiment distribution $\mathcal{P}$.

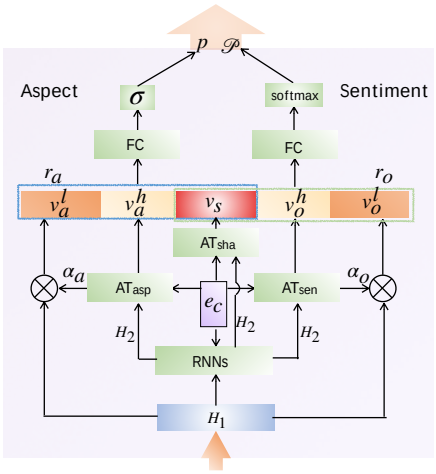

Figure 2: The architecture of a single capsule. The input to a capsule is the hidden vectors H_1 from RNN_e. e_c is the capsule embedding. The output is aspect probability p and sentiment distribution $\mathcal{P}$ of this capsule.

instance. A capsule's state is 'active' if the output of its probability module is the largest among all capsules, and 'inactive' otherwise.

There are two learning objectives in RNN-Capsule network. The first is to maximize the state probability of the capsule corresponding to the groundtruth sentiment, and to minimize the state probabilities of other capsule(s). The second is to minimize the distance between the input representation and the reconstruction representation of the capsule corresponding to the ground truth, and to maximize such distances for other capsule(s).

RNN-Capsule is not designed for aspect-level sentiment analysis and each capsule in RNN-Capsule corresponds to one sentiment category. The sentiment category predicted by RNN-Capsule therefore does not reflect the sentiment on any particular aspect. Aspect-level sentiment classification relies on aspect category heavily, so well-designed shared components for the two subtasks will benefit a lot. The high-level shared RNN between capsules is important, it allows capsules to cooperate to prevent capsules from attending conflict parts.

3.2 The AS-Capsules Model

The architecture of the proposed AS-Capsules model is depicted in Figure 1. The number of the capsules M equals to the number of predefined aspect categories. For example, we need 5 capsules to model a set of 5 categories {*Food*, *Price*, *Service*, *Ambience*, *Anecdote/miscellaneous* }, and a capsule is built for each aspect category. As in RNN-Capsule [45], we use an encoder RNN named RNN_e to encode the input text.

Given a piece of text (*e.g.*, a sentence, a paragraph, a document), RNN_e encodes the given instance and outputs the hidden representations H_1. Briefly speaking, in the encoder RNN, the hidden matrix H_1 are function of RNN_e and input word representations W, or formally:

$$H_1 = \text{RNN}_e(W) \tag{2}$$

The word representations $W = [w_1, w_2, \ldots, w_N]$ are obtained from glove, and N is the length of input text. The base unit of RNN is an LSTM, GRU, or their variants, *e.g.*, bi-directional LSTM.

All the capsules take the same hidden vectors H_1 as their input, and they share an RNN named RNN_s. Obviously, different aspect ought to attend different parts of input text, which is not well-designed in RNN-Capsule [45]. RNN_s allows capsules to communicate with each other, which is capable of preventing capsules from attending conflict parts. The high-level hidden representations are the hidden vectors of RNN_s. High-level here means that the input of RNN_s is the hidden representation of RNN_e. There are special designed attentions in capsule, and we will explain them in Section 3.3. Each capsule outputs an aspect probability and a sentiment distribution, through its aspect probability module and sentiment distribution module, respectively. Analyzer refers to the training objective strategy, which is capable of utilizing the correlation between aspect detection and aspect-level sentiment classification to improve the performance.

3.3 Structure of A Single Capsule

The structure of a single capsule is shown in Figure 2. A capsule contains *an attribute*, *a state*, *a capsule embedding*, and *four modules* (aspect representation module, aspect probability module, sentiment representation module, and sentiment distribution module).

- The attribute of a capsule reflects its dedicated aspect category, which is pre-assigned when we build the capsule. Depending on the number of aspect categories in a given problem, the same number of capsules are built to reflect each aspect category.
- The state of a capsule, *i.e.,* 'active' or 'inactive', is determined by aspect probability. To learn the model, a capsule's state is active if the current aspect appears in input text. Then AS-Capsules maximizes the aspect probability of the current active capsule. In testing, a capsule's state will be active if

its aspect probability p is above a predefined threshold *e.g.*, 0.5. Note that, a given piece of text may contain opinions on multiple aspects, then multiple capsules will be active.

- Capsule embedding e_c is a vector representation of the current capsule learned during training as in [44]. Recall that each capsule is assigned to learn one particle embedding and different aspects often demonstrate different word features for expressing the aspect and sentiment tendency. For example, "the pizza is delicious" demonstrates *food* aspect with positive sentiment. Here, the words "pizza" and "delicious" will not be applicable for other aspects like *service* or *price*. Therefore, for each capsule, we learn its capsule embedding.
- Aspect representation module learns the aspect representation r_a including three parts $[v_a^l, v_a^h, v_s]$, as shown in Figure 2. Given the hidden representations H_1 as input, we compute the high-level representation H_2 through RNN_s. The first part v_a^h of r_a is the weighted representation using the aspect-based attention AT_{asp} with capsule embedding e_c and H_2 as input. Utilizing the attention scores α_a of AT_{asp} and H_2, we can get the second representation v_a^l for aspect. The shared representation v_s, which is the output of the shared attention AT_{sha}, is the last part of r_a. AT_{sha} is shared with sentiment representation module. The aspect probability module then predicts the capsule's aspect probability p based on r_a. Similarly, sentiment representation module computes sentiment representation r_o of this capsule through similar method. Based on r_o, the sentiment distribution module generates sentiment distribution $\mathcal{P}$ on the predefined sentiment categories *e.g.*, positive, negative, neutral.

The essence of the AS-Capsules model is the four modules briefed above. Next, we detail the four modules.

Aspect Representation Module. Given the hidden vectors H_1 encoded by RNN_e, we are able to compute high-level hidden representations H_2 using RNN_s, which is shared by all capsules. Then, we use capsule embedding e_c and two attention mechanisms known as aspect-based attention AT_{asp} and shared attention AT_{sha}, to construct aspect representation r_a inside each capsule. The aspect-based attention attends the indicative words based on the aspect detection task. The shared attention benefits both aspect detection and sentiment classification. Our formulation is inspired by [2, 4, 44, 47]. Specifically, given H_1 as the low-level representations of the input text, we get a high-level hidden representations through

$$H_2 = \text{RNN}_s(H_1, e_c), \tag{3}$$

where, RNN_s is the shared encoder. The input of RNN_s is the concatenation of H_1 and e_c to enforce the RNN to attend the aspect correlated parts, inspired by AE-LSTM [44]. After getting H_2, we compute the high-level aspect representation v_a^h and attention weights α_a through aspect-based attention AT_{asp}, or formally:

$$v_a^h, \alpha_a = \text{AT}_{\text{asp}}(H_2, e_c) \tag{4}$$

Aspect-based attention, sentiment-based attention and shared attention have the same structure, so here we only detail the attention mechanism in AT_{asp}:

$$M_a = \tanh(W_h H_2 + W_c e_c \otimes N) \tag{5}$$

$$\alpha_a = \text{softmax}(w_a^T M_a) \tag{6}$$

$$v_a^h = H_2 \alpha_a^T \tag{7}$$

Here, $e_c \otimes N$ is the operator that repeatedly concatenates e_c for N times. W_h, W_c and w_a are the parameters of the current capsule for the aspect-based attention layer. The attention importance score α_a is obtained by multiplying the representations with the weight matrix, and then normalizing to a probability distribution over the words. Lastly, the high-level aspect representation vector v_a^h is a weighted summation over all the positions using the attention importance scores as weights.

The shared attention AT_{sha} is computed in a similar manner as the aspect-based attention.

$$v_s = \text{AT}_{\text{sha}}(H_2, e_c) \tag{8}$$

To obtain the original, or low-level aspect representation v_a^l from the input of capsule, we use the attention weights from aspect-based attention to weight the low-level input H_1.

$$v_a^l = H_1 \alpha_a^T \tag{9}$$

Lastly, we get the aspect representation by concatenating v_a^h, v_a^l and v_s,

$$r_a = [v_a^h, v_a^l, v_s], \tag{10}$$

where square brackets refer to the concatenation of vectors.

Aspect Probability Module. The aspect probability p is computed by a sigmoid function after getting the aspect representation r_a.

$$p = \sigma(W_p r_a + b_p), \tag{11}$$

where W_p and b_p are the parameters for the aspect probability module of the current capsule.

Sentiment Representation Module. The sentiment representation module is computed in a similar manner as the aspect representation module. The sentiment representation r_o contains three parts, known as high-level sentiment representation v_o^h, low-level sentiment representation v_o^l and shared representation v_s. The high-level sentiment representation v_o^h is computed in sentiment-based attention:

$$v_o^h, \alpha_o = \text{AT}_{\text{sen}}(H_2, e_c) \tag{12}$$

After getting the attention importance scores α_o in sentiment representation module, we utilize the low-level information through

$$v_o^l = H_1 \alpha_o^T \tag{13}$$

In the two formulas above, AT_{sen} is the sentiment-based attention. e_c is the capsule embedding. H_1 and H_2 are the hidden representations of RNN_e and RNN_s. The attention importance score for each position for sentiment is α_o. The sentiment representation vector r_o is obtained by concatenating v_o^h, v_o^l and v_s.

Note that, both the aspect representation and the sentiment representation obtained from attention layer are high-level encodings of the entire input text. The attention mechanism designed in the model is for improving the model's capability and robustness.

Sentiment Distribution Module. The sentiment distribution $\mathcal{P}$ is computed by a softmax function after getting the sentiment representation vector r_o.

$$\mathcal{P} = \text{softmax}(W'_p r_o + b'_p), \tag{14}$$

where W'_p and b'_p are the parameters for the sentiment distribution module of the current capsule.

The above four modules complement each other in the AS-Capsules model. From a macro perspective *i.e.,* the full dataset, the words attended by different capsules match the capsules' attribute. From micro perspective *i.e.,* a piece of input text, the state 'active' or 'inactive' of a capsule is determined by its aspect probability p. The sentiment distribution is with respect to the aspect category of the current capsule.

There are two different ways to utilize the correlation between aspect and sentiment. One way is to draw support from the capsule structure. In our first attempt, we design the capsule structure with two independent attentions based on their own embeddings named aspect embedding and sentiment embedding. However, the two independent embeddings have the same effect, and cannot benefit from the correlation between aspect and sentiment effectively. Motivated by shared embedding [44] and multi-head attention [43], in our current design, aspect representation module and sentiment representation module share one embedding known as capsule embedding. Specially, we design aspect-based attention, sentiment-based attention and shared attention. Aspect-based attention and sentiment-based attention are shared by low-level and high-level RNN encoders to get hierarchical representations of input text. Shared attention is used to generate shared representation for both aspect detection and sentiment classification. The other way to utilize the correlation considers the co-occurrence of aspect and sentiment pair. We use the idea of mask. That is, we only keep the cross entropy of aspect(s) that appear in the input text and ignore the irrelevant aspect(s) in the learning objective.

3.4 Training Objective

The training of the proposed AS-Capsules model has two objectives. One is to maximize the aspect probability of active capsule(s) matching the ground truth and minimize aspect probability of the inactive capsule(s). The other is to minimize the cross-entropy of sentiment distribution of active capsules.

Aspect Probability Objective. A given text may express sentiments on multiple aspects. Hence, we have both positive sample(s) (*i.e.,* the active capsule(s)) and negative sample(s) (*i.e.,* the inactive capsule(s)). Recall that our objective is to maximize the aspect probability of active capsules and to minimize the aspect probability of inactive capsules. The classification objective J can be formulated by cross entropy loss:

$$J(\theta) = \sum \frac{1}{M} \sum_{i=1}^{M} \text{cross-entropy}(y_a^i, [p_i, 1 - p_i]), \tag{15}$$

where p_i is the aspect probability of the capsule i. For a given training instance, $y_a^i = 1$ for an active capsule (*i.e.,* the corresponding aspect occurs in the given text), and $y_a^i = 0$ for an inactive capsule. M is the number of aspect categories, where is 5.

Table 1: The statistics of restaurant reviews on SemEval 2014 Task 4 dataset. The sentiment category 'conflict' is not used.

Aspect	Positive		Negative		Neural	
	Train	Test	Train	Test	Train	Test
Food	867	302	209	69	90	31
Price	179	51	115	28	10	1
Service	324	101	218	63	20	3
Ambience	263	76	98	21	23	8
Anecdote	546	127	199	41	357	51
Total	2179	657	839	222	500	94

Aspect-level Sentiment Classification Objective. The other objective is to ensure the accuracy of aspect-level sentiment classification of the active capsule(s). Similarly, the unregularized objective U can be formulated as cross entropy loss:

$$U(\theta) = \sum \frac{1}{\sum_{\forall y_a^i=1} 1} \sum_{\forall y_a^i=1} \text{cross-entropy}(y_o^i, \mathcal{P}_i) \tag{16}$$

We only utilize the cross-entropy loss of the 'active' capsule(s). y_o^i is the groundtruth sentiment of the 'active' capsule i. $\mathcal{P}_i$ is the predicted sentiment distribution of the capsule i.

Considering both objectives, our final objective function L is obtained by adding J and U:

$$L(\theta) = J(\theta) + U(\theta) \tag{17}$$

4 EXPERIMENT

We now evaluate the proposed AS-Capsules for aspect detection and aspect-level sentiment classification, against baselines.

4.1 Dataset and Model Implementation Details

Dataset. We conduct experiments on SemEval 2014 Task 4 dataset [27].[2] The dataset consists of customer reviews for laptops and restaurants, but only restaurant reviews are annotated with aspect-specific polarity. Hence we conduct experiments on restaurant reviews.

The restaurant reviews consist of about 3K English sentences from [5]. We randomly cut out $\frac{1}{8}$ as validation dataset, and the rest is the training dataset. Additional restaurant reviews, not in the original dataset of [5], are used as test data. The set of aspects $\mathcal{A}$ is {*food, service, price, ambience, anecdote*}. There are four sentiment categories: *positive*, *neutral*, *negative* and *conflict*. Each sentence is assigned one or more aspects together with a polarity label for each aspect, *e.g.,* "Staffs are not that friendly, but the taste covers all." would be assigned the aspect-sentiment pairs {⟨food, positive⟩, ⟨service, negative⟩}. In our experiments, we use the first three sentiment categories, as in most other studies.

Table 1 presents the statistics of the SemEval 2014 Task 4 dataset. The two aspects *food* and *anecdote* have the largest number of instances. However, it is hard to think about words that are indicative for aspect *anecdote*.

Implementation Details. In our experiments, all word vectors are initialized by Glove [25].[3] The pre-trained word embeddings and

Table 2: Micro F_1 of methods on SemEval 2014 Task 4 dataset. Best results are in bold face and second best underlined.

Model	micro-F_1	Model	micro-F_1
KNN	63.9	HLBL	69.7
LR	66.0	C&W	72.5
SVM	80.8	word2vec	83.3
SemEval-Average	73.8	Hybrid-WRL-300	88.6
NRC-Lexicon	84.1	Hybrid-WRL-Best	**90.1**
NRC	88.6	AS-Capsules	<u>89.6</u>

Table 3: The average F_1 and F_1 of different aspects for Subtask 1: aspect detection.

Model	Average	Food	Price	Service	Ambience	Anecdote
Bi-LSTM	83.0	92.6	79.2	88.8	74.8	<u>79.6</u>
AE-LSTM	84.5	**93.8**	83.3	88.8	78.2	78.5
AT-LSTM	84.5	91.6	83.0	85.6	<u>83.0</u>	79.2
RNN-Capsule	<u>85.5</u>	**93.8**	<u>85.4</u>	<u>89.4</u>	80.6	78.3
AS-Capsules	**87.2**	<u>93.4</u>	**85.9**	**91.0**	**83.3**	**82.4**

capsule embedding have dimensions of 300 and 256, respectively. The dimension of hidden vectors encoded by RNN is 256 (hence 512 if RNN is bidirectional). We use a single layer bidirectional LSTM in AS-Capsules. The model is trained with a batch size of 16 examples, and there is a checkpoint every 8 mini-batch due to the small size of dataset. Dropout is 0.5 for word embedding and linear layer in aspect probability module and sentiment distribution module.

We implement our model on Pytorch (version 0.4).[4] Model parameters are randomly initialized. Adam [15] is utilized to optimize our model, and we use $1e-3$ as learning rate for model parameters except word vectors, and $1e-4$ for word vectors.

4.2 Evaluation on Three Subtasks

SemEval 2014 task 4 dataset is widely used for aspect-level sentiment analysis. Because of the detailed annotation, multiple evaluations can be conducted. We report our experiments on three subtasks: aspect detection, sentiment classification on given aspects, and aspect-level sentiment analysis.

4.2.1 Subtask 1: Aspect Detection. Given a piece of text, the task of aspect detection is to predict the existence of predefined aspects, which is a typical multi-label classification task. We compare AS-Capsules with state-of-the-art baselines designed for aspect detection. Specially, we compare detailed F_1 of all categories with effective joint deep learning baselines including Bi-LSTM, AE-LSTM, AT-LSTM, and RNN-Capsule.

KNN is the baseline provided by SemEval official [28]. First, the Dice coefficient is used to calculate the similarity to find k most similar sentences in training dataset for given test sentence. Then, m most frequent aspect categories of the k retrieved sentences will be assigned to the test sentence. m is the number of most frequent aspect categories per sentence among the k sentences. Logistic Regression (LR) and Support Vector machine (SVM) are used as classifiers using unigram and bigram features. SemEval-Average is the average result of all the systems in SemEval 2014. NRC, the best system in SemEval 2014, adopts SVM as the classifier with some well-designed features including n-grams, stemmed n-grams, character n-grams, non-contiguous n-grams, word cluster n-grams and lexicons. NRC-Lexicon is the result without the lexicon feature.

Some word representation methods are compared with our AS-Capsules. C&W [3] and word2vec [20] are the powerful and accepted generally methods for word representation learning. HLBL [21] is a hierarchical model, which performs well using a carefully constructed hierarchy over words. Hybrid-WRL [50] is a word representation learning method using hybrid features including shared-features and aspect-specific features.

Table 2 lists the micro F_1 of aspect detection on restaurants reviews. Our proposed AS-Capsules model achieves the second best. Notice that, there are two kinds of Hybrid-WRL methods. The difference between them is the size of word representation. Hybrid-WRL-300 uses 300 as word representation size, 600 for Hybrid-WRL-Best. Our AS-Capsules adopts 300 as the dimension of word representation, improves 1 percentage than Hybrid-WRL at the same size of word representation. Obviously, there are more complexity and parameters with bigger size of word representation. For classical machine learning methods, SVM performs better than KNN and LR. NRC achieves the best SemEval result with the textual features and lexicons features using SVM as classifier. Without Lexicons features, NRC-Lexicon is 4 percentage lower than NRC. Word representation methods perform better than KNN, LR and SVM, however they perform worse than NRC with well-designed features.

Although classical machine learning methods have shown their effectiveness, it is better to compare with neural network methods. Bidirectional-LSTM (Bi-LSTM) is a variant of LSTM which is introduced in Section 3.1. It is capable of utilizing the content information through the bidirectional structure. Aspect Embedding LSTM (AE-LSTM) is proposed in [44], where aspect embeddings are concatenated with word vectors. AE-LSTM considers aspect information so it is expected to perform better than Bi-LSTM. Different parts of input sentence have different importance, so attention is a powerful way to address this problem. Attention based LSTM (AT-LSTM) [44] further uses attention mechanism, which performs better than other baselines. RNN-Capsule uses each capsule to detect one category, sentiment category in its original paper [45], and aspect in this experiment.

Reported in Table 3, our proposed AS-Capsules is the best performing method, followed by RNN-Capsule. Specifically, AS-Capsules achieves the best average F_1, best results on four aspects except aspect *food*. The gap between AS-Capsules and the best model in aspect *food* is very small. AE-LSTM and AT-LSTM deliver similar results and Bi-LSTM performs the poorest.

4.2.2 Subtask 2: Sentiment Classification on Given Aspects. Given a piece of text and also the annotated aspect, the task is to predict the sentiment expressed in the text on the given aspect. For this subtask, we compare AS-Capsules with four baselines: Bi-LSTM,

[4] https://github.com/pytorch

Table 4: Accuracy and F_1 of sentiment categories for Subtask 2: sentiment classification on given aspects.

Model	Accuracy	F_1-Positive	F_1-Neutral	F_1-Negative
Bi-LSTM	82.1	89.2	49.7	73.2
AE-LSTM	82.8	89.8	54.2	72.6
AT-LSTM	83.0	89.8	47.3	75.8
ATAE-LSTM	84.3	90.1	**61.9**	77.5
AS-Capsules	**85.0**	**91.2**	50.7	**78.7**

Table 5: Accuracy and F_1 of different sentiment categories for Subtask 3: aspect-level sentiment analysis.

Model	Accuracy	F_1-Positive	F_1-Neutral	F_1-Negative
Bi-LSTM	62.3	80.2	43.6	56.6
AE-LSTM	64.7	82.4	50.3	55.7
AT-LSTM	65.6	82.4	46.6	57.7
AS-Capsules	**68.1**	**83.3**	**53.6**	**61.6**

AE-LSTM, AT-LSTM, and Attention-based LSTM with Aspect Embedding (ATAE-LSTM) [44]. ATAE-LSTM unitizes aspect information to attend the important words in sentence with respect to a specific aspect. Note that RNN-Capsule cannot be applied to this subtask because RNN-Capsule is self-attentive, and it cannot take aspect as an additional input.

From the results reported in Table 4, we observe that AS-Capsules achieves the best accuracy of 85.0. It outperforms all baselines with respect to the F_1 results on the *positive* and *negative* sentiment categories. Due to less neutral data in dataset, AS-Capsules performs not good enough. Among the baseline methods, ATAE-LSTM outperforms the rest. AE-LSTM and AT-LSTM perform better than Bi-LSTM. Among three sentiment categories, *positive* is much easier to predict and *neutral* is the most difficult category due to the smallest size of data.

4.2.3 Subtask 3: Aspect-level Sentiment Analysis. Given a piece of text, subtask 3 requires a method to detect $\langle aspect, sentiment \rangle$ pair(s) from the input text. A detected pair is considered correct if both components in the pair are correctly identified. We compare AS-Capsules with Bi-LSTM, AE-LSTM and AT-LSTM. Again, RNN-Capsule is not designed to classify sentiment with given aspect(s) and ATAE-LSTM needs aspect as additional input; hence these two models are not applicable to this task.

Reported in Table 5, AS-Capsules model delivers the best results on accuracy. It also outperforms all baselines with respects to the F_1 results on the three sentiment categories. AE-LSTM and AT-LSTM perform similarly and both outperform Bi-LSTM. Similar to earlier observations, sentiment *positive* is relatively easier to detect and *neutral* is the hardest category.

5 EXPLAINABILITY ANALYSIS

We have shown that AS-Capsules model outperforms all baseline models for aspect-level sentiment analysis. Because of the attention mechanism, AS-Capsules model is able to attend meaningful words in the aspect representation module and sentiment representation module. Specifically, each word is assigned an attention weight in aspect representation module and sentiment representation module by multiplying *aspect probability* with *aspect attention weight* and *sentiment attention weight*, respectively.

Table 6: Word attended by sentiment representation module in Capsule *food*. Significant words and low frequency words are ranked by *average attention weight* $\times \log$*(word frequency)* and *average attention weight*, respectively.

No.	Significant words	Freq	Low frequency words	Freq
1	delicious	22	divine	1
2	great	67	satisfying	2
3	tasty	8	favourites	1
4	good	55	scrumptious	2
5	best	24	terrific	1
6	fresh	23	yummy	5
7	yummy	5	greatest	1
8	excellent	23	frosty	1
9	amazing	7	delicious	22
10	outstanding	5	fave	1
11	fantastic	5	luscious	1
12	wonderful	8	tasty	8
13	mouth	5	unexpected	1
14	superb	3	winner	1
15	delectable	3	refreshing	2
16	recommend	8	recomend	1
17	satisfying	2	flavor	2
18	scrumptious	2	highlight	1
19	perfect	6	lemons	1
20	sweet	5	delicate	1

As a case study, we show the words attended by AS-Capsules during test. That is, after all test instances are evaluated, we obtain two lists of attended words from each capsule with their attention weights for aspect and sentiment respectively. Due to page limit, we can only display a small number of words with some ranking criteria. A straightforward ranking is by the *averaged attention weight* of a word. By this ranking, most top-ranked words are of low frequency. That is, some words have significant attention weight (or strong aspect or sentiment tendencies) but do not appear very often. Another way of ranking is by the product of *averaged attention weight* and *the logarithm of word frequency*.

Words Attended for Aspect Detection. Table 7a lists the top-ranked 20 words by the product of average attention weight and logarithm of word frequency, for the five aspects. Table 7b lists the top-ranked 20 words by average attention weight.

From the two tables, we observe that almost attended words are self-explanatory for the assigned aspect category. For instance, the attended words by capsule *food* are mostly food categories or ingredients. Capsule *service* attends words for personnel involved and their attitude. Without the need of any linguistic knowledge, the AS-Capsules model is able to identify words that reflect the aspect categories. This provides an easy way to build domain specific lexicons on domain specific data.

Words Attended for Aspect-level Sentiment Classification. We show the sentiment words attended by AS-Capsules for capsule *food* with *positive* sentiment tendency. Other aspects are omitted

Table 7: Words attended by aspect representation module in all capsules on SemEval dataset.

due to limited space. Similarly, Table 6 lists the top-ranked 20 significant words and low frequency words ranked by *average attention weights* $\times$ *logarithm of word frequency* and *average attention weight*, respectively. These words are consistent with sentiment lexicons identified in related studies [12, 26, 31]. All of those words reflect the positive sentiment tendency significantly. The attention weights of all significant words are above 0.35. More importantly, the words are used commonly. For low frequency words, the attention weights are over 0.77. Even though the words are used not so often, they belong to small but beautiful word group. 'delicious' exists in both columns due to a very positive sentiment tendency and common use. The *neutral* sentiment attends lots of punctuation marks and meaningless words *e.g.*,, 'and', 'a' and 'is', so they are not shown. *Negative* sentiment attends significant words including 'terrible', 'worst' and 'disappointed' whose attention weights are over 0.1.

5.1 Applying AS-Capsules on Yelp Reviews

To the best of our knowledge, the SemEval 2014 Task 4 dataset is the only dataset that comes with aspect-level sentiment annotations. This limits the evaluation of our model on aspect-level sentiment

Table 8: Words attended by aspect representation module on Yelp dataset.

analysis. On the other hand, many restaurant reviews are available from other domains without aspect-level manual annotation. The Yelp dataset[5] is an example. As most reviews on Yelp are for restaurants, we can directly apply the trained AS-Capsules to conduct a qualitative evaluation. Because there are no aspect-level annotations on Yelp dataset, we are unable to report quantitative measures like accuracy or F_1. However, it is interesting to observe whether the AS-Capsules model learned on SemEval 2014 Task 4 dataset can be used to identify meaningful words on Yelp dataset, to reflects its aspects and sentiment categories.

In this case study, we take the first 1,000 reviews from Yelp dataset. As Yelp reviews are relatively long and each review has several paragraphs so we split the reviews by paragraphs and consider each paragraph a test input to AS-Capsules model. As a result, we have 3,776 test instances from Yelp dataset.

Words Attended for Aspect Detection on Yelp. Table 8 lists the top ranked words identified by AS-Capsules for the five aspects. We provide two rankings following our earlier ranking criteria. Observe that regardless word frequencies, most of them well reflect the corresponding aspect category. For example, 'beers', 'sauce' and 'pizza' are identified as important words for *food*. Interestingly, most low frequency words are meaningful to the related aspects. For example, 'porridge', 'terrine' and 'fillings' are attended by capsule *food*. More interestingly, some numbers *e.g.,* 45, 50 and 20, are attended in capsule *price*. The phenomenon reflects that our AS-Capsules model performs well for low frequency words.

Words Attended for Aspect-level Sentiment Classification on Yelp. We now present the words attended by sentiment representation module. Table 9 lists the top ranked significant words and low frequency words identified by capsule *food* for *positive* sentiments. Most of the words attended by *neutral* are not very meaningful, so they are not shown. Most of the attended words fit their sentiment tendency in sentiment lexicons. Specially, we observe that most of them are able to reflect *food* aspect. As we mentioned before, 'delicious' is a very common word for describing food, it is also shown in low frequency words because we rank the attended words by their attention weight.

[5]https://www.yelp.com/dataset/challenge

6 CONCLUSION

In this paper, we study aspect-level sentiment analysis and propose aspect-level sentiment capsules (AS-Capsules) model. The key idea of AS-Capsules model is to use capsule structure to focus on each aspect category. Each capsule outputs its aspect probability and sentiment distribution on the targeted aspect. The objective of learning is to maximize the aspect probability of the capsule(s) matching the groundtruth and to minimize its (their) sentiment cross entropy loss. Through shared components including capsule embedding, shared encoders and shared attentions, our model utilizes the correlation between aspects and corresponding sentiments effectively. Experiments show that the proposed AS-Capsules model achieves state-of-the-art performance without the need of linguistic knowledge. We show that the capsules are able to identify words best reflect the aspect category and sentiment tendency. We also show that the model can be directly applied to restaurant reviews on Yelp, demonstrating its effectiveness and robustness.

ABSTRACT

Social advertisement has emerged as a viable means to improve purchase sharing in the context of e-commerce. However, humanly generating lots of advertising scripts can be prohibitive to both e-platforms and online sellers, and moreover, developing the desired auto-generator will need substantial gold-standard training samples. In this paper, we put forward a novel seq2seq model to generate social advertisements automatically, in which a quality-sensitive loss function is proposed based on user click behavior to differentiate training samples of varied qualities. Our motivation is to leverage the clickthrough data as a kind of quality indicator to measure the textual fitness of each training sample quantitatively, and only those ground truths that satisfy social media users will be considered the eligible and able to optimize the social advertisement generation. Specifically, under the qualified case, the ground truth should be utilized to supervise the whole training phase as much as possible, whereas in the opposite situation, the generated result ought to preserve the semantics of original input to the greatest extent. Simulation experiments on a large-scale dataset demonstrate that our approach achieves a significant superiority over two existing methods of distant supervision and three state-of-the-art NLG solutions.

1 INTRODUCTION

In the era of e-commerce, the purchase sharing via social networks is an organic form of sale promotion generated by the public[1], when a growing number of people make their buying decisions from the shared product links[2]. For instance, Alibaba users share product information over 150M times per day through social media sites like Weibo and WeChat, on which those users may one-click-share what they bought to relatives or friends conveniently. While these deliveries can be just plain URLs, online stores ideally want to present attractive advertising scripts to not only explain product features adequately, but also convert audiences into potential customers, as shown in Fig. 1. However, writing such eye-catching narratives does require substantial marketing skills. Even though content experts could be employed to create the social advertisements, merchants have to struggle with the cost incurred by an army of commodities.

As a solution to save the workforce, traditional software heavily relies on settled examples to auto-generate product descriptions, which in turn challenges both personalization and copyright. More recently, neural networks enable a data-driven architecture *sequence-to-sequence* (seq2seq) for the *natural language generation* (NLG) [1, 2], in which an encoder reads a sequence of tokens into a context vector, and then from that a decoder yields a sequence of specific outcomes. But unlike the machine translation with an end-to-end nature, a majority of e-commerce sales lack a pair of concise yet appropriate texts to construct the gold-standard training samples with respect to the seq2seq paradigm. Especially in the context of mobile social apps, online sellers tend to serve shoppers with a brief title as well as many detail images to post product information for the sake of *search engine optimization* (SEO), when too lengthy presentations are not suitable for both display and edit on the limited screens of cellphones. Under this circumstance, the

[2]https://sproutsocial.com/insights/social-media-ecommerce

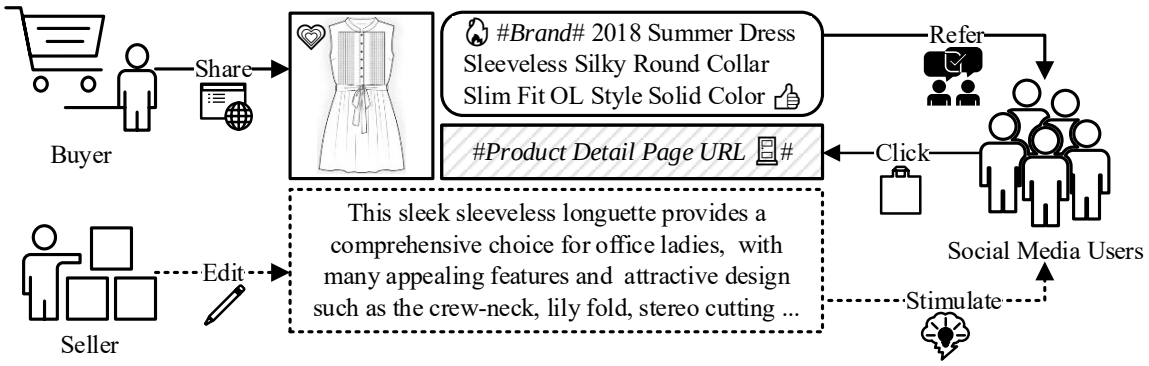

Figure 1: The illustration of the purchase sharing, in which a social advertisement (rounded textbox) is prepared for each product title (dashed textbox) accompanied by a raw URL (shaded textbox).

title often merely covers a few key attributes only, and moreover, drawing useful scripts from those photos is far more difficult.

Concerning the seq2seq NLG, a qualified training sample always requires some textual fitness to hold between its input and output, such as the semantic equivalence for machine translation, and the language logic for question answering. To address the qualities of training samples, latest studies try a widely used toolkit ROUGE [21] to calculate word co-occurrences from inputs to outputs exactly [6, 7, 24, 34]. Meanwhile, another strand of works attempt to retrieve approximate outputs as soft templates to offer additional guidelines [5]. Nonetheless, these methods of distant supervision [23] can hardly apply to the *social advertisement generation* (SAG) for the following reasons. First, due to vocabulary variation, counting the lexical overlaps could barely present the correct relationships between product titles (most readily available) and social advertisements (composed by heuristics). Second, the rough advertising templates would inevitably bring about irrelevant product details, which might confuse social media users and thus cause a decrease in the related purchase conversion rate. Last but most important, the performance of a social advertisement is highly dependent on how well it attracts audiences to click-return, and this type of quality assessment should be intrinsically dynamic because of the evolving interest of social media users outside. These reasons motivate us to re-investigate the measurement for textual fitness, and take the user-centric qualities of training samples into consideration.

In this study, we aim at the SAG to envision an innovative NLG application, in which user click behavior is leveraged to estimate the actual textual fitness of a candidate social advertisement to a particular product title. The basic idea lies in that the human-friendly advertising has a greater potential to improve the *clickthrough rate* (CTR) of shared product links for social media sites. In other words, the varying CTR can be utilized as a kind of quality indicator to characterize the matching degrees of corresponding paired texts, for which the desired evaluation involves relevance, diversity, and interestingness three criteria that are not easy to judge by computers. Note that the former two indicate the properties of generated results themselves, whereas the third one reveals the up-to-date preference of social media users accordingly. Specifically, we integrate the source paired texts with their CTR logs to establish a latent semantic space, where any pair of the product title and social advertisement could be mapped into two embeddings respectively so that the textual fitness may be measured therefrom. More formally, this measurement can be interpreted as a certain genre of supervision strength under the view of Internet crowd. With such a distant supervision, we are able to assess the qualities of training samples quantitatively, and the better the textual fitness grows, the higher the quality becomes.

The contribution of this paper is threefold. First, we explore the textual fitness measurement via a latent semantic space that features user click behavior, which enables the user-centric qualities of training samples for the seq2seq NLG. Second, we develop a novel seq2seq model to generate social advertisements automatically, where a quality-sensitive loss function is proposed to differentiate the training samples of varied qualities. Third, we conduct extensive experiments on 1.18M samples with their ground truths extracted by heuristics, and simulation results demonstrate that our approach outperforms two existing methods of distant supervision and three state-of-the-art NLG solutions.

2 RELATED WORK

This study touches on several strands of research within e-commerce NLG, click logs mining, and distant supervision as follows.

E-commerce NLG It is well acknowledged that the NLG offers dynamic improvements for e-commerce by turning product data into reader- and SEO-friendly narratives[3]. As one of the typical applications, Wang et al. [32] present a statistical framework that generates product descriptions from related attributes, in which some selected templates are combined with writing knowledge to decide what and how to say. More recently, Wang et al. [33] propose the first data-driven solution to compress product titles for the sake of SEO, which makes use of a pointer network-based model under the settings of multi-tasks. Subsequently, Gong et al. [15] and Sun et al. [28] further put forward two methods to summarize product titles, where the former utilizes three different categories of features in parallel, and the latter introduces a knowledge encoder as the auxiliary tool. Not long ago, Mathur et al. [22] employ several seq2seq models on a multi-lingual dataset, and thereby create a joint

[3]https://multichannelmerchant.com/blog/natural-language-generation-coming-ecommerce

model to produce product titles in various languages. Nonetheless, these works all conform to one formulation that the information of outputs is entirely contained in that of inputs, which differs from the SAG that parts of the social advertisements are free from or beyond their associated product titles.

Click Logs Mining In the field of information retrieval, click logs mining has proved to be a powerful means toward optimizing search engines [18, 20]. The most well-known model on query-document matching is the latent semantic analysis [9], by which a document or query can be mapped into a low-dimensional concept by the single value decomposition of corresponding document-term or query-term matrix. On this basis, Gao et al. [12, 13] develop a document ranking model trained on clicked query-document pairs, which ranks the documents by the likelihood of given query being a semantics-based translation of each document, with the assumption that the two sources of texts share the same distribution over semantic topics. As a further research, Huang et al. [17] propose a *deep structured semantic model* (DSSM) that projects both queries and documents into a common low-dimensional space respectively. This model is discriminatively trained by maximizing the conditional likelihoods of clicked documents regarding a particular query, and is considered the state-of-the-art in comparison to most previous works. However, despite these positive examples of exploiting click logs, few studies have applied the user click behavior to the NLG domain for either locating or sampling important contents.

Distant Supervision Over the past years, distant supervision has made a great success in a series of classification tasks featuring a weakly labeled training dataset [10, 23]. Inspired by this observation, Cao et al. [6] develop a seq2seq model for extractive summarization, in which each candidate sentence with comparatively high ROUGE-2 [21] score is annotated as a positive training sample. Similarly, Cheng and Lapata [7], Nallapati et al. [24], and Wang et al. [34] all adopt this labeling strategy and further raise three different seq2seq summarizers separately, where the sentence labels serve as ground truths to offer the essential guidelines for training samples. Most recently, Cao et al. [5] utilize *Lucene*[4] to retrieve approximate summaries as pseudo annotations for abstractive summarization, which enhances the textual fitness between the input and output inside each training sample. Unfortunately, although these studies improve the qualities of training samples in diverse ways, they lack an effective mechanism to integrate such kind of supervision information into the training process of the seq2seq paradigm.

In this study, our proposed seq2seq model derives from the established pointer-generator network [25], in which we put forward a quality-sensitive loss function to differentiate the training samples of varied qualities. In particular, the involved quality assessment builds upon the concept of the DSSM [17], which integrates the source paired texts with their CTR logs to develop a latent semantic space for measuring the textual fitness of a candidate social advertisement to a particular product title. To the best of our knowledge, we make the first attempt to address the problem of generating social advertisements automatically, and the practice of applying CTR data into the NLG domain is also less explored. Besides, this work is launched on a simulation environment, where a total of 180K experimental samples are constructed and hence make our results more convincing.

3 METHODOLOGY

This section formulates the SAG into a seq2seq NLG problem, as shown in Fig. 2, where the input and output are respectively a product title (green mark) and its paired social advertisement (red mark). To be detailed, Sect. 3.1 presents the encoder integrating with contextual features, Sect. 3.2 introduces the decoder making use of a pointer-generator mechanism, Sect. 3.3 elaborates how to set up the latent semantic space, and Sect. 3.4 describes the implementations for quality-sensitive training.

3.1 Contextual Encoder with NER

The goal of encoder is to transform an input sequence into a dense representation. Consider a product title of n words $T = \{t_{1:n}\}$, and each token $t_i \in \mathbb{V}$ (vocabulary list) can be represented by a word embedding $\boldsymbol{e}(t_i) \in \mathbb{R}^{d_e}$. In the NLG domain, previous studies have illustrated the superiority of *bidirectional long-short-term memory* (Bi-LSTM) in presenting sequential data, because of its capability to handle the long-range dependency and avoid the gradient vanishing [3, 26]. The Bi-LSTM encoder consists of both forward and backward two *recurrent neural networks* (RNNs), in which the hidden state at time step i can be denoted as follows:

$$\boldsymbol{h}_i = \left[\overrightarrow{\boldsymbol{h}}_i; \overleftarrow{\boldsymbol{h}}_i\right] \tag{1}$$

where each hidden state $\boldsymbol{h}_i \in \mathbb{R}^{2d_h}$ can be regarded as a local representation with focusing on the current and surrounding (before $\overrightarrow{\boldsymbol{h}}_{i-1}$ and after $\overleftarrow{\boldsymbol{h}}_{i+1}$, as Eq. 2-3) inputs simultaneously.

$$\overrightarrow{\boldsymbol{h}}_i = \text{LSTM}\left(\boldsymbol{e}(t_i), \overrightarrow{\boldsymbol{h}}_{i-1}\right) \tag{2}$$

$$\overleftarrow{\boldsymbol{h}}_i = \text{LSTM}\left(\boldsymbol{e}(t_i), \overleftarrow{\boldsymbol{h}}_{i+1}\right) \tag{3}$$

Despite the robustness of Bi-LSTM, as Fig. 1 shows that even though a product title conforms to a temporal sequence in a certain sense, a host of the phrases therein could swap their positions without any divergence, especially for those adjectives such as "*Sleeveless*" and "*Silky*". To better adapt the seq2seq paradigm, we draw out the fine-grained information from product titles via *named entity recognition* (NER) so as to enhance the sequential dependency of encoding stage. This empirical practice is derived from the contextual LSTM of [14], in which the extracted named entities are used as contextual features to capture the segment structures within text sequences. For instance, the *brand-name* is frequently followed by the *season-to-market*, whereas those adjacent modifiers seldom to restrict their appearance orders. More formally, an original token t_i is combined with its named entity $r_i \in \mathbb{V}$ as a composite input $\left[\boldsymbol{e}(t_i); \boldsymbol{e}(r_i)\right] \in \mathbb{R}^{2d_e}$ to feed the Bi-LSTM encoder, by which no additional parameters are introduced herefrom.

3.2 Attentional Decoder with Pointer

The decoder is used to generate an output sequence in terms of settled encoded representations. Given the hidden states of encoder

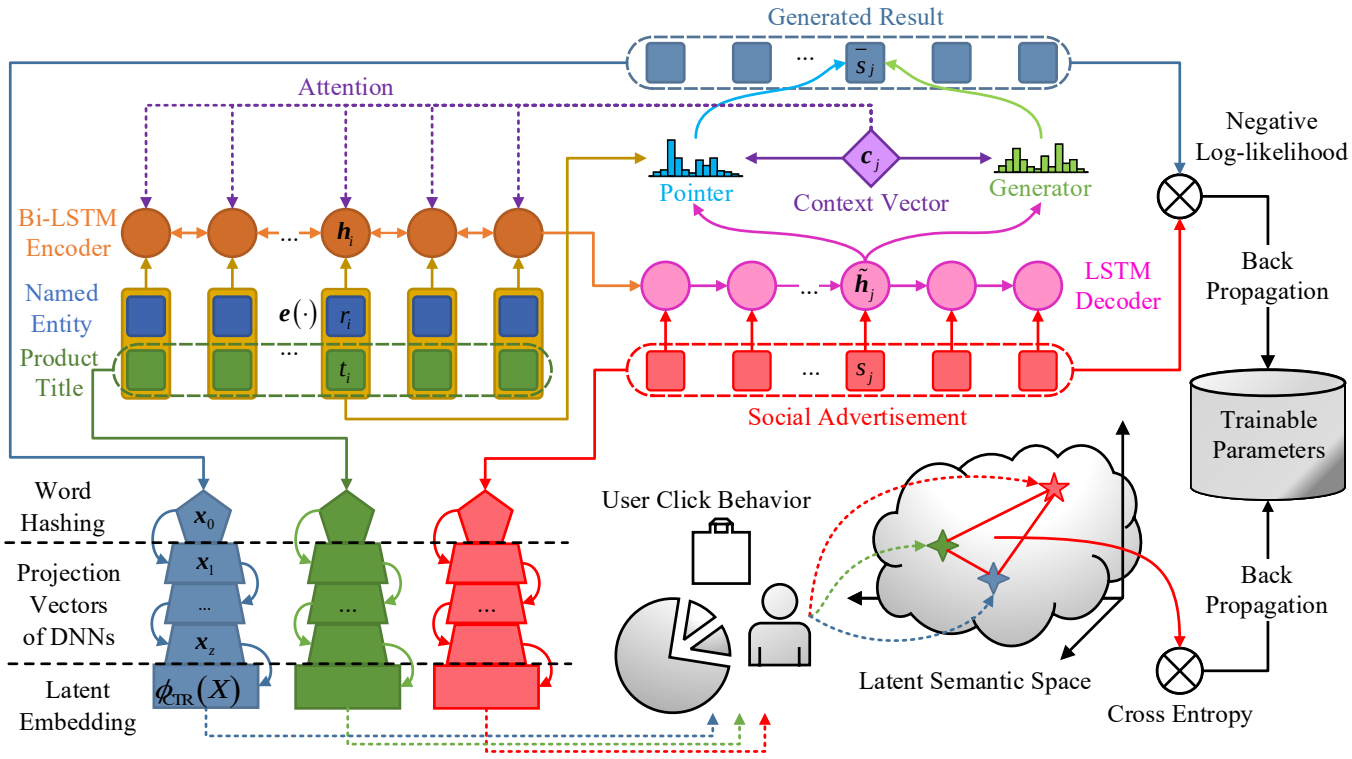

Figure 2: The seq2seq NLG framework formulated by the SAG.

$H = \{\boldsymbol{h}_{1:n}\}$, we apply an attention-based LSTM to sequentially compose a social advertisement $S = \{s_{1:m}\}$. To be specific, each hidden state of decoder $\tilde{\boldsymbol{h}}_j \in \mathbb{R}^{d_\text{h}}$ (as Eq. 5) is made by both the previous state and the last sampled word $\bar{s}_j \in \mathbb{V}$[5]. Next, this hidden state is concatenated with a context vector $\boldsymbol{c}_j \in \mathbb{R}^{2d_\text{h}}$ to feed through a linear layer and produce the vocabulary distribution $\Pr^{\text{voc}}_{j,1:|\mathbb{V}|}$ as below:

$$\Pr^{\text{voc}}_{j,1:|\mathbb{V}|} = \text{Softmax}\Big(\boldsymbol{W}_\text{v}\big[\tilde{\boldsymbol{h}}_j; \boldsymbol{c}_j\big] + \boldsymbol{b}_\text{v}\Big) \tag{4}$$

where $\boldsymbol{W}_\text{v} \in \mathbb{R}^{|\mathbb{V}|\times 3d_\text{h}}$ indicates a learnable matrix, and $\boldsymbol{b}_\text{v} \in \mathbb{R}^{|\mathbb{V}|}$ denotes a bias term. In particular, $\boldsymbol{c}_j$ (as Eq. 6) is the weighted sum of encoder hidden states, and the attention weight $\alpha^i_j \in [0, 1]$ (as Eq. 7) demonstrates how much the title token t_i contributes to sample the advertisement word s_j. This mechanism actually acts as an intermediate phase to determine which parts of the encoder to highlight for current samplings [1], in which a bi-linear learner $\boldsymbol{M} \in \mathbb{R}^{d_\text{h}\times 2d_\text{h}}$ is employed to measure such kind of relationship.

$$\tilde{\boldsymbol{h}}_j = \text{LSTM}\Big(\boldsymbol{e}(\bar{s}_j), \tilde{\boldsymbol{h}}_{j-1}\Big) \tag{5}$$

$$\boldsymbol{c}_j = \sum_{i=1}^{n} \alpha^i_j \boldsymbol{h}_i \tag{6}$$

[5]If during the training process, $\bar{s}_j$ is the current token of ground truth, or the last emission of decoder otherwise.

$$\alpha^i_j = \frac{\exp\left(\tilde{\boldsymbol{h}}^\top_j \boldsymbol{M}\boldsymbol{h}_i\right)}{\sum_{k=1}^{n}\exp\left(\tilde{\boldsymbol{h}}^\top_j \boldsymbol{M}\boldsymbol{h}_k\right)} \tag{7}$$

$$\Pr^{\text{opt}}_j = \text{Sigmoid}\Big(\boldsymbol{W}_\text{o}\big[\tilde{\boldsymbol{h}}_j; \boldsymbol{c}_j; \boldsymbol{e}(\bar{s}_j)\big] + \boldsymbol{b}_\text{o}\Big) \tag{8}$$

Unlike conventional NLG problems, the neologisms including coming trends and emerging fashions bloom in e-commerce every day, which results in a lot of *out-of-vocabulary* (OOV) words necessarily. To this end, we introduce an established pointer from [25] to transport title contents into our target advertisements directly. More formally, a probability $\Pr^{\text{opt}}_j \in \mathbb{R}$ (as Eq. 8, where $\boldsymbol{W}_\text{o} \in \mathbb{R}^{3d_\text{h}+d_\text{e}}$ and $\boldsymbol{b}_\text{o} \in \mathbb{R}$) is utilized to switch on the option for whether making a copy or not, and hence the final distribution $\Pr^{\text{dis}}_{j,1:|\mathbb{V}|}$ is obtained by adding a pointer component $\Pr^{\text{ptr}}_{j,1:|\mathbb{V}|}$ to a generator basis $\Pr^{\text{voc}}_{j,1:|\mathbb{V}|}$ as follows:

$$\Pr^{\text{dis}}_{j,1:|\mathbb{V}|} = \Pr^{\text{opt}}_j \times \Pr^{\text{voc}}_{j,1:|\mathbb{V}|} + \Big(1 - \Pr^{\text{opt}}_j\Big) \times \Pr^{\text{ptr}}_{j,1:|\mathbb{V}|} \tag{9}$$

$$\Pr^{\text{ptr}}_{j,k} = \begin{cases} \alpha^i_j, & \text{if} \quad k = \mathbb{V}_{t_i} \\ 0, & \text{otherwise} \end{cases} \qquad \forall k \in \mathbb{N}_+ \wedge k \le |\mathbb{V}| \tag{10}$$

where $\mathbb{V}_{t_i} \in \mathbb{N}_+$ returns the index of t_i in $\mathbb{V}$.

3.3 Latent Semantic Space Featuring CTR

Numerous works have confirmed the CTR as one of the most promising channels to access human evaluation on the Internet [20, 31]. In this study, we aim at the SAG to verify this hypothesis, by leveraging user click behavior to measure the textual fitness between product titles and social advertisements.

Generally speaking, a well-designed product title T is pieced by the main characteristics of sale promotion due to length limits. This messy display would certainly affect audiences' returning experiences, for which an appropriate social advertisement S is required to stimulate their shopping impulses effectively. Since evaluating such textual fitness is fairly computer-hard, we take the CTR as an alternative means to estimate the matching degrees of corresponding paired texts, as shown in Eq. 11.

$$\mathcal{Q}(T,S) = \text{Cosine}(T,S \mid \text{CTR}) = \frac{\phi_{\text{CTR}}(T)^\top \phi_{\text{CTR}}(S)}{\left\|\phi_{\text{CTR}}(T)\right\| \times \left\|\phi_{\text{CTR}}(S)\right\|} \tag{11}$$

where $\text{Cosine}(T,S \mid \text{CTR})$ represents the affinity of T to S within the latent semantic space $\phi(\cdot)_{\text{CTR}} \in \mathbb{R}^{d_{\text{s}}}$ featuring the CTR, which equates to promote an ocean of social media users to infer the textual fitness between T and S from semantics. In this manner, the consumer preference for social advertisements can be depicted to help assess the user-centric qualities of training samples quantitatively.

Specifically, we follow the mature practice of [17] to apply a stack of z *deep neural networks* (DNNs) for deriving the latent embedding of a text sequence X (T or S) as below:

$$\boldsymbol{x}_0 = \text{Hashing}(X) \tag{12}$$

$$\boldsymbol{x}_l = \tanh\left(\boldsymbol{W}_l \boldsymbol{x}_{l-1} + \boldsymbol{b}_l\right), \quad \forall l \in \{1, 2, \cdots, z\} \tag{13}$$

$$\phi_{\text{CTR}}(X) = \tanh\left(\boldsymbol{W}_{\text{s}} \boldsymbol{x}_z + \boldsymbol{b}_{\text{s}}\right) \tag{14}$$

where $\text{Hashing}(\cdot)$ indicates a function that converts from the one-hot representation X into the letter n-gram denotation $\boldsymbol{x}_0$ [27], $\boldsymbol{x}_{1:z} \in \mathbb{R}^{d_{\text{x}}}$ represents z projection vectors at different layers of the DNNs, and $\boldsymbol{W}_l \in \mathbb{R}^{d_{\text{x}} \times d_{\text{x}}}$, $\boldsymbol{b}_l \in \mathbb{R}^{d_{\text{x}}}$, $\boldsymbol{W}_{\text{s}} \in \mathbb{R}^{d_{\text{s}} \times d_{\text{x}}}$, $\boldsymbol{b}_{\text{s}} \in \mathbb{R}^{d_{\text{s}}}$ denote $2z + 2$ tensors for the linear maps within Eq. 13-14. In practice, the pairwise ranking strategy of [8] is adopted to tune all these parameters, in which a training sample with its own CTR above the threshold $\Theta \in \mathbb{R}$ is selected as a qualified individual (T, S^+), and otherwise as an unqualified one (T, S^-), with the purpose of assigning the qualified higher scores in comparison to the unqualified. More formally, our objective is to minimize the cost function $\mathcal{L}_{\text{rank}}$ defined as follows:

$$\mathcal{L}_{\text{rank}} = \text{Max}\Big(0, \Omega - \mathcal{Q}(T,S^+) + \mathcal{Q}(T,S^-)\Big) \tag{15}$$

where $\Omega \in \mathbb{R}$ denotes the marginal threshold. Once set up, the optimized latent semantic space will be responsible for inference only, and no longer get updated during training the SAG subsequently.

3.4 Quality-sensitive Loss Function

Conceptually, the seq2seq paradigm can be considered as a kind of conditional language model for the transduction tasks like machine translation [19, 29], in which the ground truths simply play the roles of data labels while their contained semantics are consistently ignored. It is fine if the every training process is quite perfect, but what if a significant portion of the training samples are not satisfactory? In this study, we aim at the SAG to put forward a quality-sensitive loss function $\mathcal{L}_{\text{qs}}$, as shown in Eq. 16.

$$\mathcal{L}_{\text{qs}} = \mathcal{Q}(T,S) \times \mathcal{L}_{\text{neg}} + \Big(1 - \mathcal{Q}(T,S)\Big) \times \mathcal{L}_{\text{ce}} \tag{16}$$

where $\mathcal{L}_{\text{neg}}$ and $\mathcal{L}_{\text{ce}}$ represent two different losses for the conventional negative log-likelihood (as Eq. 17) and the introduced cross entropy (as Eq. 18) respectively. Note that $\mathcal{L}_{\text{ce}}$ achieves the minimum value if and only if $\mathcal{Q}(T,S) = \mathcal{Q}(S,\bar{S})$.

$$\mathcal{L}_{\text{neg}} = -\log \Pr(S \mid T, \bar{S}) = -\sum_{j=1}^{m} \log \Pr^{\text{dis}}_{j,\mathbb{V}_{s_j}} \tag{17}$$

$$\begin{aligned} \mathcal{L}_{\text{ce}} = &-\mathcal{Q}(T,S) \times \log \mathcal{Q}(S,\bar{S}) \\ &- \Big(1 - \mathcal{Q}(T,S)\Big) \times \log\Big(1 - \mathcal{Q}(S,\bar{S})\Big) \end{aligned} \tag{18}$$

The rationale behind our loss allocation is as follows. Regarding the qualified case $\mathcal{Q}(T,S) \uparrow$, the ground truth S should be utilized as much as possible to supervise the whole training phase, and consequently reproduce itself into the generated result $\bar{S}$, namely $\bar{S} \cong S \rightarrow \mathcal{L}_{\text{neg}} \downarrow$. However, in the opposite situation $\mathcal{Q}(T,S) \downarrow$, we would like $\bar{S}$ to be as similar as the original input T within the latent semantic space $\phi_{\text{CTR}}(\cdot)$, namely $\mathcal{Q}(T,\bar{S}) \cong 1 \rightarrow \bar{S} \cong T \rightarrow \mathcal{Q}(T,S) \cong \mathcal{Q}(S,\bar{S}) \rightarrow \mathcal{L}_{\text{ce}} \downarrow$. In particular, $\mathcal{L}_{\text{qs}}$ will be immediately reduced to the common quality-insensitive training mode once $\mathcal{Q}(T,S) = 1$. To sum up, $\mathcal{Q}(T,S)$ is exactly a conditioner for the model outcome $\bar{S}$ to decide between the expected answer S and the trivial response T. Note that $\phi_{\text{CTR}}(\cdot)$ is employed here to not only assess the user-centric qualities of training samples, but also forecast the textual fitness of S and newly observed $\bar{S}$.

In essence, the proposed quality-sensitive training mode equips the seq2seq model with a potential pipeline to exploit source paired texts from the semantic level. Especially for the unqualified case, we cannot expect that the ground truth therein could supply positive word-by-word supervision during the training period, and instead it should serve as a benchmark to restrict the semantic scopes of all results to be produced, i.e., to prevent the decoding stage from being too random and thus avoid $\mathcal{Q}(T,S) \geq \mathcal{Q}(T,\bar{S})$. It is mainly because that an incompatible social advertisement is often prone to puzzle audiences and further lessen the related purchase conversion rate, for which we only hope that $\bar{S}$ could preserve the semantics of T to the greatest extent. This is somewhat analogous to impose a specific orientation into the common beam search [29] that is frequently embedded at decoder.

4 EXPERIMENT

4.1 Experimental Setup

This section presents the experimental setup for assessing our approach, including 1) the dataset used for training and testing, 2)

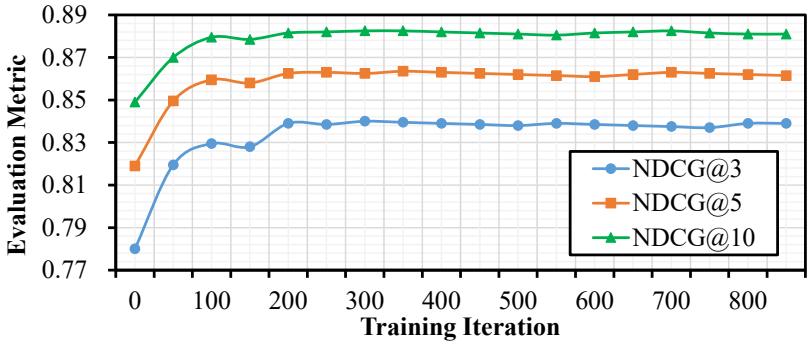

Figure 3: The optimization process of the latent semantic space, where the *normalize discounted cumulative gain* (NDCG) is applied to measure the accuracy of the pairwise ranking strategy.

the implementation details, 3) the evaluation metrics, and 4) the contrast methods.

Dataset We conduct extensive experiments on a dataset created from *Taobao*[6], in which all social advertisements are extracted from the associated product displays on search guide tabs (the heuristic rule: > 100 words and contain corresponding product names). Specifically, we select the clothing category (most actively traded) as our experimental subject and the dataset includes a total of 1.18M samples, where 1M of which are applied to build the latent semantic space, and the remaining 180K are used for developing the proposed seq2seq model. To be detailed, the 180K samples split into approximately 90% for training, 5% for validation, and 5% for testing. Once constructed, these samples are deployed in the context of purchase sharing via an online simulation environment (an instant messaging social app), and their CTR logs within a week are traced down to monitor the user click behavior. As a side note, we choose this dataset for the reason that no other open source data satisfy the condition to access an ocean of the CTR logs.

Implementation We use *Tensorflow*[7] for our implementations, in which the dimensions of word embeddings and hidden states are 128 and 256 respectively. More concretely, a vocabulary list of 70K words is built according to all training samples, and no pre-train operation is applied to the word embeddings in advance. Meanwhile, the maximum time step of encoder is set to 400, whereas that of decoder is fixed to 100 for training, and 35 for both validating and testing. Note that every LSTM parameter is randomly initialized over a uniform distribution within $[-0.02, 0.02]$. Based on these settings, we optimize the proposed seq2seq model using the AdaGrad [11] with a learning rate of 0.001, and perform the mini-batch gradient descent with a batch size of 16 for around 190K iterations (20 epochs in total). Moreover, as for the latent semantic space, we follow the established setup from [17] to utilize a stack of 3-layered DNNs for deriving the hierarchical text features, and the pairwise ranking strategy of [8] is adopted to tune the parameters therein. As can be seen from Fig. 3, the optimized space reaches an accuracy of at least 80% to discriminate the textual fitness for any pair of the product title and social advertisement.

Evaluation We take the widely used toolkit ROUGE [21] to evaluate the generated social advertisements automatically. To this end, we report both ROUGE-1 and ROUGE-2 (lexical overlaps for unigram and bigram) as a way to assess the informativeness, and ROUGE-L (the longest common subsequence) as a means to determine the fluency, in terms of the bytes of ground truths.

In addition, we conduct a human evaluation through the online simulation environment, on which a number of crowdsourcing workers are employed from *Datacrowd*[8] to compare between a list of social advertisements produced by all methods. Specifically, three criteria considered independently are as follows: 1) How *relevant* are the social advertisements to the corresponding product titles? 2) How *diverse* are the social advertisements for readers to easily grasp the expression changes? 3) How *interesting* are the social advertisements for audiences to proactively know about the product features? Note that we do not allow any correlation among workers during this evaluation, and each criterion is assigned with a 2-point scale of 0 (fail) and 1 (pass). By this means, each worker browses a set of 10 social advertisements of the same origin at random per session, and subsequently submits a score to judge every aspect of that paired method. To be exact, a total of 10 workers are responsible for each generated social advertisement, together with the Majority Voting [4] function to aggregate a final decision. Meanwhile, we also ask those workers to mark the ground truths so as to examine the raw qualities of whole experimental samples.

Benchmark To validate the proposed textual fitness, we compare our approach (denoted as P._{CTR}) against its four variants. The first one is to eliminate the cross entropy loss from Eq. 16, and thus adopt the common quality-insensitive training mode (denoted as P._{None}), which equates to setting $Q(T, S) = 1$ by default, namely no measurement for the textual fitness. The other three are all derived from the heuristic practice of [24], which applies the ROUGE as a substitute means to calculate the textual fitness from inputs to outputs, denoted as $\text{P.}_{\text{ROUGE-1}}$, $\text{P.}_{\text{ROUGE-2}}$, and $\text{P.}_{\text{ROUGE-L}}$ respectively.

To better verify the effectiveness of our approach, we also select five representative NLG methods as another benchmark group, including: 1) Re3Sum: using approximate outputs as soft templates to guide the seq2seq model [5]; 2) Transformer: a sequence transduction model based entirely on the self-attention [30]; 3) PGenerator:

[6]https://www.taobao.com
[7]https://www.tensorflow.org
[8]https://datacrowd.taobao.com

a hybrid pointer-generator network with the trade-off between copying and producing [25]; 4) CopyNet: the first work to incorporate copying into the neural network-based seq2seq learning [16]; and 5) Seq2ASeq: a standard seq2seq model with the attention mechanism [1].

For clarity, $P_{\cdot\text{ROUGE-1}}$, $P_{\cdot\text{ROUGE-2}}$, $P_{\cdot\text{ROUGE-L}}$ and Re3Sum belong to the two categories of existing solutions to address the qualities of training samples, where the former three focus on computing lexical overlaps, and the latter one turns to obtain additional information from similar outputs. Meanwhile, Transformer, PGenerator and CopyNet are three of the state-of-the-art solutions in the NLG domain, each with a different copying fashion to handle the OOV problem. Besides, Seq2ASeq is a classic model that integrates the seq2seq paradigm with the attention mechanism, which has witnessed a great success in various NLG applications like the machine translation.

4.2 Results and Discussion

Table 1 reports the ROUGE comparison between our approach and its four variants, in which $P_{\cdot\text{CTR}}$ gets the highest score on all three evaluation metrics, whereas $P_{\cdot\text{ROUGE-1}}$ receives the lowest ranking of the whole group. To be specific, we further draw the following conclusions:

1) $P_{\cdot\text{None}}$ vs. $P_{\cdot\text{CTR}}$: The use of the proposed textual fitness does contribute to improve both the informativeness (ROUGE-1 and ROUGE-2) and fluency (ROUGE-L) of the generated social advertisements.

2) $P_{\cdot\text{None}}$ vs. $P_{\cdot\text{ROUGE-1}}$: The unigram overlaps cannot provide enough evidence to characterize the textual fitness for any pair of the product title and social advertisement that might experience a drastic vocabulary variation.

3) $P_{\cdot\text{ROUGE-1}}$ vs. $P_{\cdot\text{ROUGE-2}}$ vs. $P_{\cdot\text{ROUGE-L}}$: The larger-grained word co-occurrences may present a deeper level of natural language understanding to capture the semantic affinity between product titles and social advertisements, and ROUGE-2 is the best choice among all its related versions to calculate the textual fitness, which conforms to the previous studies of [6, 7, 24, 34].

4) $P_{\cdot\text{ROUGE-2}}$ vs. $P_{\cdot\text{CTR}}$: The CTR indeed has a better ability than the literal alignment ROUGE to distinguish whether a candidate social advertisement suits to a particular product title, owing to its reflecting consumer preference for the advertising.

To better illustrate the power of user click behavior, Fig. 4 visualizes the value distributions of various textual fitness over all experimental samples. From this graph, the curve of the proposed measurement is extremely similar to the Gaussian distribution, whereas those of the other counterparts have a relatively narrow range of span, and thus would suffer difficulties to differentiate the training samples of varied qualities accurately. In addition, Table 2 summarizes the correlation tests between the proposed textual fitness and each of ROUGE-1, ROUGE-2, and ROUGE-L separately. It can be seen that ROUGE-2 obtains a bit greater coefficient than the others, which could partly explain the reason why $P_{\cdot\text{ROUGE-2}}$ ranks the second in Table 1.

Table 3 demonstrates the superiority of our approach over five representative NLG solutions, in which $P_{\cdot\text{CTR}}$ gains the highest ranking of all six methods. Specifically, $P_{\cdot\text{CTR}}$ achieves the maximum value on ROUGE-1 and ROUGE-2 simultaneously, but is slightly surpassed by Seq2ASeq and PGenerator respectively on ROUGE-L. However, the two counterparts' leading-edge is not statistically significant, and they both fall far behind our approach in terms of the informativeness (ROUGE-1 and ROUGE-2). To further explore the performance comparison, Table 4 presents the human evaluation on a total of 4,500 testing samples of varied qualities, where each percentage indicates the proportion of crowdsourcing workers who pass the corresponding criterion. Obviously, $P_{\cdot\text{CTR}}$ still occupies the first place of the whole group, which means that the conclusion drawn by Table 3 is sustained. More concretely, we can reach the following findings:

1) Ground Truth ranks the third only, and therefore is by no means the gold standard for developing an ideal seq2seq model, which is consistent with our above analysis, i.e., constructing qualified training samples toward the SAG is not an easy matter.

2) Nearly no diversity and interestingness (below 5%) exists in the social advertisements generated by Seq2ASeq, CopyNet, and PGenerator. In addition, we also find that these three generic RNN-based solutions repeatedly return several frequent patterns like "*This is the newest*" of evidently sequential dependency, which results in their higher scores on ROUGE-L (fluency) in Table 3.

3) With the ability to draw global dependencies from inputs to outputs, Transformer significantly improves the scores on all three criteria in comparison to the former baselines. However, because of adopting the conventional quality-insensitive training mode, this method will more or less be polluted by those unqualified (what social media users are disinteresting of) training samples, which consequently causes an obvious gap in the interestingness with either $P_{\cdot\text{CTR}}$ or Ground Truth.

4) While Re3Sum leverages the rough advertising templates to enhance both the diversity and interestingness, it still gets trapped into the poor relevance apparently due to introducing some irrelevant product details.

5) It is noteworthy that $P_{\cdot\text{CTR}}$ obtains significantly better diversity than Ground Truth. This is partly because that $P_{\cdot\text{CTR}}$ requires the ground truths to offer additional (user-centric) semantic constraints instead of merely word-by-word supervision for generating the social advertisements, which is particularly useful when facing the training samples with imbalanced textual fitness.

6) There is a large discrepancy in the evaluation results between ROUGE and crowdsourcing. For example, the ranking of Transformer in Table 4 is clearly higher than that in Table 3, and meanwhile it exceeds the lower expectation Seq2ASeq successfully, which to a certain degree proofs the usefulness and importance of human evaluation (user click behavior) in measuring the textual fitness.

4.3 Case Study

To better understand the effect of quality-sensitive training mode, Fig. 5 displays two typical examples from both the qualified and unqualified samples separately. For simplicity, we only compare the top three methods ($P_{\cdot\text{CTR}}$, Transformer, Re3Sum) in Table 4 against Ground Truth, and reasonably come to the following analysis:

1) While the rough advertising templates can offer a majority of proper details on sale promotion, Re3Sum still carries the risk to

replace the given product names with the relevant yet inaccurate ones, just as in both the cases where "*hoodie*" and "*down pant*" respectively change into "*blouse*" and "*trousers*" of much higher generality.

2) Even though the self-attention can capture the correlation between specific products and associated descriptions, Transformer tends to produce some more common modifiers, such as "*round collar design → hoodie*" and "*with whatever T-shirts on → down pant*", which lacks of a few specialized adjectives toward the given product names. The reason is that, in terms of the conventional quality-insensitive training mode, the universal outcomes usually possess a lower damage to affect those unqualified training samples at decoding end.

3) Regarding the qualified case (left), $P_{\cdot CTR}$ can almost acquire an amount of product details as equal as Ground Truth does. But surprisingly, the former creates a far better narrative than the latter in the opposite situation (right), where Ground Truth yields the correct product names only, whereas $P_{\cdot CTR}$ generates several customized phrases with respect to the corresponding title contents. For instance, "*fits any figure well → slim*" and "*keeps warming → winter*". To sum up, the proposed quality-sensitive training mode provides the decoder a chance to take original inputs as a kind of backup ground truths and further consume the information therein.

5 CONCLUSION

In this paper, we highlight user click behavior in the context of the SAG via a latent semantic space that features the CTR, and on this basis, measure the textual fitness to quantitatively assess the user-centric qualities of training samples toward the seq2seq NLG. Notably, while social media users' interest varies over time, both the latent semantic space and quality assessment can change correspondingly. More specifically, we develop a novel seq2seq model to generate social advertisements automatically, in which a quality-sensitive loss function is proposed to characterize the quality distinction among training samples. In particular, for the qualified case, the ground truth should be utilized as much as possible to supervise the entire training process, but in the opposite situation, the generated result ought to retain the semantics of original input to the greatest extent. To sum up briefly, after an ocean of training samples are carefully projected into the CTR-based latent semantic space, only those relevant, diverse, and interesting contents will be oversampled to optimize the social advertisement generation. This strategy can be especially important for the purchase sharing concerning social media sites. Extensive experiments with real users demonstrate the validity of the proposed textual fitness, and the superiority of our approach over two representative methods of distant supervision and three state-of-the-art NLG solutions.

In future work, an appealing direction is to generalize our approach for other NLG applications as long as the user behavior information is available. For instance, in an explainable search scenario where the CTR logs are already prepared, we will be able to tailor the proposed seq2seq model so as to enhance the dynamic performance of content service.

ABSTRACT

Social media provide access to behavioural data at an unprecedented scale and granularity. However, using these data to understand phenomena in a broader population is difficult due to their non-representativeness and the bias of statistical inference tools towards dominant languages and groups. While demographic attribute inference could be used to mitigate such bias, current techniques are almost entirely monolingual and fail to work in a global environment. We address these challenges by combining multilingual demographic inference with post-stratification to create a more representative population sample. To learn demographic attributes, we create a new multimodal deep neural architecture for joint classification of age, gender, and organization-status of social media users that operates in 32 languages. This method substantially outperforms current state of the art while also reducing algorithmic bias. To correct for sampling biases, we propose fully interpretable multilevel regression methods that estimate inclusion probabilities from inferred joint population counts and ground-truth population counts.

In a large experiment over multilingual heterogeneous European regions, we show that our demographic inference and bias correction together allow for more accurate estimates of populations and make a significant step towards representative social sensing in downstream applications with multilingual social media.

1 INTRODUCTION

Data representing the attitudes and behaviors of a (national) base population is of great importance to policy making, social science research and commercial prediction tasks, but representative surveys are expensive and infrequent. Social media data has been proposed as a real-time and inexpensive way to measure social phenomena—this area of research is known as "social sensing." Social media data has been used, with various levels of success, in areas such as infectious disease [30, 31, 51], migration and tourism [7, 50, 81], and box office takings for films [21, 55].

However, despite social media data being easily accessed, large in scale, and detailed, it is generally not representative of indicator variables measured in any broader (offline) population due to various biases [43, 67]. Especially the self-selection of users joining and participating on any given social media platform is a large source of error. In the UK for instance, Twitter users are more likely to be male and young compared to the national population [71], and in the U.S. men and residents of densely populated areas are overrepresented [35], while there exists a mix of over- and undersampling on Twitter for users with specific racial backgrounds [56]. In general, however, the exact inclusion probabilities for a specific demographic group on any platform in a given country or region are unknown. And while not all social sensing tasks require representative data [3], recent studies have pointed out the fallacies in predicting phenomena via social sensing without controlling for sampling biases in social media data [28, 29, 44], with research applications aiming to draw inferences for nation-wide target populations often relying on such attribute data. Consequently, a systematic methodology for estimating them is needed.

Survey analysis researchers have dealt with non-representative polls and non-response through sample re-weighting—with post-stratification being a well-known technique [10, 37]. These methods make use of basic demographics attributes: most prominently age, gender and location [60, 77]. Where demographic details are provided, post-stratification has been a valuable technique [77, 81].

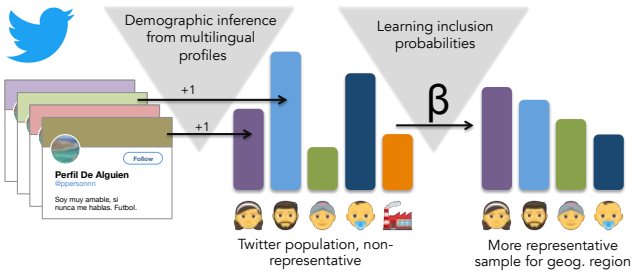

Figure 1: Our two-stage approach debiases non-representative Twitter data by (i) inferring demographics with state-of-the-art accuracy from multilingual, profile-only data and (ii) learning inclusion probabilities to create more representative samples for Europe-wide subregions

However, most social media platforms do not provide demographic data about their users, making it difficult to know or correct for such biases. Although promising techniques for extracting demographic attributes from social media have been proposed, there exists no robust multilingual approach for this task. We address these challenges by inferring basic demographic attributes and correcting for selection biases on a large sample of multilingual profile data from Twitter (Figure 1), one of the most used platforms for social sensing given its ease for obtaining data.

This work offers the following three contributions. First, we introduce a new multilingual, multimodal, multi-attribute deep learning system for inferring demographics of users (§2). This pipeline is built from the ground up to enable inference in 32 different languages, addressing the need for such methods beyond English and outperforming state-of-the-art methods on the tasks of predicting the age, gender and is-organization state of Twitter users. We show this system reduces algorithmic bias with respect to skin tone over the best-performing commercial systems. Second, we formalize a statistical framework for models that debias non-representative samples (§3). Our models explicitly learn per-stratum inclusion probabilities from data, whereas typical post-stratification methods either assume their knowledge or focus on obtaining a post-stratified estimator of a response variable. Third, in real-world evaluations, we show that our debiasing models significantly reduce the error rate in comparison to a model without post-stratification on the inferred demographic attributes (§4). In these ways, we make a significant step towards *representative social sensing* in downstream applications using multilingual social media.

2 DEMOGRAPHIC INFERENCE

We propose a new demographic inference model for three attributes: gender, age, and a binary organization indicator ("is-organization"). The first two attributes, gender and age, are widely reported in census data and are core features to accurately measure demographic biases. The third attribute was selected based on a known confounder for people-based studies of online platforms: the presence of accounts belonging to organizations [2, 54], which shall be distinguished from individual accounts. Next, we describe the model, its data, and its evaluation.

2.1 Classification Task

We consider the task of estimating population count in Twitter given a stream of user tweets. This scenario is motivated by the common research use case for social sensing on Twitter, where a researcher consumes one of the Twitter streams (e.g., the 10% or 1% sample streams) and desires to make some analysis from the tweets of a broader phenomena that extends beyond Twitter. In such a scenario, many users are expected to appear rarely–possibly only once–which hinders the use of existing demographic methods that rely upon large amounts of text to infer gender [13, 17, 18, 25, 45, 49, 72, 73, 82] and age [33, 58, 59, 63, 65, 68].

Instead, we avoid making inferences based on tweets and focus on using only the information associated with a user's account, which allows our method to easily scale to large volumes of users without the need for significant quantities of text. Not stratifying users based on tweets has the added advantage of preventing downstream demographic biases to any social sensing tasks that analyze the same language. Ultimately, our method uses four sources of information, username, screen name, biography, and profile image, and is designed to operate effectively on multilingual data.

We formalize the three classification tasks as follows. Gender and is-organization are modeled as binary classification tasks.[1] Age is known to be a difficult inference task in social media [58, 82]. Here, we opt to categorize age in four levels: ≤ 18, $(18, 30)$, $[30, 40)$, $[40, 99)$. Our choice is motivated by (i) our ability to align these age ranges with census data reports and surveys [74, 75], and (ii) the difficulty of the task (even for humans) when finer-grained age classes are used [23, 76], while (iii) still making the resulting classes amenable to downstream tasks. While other attributes are possible for use in debiasing (e.g., education, income, etc.), ground truth population statistics for these attributes are not widely available in censuses, making it difficult to train and evaluate any model.

2.2 Method and Training Procedure

Demographic attributes are often expressed in both image and text. We propose a new multimodal inference model with a novel training technique that leverages both of these sources to significantly augment our predictive accuracy. We first describe the model and each modality and then discuss the training procedure.

2.2.1 Model. The full model comprises two separate pipelines for processing a profile image and each of the three text sources of information, as shown in Figure 2. Here, we use a shared pipeline for all three attributes, using multi-task learning for the output. We refer to this as the **M3** model, after its multimodal, multilingual, and multi-attribute abilities. Following, we describe the architectures of each modality and how they are combined.

Image Model The image classifier was constructed using DenseNet [38] based on initial performance experiments over current state-of-the-art vision models on our data. We scale all profile images to 224x224 to meet the input size of the model.

[1] We base our notion of gender as one of performance [22], in which individuals adapt their style, name, and picture to (de)emphasize certain aspects of their gender identity [24]. While our training data uses self-declared binary gender identities, the M3 model reports gender identity as a continuum using prediction probability along a graded scale. We recognize that the current approach does not yet support non-binary gender identities, which we view as an important future task for full representation.

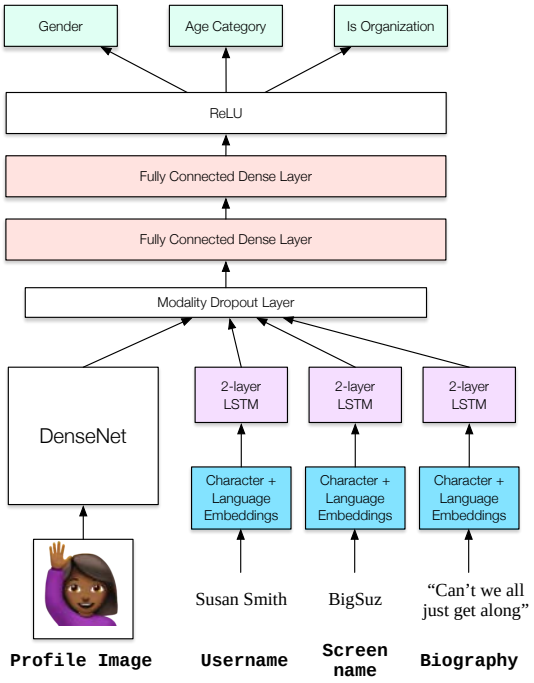

Figure 2: The M3 model for inferring gender, age, and organization-identity from image and text data.

Text Model Separate character-based neural models were trained for each text input and then a multi-input model was tuned based on the weights from each single model. Embeddings for username and biography were limited to the 3000 most frequent characters in our training corpus, with remaining characters represented with an encoding for their unicode category; screen name are embedded in the ASCII range. We use 2-stack bidirectional character-level Long-short Term Memory (LSTM) architecture [36] to capture necessary information. To incorporate potential different meanings in different languages for the same character, we concatenate a separate trainable language embedding to each character embedding and add a fully connected layer before being fed into an LSTM. The fusion of character-based input with language embeddings provides two critical benefits that let us scale to the linguistic diversity seen in global platforms like twitter. (1) Character-based RNNs are able to capture morphological regularity within a language and substantially reduce the parameter space due to the reduced vocabulary size of the model (i.e., the set of characters) as compared with word-based models with orders-of-magnitude larger vocabularies [15, 27, 46]. (2) By fusing language embeddings with character embeddings, the joint embedding lets us represent shared linguistic regularity *across* languages, which lets us better scale to the multilingual environment.

Full Multimodal Model To construct the full model, separate models are fully trained for image and text for all attributes. Then, the softmax output layer of each is removed and the two models are joined into a new model with a modality drop-out layer (described next), two fully connected layers of size 2048, a Rectified Linear Unit (ReLU) layer [57], and separate output layers for each task. This full model is then fine-tuned using the pretrained single-modality models' parameters for initialization.

2.2.2 Training Procedure. Rather than training M3 end-to-end initially, we combine three procedures for the training process: co-training, multilingual data augmentation, and modality drop out.

Co-Training Both image and text can have clear signal of demographics. Given the potentially-limited training data for speakers of less common languages, we take advantage of the multiple views of the same users by incorporating co-training: a semi-supervised learning technique. Co-training first learns a separate classifier for each view using any labeled examples. The most confident predictions of each classifier on the unlabeled data are then used to iteratively construct additional labeled training data [11]. Ardehaly and Culotta [4] recently showed co-training was effective for demographic classification in social media data using images and text in a graph-based co-training learning procedure.

In comparison to the variance of gender and age expressions in textual data across sociolinguistic contexts [6, 70], image data provides a more universal depiction, acting as an analog to a universal pivot language in machine translation [80]. Thus, we train the image-based portion of the M3 model first, which identifies high confidence labeled data from an unlabeled multilingual dataset. Second, the text-based portion of the M3 model is trained using the original dataset plus the text data associated with any high-confidence image-based classifications. Finally, we train the full M3 model with the training dataset and all high-confidence predictions from the unlabeled data. All models are trained as multi-task, where a common input representation and architecture is used to predict each output tasks. The probabilities for each task were represented using a top softmax layer.

Multilingual Data Augmentation The M3 model is designed to operate in online environments on tens of languages. However, few approaches and little labeled data exists for this task for languages other than English, with some exceptions [16, 32, 62]. Even with co-training, the relative differences in number of speakers between languages (e.g., English vs. Slovenian) create a substantial class imbalance which would prevent the model from effectively learning signals of each attribute in users' biographies written in less-frequent languages. Therefore, we perform data augmentation by using automatic machine translation of the training data.

Given the scale of our training data (described later in §2.3), the use of online translation services is prohibitive both in terms of time and cost. Instead, we opt to use word-based translation using the MUSE bilingual dictionaries [20]. For each instance in the training data, all words in the bilingual dictionary are replaced with the translation. A translated instance is only kept if 80% or more of its words could be translated. While word substitution typically produces translations that are more incorrect and less fluent, we observed that the remaining biography translations were often of reasonable quality due to the declarative nature of biographies, which often consist primarily of lists of readily-translatable noun descriptions or attributes of the user without using full grammatical sentences. Such translations also largely capture topical and semantic regularity, even if the morphology is not precise.

Modality Drop-out The co-training model uses a conjoining architecture with pre-trained weights from the image model and the

multi-input text model. To facilitate the model using each source of information, we introduce a new technique, modality dropout, that can fully hide a source of information (e.g., the biography) during training. We add an extra input dropout with a probability of 0.25 (i.e., keep 3 out of 4 input sources on average) to better regularize the model and support use cases where not all 4 input sources are available. When doing dropout, images were replaced by a random matrix while text was turned to a specific empty embedding.

2.3 Data

Training and evaluating M3 uses five distinct datasets: (1) a large dataset of Twitter profiles whose gender and age are heuristically identified, predominantly in English, (2) a curated dataset of Twitter accounts belonging to organizations, (3) an image dataset of faces from IMDB and Wikipedia, (4) a massive unlabeled set of users, and (5) a crowdsourced dataset for all three attributes that spans all 32 languages in our study. We describe each next.

2.3.1 Heuristically-identified users. Heuristically-identified users were drawn from a 10% sample of Twitter from 2014 to 2017 on Twitter, where roughly 40% of the users are English speakers [34]. Here, we identify gender and age from fixed expression in users' biographies that signal age or gender, e.g., "mother of two wonderful kids" or "26 y/o dude" using a gender- or age-signaling word. Age data was further augmented by identifying tweets wishing another user a happy birthday (cf. Al Zamal et al. [1]). These pattern-based approaches are known to be highly precise for certain attributes when properly constructed [8, 9]. Patterns were created for five languages: English, Spanish, French, German, and Swedish.[2] Organization accounts were manually curated by identifying 676 Twitter lists that primarily contained organizations, such as non-profits, local clubs, companies, or municipal services. These lists resulted in 59.92K unique organization accounts. For heuristically-identified users and organization accounts, we collect their current profile image, screen name, username, and biography. User age is adjusted to the present day. For heuristically-identified users, the biography is altered to replace the gender- or age-indicating word with a special token so that the model is forced to look for additional cues to recognize each attribute. The IMDB-WIKI dataset [66] consists of 523,051 images from headshots of actors in the IMDB and profile pictures in Wikipedia. This dataset provides an auxiliary source of information for fine-tuning the image-based part of the M3 model. These three datasets constitute our *initial data* prior to performing the three-step annotation procedure. Table 1 shows the detailed statistics of the data for each step.

Co-training depends on having access to a large set of unlabeled users whose high-confidence labels from one modality (e.g., profile image) can be used to augment the training set for another modality. Here, we collect 36.97M profiles speaking one of the 32 languages commonly spoken in Europe but for which we have no groud truth label. Languages were identified using CLD2 [53]. Note that users in this unlabeled dataset will only become training instances if one view's classifier (text or image) labels them with high confidence.

2.3.2 Crowdsourcing Data. Current gender, age, and organization datasets are nearly all produced for English-speaking users, which prevents us from evaluating the M3 model in the multilingual environment. Therefore, we constructed a new dataset of up to 200 randomly-selected Twitter users speaking one of each of the 32 languages in our study. Three annotators on Figure Eight[3] were shown the usernames, screen names, short biographies, and profile images of each Twitter account. We instructed workers to determine gender and age of a given user from two drop-down menus based only on this information. The selection options regarding gender also included a category for profiles belonging to multiple persons, and to a non-person (e.g., organization/bot). Regarding age, annotators were given seven categories to choose from: <= 18, $(18, 30)$, $[30, 40)$, $[40, 50)$, $[50, 60)$, $[60, 70)$, >= 69. They could select "don't know" for all questions, if they felt not enough information was available. We employed Figure Eight's selection mechanism for speakers of the target language of the set to be annotated, or chose workers by their country of residence, if one of that country's main spoken languages was identical with the target language of the task. Additionally, each job included a set of 30 test questions, annotated as a gold standard by the authors. These were used to screen for spam but also for any non-speakers of the target language remaining after our first filter; to this end, at least 10 questions were only solvable by sufficiently understanding the target language.

Annotation reliability was measured for each Figure Eight job using Krippendorff's α [48]. For the computations of α, we excluded all English test-questions from the 31 non-English jobs, profiles with only one annotation, and included "don't know" answers as an answer option. To establish a measure of how well workers did on the age classification in respect to the age brackets classified by M3, we collapsed age bracket encodings over 40 into one category. Across all languages, the mean α for the gender annotations lies at 0.81 and at 0.57 regarding the age brackets, hinting at the high difficulty of the Twitter profile age classification task for humans. For a separate measure, we recoded all gender and organization annotations into the two categories "is organization" and "is not organization" and calculated Krippendorff's α based on these data, resulting in a mean of approximately 0.75 across all languages, showing that workers could identify non-personal accounts reasonably well. The final dataset is constructed from all instances where at least two annotators agreed on the label for a particular attribute (majority vote), resulting in 4,732 profiles across 32 languages.

2.3.3 Data Partitions. All self-reported labeled data is partitioned into 80% train, 10% development, and 10% test splits. No official

Table 1: Sizes of datasets used for training and testing. Incremental numbers are shown for the outputs of data-augmentation from co-training and translation.

Dataset	**Gender**	**Age**	**Is-Org.**
Initial	3.98M	1.20M	59.92K
After Image Co-Training	+2.26M	+0.62M	+6.31M
After Translation Augmentation	+5.74M	+1.54M	+4.74M
After Text Co-Training	+8.28M	+0.78M	+11.87M
Final	14.53M	2.61M	23.86M
Held-out Evaluation	0.38M	0.36M	6.91K

[2]Languages were selected to capture linguistic diversity and where high precision demographic-identify patterns could be created easily.

[3]https://www.figure-eight.com/

train/test/dev splits are available for the IMBD-WIKI datasets so we perform our own partition with the same percentages as for self-reported. During model training, only the development set for self-reporting users are used for model selection. Owing to its small size, crowdsourcing data was only used for testing purposes. For the organizational data, we create a full dataset with non-organizational accounts by randomly sampling accounts from the heuristically labeled data to attain a 1:9 ratio, following the report in McCorriston et al. [54] that organizations make up 10% of the accounts on Twitter.

2.3.4 Co-Training Setup. The training data is balanced for each stage, where we oversampled gender and organization status, and undersampled the two most-frequent classes (0-18 and 19-29) while oversampling the other two age classes. High confidence thresholds were set to 0.9 for gender and organization status in both the image and text modalities. As a four-class classification task, the high-confidence for age is set to 0.7 in the image classifier, based on early examination of the prediction quality. We observed that age is more readily predictable in text and therefore used a threshold of 0.9 to keep quality high while also providing a sufficient number of new accounts for co-training.

Separate image and text models are each trained for 10 epochs. Due to the imbalanced number of instances per attribute (Table 1), each epoch contains 10000 steps where each step contains a mini-batch of 128 instances balanced across the three attributes. This setup ensures the model sees instances of the smaller datasets (age and organization). The image model is trained first, and its high-confidence instances are then used to train the text model. The final co-training model was trained for 5 epochs with input dropout and another 3 epochs without input dropout for better convergence. Amsgrad optimizers [64] were used in all training process, with a learning rate of 0.001 for ground-up models and 0.0005 for fine-tuning models. Text models were trained on one GPU, while the image and co-training models were trained in parallel on 4 GPUs. The full pipeline was built in PyTorch [61].

2.4 Evaluations

Accurate inference of representative attitudes from social media relies upon accurate stratification approaches. Here, we test the M3 model against current state of the art systems to describe the potential for error to affect demographic bias.

2.4.1 Comparison Systems and Data. The M3 model is compared with state-of-the-art systems from each modality and attribute. For images, we compare with Face++ [42] and Microsoft Face API [5] on age and gender performance. For text, we compare with three current state-of-art systems for inferring gender from usernames, genderperformr [78], demographer [47] and Jaech et al. [39], which could feasibly operate on names from multiple languages.

No multilingual organization recognition system exists; so, we limit our evaluation to the only publicly-available dataset of person-vs-organization which was scored by the Humanizr [54] and Demographer [79] systems. This data consists of a uniform sample across Twitter accounts, which were approximately 10% organizations. Here, we recollect the user profiles for their 20,273 accounts, of which 18,587 (91.6%) were still available as of October 2018,

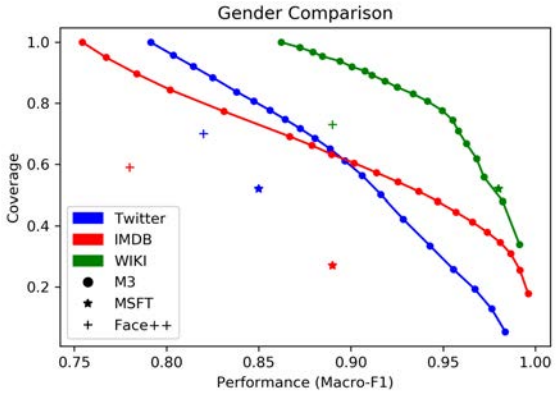

Figure 3: Model performances on gender classification for the three image datasets, as measured through F1. Coverage equals % of returned results at varying confidence levels for M3 and is the maximum available for the commercial APIs.

which matched the distribution originally reported. Their model was evaluated on the dataset using cross-validation, whereas we treat the entire data as a test set and report performance.

2.4.2 Gender Recognition. M3 produces state-of-the-art gender recognition for each of the three image-based datasets (IMDB, WIKI, and Twitter), as seen in Figure 3. M3 provides significant improvements in performance (F1) at each comparison system's level of recall.[4] The one exception to this trend is the performance of the MSFT classifier on the WIKI dataset, which has highly similar performance to M3. Given the MSFT's model large jump in performance, we hypothesize that their model may have been trained on Wikipedia data, although this cannot be confirmed. We observed that the increase in coverage of M3 is due in part to the model learning non-facial attributes associated with more than one gender, e.g., certain sports with the male gender, which allow M3 to process profile photos that other models cannot.

On the text-based data, M3 outperforms all systems except one when using just the username and masking all other information, shown in Table 2. When the model is allowed to see all other text information, M3 performance improves substantially, indicating it can effectively fuse several sources of information. While this latter setup uses more information than comparison systems, in practice, the Twitter API includes all text information used by M3 by default; so the only additional step is downloading the profile image.

2.4.3 Age Recognition. Age recognition is a significantly more difficult task in social media, as seen by the performances in Figure 4. The M3 model offers similar performance to commercial models on the IMDB and WIKI datasets, which primarily feature face-forward headshots in good lighting. However, in real-world Twitter profiles (shown in blue), the M3 model substantially outperforms both in F1 at each of their respective coverage levels, with 0.16 and 0.11 absolute improvements over Face++ and Microsoft, respectively.

[4]The coverage reported is the maximum available from the commercial APIs, which did not find a face or did not provide a gender/age estimate for each photo.

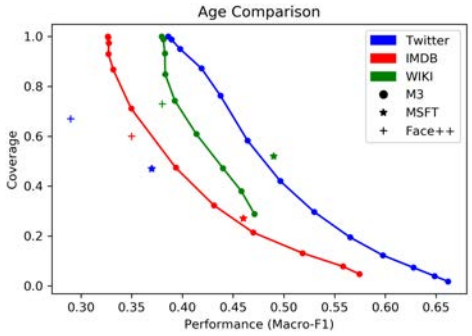

Figure 4: Model performances on age classification for three datasets, as measured through F1 on classified images and Coverage on the % of images classified.

2.4.4 Organization Recognition. For any task that draws inferences about human actors, non-human and specifically organizational accounts are a major source of error. The results of Table 3 show that our model is able to identify these accounts with 16.3% higher accuracy than the next closest system with no drop in performance at recognizing humans. Results on our test set from our organization data (§2.3) in Table 4 (top right) show similar performance, with an overall F1 of 0.898 that indicates high performance for both classes.

2.4.5 Multilingual Performance. As a full test of M3, we evaluate it against our crowdsourced account labels in 32 languages, shown in Table 4 top right. Performance in this multilingual setting is on par with the performance on the primarily-English heuristically-labeled data, though age classification remains the most difficult task. Figure 5 shows the performance per language for each attribute. Performance at predicting gender and is-organization are similar for most languages, while age performance varies significantly by language from 0.28 F1 for Bosnian to 0.73 for Slovenian and Welsh. These results together indicate that M3 is sufficiently accurate in the multilingual European environment.

2.4.6 Ablation Study. To examine which parts of the system are contributing to performance, we perform an ablation study by (i) restricting the model to one modality and (ii) training a model without using co-training or translation for data augmentation. We test each model on (i) the heuristically-labeled and organisation data and (ii) the multilingual data, which is representative of the performance on the data used in our downstream task.

The results shown in Table 4 reveal two main trends. First, the model benefits from both modalities. The removal of textual information causes the biggest performance drop. Second, although co-training and translation hurt performance in the heuristically-labeled data, they produced a substantially better model when evaluated on multilingual data. Since the heuristically-labeled data is primarily in English, translation potentially adds noise and forces the model to represent a larger space of inputs that are not represented in the test data. This performance difference indicates that the two data augmentation techniques are highly beneficial when bootstrapping a model from mostly monolingual data.

Table 4: Performance (Macro-F1) for (1) full M3 model, (2-3) model with modality dropouts, (4) model trained without co-training or translation, (5-6) Random and and Majority-class baselines.

2.4.7 Test for Algorithmic Bias. Image-based models for gender recognition are known to suffer from algorithmic bias in recognizing darker-skinned individuals [12]. This bias is thought to be a result of non-representative training data the underreprentation of darker skin tones in the training data. As our focus is on European countries, such a bias could be present in the M3 data. However, because our co-training procedure uses a large unlabeled set of users from across the globe, these users can potentially provide a more representative sample and reduce algorithmic disparity. To test for algorithmic bias, we compare the M3 model's performance on the Gender Shades dataset [12], which contains 3964 gender-annotated facial images balanced across light and dark skin tones. In this earlier algorithmic audit, the Microsoft (MSFT) and Face++ gender classifiers performed substantially worse on women, especially darker skinned women.

The gender inference performance, shown in Table 5, reveals that M3 has substantially less algorithmic bias relative to the two best-performing commercial systems also tested on Gender Shades. Our model significantly improves performance on dark-skinned women in comparison to the other two systems which had the largest performance disparity on that demographic. However, M3 is least accurate on darker-skinned males, which indicates that additional work is needed to reach performance parity in skin tones. Nevertheless, this analysis also indicates that M3 is more suitable than existing systems for operating in the global environment and increases the robustness of downstream social sensing applications.

3 LEARNING INCLUSION PROBABILITIES

In social sensing studies, the results of measurements performed on a given platform, e.g., a social media site, are studied to understand the behavior of a population. Often, such measurements are biased [67], as individuals with certain demographics are more likely to join these platforms, e.g., young people may be more likely to join Twitter. Obtaining representative estimates in these scenarios is challenging, as the probability of an individual with given demographics to be on a given platform, also referred to as *inclusion probability* in sampling methodology, is typically unknown.

Here, we estimate these inclusion probabilities as a function of demographics. To this end, we learn the debiasing coefficients on the grounds of statistical survey analysis with missing data [10, 52, 69]. Specifically, we derive estimators for the numbers of individuals by making an assumption that per-strata inclusion probabilities are equal for individuals within a group (e.g., a country) and different between groups (e.g., between countries). This assumption allows us to get both across-groups global debiasing coefficients (i.e., the biases of Twitter users) and the group-specific debiasing coefficients (i.e., per-country demographics on Twitter, e.g., developed countries may have more and diverse users on Twitter). Our approach learns the inclusion probabilities, while typical post-stratification methods either assume these probabilities are known or focus on obtaining a post-stratified estimator of a response variable.

3.1 Formulation of Debiasing Models

Consider a population U of $N = |U|$ individuals with certain demographics. For simplicity, we focus on the case of only two discrete demographic variables, say age a and gender g, which are distributed following $P_{\mathrm{N}}(a, g)$, but the following reasoning applies to other demographics as well. Out of these N individuals, say, $M \leq N$ joined a certain online platform with a probability depending on their demographics. For instance, individuals joined Twitter and younger people were more likely to join than older ones.

In survey analysis, the probability that an individual with certain demographics joined a certain platform corresponds to the inclusion probability of the stratum representing these demographics [10, 69]. In the simplest scenario, when the probability of joining the platform is homogeneous in time and across individuals, this probability can be expressed as the ratio of the number of Twitter users with the demographics a and g to all individuals, i.e., $\pi(a, g) = \frac{M(a,g)}{N(a,g)} = \frac{MP_{\mathrm{M}}(a,g)}{NP_{\mathrm{N}}(a,g)}$, where $P_{\mathrm{M}}(a, g)$ and $P_{\mathrm{N}}(a, g)$ are the distributions of demographics of Twitter users and the overall population, respectively. However, the inclusion probability may vary between individuals. To account for this, we discuss the homogeneity of inclusion probability for a given partition of the population. A partition of the population U is defined through non-overlapping and non-empty subsets U_i of the population that together constitute U, i.e., $\bigcup_i U_i = U$. Typically such subsets will have a certain meaning, e.g., a natural partition of a population is a split by countries, regions, or cities. The total number of individuals in the subset i is N^i and the number of individuals having particular demographics is $N^i(a, g)$.

3.1.1 Homogeneous bias. The inclusion probability, which governs the bias, is homogeneous with respect to a given set of demographics and a given partition of the population, if and only if $\pi^i(a, g) = \pi(a, g)$ for each subset i of the partition, i.e., the inclusion probability does not depend on the elements of the partition.

If the inclusion probability is homogeneous, then we can write

$$N^i = \sum_a \sum_g N^i(a, g) = \sum_a \sum_g \frac{M^i(a, g)}{\pi(a, g)}. \tag{1}$$

Thus, to obtain the inclusion probabilities, we regress N^i against $M^i(a, g)$. If the condition of homogeneity holds, then the regression coefficients are equal to $1/\pi(a, g)$.

3.1.2 Inhomogeneous bias. If the inclusion probability is inhomogenous for given demographics and partition, then we shall model each subset of the partition separately or use a different model that relaxes the homogenity assumption by specifying the functional form of inhomogeneity. Here, we consider the inhomogeneity of

the form

$$\pi^i(a,g) = M^i(a,g)^v f_1(a) f_2(g), \quad (2)$$

where v is an unknown exponent and f_1 and f_2 are unknown functions.[5] Under this assumption, $\log N^i(a,g) = \log \frac{M^i(a,g)}{\pi^i(a,g)} = (1-v)\log M^i(a,g) - \log f_1(a) - \log f_2(g)$. This time, to obtain the debiasing coefficients and corresponding inclusion probabilities, we regress the ground-truth population, $\log N^i(a,g)$, against the biased measurements, $\log M^i(a,g)$, and the demographic indicator variables, i.e.,

$$\log N^i(a,g) = \beta_1 \log M^i(a,g) + \sum_{\tilde{a}} \beta_{\tilde{a}} \delta_{\tilde{a}a} + \sum_{\tilde{g}} \beta_{\tilde{g}} \delta_{\tilde{g}g} \quad (3)$$

where δ_{ij} is Kronecker delta, i.e., $\delta_{ij} = 0$ if $i \neq j$ and $\delta_{ij} = 1$ if $i = j$, $\beta_1 = (1-v)$, $\beta_a = -\log f_1(a)$, and $\beta_g = -\log f_2(g)$. From these regression coefficients we can obtain the inclusion probability $\pi^i(a,g)$ of a set of samples i with the demographics a and g via Equation 2. This debiasing model has been proposed recently by Zagheni et al. to predict the number of migrants based on Facebook data [81], but its derivation and explicit formal interpretation have not been provided until now, to the best of our knowledge. Note that this estimation method of inclusion probabilities requires the ground-truth joint counts $N^i(a,g)$ at the time of training, whereas the model based on the homogeneity assumption requires only the total counts N^i. The availability of the joint counts is often limited in practice because of insufficient number of samples per stratum.

3.2 Discussion

We derived debiasing models by making homogeneity or inhomogeneity assumptions. These models predict population size, so they can be evaluated by measuring the error of predictions in cross-validation settings or via model selection methods. In this way, we test which assumption is closer to reality and find the most accurate method for the given dataset. We evaluate these models in the next section using the population of regions in EU countries.

4 EUROPEAN POPULATION INFERENCE FROM TWITTER DATA

Here, we use the debiasing models formulated in the previous section to obtain the debiasing coefficients and the corresponding inclusion probabilities for Twitter users of different countries. To this end, we regress the country-level ground-truth number of people living in a certain location against the number of Twitter users of different demographics.

4.1 Debiasing Models for Population Inference

More specifically, we evaluate five models requiring different amounts of data. The first model is a baseline, the next three models are based on the assumption of homogeneous inclusion probabilities (Equation 1), whereas the last one is based on the inhomogeneity assumption (Equation 3):

- $\mathbf{N} \sim \mathbf{M}$ is our base model that uses only the total population count from the census (N) and Twitter (M).
- $\mathbf{N} \sim \sum_{\mathbf{g}} \mathbf{M(g)}$ uses gender marginal counts only (i.e., the total counts of males and females not broken down by ages).
- $\mathbf{N} \sim \sum_{\mathbf{a}} \mathbf{M(a)}$ uses age marginal counts only.
- $\mathbf{N} \sim \sum_{\mathbf{a,g}} \mathbf{M(a,g)}$ uses the joint histograms inferred from Twitter but only the total population values from the census.
- $\mathbf{\log N(a,g) \sim \log M(a,g) + a + g}$ uses the joint histograms inferred from Twitter and the joint histograms from the census.

Note that Twitter users are biased in various ways: the platform is more accessible to tech-savvy individuals and citizens of various countries use it to a different extent [34]. To distinguish the global effect of Twitter on the overall bias from the local effect of country, we use multilevel models. Namely, all slopes and intercepts in the introduced models have random effects specific to a country. Thus, from fixed effects of the model, we obtain global debiasing coefficients (i.e., the biases of Twitter users) and, from random effects, the country-specific debiasing coefficients (i.e., a given country has its own bias towards Twitter).

Note that the homogeneity and inhomogeneity assumptions apply within each country separately. Namely, we group samples by regions of a country, described next. Then, the homogeneity assumption translates into the same inclusion probability for a given demographic across all regions of a country, whereas the inhomogeneity assumption translates into a dependence of the inclusion probability on regions of a country that follows Equation 2.

4.2 Data

We retrieved joint population distributions for age and gender on a regional level (NUTS3) for 26 countries of the European Union plus four EFTA members as made available through the CensusHub system of Eurostat, the European Statistical Office.[6] All census data is from 2011, the most recent year for which comprehensive census data was collectively reported to Eurostat. NUTS3 regions are the finest-grained level of the "Nomenclature of Territorial Units for Statistics" used as a standard for statistical reporting in EU member states [26]. They are based on existing local administrative boundaries and are usually at the level of local districts. Although sizes differ to a certain extent per country, NUTS3 provide the most standardized cross-country geographical units to subdivide populations. We use the 2010 iteration of the NUTS3 regions as these correspond with the 2011 census subdivisons and is the most recent census available.

Our sample of social media users is derived from the random 10% stream of tweets from Twitter. We recorded all users observed from September 2015 to January 2016 and downloaded profile photos for all users in spring 2018. The location of each user is inferred using the method of Compton et al. [19]. This model predicts a user's latitude and longitude and was shown to be least biased with respect to urban and rural areas [41], which is important given the diversity in population centers in our study. The model was trained on a social network of 781M edges constructed from Twitter data spanning 2012 to 2017. Five-fold cross validation reports a median inference error of 7.9km, which is sufficiently accurate for the geographic granularity we use here. Each user is assigned to a NUTS3 region in Europe if the inferred latitude-longitude pair of

[5] Note that the aforementioned homogeneity assumption is a special case of this assumption, i.e., this assumption relaxes the homogeneity assumption.

[6] https://ec.europa.eu/CensusHub2/: Luxembourg and Belgium were not available. Additional EFTA countries: Switzerland, Iceland, Liechtenstein and Norway.

that user lies within the boundaries of the NUTS3 regions; users not in these regions are discarded. Ultimately, we obtain a dataset of 3,202,964 users within the NUTS3 regions for our study. In the remainder, we will refer to NUTS3 regions simply as "regions."

The age, gender, and is-organization variables for each user in our dataset are inferred using M3. As an additional experiment to quantify the impact of including non-human accounts, we ignore any organization classification and treat all accounts as humans, grouping them according to their inferred demographics.

4.3 Results

We evaluate the debiasing models in the following cross-validation settings: leave one region out, leave one country out (i.e., leave out all regions from a given country), and leave one stratum out (e.g., leave out only males aged 30-39). Per case, we measure the mean absolute percentage error of the population estimates for the left-out samples, i.e., $\text{MAPE}(N) = \frac{100\%}{n} \sum_i \frac{|\hat{N}_i - N_i|}{|N_i|}$, where $\hat{N}_i$ and N_i are the predicted and actual population sizes, respectively, and the sum is over all regions. Note that the model $\log N(a,g) \sim \log M(a,g) + a + g$ operates naturally in the log space; hence, before calculating the error of this model we first exponentiate the predicted population sizes to make the results more comparable across all models. Its results should further be compared to the remaining models with care, as the effects of moving to log space cannot be clearly untangled from gains due to learning on joint age and gender attributes.

The results of the leave-one-region-out evaluation show a clear benefit to debiasing based on the inferred demographics (Figure 6). For the $N \sim M$ model without demographics, MAPE is 88%. The inclusion of the inferred gender or age demographics in the debiasing models, via $N \sim \sum M(a)$ and $N \sim \sum M(g)$, decreases MAPE to 59% and 61%, respectively. Including inferred joint distributions, e.g., the number of males of age 30-39, in the model $N \sim \sum M(a,g)$, decreases MAPE further to 54%, even though we do not use joint-distribution data from the census for training. In fact, the use of census joint distributions at the stage of model training along with a move to log space, via $\log N(a,g) \sim \log M(a,g) + a + g$, further improves the accuracy, bringing the MAPE down to 33%. To understand the effect of accounts belonging to organizations on this population prediction task, we compare the results of the debiasing models with and without removing the organizations (Figure 6). Removing organizations results in a small reduction in error for all but the model trained with only marginal gender counts, though these differences are not statistically significant. A further analysis shows that the presence of organizations is heavily skewed towards populous metropolitan cities and most regions have very few organizations (i.e., organizations are not equally geographically distributed). However, for populous regions, organizations can create significant error.

To gain further insights into the introduced models, we show scatter plots of true and predicted population sizes for each model (Figure 7). The model with joint Twitter and census counts is noticeably closer to the $y = x$ line, likely because this models is trained in log space. For this model, we also depict the geographical variation of MAPE across the EU regions (Figure 8).

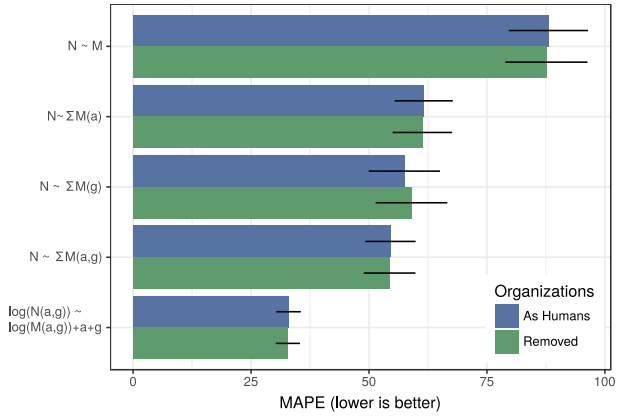

Figure 6: Performance on leave-one-region-out population inference across different debiasing models. Bars show mean MAPE(N) with 95% confidence intervals. The results of the last model are exponentiated to compute MAPE(N).

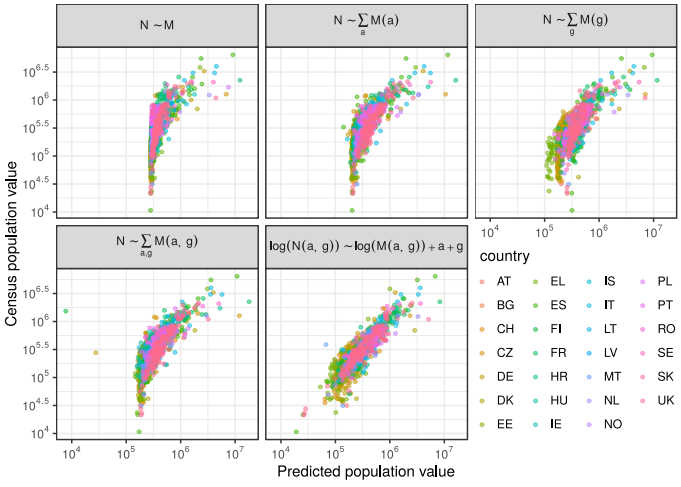

Figure 7: Comparing the census population and debiased estimates for leave-one-region-out evaluations shows that the model with joint Twitter and census distributions correlates best with the real values for large and small regions.

The above results test predictions when one region is left out and its population is predicted. However, in different circumstances, more or less census information could be available. We test two other cross-validation settings: leave one stratum out (e.g., leave out only females aged 30–39) and leave one country out (i.e., leave out all regions from a given country). The latter reflects the generalizability of the model to completely unseen countries where platform adoption probabilities and country-specific biases are not known. The evaluation results for all three cross-validation settings are plotted in Figure 9 for the most accurate model, i.e., $\log N(a,g) \sim \log M(a,g) + a + g$. From the first additional cross-validation setting, we learn that hiding the population sizes for a specific stratum in all regions results in a minimal penalty to the prediction accuracy. For the second additional cross-validation setting, we see that the error rate nearly doubles with an average MAPE of 81%. This result suggests that knowledge of country-specific

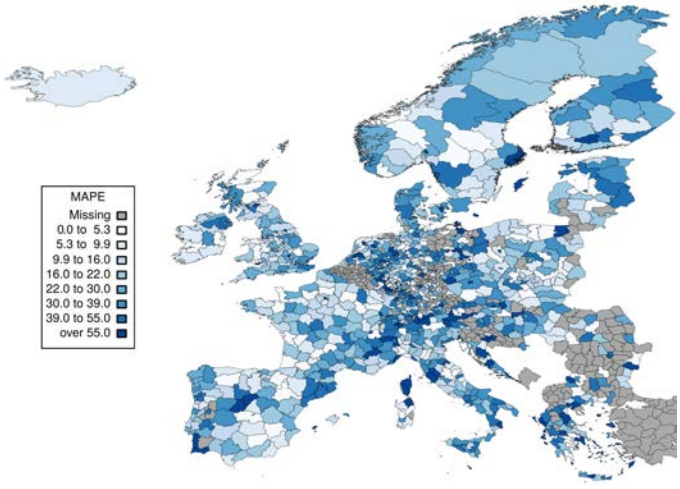

Figure 8: MAPE for $\log N(a,g) \sim \log M(a,g)+a+g$ model across regions shows that many regions have population estimate errors below 10% of the true population, with high-error regions found infrequently in all countries. For greyed regions we either miss NUT3 data or Twitter counts are zero.

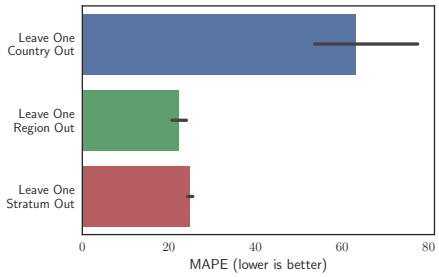

Figure 9: Comparisons of the model with joint Twitter and census distributions as increasing amounts of information are held out from training: (i) leaving out one stratum, (ii) leaving out all the strata from one region, and (iii) leaving out all regions in one country.

platform biases is important for accurate estimates and that at least some regions within the country should be seen during a model's training time to reach high performance.

4.4 Discussion of Debiasing Results and Potential Sources of Error

Debiasing social media data samples is a difficult task, but our results show that automatic post-stratification with respect to inferred age and gender notably improves population estimation results. Furthermore, our predictive models are fully interpretable, which allows us to estimate the inclusion probabilities and share them with the research community for future reuse.

Even when joint distributions are not given by the census, inferring joint distributions from social media data with the model $N \sim M(a,g)$ provides a significant increase in accuracy in population prediction tasks compared to the baseline without debiasing.

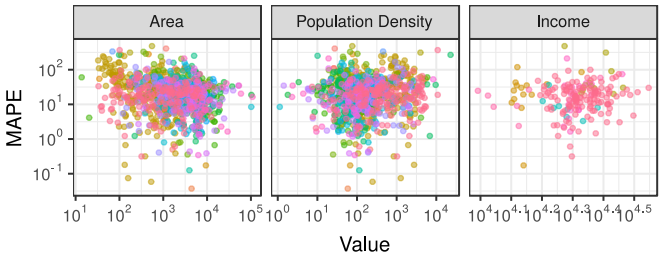

Figure 10: Comparing the model with joint Twitter and census distributions MAPE to region area (km^2), population density (people/km^2), and income (USD per capita) shows that the model performance is not biased towards particular types of regions. Colors represent countries as in Figure 7.

However, the model $\log N(a,g) \sim \log M(a,g) + a + g$ is notably more accurate, suggesting that the assumption of homogeneity does not hold for the partition of citizens of a particular country, gender, and age into regions. Note, however, that the predictions of the most accurate model are not perfect. This may be caused by the time mismatch of about 5 years between the Twitter and NUTS3 datasets. On the other hand, this point opens the door for developing debiasing models based on other inhomogeneity assumptions and searching better partitions, e.g., our multilevel model could have more levels to capture biases shared by smaller regions within a country.

To learn more about potential confounders, we compare the MAPE of the model $\log N(a,g) \sim \log M(a,g) + a + g$ to three variables: the area of the region, its population density, and average income (Figure 10). NUTS3 regions are defined by each country and vary considerably in land area from city-states in Germany to large regions in Sweden (up to 98,000 km^2). We do not find correlations of land area with the MAPE error. Hecht and Stephens [35] found a clear urban–rural bias in social media data: there tend to be more users, more information, and higher quality information per capita within metropolitan areas. Despite this bias, we find our estimates not heavily correlated with population density, suggesting our models do well at debiasing these differences in inclusion probabilities. Only two countries (Czech Republic and Norway) show a correlation that is statically different from zero across our models. Finally, income has been suggested as an important explanatory variable for who uses Internet-based platforms and hence could be a potential confound to our estimates [14, 40]. However, we similarly find that income and MAPE are not correlated significantly in our models.

5 CONCLUSION

The everyday opinions expressed in social media provide promising opportunities for measuring population-level statistics for health metrics, political outcomes, or general attitudes. However, social media is a non-representative sample of the population due to demographic skew in usage frequencies and access rates. As such, any direct estimate from a platform is likely biased towards certain demographics. This work provides a holistic solution to this problem by developing a novel method for assigning users to demographic strata and exploiting it in a regression framework for debiasing that allows direct estimation of the probability of an individual

with given demographics to be on the given social media platform. Our work provides three main contributions. First, we introduce a state-of-the-art neural system for multi-attribute classification in 32 languages. This contribution also includes the system release and the creation of a new dataset of gender, age, and is-organization annotations in 32 languages. Second, we derive a series of models to debias social media measurements and provide their explicit formal interpretations. Third, in a massive study of all of Europe, we show that our two methods are able to infer regional population counts accurately and provide demographic corrections for all downstream measurements on the grounds of the estimated inclusion probabilities. These results pave the way for more accurate social sensing by laying a foundation of representative population sampling in social media. Code, software, and debiasing coefficients pertaining to this work are released for public use at https://github.com/euagendas/.

ABSTRACT

The increasing utilization of massive open online courses has significantly expanded global access to formal education. Despite the technology's promising future, student interaction on MOOCs is still a relatively under-explored and poorly understood topic. This work proposes a multi-level pattern discovery through hierarchical discriminative tensor factorization. We formulate the problem as a hierarchical discriminant subspace learning problem, where the goal is to discover the shared and discriminative patterns with a hierarchical structure. The discovered patterns enable a more effective exploration of the contrasting behaviors of two performance groups. We conduct extensive experiments on several real-world MOOC datasets to demonstrate the effectiveness of our proposed approach. Our study advances the current predictive modeling in MOOCs by providing more interpretable behavioral patterns and linking their relationships with the performance outcome.

1 INTRODUCTION

While massive open online courses (MOOCs) have been attracting an ever-increasing number of students, the low completion rate (between 5%-10% [19]) has been a major obstacle to the transformative potentials of MOOCs. The predictive analysis of student performance thus emerged an an important research topic offering insights to platform developers and instructors in arranging proper learning support and allocating resources to students. To find informative predictors, researchers have focused on extracting features from students' interaction with the MOOC platform, such as watching videos, working on assignments, and viewing or contributing to discussion forums. Applied predictive models range from standard machine learning methods [23, 28] to more advanced ones such as deep learning [7]. These prediction models could be useful in predicting learning outcomes but are notably limited in helping understand the underlying learning behavior.

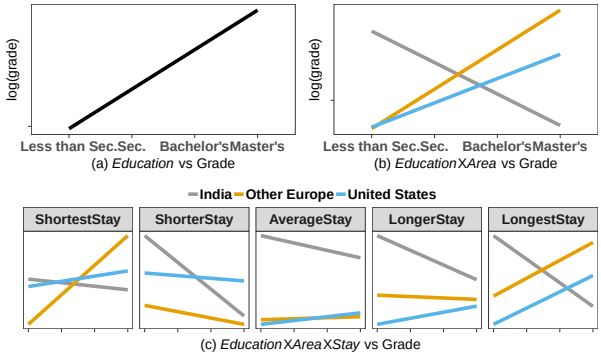

Figure 1: Association analysis of student performance on MOOCs. (a) shows the positive association between the grade and education level; (b) shows the mixed associations when including the area where the student is from; (c) further breaks down the observed groups into different level of activity (five quantiles w.r.t. the number of days students remained active on the platform).

There is abundant work that aims to better understand the behavior patterns that relate to the learning outcomes. For example, Coleman et al. [4] correlates each "behavior topic" to the learning outcomes based on topic modeling. However, the research to date fails to consider the multi-dimensional nature of the features and their potential interactions in outcome learning. Meanwhile, the famous Simpson's paradox points out that the direction of an association at the population-level may be reversed within the subgroups comprising that population [20]. To further explain this in the context of the MOOC platform, we use the Edx MOOC dataset [14] and investigate the factors associated with the students' grade on it.

We extract the education, area (the region where the student is from), the number of active days and the final grade of each student in the course "Introduction to Computer Science and Programming" offered by MITx in Spring 2013. The course had more than 44,000 online participants. Figure 1 shows the association between the selected factors and the final grades of the students. By comparing

Figure 1(a) and Figure 1(b), we observe that when the factor of area is considered, mixed associations occur. For example, the subgroup of Indian participants exhibited a negative association between education level and grade, which potentially suggests a more conservative understanding of the relationship between educational background and course outcome. Moreover, when we consider the number of active days, as in Figure 1(c), we notice that for the participants from the "other European" area, the positive association has a strong presence— but only with *ShortestStay* and *LongestStay*. Thus, in comparison to typical correlation analysis, a prediction model that can take advantage of the multi-way interactions of the features could potentially yield better performance.

A growing body of research seeks to resolve Simpson's paradox through causality inference [34]. However, causality is not the focus of this study as we aim for a data-driven approach to subgroup comparisons and explorations. In many cases, this can be interesting and important even in non-causal settings. A straightforward solution is to perform regression with feature interactions, or use Factorization Machines [37] that allow for the estimation of high-order interaction effects. However, the drawback of these methods is that they offer little understanding of the underlying multi-way learning behavior dynamics and their relationship to the learning outcomes. On the other hand, Factorization models like Matrix Factorization (2-way) and Tensor Factorization (m-way) are able to provide an in-depth understanding of meaningful behavior dynamics [9], but there are a few drawbacks preventing them from being more widely adopted by researchers in the field. First, the associations are isolated, with each of them capturing a certain trend of the behaviors separately (e.g., Figure 2(c)). Second, conventional pattern discovery through factorization models provides little support for contrasting pattern exploration that aims to identify the shared and discriminative behavior characteristics among different groups of users. Being able to do this can tremendously improve knowledge of user behaviors in the context of user group analysis.

In this work, we formulate the problem of understanding learning behavior in MOOCs as (1) the simultaneous factorization of the association between students' multi-aspect features and their performance, and (2) the iterative discovery of interpretable shared and discriminative patterns at multiple levels. The critical challenge is how to utilize the multi-way interaction of the features while providing interpretable patterns to help domain experts understand the learning dynamics. We propose a tensor-based learning method—iterative Discriminative tensor factorization (`iDisc`)—that discovers the common and discriminative learning patterns at multiple levels, and based on which we project users to a latent space (i.e. *embedding* for the downstream prediction tasks) to identify the association between the multi-way interaction of the features and the students' performance. To this end, we first represent the behaviors of the students from the opposite performance groups as *coupled tensors*. Since the coarse-grained joint factorization of these behavior tensors may not be capable of revealing behavior patterns at the subgroup level, `iDisc` iteratively performs discriminative pattern discovery at multiple levels. To increase the interpretability of the entire pattern space, we also introduce the inference of pattern hierarchy. To make the solution capable of handling unseen students, we project the students' behavior tensors into a latent space, by considering the multi-way interactions at different levels as the loading matrix. The empirical studies with the dataset from different MOOC platforms have shown the promising results on the effectiveness and efficiency of `iDisc`.

Contributions Our contributions can be summarized as follows:

- We formulate the problem of identifying the multi-way feature interaction with interpretable pattern discovery for understanding user behavior on the MOOC platforms.
- We propose a framework of iterative discriminant factorization for multi-way data. By factorizing the residual tensors at each level, our method enables the discovery of common and discriminative patterns at different granular levels. To ensure the parsimony of the discovered structure, we employ sparse learning to effectively capture enforcing relationships between the top-level and bottom-level patterns.
- We perform extensive experimentation of our methodology using several real-world datasets, and show the efficiency and interpretability of our proposed method.

2 RELATED WORK

Predictive Modeling in MOOCs. There are several types of predictive models in MOOCs that are closely related to this work. One direction is to utilize more complex feature types, including higher-order n-gram representations of learner activity data. For instance, features are constructed using the occurrence of pre-defined sequential activities [44], or from sequential pattern mining [11, 17, 26, 40]. Another line of work proposes to utilize the temporal nature of the activity data for student success prediction. Qiu et al. [36] propose a latent dynamic factor graph (LadFG) to model and predict learning behavior in MOOCs. LadFG captures the dynamic information and homophily correlations between students. It also projects students' learning behavior into a latent continuous space for predicting student performance. Another approach is the latent variable modeling as a way of inferring complex relationships between predictors [13, 25, 27]. For instance, Halawa et al. [13] explore the use of count-based learning activity features to predict dropout; this approach suggests that both observable learner activity and dropout are driven by latent, unobservable "persistence" factors.

Common and Discriminative Subspace Learning. The increasing availability of data from diverse sources has enabled the study on joint analysis of heterogeneous data. Gupta et al. [12] propose a joint Non-negative Matrix Factorization (NMF) approach to separate the common and discriminative subspace. Following the same idea, Kim et al. [22] relax the framework by requiring the shared subspace to be *similar* rather than strictly identical. Wen et al. [46, 47] propose a data-driven method of jointly factorizing the paired tensors with auxiliary tensors that preserve the common and distinctive signals. However, existing works focus primarily on pattern discoveries. This limits their use in downstream tasks (e.g., prediction or classification).

Multi-Level Tensor Factorization. Multi-Level Tensor Factorization addresses the problem of approximating the hierarchical low-rank tensor format. This process allows the representation of the tensors in a nested subspace, in one of Tree-Tucker format [30], tensor train format [29], or tensor networks format [3]. Huang et al. [18] employ a tree-guided learning via tensor decomposition

Table 1: Description of Notations.

Symbol	Meaning
R	the rank of tensor decomposition
l	the level index
R_l	the rank at l-th level
$\mathbf{v}^l$	the tensor-based user embedding at l-th level
$\mathbf{P}^l$	the projection matrix that maps from the l-th level patterns to the patterns at the $(l-1)$-th level
$\mathcal{X}$, $\mathbf{X}$, $\mathbf{x}$, x	Tensor, matrix, vector, scalar
$\mathbf{X}_{(i,j)}$	the scalar at the $\{i, j\}$ position of matrix $\mathbf{X}$
$\mathbf{X}_{(r,:)}$	the r-th row of matrix $\mathbf{X}$
$\mathbf{X}_{(m)}$	the mode-m unfolding of tensor $\mathcal{X}$
$\mathbb{U}$	the set of factor matrices
$\mathbf{U}_c^{(m)}$	the m-th mode factor matrix from the tensor of class c
$\mathbf{U}_c^l$	the l-th level factor matrix from the tensor of class c
I_1,..., I_M	the dimensionality of mode 1, ..., M

and matrix factorization in the context of experts recommendation in multiple areas simultaneously. However, there is limited research that discovers hierarchical nested subspace in the tensor subspace [31]. Özdemir et al. [31] construct a data-dependent multi-scale subspace to better represent the data. To do so, the authors first construct a tree structure by partitioning the tensor into a collection of permuted sub-tensors, and then construct the multi-scale subspace by applying HoSVD to each sub-tensor.

Summary. The existing predictive analytics on MOOCs considers various ways of constructing a matrix-based feature space. We argue that tensors could be a more suitable representation for student behavioral modeling due to their flexibility in representing the multi-way interaction of the behavioral data. In this regard, Sahebi et al. [39] have shown success in using a tensor-based approach to model the students' learning process, and predict student performance. However, the multi-way interactions as behavior patterns have not been discussed, and a more interpretable pattern discovery that can support a comprehensive understanding of student behaviors is missing. On the other hand, most hierarchical tensor factorization methods tend to recursively decompose the tensor modes by a pre-specified dimension tree [3, 29]. Our work, instead, is closer to the multi-level tensor factorization approach by [32], which recursively factorizes the residual tensors to obtain a multi-level representation of the subspace. However, to the best of our knowledge, there has been no work yet that discovers the common and discriminative patterns at multiple levels, especially in the area of predictive modeling in educational data mining.

3 PROBLEM FORMULATION

In this section, we start with a brief introduction to tensor notions and operations and then formulate the problem considered in this study. Table 1 summarizes the notations used in this paper.

3.1 Preliminaries

3.1.1 Tensors. A tensor is a multidimensional array. Let x denote a scalar, $\mathbf{x}$ a vector, $\mathbf{X}$ a matrix, and then $\mathcal{X}$ is the extension of these concepts to higher dimensions. The *order* of the tensor is the number of modes (or ways) in the tensor.

3.1.2 Tensor Operations. The basic tensor operations that we use in this study are:

Mode-n unfolding, or matricization, is the process of re-ordering elements of tensor $\mathcal{X}$ to form a matrix $\mathbf{X}_{(n)}$, where n is the dimension index upon which the unfolding performs. In the case of the three-way tensor $\mathcal{X} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$, its matricization in the first mode can be denoted as $\mathbf{X}_{(1)} \in \mathbb{R}^{I_1 \times (I_2 \times I_3)}$.

CP Decomposition [15] or CANDECOMP/PARAFAC decomposition expresses an m-way tensor $\mathcal{X}$ of size $I_1 \times \cdots \times I_M$ as $\mathcal{X} \approx \sum_{r=1}^{R} \mathbf{u}_r^{(1)} \circ \cdots \circ \mathbf{u}_r^{(M)}$, where $\mathbf{u}_r^m \in \mathbb{R}^{I_m}$ for $m = 1, \ldots, M$ and $r = 1, \ldots, \mathbf{R}$. By using "kruskal operator," [24], we can shorthand the CP decomposition as $\mathcal{X} \approx \left[\mathbf{U}^{(1)}, \ldots, \mathbf{U}^{(M)}\right]$, where the factor matrix $\mathbf{U}^m$ is defined as $\mathbf{U}^m = \left[\mathbf{u}_1^{(m)} \cdots \mathbf{u}_R^{(m)}\right]$.

3.2 Problem Formulation with Tensors

To motivate the problem in the context of a real-world dataset, we discuss the application of NMF, Non-negative Tensor Factorization (NTF), discriminative NTF, and hierarchical NTF with a toy dataset. This dataset was extracted from one of the most popular courses in the XueTangX dataset (full dataset details in Section 5.1). Each student event, or *activity*, is associated with three attributes: *time* (d_1, d_2), *source* (s_1, s_2), and *type* ($t_1, t_2, \ldots, t_7$).

3.2.1 NMF. Let matrix $\mathbf{X}$ denote the aggregated activities that users have been recorded engaging in on the XueTangX platform for this course. The nature of matrix $\mathbf{X}$ is a two-dimensional array, which restricts its capability of integrating further information [38]. In this way, we can either drop one of the attributes or force the third dimension to be combined with the second dimension. Figure 2(a) shows the case where $\mathbf{X}'$ contains only *source*×*type*, and Figure 2(b) shows the case where $\mathbf{X}''$ contains *source*×(*type*+*type*), where (*type*+*type*) can be considered as a repeated vector to jointly represent the event activity and the day.

With the behavior described by $\mathbf{X}$, the bottom part of Figure 2(a-b) show the respective low-rank factor matrices approximated by NMF, the *source* factors (left), and the *type* factors (right), since they provide the low-dimensional representations of each source and each activity, respectively. Compared to $\mathbf{X}'$, $\mathbf{X}''$ has the additional advantage of revealing the low-dimensional representation of each activity on different days.

3.2.2 NTF. Alternatively, we can use a tensor to represent the same dataset (Figure 2(c)). With the given data of a ternary relation nature [43], we could use a third-order tensor $\mathcal{X}$ to denote a *source*×*day*×*type* activity.

NTF techniques can be applied to obtain three low-dimensional representations: *source* factors, *day* factors, and *type* factors, as $\mathcal{X} \approx \left[\mathbf{S}, \mathbf{D}, \mathbf{T}\right]$. As a result, each pattern comes with a set: a between-activity vector $\mathbf{t}$ to describe the activity dynamics; a between-source vector $\mathbf{s}$ to describe the usage tendency between different sources; and an across-day vector $\mathbf{d}$ to describe the temporal dynamics (e.g., p_1 in Figure 2(c)). Compared to factorizing the unfolding matrix $\mathbf{X}''$ (Figure 2(b)), NTF introduces the day-specific factors. This significantly increases the presentation capability of the patterns by revealing a more direct across-day (temporal) dynamics. Each pattern now represents the interplay of three factors, describing the tendency from different perspectives. With the rich attributes in the behavioral dataset on MOOCs, we thus use tensors to model

the behaviors, with the hope that doing so can provide behavioral patterns with the interpretations from different aspects.

3.2.3 Discriminant NTF. Standard NTF provides meaningful patterns for simultaneously analyzing the behaviors from multiple aspects. This substantially increases the capability of studying and interpreting the behaviors on MOOC platforms with rich dynamics. However, this still does not sufficiently serve the desire to comprehensively understand and investigate student behaviors on these platforms. For example, one of the most interesting questions is which behavior patterns are shared by *completed* students and *dropout* students, and which differentiate the two groups (Figure 2(d)). Through understanding the commonality and differences, researchers can better design course interactions and content to help more students successfully complete the course.

One could easily use NTF to fit the behavior tensors from each group of users, separately. However, this approach does not take advantage of any shared behavior patterns between the two groups. As the behavior moves to high-dimensional tensor space, this could potentially lead to the under-fitting problem. Besides, with patterns generated for each data tensor separately, it needs to perform an additional post-hoc analysis to determine common and discriminative patterns. This is a non-trivial attempt to align the common and discriminative patterns, in the case of each pattern being represented by multiple vectors from different aspects. In this regard, discriminative NTF is set to jointly factorize the tensors constructed from different groups of users with the following objective considering CP decomposition:

$$\mathcal{L}_{\text{disc}} = \left\|\mathcal{X}_{\text{Completed}} - \left[\mathbf{S}, \mathbf{D}, \mathbf{T}\right]\right\|^2 + \left\|\mathcal{X}_{\text{Dropout}} - \left[\mathbf{S}', \mathbf{D}', \mathbf{T}'\right]\right\|^2 + \Omega(\mathbf{S}, \mathbf{D}, \mathbf{T}, \mathbf{S}', \mathbf{D}', \mathbf{T}'), \tag{1}$$

where $\Omega(\cdot)$ is the function to promote the simultaneous discovery of the common and discriminative patterns [22, 47].

3.2.4 Hierarchical NTF. Previous works on NTF or discriminative NTF for unsupervised pattern discovery focus on finding a set of patterns at equal granularity, or in a flat structure. Although they are adequately expressive to reveal the behavior dynamics from different aspects, they can not provide the relations between patterns (such as parent-child and sibling relations).

A hierarchical non-negative tensor factorization (HierNTF) is more desirable than a set of "flat" patterns, because one can work with the pattern exploration in a hierarchy. As opposed to going through each pattern individually, this results in more efficient pattern understanding. HierNTF can be analogous to hierarchical topic modeling, such as hierarchical Latent Dirichlet Allocation (hLDA) [10], where patterns at higher levels in the hierarchy present "abstract" behavior topics, and ones at lower levels reveal more "specific" behavior topics.

3.2.5 Problem Statement. Our problem falls into the combination of the discriminative NTF and HierNTF. We would like to identify common and discriminative patterns nested at multiple levels for a deeper understanding of the relationship between students' multi-way behavior dynamics and their course performance. Before we give the formulation of the studied problem, we would like to first clarify some basic concepts used later.

Definition 3.1. *Individual Behavior Tensor.* Let $\mathcal{X}^{(u)} \in \mathbb{R}^{I_1 \times I_2 \cdots \times I_M}$ be an M-way tensor representing an individual user u, with each entry in the $\mathcal{X}^{(u)}$ being an activity from user u that is jointly described by M attributes.

The attributes can be data or platform dependent, such as a time-varying attribute tensor constructed from demographic and behavior attributes associated with users at different time stamps [36]. The individual behavior tensor can be considered as a multi-way representation of each student. With that, for each performance group, we can compute the *collective behavior tensor*.

Definition 3.2. *Collective Behavior Tensor.* Let $\mathcal{X}_c \in \mathbb{R}^{I_1 \times I_2 \cdots \times I_M}$ be an M-way tensor that users M attributes to describe the collective activities from a group of users indexed by c.

Students at each performance group can be jointly represented by a collective behavior tensor that captures the full multi-way feature interactions of their activities. Then, we can combine the tensors for the two opposite performance groups to construct the *coupled tensors*.

Definition 3.3. *Coupled Tensors.* Coupled Tensors $\boldsymbol{\mathcal{X}} = \{\mathcal{X}_c\}$ is a pair of tensors with identical attributes, i.e., $I_1^c = I_1^{\bar{c}}, I_2^c = I_2^{\bar{c}}, \ldots, I_M^c = I_M^{\bar{c}}$, where c is the index of user group that tensor $\mathcal{X}$ is constructed from and $\bar{c}$ represents the counterpart class.

The coupled tensors $\boldsymbol{\mathcal{X}}$ can be constructed in various ways, depending on the performance metric selected, such as $c \in$ {dropouts, completion} or $c \in$ {certificates, no-certificates}. Inspired by [35], we construct the coupled tensor as follows:

$$\mathcal{X}_c = \frac{1}{|U_c|} \sum_{u \in U_c} \mathcal{X}^{(u)}, \tag{2}$$

where U_c is the subset of users u with u belonging to class c. While each individual behavior tensor captures the full-order feature interactions explained by her activities, the full interplay between the M attributes for each group of students can be contained within the tensor structure corresponding to the group.

Definition 3.4. *Multi-way Behavior Pattern.* A multi-way behavior pattern is a a collection of M vectors $(x^{(1)}, x^{(2)}, \ldots, x^{(M)}), M \geq 2$, where $x^{(m)} \in \mathbb{R}^{I_m}$ is a vector to describe the pattern with the m-th attribute.

Definition 3.5. *Pattern Hierarchy.* Let $\mathbf{P}^l \in \mathbb{R}^{R_l \times R_{l-1}}$ denote a pattern hierarchy that specifies the relationships between the behavior patterns in the consecutive levels, i.e., level l and level $l-1$, where $1 \leq l \leq L$. $\mathbf{P}^l$ can be considered as a projection matrix that maps the pattern from the l-th level to the ones at the $(l-1)$-th level.

Definition 3.6. *Tensor-based User Embedding.* A tensor-based user embedding $v \in \mathbb{R}^R$ is the student's vector representation that preserves each student's behavior tensor with a lower-dimensional feature space $\mathbb{R}^R$, given the tensor's rank R.

With the definitions above, we define the iterative common and discriminative pattern analysis as follows:

Problem 1. Given a set of individual behavior tensors $\mathcal{X}^{(u)} \in \mathbb{R}^{I_1 \times I_2 \cdots \times I_M}, (u = 1, 2, \ldots, N)$ corresponding to C categories, $C = 2$, and a set of unseen test data $\mathcal{X}^{(t)} \in \mathbb{R}^{I_1 \times I_2 \cdots \times I_M}, (t = 1, 2, \ldots, T)$, our goal is to iteratively identify a set of patterns that reveal the

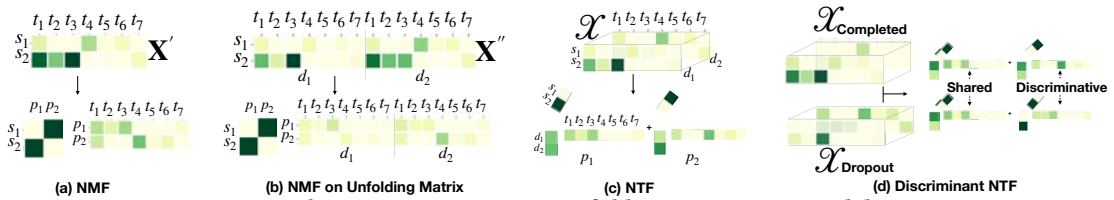

Figure 2: Comparison between NMF, NMF on unfolding Matrix, NTF and discriminant NTF.

common and discriminative behaviors at multiple levels, and then use the learned patterns as bases to infer the user embeddings for prediction of the group membership from the unseen students.

Specifically, the task is threefold: (1) collective behavior pattern inference for discovering the common and discriminative patterns; (2) iterative pattern discovery at multiple levels with hierarchy; and (3) embedding projection for test samples based on the iterative patterns for classification. In other words, the first two tasks are aimed at revealing interpretable patterns that could explain the interplays between the behavior attributes, and the last task is to discover the relationship between student performance and the multi-way patterns.

4 SOLUTIONS

In this section, we introduce an iterative tensor factorization method named `iDisc` for the coupled tensors, $\boldsymbol{\mathcal{X}} = \{\mathcal{X}_c\}$. Figure 3 illustrates the overview of `iDisc`. There are two-stages: (1) iterative application of discriminative tensor subspace learning; and (2) representation learning for the unseen student based on the multi-level patterns.

4.1 Iterative Discriminative Tensor Subspace Learning

This component iteratively applies the following two-step approach: (1) discriminant low-rank tensor approximation, followed by (2) computing and passing the residual tensor into the next level.

4.1.1 Discriminant Tensor Factorization. Conventional tensor factorization seeks a set of N factor matrices $\left[\mathbb{U}\right] = \left[\mathbf{U}^{(1)}, \mathbf{U}^{(2)}, \ldots, \mathbf{U}^{(N)}\right]_c^l$ from a behavior tensor $\mathcal{X}_c^l$ at level l for class c. One such example is:

$$\mathcal{L}^l = \underbrace{\sum_c \left\| {\mathcal{X}_c}^l - \left[\mathbb{U}\right]_c^l \right\|^2}_{\text{Loss for Coupled Tensors Factorization}} . \tag{3}$$

Through Eq. 3, we could obtain a set of independent factor matrices (or behavior patterns) for each of the performance groups, respectively. However, this does not consider the commonality and differences among the coupled tensors.

In order to take the commonality between the two behavior tensors into consideration and allow discrimination against each other, we introduce two sets of auxiliary tensors $\mathcal{S}_c^l$ and $\mathcal{Z}_c^l$ that capture the shared behavior and the discriminative behaviors among the coupled tensors. Inspired by [47], $\mathcal{S}_c^l$ and $\mathcal{Z}_c^l$ are computed based on the coupled tensors $\boldsymbol{\mathcal{X}}$ with the clamping function (Eq. 7 and Eq. 9 in [47]). The rational behind the auxiliary tensors is that; we would like to have discriminative tensors that contain only the unique signals for each class, and common tensors to hold what is shared among the coupled tensors. A collective tensor factorization framework is then leveraged to jointly factorize the coupled tensors and the auxiliary tensors as follows:

$$\begin{aligned}\mathcal{J}^l = \mathcal{L}^l + \underbrace{\lambda_0\Big(\sum_c \left\| {\mathcal{Z}_c}^l - \left[\mathcal{W}_{\mathcal{Z}}; \mathbb{U}\right]_c^l \right\|^2 + \sum_c \left\| {\mathcal{S}_c}^l - \left[\mathcal{W}_{\mathcal{S}}; \mathbb{U}\right]_c^l \right\|^2\Big)}_{\text{Loss for Auxiliary Tensor Factorization}} \\ + \underbrace{f\big(\mathbf{U}_c^l, \mathbf{U}_{\bar{c}}^l, \mathcal{W}_{\mathcal{S}}^l\big)}_{\text{Loss for Pattern Alignment}} + \underbrace{g\big(\mathbf{U}_c^{l-1}, \mathbf{U}_c^l, \mathbf{P}^l\big)}_{\text{Loss for Pattern Hierarchy}} + \underbrace{h\big(\mathbf{P}^l\big)}_{\text{L1 penalty}} \\ s.t. \left\|\mathbf{U}_c^l\right\|_2 = 1, \forall\, c,\end{aligned} \tag{4}$$

where:

- $\mathcal{W}_{\mathcal{Z}}$ and $\mathcal{W}_{\mathcal{S}}$ are the core tensors with super diagonal entries;
- $f\big(\cdot\big)$ is the function to enforce the similar components to be aligned correspondingly and defined as:

$$f\big(\mathbf{U}_c^l, \mathbf{U}_{\bar{c}}^l, \mathcal{W}_{\mathcal{S}}^l\big) = \lambda_1 \sum_m \left(\left\| \mathrm{diag}\big(\mathcal{W}_{\mathcal{S}q}\big)\mathbf{U}_c^m - \mathrm{diag}\big(\mathcal{W}_{\mathcal{S}\bar{c}}\big)\mathbf{U}_{\bar{c}}^m \right\|^2 \right); \tag{5}$$

- $g\big(\cdot\big)$ is the function that learns the shared mapping $\mathbf{P}^l$ by the coupled tensors, between the patterns at the consecutive levels. We can consider this operation as performing a matrix decomposition from $\mathbf{U}_c^{l-1}$ to $\mathbf{U}_c^l$ and $\mathbf{P}^l$ as:

$$g\big(\mathbf{U}_c^{l-1}, \mathbf{U}_c^l, \mathbf{P}^l\big) = \lambda_2 \left\| \mathbf{U}_c^{l-1} - \mathbf{U}_c^l \mathbf{P}^l \right\|^2, \tag{6}$$

  assuming that we already have the values of $\mathbf{U}_c^{l-1}$ for l-th level pattern discovery;
- $h\big(\cdot\big)$ is an $L1$ penalty function that encourages sparsity in $\mathbf{P}^l$ to promote the exclusive mapping between the factor matrices at the consecutive levels. Considering a more interpretable pattern hierarchy, we use $L1$-norm, since it can function as a proxy for the $L0$ norm, to minimize the number of nonzero elements while maintaining the convexity of the cost function when estimating P the others fixed. In this manner, we ensure the higher-level patterns are mapped to exclusive lower-level ones; and
- $\lambda_0, \lambda_1, \lambda_2, \lambda_3$ are the respective parameters to weigh in each objective.

With Eq. 4, common and discriminative patterns discovery at the l-th level becomes an optimization objective as:

$$\theta^l = \mathrm{argmin}_\theta^l \; \mathcal{J}^l, \tag{7}$$

where $\theta^l = \{\mathbb{U}, \mathcal{W}_{\mathcal{Z}}, \mathcal{W}_{\mathcal{S}}, \mathbf{P}\}_c^l$.

4.1.2 Obtain the residual tensors. Once θ^l is determined, the reconstructed tensor can be obtained by:

$$\hat{\mathcal{X}}_c^l \approx \left[\mathbb{U}_c^l\right], \tag{8}$$

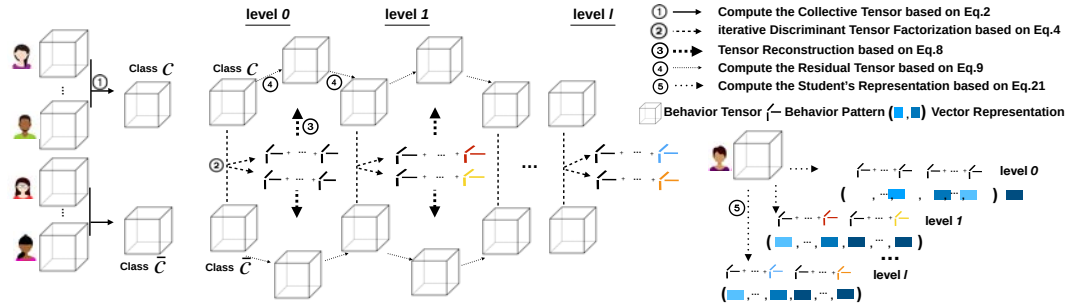

Figure 3: The overview of iDisc's workflow.

and therefore the residual tensor can be computed as:

$$\mathcal{E}_c^l = \mathcal{X}_c^l - \hat{\mathcal{X}}_c^l, \forall\, c. \tag{9}$$

Let $\mathcal{X}_c^{l+1}$ denote the tensors for the identification of common and discriminative patterns at the next level $l+1$. We first obtain $\mathcal{X}_c^{l+1}$ as: $\mathcal{X}_c^{l+1} = \mathcal{E}_c^l$, where $\mathcal{E}_c^l$ is the residual tensor as aforementioned. With $\mathcal{X}_c^{l+1}$, we can further identify the common and discriminative patterns at level $l+1$ with Eq. 4.

Algorithm 1: Algorithm iDisc for discovering the shared and discriminative subspace from coupled tensors at multiple levels.

Input : Coupled tensors $\mathcal{X}$, $\{R\}_l^L$, and $\{\lambda_0, \lambda_1, \lambda_2, \lambda_3\}$
Output: $\{\theta\}_l^L$, where $\theta = \{\mathbb{U}, \mathcal{W}_\mathcal{Z}, \mathcal{W}_\mathcal{S}, \mathbf{P}\}_c$

```
Let l = 0;
while l < L do
    Construct {Z_c}^l and {S_c}^l from {X_c}^l based on Eq.7 and Eq.9 in [47];
    Obtain θ^l by solving Eq. 4;
    Reconstruct {X_c}^l based on Eq. 8;
    Compute E_c^l based on Eq. 9;
    Let l = l + 1;
    Let X_c^l = E_c^l
end
```

4.1.3 Parameter Optimization of iDisc. For simplicity of notation, we omit the level l in all notations since the optimization is performed per level with the focus on the unknown θ^l and the θ^{l-1} are learned at level $l-1$. We also omit the mode notation m because all modes share the same optimization process. Let $\mathbf{U}_c$ represent the mode-m factor matrix at level-l, instead of the rather complex form of $\{\mathbf{U}_c^{(m)}\}_l$. We use $\overline{\mathbb{U}}_c$ to denote the set of factor matrices for $\mathcal{X}_c$ that correspond to modes other than m, and $\bar{c}$ to denote the class that is not c.

Since objective function $\mathcal{J}$ is not convex with respect to θ, we aim to find a local minimum for $\mathcal{J}$ by iteratively updating each in θ.

1. Update $\mathbf{U}_c$*, fix others.* The optimization of $\mathbf{U}_c$ is equivalent to the following least squares loss functions [47]:

$$\begin{aligned}\mathbf{U}_c \leftarrow \underset{\mathbf{U}_c \geq 0}{\operatorname{argmin}} \frac{1}{2}\Big(\frac{1}{n_c}\Big\|\mathbf{X}_c - \mathbf{U}_c\,(\odot\overline{\mathbb{U}}_c)^T\Big\|_F^2\Big) \\ + \lambda_0\Big(\Big\|\mathbf{Z}_c - \mathbf{U}_c\Lambda_{\mathbf{w}_{Z_c}}(\odot\overline{\mathbb{U}}_c)^T\Big\|_F^2 + \Big\|\mathbf{S}_c - \mathbf{U}_c\Lambda_{\mathbf{w}_{S_c}}(\odot\overline{\mathbb{U}}_c)^T\Big\|_F^2\Big) \\ + \lambda_1\Big\|\mathbf{U}_c\Lambda_{\mathbf{w}_{S_c}} - \mathbf{U}_{\bar{c}}\Lambda_{\mathbf{w}_{S_{\bar{c}}}}\Big\|_F^2 + \lambda_2\Big\|\mathbf{U}_c^{l-1} - \mathbf{U}_c\mathbf{P}\Big\|^2,\end{aligned} \tag{10}$$

where $\mathbf{X}_c$ is the mode-m unfolding of tensor $\mathcal{X}_c$. Then the gradient update of $\mathbf{U}_c$ can be computed as:

$$\begin{aligned}\nabla_{\mathbf{U}_c}\mathcal{J} = \frac{1}{n_c}\Big(\mathbf{U}_c(\odot\overline{\mathbb{U}}_c)^T - \mathbf{X}_c\Big)(\odot\overline{\mathbb{U}}_c) \\ + \lambda_0\Big(\Big(\mathbf{U}_c\Lambda_{\mathbf{w}_{Z_c}}(\odot\overline{\mathbb{U}}_c)^T - \mathbf{Z}_c\Big)(\odot\overline{\mathbb{U}}_c)\Lambda_{\mathbf{w}_{Z_c}}^T + \Big(\mathbf{U}_c\Lambda_{\mathbf{w}_{S_c}}(\odot\overline{\mathbb{U}}_c)^T - \mathbf{S}_c\Big)(\odot\overline{\mathbb{U}}_c)\Lambda_{\mathbf{w}_{S_c}}^T\Big) \\ + \lambda_1\Big(\mathbf{U}_c\Lambda_{\mathbf{w}_{S_c}} - \mathbf{U}_{\bar{c}}\Lambda_{\mathbf{w}_{S_{\bar{c}}}}\Big)\Lambda_{\mathbf{w}_c} - \lambda_2\mathbf{P}\Big(\mathbf{U}_c^{l-1} - \mathbf{U}_c\mathbf{P}\Big).\end{aligned} \tag{11}$$

2. Update $\mathcal{W}_{\mathcal{Z}_c}$*, fix others.*
Let $\mathbf{w}_{Z_c}$ denote $\mathbf{w}$ for tensor $\mathcal{X}_c$. The optimization of $\mathbf{w}_{Z_c}$ is equivalent to the following problem:

$$\mathbf{w}_{Z_c} \leftarrow \underset{\mathbf{w}_c \geq 0}{\operatorname{argmin}}\ \lambda_0\Big\|\mathbf{Z}_c - \Lambda_{\mathbf{w}_{Z_c}}(\odot\mathbb{U}_c)^T\Big\|^2, \tag{12}$$

where $\Lambda_{\mathbf{w}_{Z_c}} \in \mathbb{R}^{R\times R\times R}$ is the tensor with $\mathbf{w}_{Z_c}$ as its super-diagonal entries. The gradient update of $\mathbf{w}_c$ is:

$$\nabla_{\mathbf{w}_{Z_c}}\mathcal{J} = \lambda_0\Big(\Lambda_{\mathbf{w}_{Z_c}}(\odot\mathbb{U}_c)^T - \mathcal{Z}_c\Big)(\odot\mathbb{U}_c). \tag{13}$$

3. Update $\mathcal{W}_{\mathcal{S}_c}$*, fix others.*
Let $\mathbf{w}_{S_c}$ denote $\mathbf{w}$ for tensor $\mathcal{X}_c$. The optimization of $\mathbf{w}_{S_c}$ is equivalent to the following problem:

$$\mathbf{w}_{S_c} \leftarrow \underset{\mathbf{w}_{S_c} \geq 0}{\operatorname{argmin}}\ \lambda_0\Big\|\mathbf{S}_c - \Lambda_{\mathbf{w}_{S_c}}(\odot\mathbb{U}_c)^T\Big\|^2 + \lambda_1\Big\|\mathbf{U}_c\Lambda_{\mathbf{w}_{S_c}} - \mathbf{U}_{\bar{c}}\Lambda_{\mathbf{w}_{S_{\bar{c}}}}\Big\|^2. \tag{14}$$

The gradient update of $\mathbf{w}_{S_c}$ can be derived as:

$$\nabla_{\mathbf{w}_{S_c}}\mathcal{J} = \lambda_0\Big(\Lambda_{\mathbf{w}_{S_c}}(\odot\mathbb{U}_c)^T - \mathcal{S}_c\Big)(\odot\mathbb{U}_c) - \lambda_1\Big(\mathbf{U}_c{}^T\Big(\Lambda_{\mathbf{w}_{S_c}}\mathbf{U}_c - \Lambda_{\mathbf{w}_{S_{\bar{c}}}}\mathbf{U}_{\bar{c}}\Big)\Big) \tag{15}$$

4. Update $\mathbf{P}$*, fix others.* The optimization of $\mathbf{P}$ is equivalent to a co-regularized collective matrix factorization problem with sparsity constraints [6, 41]:

$$\mathbf{P} \leftarrow \underset{\mathbf{P}\geq 0}{\operatorname{argmin}}\ \lambda_2\Big(\frac{1}{2}\Big\|\mathbf{U}_c^{l-1} - \mathbf{U}_c\mathbf{P}\Big\|^2 + \frac{1}{2}\Big\|\mathbf{U}_{\bar{c}}^{l-1} - \mathbf{U}_{\bar{c}}\mathbf{P}\Big\|^2\Big) + \lambda_3\|\mathbf{P}\|_1. \tag{16}$$

Since the sparsity is applied to each row of $\mathbf{P}$, each row $\mathbf{P}_{(r,:)}$ can be updated based on the following gradient:

$$\nabla_{\mathbf{P}_{(r,:)}}\mathcal{J} = -\lambda_2\Big(\mathbf{U}_{c\,(r,:)}^{T}(\mathbf{U}_{c}^{l-1} - \mathbf{U}_{c\,(:,r)}\mathbf{P}_{(r,:)}) + \mathbf{U}_{\bar{c}\,(r,:)}^{T}(\mathbf{U}_{\bar{c}}^{l-1} - \mathbf{U}_{\bar{c}\,(:,r)}\mathbf{P}_{(r,:)})\Big) + \lambda_3 \mathrm{sgn}(\mathbf{P}_{(r,:)}). \tag{17}$$

The details of iDisc are summarized in Alg. 1 [1].

4.1.4 Time Complexity Analysis. The time complexity is mainly consumed by updating each factor matrix $\mathbf{U}_c$ in iDisc from computing $\nabla_{\mathbf{U}_c}\mathcal{J}$. From Eq. 11, we need to compute $\mathbf{U}_c(\odot\overline{\mathbb{U}}_c)^T(\odot\overline{\mathbb{U}}_c)$ and $\mathbf{X}_c(\odot\overline{\mathbb{U}}_c)$ in the first term. Note $\mathbf{U}_c \in \mathbb{R}^{I_m \times R}$ and $\mathbf{X}_c \in \mathbb{R}^{I_m \times \prod_{i\neq m} I_i}$ and therefore we have $\mathbf{U}_c(\odot\overline{\mathbb{U}}_c)^T(\odot\overline{\mathbb{U}}_c) \in \mathbb{R}^{I_m \times R}$ and $\mathbf{X}_c(\odot\overline{\mathbb{U}}_c) \in \mathbb{R}^{I_m \times R}$. The operation of matricized tensor times Khatri-Rao product ($\mathbf{X}_c(\odot\overline{\mathbb{U}}_c)$) is often considered a bottleneck for CP decomposition due to the expensive computational cost [48]. In practice, the sparsity of the tensor is leveraged for an efficient computation for this operation [2, 48]. Particularly, the complexity can be reduced by only considering the computation for nonzero observations in $\mathcal{X}_c$. Let x_h denote the h-th nonzero observation in $\mathcal{X}_c$ and its subscripts in $\mathcal{X}_c$ as $(I_{1_h}, I_{2_h}, \ldots, I_{M_h})$. If there are H non-zeros, i.g, $H = nnz(\mathcal{X}_c)$, we would just need an H-vector to store the real values of $\mathcal{X}_c$. In this case, the element-wise computation for $\mathbf{X}_c(\odot\overline{\mathbb{U}}_c)$ can be written as:

$$\Big(\mathbf{X}_c(\odot\overline{\mathbb{U}}_c)\Big)_{(i,r)} = \sum_{\substack{h=1 \\ I_{m_h}=i}}^{H} x_h \prod_{\substack{m'=1 \\ m'\neq m}}^{M} \mathbf{U}^{(m')}_{(I_{m'_h},r)}, \quad \text{for } i = 1, \ldots, I_m \text{ , and } r = 1, \ldots, R, \tag{18}$$

where the computation of Khatri-Rao product can be ignored when $x_h = 0$. Therefore, the time complexity for computing $\mathbf{X}_c(\odot\overline{\mathbb{U}}_c)$ for each mode per iteration is $O(nnz(\mathcal{X}_c)I_m R)$. The element-wise of $\mathbf{U}_c(\odot\overline{\mathbb{U}}_c)^T(\odot\overline{\mathbb{U}}_c)$ can be efficiently computed as [1, 42]:

$$\Big(\mathbf{U}_c(\odot\overline{\mathbb{U}}_c)^T(\odot\overline{\mathbb{U}}_c)\Big)_{(i,r)} = \sum_{j=1}^{R}\left(\mathbf{U}^{(m)}_{(i,j)} \prod_{\substack{m'=1 \\ m'\neq m}}^{M} \sum_{i=1}^{I_{m'}} \mathbf{U}^{(m')^T}_{(i,j)} \mathbf{U}^{(m')}_{(i,r)}\right). \tag{19}$$

Therefore, the time complexity as $O(\hat{I}\,R^2)$, where $\hat{I} = \sum_{m'=1}^{M} I_{m'} - I_m$ and the overall time complexity for the above two terms is $O(HI_mR + \hat{I}\,R^2)$. Similarly, the time complexity for terms involving tensors $\mathcal{Z}$ and $\mathcal{S}$ becomes $O(H' I_m R^2 + \hat{I}\,R^3)$ due to the additional loop introduced by the weight vector $\mathbf{w}$, where H' is the respective nonzero observations in the auxiliary tensors. Since $H' \leq H$, with $M \ll H$, $R \ll H$, and $\hat{I} \ll H$, we can see that the running time is expected to scale linearly with the number of nonzero observations in $\mathcal{X}_c$.

4.2 Embedding Learning for the Unseen Student

This section explains the inference of the student's embedding in the latent space anchored by the factor matrices. The individual behavior tensor $\mathcal{X}_t$ for unseen student t with an unknown class is constructed based on his or her logs with the system. The mode settings of tensor $\mathcal{X}_t$ are the same as for the collective behavior tensors (e.g., $\mathcal{X}_c$). With the students' individual tensor and the factor matrices, we follow iDisc to first obtain the corresponding auxiliary $\mathcal{Z}$ tensors at l-th level, $\mathcal{Z}^l_{t_{\hat{c}}}, \forall\, \hat{c} \in \{c, \bar{c}\}$, for student t, by following the clapping function in Eq. 7 in [47]. Then, the equation to compute the embedding becomes:

$$\mathbf{v}^l_{t_{\hat{c}}} = \mathcal{Z}^l_{t_{\hat{c}}} \times_m \left\{\mathbf{U}^{(m)}\right\}^l_{\hat{c}}, \forall\, \hat{c} \in \{c, \bar{c}\}, \tag{20}$$

which follows a typical computation of the core tensor, given the data tensor and its factor matrices.

It is worth noting that since PARAFAC decomposition does not enforce the orthogonal property in each of the factor matrices, direct computation of Eq. 20 is not feasible. Recent work by [8] proposes an efficient estimation of the core tensor for PARAFAC decomposition. By following the algorithm 1 in [8] to efficiently estimate $\mathbf{v}^l_{c_t}$ and then the embedding of student s at l-th level $\mathbf{v}^l_t \in \mathbb{R}^{2R_l}$ can be obtained by:

$$\mathbf{v}^l_t = \left[\mathbf{v}^l_{t_c} | \mathbf{v}^l_{t_{\bar{c}}}\right]. \tag{21}$$

5 EXPERIMENTS

In this section, we conduct systematic experiments to evaluate the quality of iDisc. In following, we first describe the data used for the experiments. The content of the rest of this section is structured to answer the following questions:

- Can iDisc reveal meaningful patterns?
- How does iDisc perform in comparison with state-of-art methods from predictive modeling in learning analytics?
- Can iDisc scale for the dataset at a massive scale?

5.1 Data

We experiment with nine courses/sessions from three publicly-available MOOC platforms: edX, ASSISTments, and XueTangX. The statistics of the datasets are provided in Table 2.

Table 2: Dataset and Tensor Modes Description.

edX. The edX [33] dataset is comprised of de-identified data from "Introduction to Computer Science" (Fall 2012, Spring 2013, and Summer 2013) from MITx (Course A and B in Table 2) and HarvardX (Course C). This dataset does not have detailed event logs. However, the data are aggregated records, where each record represents the summary statistics for one individual's activity in the edX course with her demographic information. We select the three most popular courses from this dataset. For this dataset, we construct a 34x5x5 tensor as *Area*×*Education*×*Stay*. Our goal is to predict whether the course completion certificate is earned by a student at the end of the course.

[1] Code is available at https://github.com/picsolab/iDisc

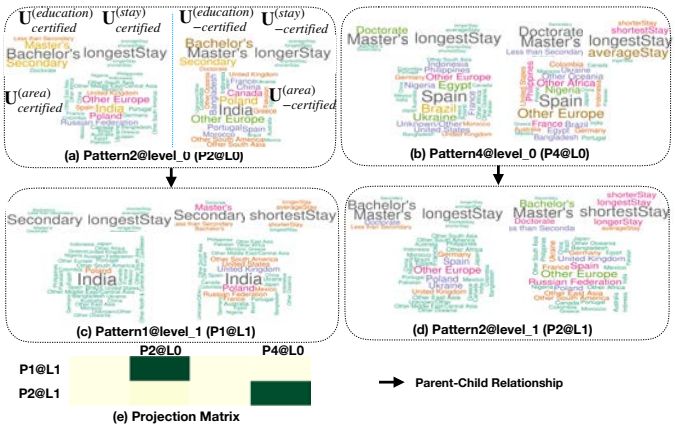

Figure 4: Output generated by `iDisc` on the MITx dataset. (e) shows the relationships between patterns in the first two levels; (a-d) show the associated patterns in the hierarchy.

XueTangX. XueTangX [50] is one of the largest MOOC platforms in China. The full dataset includes 79,186 students enrolled in 39 classes. Each enrollment is associated with a log of the student's activities, including watching lecture videos, working on course problems, accessing course modules, and so on. In total, there are 8,157,277 activity logs, and the longest lifetime of enrollment is five weeks. We take the three most popular courses from this dataset. The dataset statistics are shown in Table 2. We use the first two weeks to learn the factor matrices by constructing a 14x7x2 tensor as *Day×EventType×EventSource*. The goal is to correctly predict course completion.

ASSISTments. ASSISTments [16] is an online tutoring system used by more than 50,000 students around the world [5]. On ASSITments, students attempt to solve problems and receive feedback on those attempts. To assist the learning process, each problem is also associated with multiple knowledge components. We take the public dataset of the Math course on ASSISTments over three years (2004, 2005, and 2006) and the dataset characteristics are shown in Table 2. For each dataset, we construct a four-way tensor as *Problem×KnowledgeComponent×ProblemView ×ActionDuration*. Our aim is to classify the students as over-performing students and under-performing students, in terms of error-rate [2].

5.2 Qualitative Examination of the Patterns

In this section, we use "Introduction to Computer Science" on MITx during Spring 2013 to illustrate the outputs of `iDisc`. We first qualitatively examine the patterns, as well as the pattern hierarchy generated and then explain the relationship between the patterns and the performance outcome.

5.2.1 Common and Discriminative Pattern Discovery. Figure 4 describes the outputs by `iDisc`, with $\{R\}_l^L = \{4, 2\}$ (rank-4 at the first level and rank-2 at the second level). Particularly, Figure 4(e) shows the project matrix $\mathbf{P}^1 \in \mathbb{R}^{2\times4}$ that represents the hierarchical relationships between the set of patterns at the first two levels, where darker colors indicate stronger associations. We observe that pattern #1 at level 1(P1@L1) is strongly associated with pattern #2 at level 0(P2@L0). This suggests that P1@L1 could be a child pattern for P2@L0. Similarly, we observe the parent-child relationship between P4@L0 and P2@L1. Since the projection matrix is shared by the factor matrices from the coupled tensors, it is important to note that each of figures 4(a) through 4(d) refers to both patterns for the certified and non-certified group (i.e. as shown left and right in Figure 4(a)).

[2] https://pslcdatashop.web.cmu.edu/help?page=terms#error_rate

Table 3: Regression results for course end performance. Explanatory variables are the students' embeddings that correspond to the patterns presented in Figure 4 (a-d) (e.g., $\mathbf{v}^0_{certified}(2)$ refers to the values in students' embedding vector v for P2@L0 from the certified group). *Note:* **:p<.05; ***:p<.01.

	Certified (M1)		Certified (M2)
$\mathbf{v}^0_{\text{certified}}(2)$	−0.058 (0.046)	$\mathbf{v}^1_{\text{certified}}(1)$	−0.282 (0.188)
$\mathbf{v}^0_{\text{certified}}(4)$	−0.004 (0.046)	$\mathbf{v}^1_{\text{certified}}(2)$	2.285^{***} (0.649)
$\mathbf{v}^0_{\text{-certified}}(2)$	-0.113^{**} (0.048)	$\mathbf{v}^1_{\text{-certified}}(1)$	-0.620^{***} (0.080)
$\mathbf{v}^0_{\text{-certified}}(4)$	0.026 (0.046)	$\mathbf{v}^1_{\text{-certified}}(2)$	0.733^{***} (0.061)

Due to the space limit, we only discuss the details of two sets of multi-way patterns as word clouds in Figure 4(a) for P2@L0 and Figure 4(c) for P1@L1. Figure 4(a) describes a subgroup of students that are from the most populated countries (e.g., the United States, India, and Poland, based on $\mathbf{U}^{(area)}$) with education background mostly from Secondary to Master's ($\mathbf{U}^{(education)}$), and most of whom tend to stay on the edX platform ($\mathbf{U}^{(stay)}$) for a relatively long period. While the pattern from the certified group of students shares almost identical distributions in the area and educational background, what makes them slightly different was primarily the time spent on the platform; certified students($\mathbf{U}^{(stay)}_{\text{certified}}$) spend relatively longer than un-certified students ($\mathbf{U}^{(stay)}_{\text{-certified}}$). The set of patterns in Figure 4(c) is the child patterns of the Figure 4(a). Compared to their counterpart in level 0, they primarily describe the students from Indian (although the area distribution from the un-certified group of students spans more countries ($\mathbf{U}^{(area)}_{\text{-certified}}$)) with more focus on the middle level of education background (e.g., Secondary($\mathbf{U}^{(education)}_{\text{certified}}$)). The difference in their length of stay on the platform was more prominent in this set of patterns, where certified students have the longest stays with the edX platform ($\mathbf{U}^{(stay)}_{\text{certified}}$), and un-certified students generally have the least ($\mathbf{U}^{(stay)}_{\text{-certified}}$).

5.2.2 Simpson's Paradox Revisited. We performed multivariate logistic regression analysis to identify the patterns that can explain students' variation in obtaining the certificate for each level (M1 for level 0 and M2 for level 1). The dependent variable is whether or not the users are certified at the end of the course. The explanatory variables include the students' embeddings for the aforementioned patterns in Figure 4(a-d) in each level (e.g., $\mathbf{v}^1_{\text{certified}}(1)$ refers to the embeddings corresponding to P1@L1$_{\text{certified}}$). The embeddings are standardized to facilitate comparison among different variables.

Table 3 shows the estimated coefficients for M1 and M2. The only significant variable in M1 is the embeddings $\mathbf{v}^0_{\text{-certified}}(2)$ ($\beta = -0.113$, $p < .05$). This suggests that users who have shown more

activities in line with pattern P2@L0$_{\text{-certified}}$ appear to have less chance to earn the certificate. M2 shows that both embeddings $\mathbf{v}^1_{\text{certified}}(2)$ ($\beta = 2.285, p < .01$) and embeddings $\mathbf{v}^1_{\text{-certified}}(2)$ ($\beta = 0.733, p < .01$) reveal a significant and positive effect towards earning the certificate, with $\mathbf{v}^1_{\text{certified}}(2)$ having a much larger effect size. On the other hand, M2 also shows a significant and negative effect of having a larger value in $\mathbf{v}^1_{\text{-certified}}(1)$ ($\beta = -0.620, p < .01$).

We can consider multi-way patterns as principal components in PCA that bridge the original feature interactions in the high-dimensional space and the associated *loadings*. In this case, we would expect students from one class to have higher loading scores associated with patterns that are extracted from the same class. The regression result in M1 shows that the un-certified group of students does have larger loading scores. However, that is true only in $\mathbf{v}^0_{\text{-certified}}(2)$ for P2@L0 . This is not surprising, because in level 0 the two sets of patterns are in fact very similar to each other, as shown in Figure 4. The results in M2 confirm this expectation, with significantly higher loading scores $\mathbf{v}^1_{\text{certified}}(2)$ for certified students and significant higher loading scores $\mathbf{v}^1_{\text{-certified}}(1)$ for un-certified students. Contrary to our expectation, the certified group of students also have higher loading scores in $\mathbf{v}^1_{\text{-certified}}(2)$ (although much lower than $\mathbf{v}^1_{\text{certified}}(2)$). This could be explained by our observation in Figure 1, where P2@L1 captures a cluster of highly-educated students from certain European areas. They have a much higher chance of obtaining the certificate, regardless of having the longest stay or shortest stay with the platform.

Summary. We qualitatively examine the outputs generated by `iDisc`. The results show interesting properties of the proposed method. Our model reveals common and discriminative patterns at each level with their relationship explained via the projection matrix. Our regression analysis first explains the discriminative capability of the students' embeddings based on this set of patterns. More importantly, the analysis validates that the students' embeddings can be used to measure the relationship between the performance outcome with multi-way patterns from `iDisc`.

5.3 Quantitative Comparison

In this section, we report the results from the quantitative experiments in comparison with existing work commonly used in predictive analytics. Specifically, we conduct a classification task, in which the goal is to predict the students' performance at the end of the course defined in Section 5.1.

5.3.1 Baselines. We include baselines that are commonly seen in the area of predictive analytics in educational data mining as:

- Raw. We use the raw activity counts each day as features to train classifiers for prediction. This is the most common approach in predictive modeling for MOOCs.
- LDA. Coleman et al. [4] use LDA to capture the temporal element of the behavior data. We first discover the latent behavior patterns from Raw features with a varying number of topics, and use the topic membership of each student for the classification task.
- LadFG [36]. As one of the most cited works in MOOC predictive modeling, LadFG is a latent dynamic factor graph model that finds a mapping from students' time-varying attribute tensor to the observed learning outcome. We only evaluate the performance of LadFG in XueTangX dataset because it is the only one of the three that contains the necessary temporal dynamics.
- Factorization machines (FM) [37]. Factorization machines have been proposed and successfully applied to recommendation and prediction tasks. As the factorization model projects the input feature space into a latent space, it enables the learning of more complex interactions between features. We first convert each dimension as dummy variables for each student, and then concatenate all dimensions as a wide feature matrix.

It is worth noting the recent use of Deep Neural Nets (DNN) and their variants have shown promising performance compared to conventional machine learning approaches (e.g., [21, 45, 49]). However, the lack of interpretability of these models prevents their further application in problems driven by both interpretations and performance gains. We also compare `iDisc` with the existing work on discovering the common and discriminative patterns from multi-way data.

- `SDCDNTF`. `SDCDNTF` extends [22] and learns the common and discriminative patterns with different ranks. The input to the model consists of the rank and the number of shared patterns, along with the coupled tensors.
- `PairFac`. `PairFac` [47] learns the common and discriminative patterns with different ranks. Comparing to `SDCDNTF`, it does not require the input of the split.

We would like to point out that standard tensor factorization could serve as another baseline to compare with, in which students or their class reside as one of the dimensions and the corresponding factor matrix can naturally become features for downstream prediction tasks. However, we did not include it for two reasons: first, because the aforementioned baselines work as inductive models, where unseen students can be predicted based on the learned parameters, while simple tensor factorization serves as a transductive model and only predicts for the students that are available in the factorization; and second, because student populations on MOOC platforms can be of any size, from small to very large, the efficiency of standard tensor factorization with a large dimension size could be a practical problem for its real-world application.

5.3.2 Experiment Settings. For each dataset, we draw a training set of students from each class with replacement, and then obtain the embeddings of the out-of-bootstrap students. For this set of students, we perform a five-fold cross-validation with a k Nearest Neighbors classifier. We conduct five independent trials of this experiment and report the average classification accuracy. We select accuracy since both the training and testing dataset are constructed in a way that each class has an equal amount of students. For `SDCDNTF`, we experiment with α, β and $\gamma \in \{10^{-5}, 10^{-4}, 10^{-3}\}$. Finally, we set α and β in the same range, and $R = 6$ for both `PairFac` and `SDCDNTF` and derive two versions of `SDCDNTF` using $K \in \{2, 4\}$. To make a fair comparison with `PairFac` and `SDCDNTF` , we use two-level pattern discovery with rank-4 and rank-2 in each level for `iDisc`, respectively. For LDA and FM, we experiment with a varying number of topics /factors and report the best performance. For LadFG, we keep the suggested parameters from their paper.

Table 4: Classification Results in Accuracy.

Dataset		edX Course A	edX Course B	edX Course C	XueTangX Course 1	XueTangX Course 2	XueTangX Course 3	ASSISTments Year 2004	ASSISTments Year 2005	ASSISTments Year 2006

5.3.3 Experiment Results. Table 4 shows the classification results. The raw features perform poorly, especially in XueTangX and ASSISTments dataset, with the score on accuracy in the range of 60-70%, which suggests the difficulty of the prediction task. LDA saw different performance, with noticeable drops in the edX dataset in comparison to raw features. We conjecture that the construction of the raw features results in a high dimensional and sparse feature space, which could potentially cause LDA to suffer from learning merely meaningful latent topics. Factorization machines slightly improve the performance. FMs can be considered as a generalization of tensor factorization with the additional modeling of interactions within each dimension [37]. Although we observe noticeable gains from FMs over Raw features and LDA, FMs do not perform as well as tensor-based methods. We suspect there might be two reasons for this: 1) the current feature space might not be as well tuned for general prediction tasks as it is for the more commonly seen recommendation tasks; 2) compared to tensor-based methods that only consider the interactions between different dimensions, FMs could potentially over-fit the interaction effects between and within dimensions in the training data. We observe that LadFG achieves large gains over the raw features for the XueTangX dataset. This indicates there could exist some hidden patterns that can capture the temporal elements of the behavior data. We also notice that tensor-based models such as PairFacand SDCDNTFperform better than LDA, especially in Course 2 and Course 3. This suggests that by systematically considering the multi-way interactions, the performance could be further improved. Finally, the best performance of iDisc is statistically comparable with the state-of-art LadFG and significantly better than the rest of the baselines. While LadFG is geared towards student performance predictions, iDisc can provide comparable prediction performance as well as meaningful patterns.

Summary. iDisc constructs students' embeddings that integrate relations between the multi-way interactions and the performance outcome. The quantitative experiment demonstrates the discriminative capability of iDisc, and iDisc outperforms the baselines in nine datasets from three MOOC platforms. Higher-level embeddings from iDisc have shown stronger discriminative powers over ones from the lower levels, which we will discuss in next section. Since there is no trivial solution in determing the rank of the tensor decomposition, we experimented with different rank settings for iDisc (e.g., {2, 4}, {3, 3}) and this observation still holds.

Table 5: Running time for varying number of observations.

#observations	10^2	10^3	10^4	10^5	10^6
running time/epoch	0.31s	0.35s	1.13s	1.23s	2.05s

5.4 Scalability

Since many of the education platforms have seen exponential growth in usage, scalable solutions of learning analytic are another critical aspect of adoption. In this section, we test the scalability of iDisc. In this experiment, we choose the ASSISTments dataset for the year of 2006, since it has the largest tensor settings in our experiment. We run iDisc with a varying number of entries in the data tensor, from $\{10^2, 10^3, 10^4, 10^5, 10^6\}$. Table 5 reports the average running time per epoch, and we observe that the running time scales almost linearly with the exponential increase in observations in the tensor. This result is consistent with the analysis in Section 4.1.4.

6 CONCLUSION

In this paper, we present a tensor-based learning framework, iDisc, to perform common and discriminative pattern discovery at multiple levels for understanding of high-dimensional student behavior and performance prediction in MOOCs. We first use tensors to represent each user's behavior, and construct coupled tensors to aggregate behavior for users with contrasting performance groups. Then, we iteratively identify the shared and distinct behavioral patterns at various levels, while revealing the hierarchical relationship between them to further increase the interpretability of the output. Finally, we use these patterns as anchors to generate the students' latent representation for down-stream performance prediction. Our qualitative examination of the patterns has shown the multi-level, multi-aspect and hierarchical characteristics of behavior patterns on the edX platform. The quantitative experiments, compared to both traditional predictive methods as well as existing discriminative tensor factorization models, suggest promising results by iDisc in several datasets from different MOOC platforms.

To the best of our knowledge, this is the first attempt to tackle the joint problem of discriminant tensor factorization and hierarchical pattern discovery for understanding such behavior on MOOC platforms. This enables the in-depth comprehension of students' multi-way behavior dynamics, as well as its association with course performance. Nevertheless, one of the limitations is that it merely

provides the relationships between the latent multi-way interaction and the performance outcome, with no intention to draw causal reasoning between them. In practice, iDisc can be developed as a plugin for MOOC platforms, where instructors can examine the multi-aspect contrasting behavior and connect the difference to the course outcome. Considering the XueTangX platform, one of the multi-aspect patterns could refer to a set of events at the beginning of the course that trigger from the server. if iDisc reveals its positive association to the success of students' course end performance, this pattern can be used as guidance of promotions for both the instructor and the platform to improve the students' learning outcome. Last, but not least, compared to other tensor factorization methods, iDisc provides a more efficient exploration of the multi-aspect patterns due to its multi-level nature. However, we understand that the interpretation of the multi-aspect pattern itself is not straightforward in general. In our future work, we would like to follow a more human-centric approach and develop a visual analytic system that helps domain experts interpret and understand the multi-aspect patterns.

ABSTRACT

Recommender systems have to handle a highly non-stationary environment, due to users' fast changing interests over time. Traditional solutions have to periodically rebuild their models, despite high computational cost. But this still cannot empower them to automatically adjust to abrupt changes in trends caused by timely information. It is important to note that the changes of reward distributions caused by a non-stationary environment can also be *context dependent*. When the change is orthogonal to the given context, previously maintained models should be reused for better recommendation prediction.

In this work, we focus on contextual bandit algorithms for making adaptive recommendations. We capitalize on the unique context-dependent property of reward changes to conquer the challenging non-stationary environment for model update. In particular, we maintain a dynamic ensemble of contextual bandit models, where each bandit model's reward estimation quality is monitored regarding given context and possible environment changes. Only the admissible models to the current environment will be used for recommendation. We provide a rigorous upper regret bound analysis of our proposed algorithm. Extensive empirical evaluations on both synthetic and three real-world datasets confirmed the algorithm's advantage against existing non-stationary solutions that simply create new models whenever an environment change is detected.

1 INTRODUCTION

The overwhelming volume of online content make personalized recommendation an indispensable component in modern information service systems. Traditional solutions, including content-based filtering [17, 26], collaborative filtering [6, 30], and hybrid approaches [22], provide recommendations by leveraging users' interests as demonstrated in their past activities. However, in many practical applications, such as news recommendation, both content popularity and user interests evolve frequently over time, which make the traditional offline learning approaches incompetent [18].

In recent years, multi-armed bandits, and more specifically contextual bandits, have become a referenced online learning solution to deal with this dynamic nature of recommendations [1, 20, 27, 32, 33, 36, 37]. Contextual bandit solutions explore the unknowns by collecting users' feedback in real time to estimate the utility/reward of new content with available side-information or context information. They provide a principled way to find optimal trade-offs between exploration and exploitation [3, 4], and have been successfully deployed in many important practical scenarios [20, 23].

However, most existing contextual bandit algorithms assume a stationary environment [4, 20], where the expected reward on each arm is drawn from an unknown yet fixed reward mapping function based on the given context. This assumption, however, rarely holds in many real-world applications, where the underlying reward mapping undergoes slow or abrupt changes due to various factors. For example, Liu et al. [24] reported that readers' preferences over news articles shift with time and events in Google News. By analyzing more than 20,000 twitter users over a four-months period, Abel et al. [2] found that the interests of individual users into a topic evolve differently over time. More importantly, the duration during which users are interested in an event-like topic differs significantly among each other. In other words, users' interest change over time but the change is unknown beforehand.

In this work, we focus on the setting where there are unknown (to the learner) and abrupt changes in terms of user preferences. Between consecutive changes, the reward distribution remains stationary yet unknown, i.e., *piecewise stationary*. Existing bandit algorithms address such a dynamic environment by either introducing a forgetting mechanism to downweight historical observations [12, 15], or creating a bandit model for each newly detected stationary period [7, 14, 35, 38]. These strategies, nevertheless, failed to recognize an important property of this non-stationary environment: the changes of user interests can be *context dependent*. Even though one's interest could change frequently, his/her preference on a particular type of items might be stable over a longer period

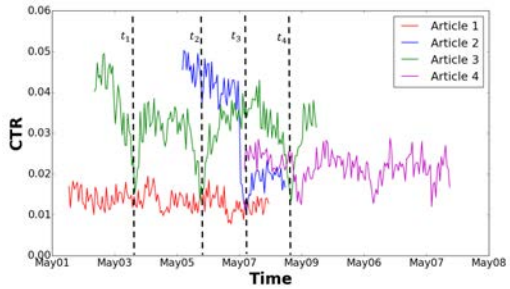

Figure 1: Real-time click-through-rate of four sample news articles collected from Yahoo user click log dataset [20, 21].

of time. For example, in the news recommendation scenario mentioned above, users' preferences over sports news may change with sport seasons. However, at the same time, their preferences over political news may stay stationary, independent of the sport season.

This phenomenon can be verified in Figure 1, where we collect real-time click-through-rate (CTR) of four sample news articles from the public Yahoo front-page user click log [20, 21] over a week's period. In the figure, each point denotes average CTR over 4000 log records. We can clearly observe the changes of user interest on article 2 at time t_3 and on article 3 at time t_1, t_2 and t_4 in this period. In the meanwhile, the CTR of article 1 and 4 remain quite stable, i.e., the expected reward for recommending these two articles remain unchanged. As a result, the experience recorded in old models can still be used to make accurate reward estimations for these two articles. On the contrary, strategies that discount observations or abandon the "old" models must regain confidence in their newly estimated parameters, which many lead to higher regret due to redundant explorations. The key is thus to recognize the reward change in a per-arm basis regarding the context.

To capitalize on such a unique property of the changing environment, we develop our contextual bandit algorithm that adapts its arm selection and model update strategy with regard to users' interest changes in a context-dependent manner. Our solution consists of a dynamic set of contextual bandit models, collectively referred to as *bandit experts*, which are maintained to estimate the underlying reward distribution. In the meanwhile, we monitor each bandit expert's reward estimation quality regarding specific context through another bandit model, referred to as *bandit auditors*. The auditor predicts whether a bandit expert is 'admissible' to a specific arm under the given context. At each round of interaction, an ensemble of admissible bandit experts is created to estimate the reward of each arm; and the arm with the highest upper confidence bound of estimated reward will be selected. The acquired feedback is used to update all admissible bandit experts for this chosen arm, and their corresponding auditors. When no admissible bandit expert exists, a new bandit expert will be created and added to the set before evaluating the recommendation candidates.

We rigorously prove a sublinear upper regret bound of our proposed algorithm, which guarantees that the number of sub-optimal recommendations from our algorithm reduces rapidly over time. We also show that if one fails to model the context dependent changes, a much worse upper regret bound is inevitable.Extensive empirical evaluations in one synthetic and three real-world datasets also confirmed the effectiveness of the proposed algorithm, especially in handling the changing popularity and user preferences in practice.

2 RELATED WORK

In this work, we focus on the stochastic setting of multi-armed bandit problems [29]. Under this setting, various exploration strategies have been proposed to conquer the exploit-explore dilemma, such as upper confidence bound [3, 4, 20], epoch greedy [19] and posterior sampling [9, 16]. However, most of these algorithms assume a static environment, which is often violated in practice. A number of bandit models hence have been proposed to deal with non-stationary environments, and there are mainly two types of environment changes studied: gradual changes and abrupt changes.

For gradual changes, Whittle [34] introduced the restless bandits, where the states of arms can change in each step according to a stochastic transition function. But this setting is notoriously intractable [5, 25, 31].

Our work concerns abrupt changes of environment, where most solutions only focus on context-free bandits. Hartland et al. [15], and Garivier and Moulines [12] proposed a γ-Restart algorithm and a discounted-UCB algorithm, in which a discount factor is introduced to exponentially decay the effect of past observations. Both algorithms need properly designed hyper-parameters, such as the discount factor. Yu and Mannor [38] proposed a windowed mean-shift detection algorithm to detect the changes in the environment. They assume that at each iteration, the agent can not only get feedback from the selected arms but also query a subset of arms for additional observations, which would be very expensive in practice. Raj and Kalyani proposed discounted Thompson Sampling in [28]. Recently Cao et al. [7] proposed a UCB based algorithm with change detection module to detect changes and restart exploration accordingly. Liu et al. [10] proposed to use cumulative sum and Page-Hinkley test to detect sudden changes in the environment. A sublinear upper regret bound is proved for a simplified Bernoulli bandit environment with a strong detectability assumption. All of the aforementioned solutions are non-contextual bandit solutions, which are incapable to leverage the rich side information in real-world applications.

Some recent works have realized the lack of contextual bandits in a non-stationary environment, and extended corresponding solutions. Hariri et al. [14] proposed a contextual Thompson sampling algorithm with a change detection module, which involves iteratively applying a combination of cumulative sum charts and bootstrapping to capture potential changes. But due to its empirical nature, no theoretical property is known about it. Wu et al. [35] developed a two-level hierarchical bandit algorithm, which detects and adapts to changes in the environment by maintaining a suite of contextual bandit models. Regret analysis is provided under a strong assumption about the change. However, to the best of our knowledge, among the existing non-stationary bandit solutions, no work utilizes the context dependent property of reward changes in a piece-wise stationary environment. Hence, none of them is able to exploit the existence of *context dependent changes*. Our algorithm

avoids the unnecessary penalties in regret incurred by indiscriminately dismissing existing bandit models and tries to reuse the existing models when judged 'admissible.'

3 METHODOLOGY

In this section, we first introduce our notations and assumptions about the non-stationary environment, then illustrate our proposed algorithm, followed with a rigorous regret bound analysis.

3.1 Problem Setups

In a multi-armed bandit problem, a learner sequentially selects an arm a_t from a candidate pool $\mathcal{A} = \{a_1, a_2, ..., a_k\}$ to interact with the environment, and receives the corresponding reward r_{a_t}. The goal of the learner is to maximize its accumulated reward over a finite time horizon T. In a stochastic contextual bandit setting, each candidate arm a is associated with a feature vector $\mathbf{x}_a$ (assume $\|\mathbf{x}_a\|_2 \leq 1$ without loss of generality), referred as context. The corresponding reward r_a is determined by the context vector and an underlying bandit parameter $\boldsymbol{\theta}^*$ (assume $\|\boldsymbol{\theta}^*\|_2 \leq 1$ without loss of generality). When applying to the recommendation scenario, the bandit parameter $\boldsymbol{\theta}^*$ can be interpreted as the underlying parameter that controls users' interests and $\mathbf{x}_a$ is the available context information about the candidate item a. Most existing contextual bandit algorithms consider $\boldsymbol{\theta}^*$ as constant over time [1, 20], which imposes a strong stationary assumption about the environment.

In this work, firstly, we relax this stationary assumption by allowing abrupt changes in $\boldsymbol{\theta}^*$: the ground-truth $\boldsymbol{\theta}^*$ changes arbitrarily at unknown time points, but remains constant between any two consecutive change points [12, 14, 15] as follows:

$$\underbrace{r_0, r_1, \cdots, r_{t_{c_1}-1}}_{\text{governed by } \boldsymbol{\theta}^*_{c_0}}, \underbrace{r_{t_{c_1}}, r_{t_{c_1}+1}, \cdots, r_{t_{c_2}-1}}_{\text{governed by } \boldsymbol{\theta}^*_{c_1}}, \cdots, \underbrace{r_{t_{c_{\Gamma_T}}}, r_{t_{c_{\Gamma_T}}+1}, \cdots, r_T}_{\text{governed by } \boldsymbol{\theta}^*_{c_{\Gamma_T}}}$$

where the change points $\{t_c\}_{c=c_1}^{c_{\Gamma_T}}$ and the corresponding bandit parameters $\{\boldsymbol{\theta}^*_c\}_{c=c_0}^{c_{\Gamma_T}}$ are unknown to the learner. We only assume there are at most Γ_T change points in the environment up to time T, with $\Gamma_T \ll T$. To simplify the discussion of our developed algorithm, a linear reward structure is postulated, but it can be readily extended to more complicated structures, such as generalized linear models [11]. Specifically, we have $r_{a,t} = \mathbf{x}_a^\intercal \boldsymbol{\theta}^*_t + \eta_t$, where η_t is Gaussian noise drawn from $N(0, \sigma^2)$.

Secondly, we capitalize on the unique property that in a contextual bandit setting the changes of reward distribution are context-dependent. Thus we categorize arms into two types, *change-invariant* and *change-sensitive*, between any two stationary periods. For stationary periods i and j with their ground-truth bandit parameters $\boldsymbol{\theta}^*_i$ and $\boldsymbol{\theta}^*_j$, the arm that satisfies $|\mathbf{x}_a^\intercal \boldsymbol{\theta}^*_i - \mathbf{x}_a^\intercal \boldsymbol{\theta}^*_j| \leq \Delta_L$ (with $\Delta_L > 0$) is referred as a change-invariant arm; otherwise as a change-sensitive arm. Δ_L is a parameter to introduce flexibility and accommodate stochastic noise, which relaxes the requirement that the change has to be completely orthogonal to the context vector of a change-invariant arm. This makes our problem setting more general than those in [10, 38]. An illustration of these two types of arms is provided in Figure 2: when the ground-truth bandit parameter changes from $\boldsymbol{\theta}^*_c$ to $\boldsymbol{\theta}^*_{c+1}$, although there are *change-sensitive arms*, for example arm a_1, whose expected reward changes

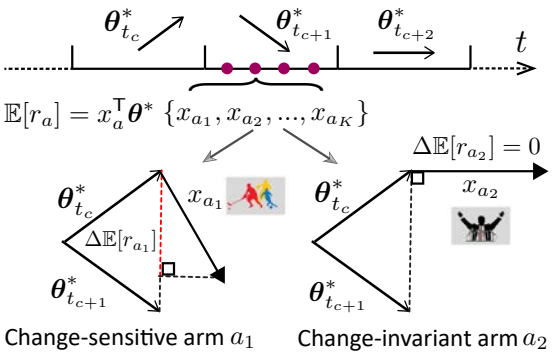

Figure 2: An illustrative example of context-dependent changes in a piecewise stationary environment. A linear reward assumption is postulated to simplify the illustration.

dramatically, there are also *change-invariant arms*, for example arm a_2, whose context vectors are orthogonal to the change, i.e., $\mathbf{x}_a^\intercal(\boldsymbol{\theta}^*_c - \boldsymbol{\theta}^*_{c+1}) = 0 < \Delta_L$, so that their expected reward does not change significantly even after the environment changes. For example, mapping it back to our previous news recommendation example, if the reward change in a user was caused by the change of sports season, the sports news and political news could be considered as the change-sensitive and change-invariant arms respectively for this user.

To differentiate the actual reward change from stochastic noise, we impose the following assumption about the non-stationary environment, which characterizes the detectability of reward changes between the stationary period i and j,

Assumption 1. *Among the change-sensitive arms between stationary period i and j, there are at least ρ portion of them satisfying $|\mathbf{x}_a^\intercal \boldsymbol{\theta}^*_i - \mathbf{x}_a^\intercal \boldsymbol{\theta}^*_j| > \Delta_H$.*

This assumption requires that between any two stationary periods, there are a number of change-sensitive arms undergo perceivable reward changes, which differentiate these two periods.

3.2 A Dynamic Ensemble of Bandits

In the non-stationary environment specified above, where the changes of users' interests occasionally happen at unknown time points, new bandit models should be rebuilt in accordance with the changes of underlying user interest. In addition, the possible existence of change-invariant arms urges us to reuse the bandit models estimated for those earlier periods, so that more accurate reward estimation on such arms can be achieved sooner so as to obtain reduced regret in a new stationary period.

In order to achieve these goals, three challenges have to be addressed: 1) as the changes of environment are unknown to the learner, how to detect the potential change of user interests and create new bandit models to account for the change-sensitive arms in a new environment? 2) as the reward changes in each arm are context-dependent, how to recognize the change-invariant arms at current period such that experience from old models can be fully utilized? and 3) which arm to choose given multiple bandit models might exist at the same time? To avoid any potential ambiguity in our later discussions, we refer to the contextual bandit models created for reward estimation as *bandit experts*.

We address the first two challenges by creating a companion bandit model for each bandit expert to monitor its reward estimation quality. We refer to this companion bandit model as a *bandit auditor*. In a nutshell, a bandit expert, who works with the context features and reward collected from its chosen arms, is responsible for reward estimation regarding its corresponding environment. Its companion bandit auditor works with the context features of the expert's choices and the observed prediction errors from the bandit expert. The auditor is responsible for assessing the expert's prediction accuracy. At each round, every bandit auditor evaluates whether the monitored bandit expert is *admissible* to make an accurate reward estimation for a given arm, with respect to potential environment changes. A bandit expert being identified as admissible to a particular arm indicates with a high probability that, either 1) no change has happened since the creation of this bandit expert, or 2) the environment has changed but the arm is change-invariant between this bandit expert's estimated reward distribution and the current period's underlying reward distribution. This addresses the second challenge. When no admissible bandit expert exists for a given arm, it is thus highly likely to be a change-sensitive arm in a new environment, and a new bandit expert is needed. This addresses the first challenge.

To address the third challenge, at each round of interaction, following the principle of optimism in the face of uncertainty [1, 20], an arm is chosen by the upper confidence bound of reward estimation based on an ensemble of all its admissible bandit experts. The acquired feedback for the selected arm/item is used to update all corresponding bandit experts and their auditors. We name the resulting bandit algorithm as Dynamic Ensemble of Bandit Experts, or DenBand in short. We describe DenBand in Algorithm 1 [1] and discuss the key components of it in details as follows.

Bandit Expert. Define t_m as the time when bandit expert m is created. Each bandit expert m maintains an estimated bandit parameter $\hat{\boldsymbol{\theta}}_t(m)$ for the stationary period at t_m. Define $\mathcal{I}_t^{\theta}(m)$ as a set of timestamps when observation $(\mathbf{x}_{a_i}, r_{a_i,i})$ is assigned to the bandit expert m for model update till time t (in line 24-25 of Algorithm 1). $r_{a_i,i}$ is the observed reward on arm a_i at time i. Because of our linear reward structure, $\hat{\boldsymbol{\theta}}_t(m)$ can be readily estimated by $\hat{\boldsymbol{\theta}}_t(m) = \mathbf{A}_t^{-1}(m)\mathbf{b}_t(m)$, in which $\mathbf{A}_t(m) = \lambda\mathbf{I} + \sum_{i\in\mathcal{I}_t^{\theta}(m)} \mathbf{x}_{a_i}\mathbf{x}_{a_i}^{\mathsf{T}}$, $\mathbf{I}$ is a $d \times d$ identity matrix, λ is the regularization coefficient in the least square regression, and $\mathbf{b}_t(m) = \sum_{i\in\mathcal{I}_t^{\theta}(m)} \mathbf{x}_{a_i} r_{a_i,i}$.

Bandit Auditor. Denote the reward estimation error of bandit expert m on arm a at time t as $e_{a,t}(m) = \hat{r}_{a,t}(m) - r_{a,t}$, in which $\hat{r}_{a,t}(m) = \mathbf{x}_a^{\mathsf{T}}\hat{\boldsymbol{\theta}}_t(m)$. We have $\mathbb{E}[e_{a,t}(m)] = \mathbf{x}_a^{\mathsf{T}}(\hat{\boldsymbol{\theta}}_t(m) - \boldsymbol{\theta}_t^*)$, which is referred as 'badness' of bandit expert m on arm a at time t and leads to a linear structure for badness estimation. We create a new bandit model with the target parameter for estimation as $\boldsymbol{\beta}_t^*(m) = \hat{\boldsymbol{\theta}}_t(m) - \boldsymbol{\theta}_t^*$, and refer to it as the bandit auditor of bandit expert m. We maintain and update the bandit auditors in a similar manner as that in bandit experts. Denote $\mathcal{I}_t^{\beta}(m)$ as a set of timestamps when observation $\left(\mathbf{x}_{a_i}, e_{a_i,i}(m)\right)$ is assigned to the bandit auditor for bandit expert m up to time t (line 21-23 in Algorithm 1). The bandit auditor estimates $\boldsymbol{\beta}_t^*(m)$ by $\hat{\boldsymbol{\beta}}_t(m) = \mathbf{C}_t^{-1}(m)\mathbf{d}_t(m)$, in which

Algorithm 1 Dynamic Ensemble of Bandit Experts (DenBand)

1: **Inputs:** $\alpha \in \mathbb{R}_+$, $\lambda > 0$, δ_1, $\delta_2 \in (0, 1)$, τ, Δ_L
2: **Initialize:** Create and initialize bandit expert m: $\mathbf{A}_1(m) = \lambda\mathbf{I}$, $\mathbf{b}_1(m) = \mathbf{0}$, $\hat{\boldsymbol{\theta}}_1(m) = \mathbf{0}$, and its auditor: $\mathbf{C}_1(m) = \lambda\mathbf{I}$, $\mathbf{d}_1(m) = \mathbf{0}$, $\hat{\boldsymbol{\beta}}_1(m) = \mathbf{0}$. Initialize the bandit expert set $\mathcal{M}_1 = \{m\}$
3: **for** $t = 1$ to T **do**
4: **for** $a \in \mathcal{A}_t$ **do**
5: Create an admissible model set for arm a: $\mathcal{M}_t^a = \emptyset$
6: **for** $m \in \mathcal{M}_t$ **do**
7: $\hat{e}_{a,t}(m) = \mathbf{x}_a^{\mathsf{T}}\hat{\boldsymbol{\beta}}_t(m)$
8: Compute $B_{a,t}^{\beta}(m)$ and $B_{a,t}^{\theta}(m)$ by Eq (1) and (2)
9: **if** $|\hat{e}_{a,t}(m)| < B_{a,t}^{\theta}(m) + B_{a,t}^{\beta}(m) + \Delta_L$ **then**
10: Add m into $\mathcal{M}_t^a$
11: **end if**
12: **end for**
13: **if** $|\mathcal{M}_t^a| = 0$ **then**
14: Create and initialize a new bandit expert m and its auditor as in Line 2; Add m to $\mathcal{M}_t^a$ and $\mathcal{M}_t$
15: **end if**
16: Compute $\text{UCB}_{a,t}$ of arm a with bandit experts in $\mathcal{M}_t^a$
17: **end for**
18: Select an arm by $a_t = \arg\max_{a\in\mathcal{A}} \text{UCB}_{a,t}$
19: Observe reward $r_{a_t,t}$
20: **for** $m \in \mathcal{M}_t^{a_t}$ **do**
21: $\hat{r}_{a_t,t}(m) = \mathbf{x}_{a_t}^{\mathsf{T}}\hat{\boldsymbol{\theta}}_t(m)$, $e_{a_t,t}(m) = \hat{r}_{a_t,t}(m) - r_{a_t,t}$
22: Update $\{e_{a_i,i}\}_{i\in\mathcal{I}_t^{\beta}(m)}$ according to $\hat{\boldsymbol{\theta}}_t(m)$, and keep the size of $\mathcal{I}_t^{\beta}(m)$ to τ
23: $\mathbf{C}_{t+1}(m) = \mathbf{C}_t(m) + \mathbf{x}_{a_t}\mathbf{x}_{a_t}^{\mathsf{T}}$, $\mathbf{d}_{t+1}(m) = \sum_{i\in\mathcal{I}_t^{\beta}(m)} \mathbf{x}_{a_i} e_{a_i,i}$
24: **if** $m \in \mathcal{M}_t^{a_t}$ and $|\hat{r}_{a_t,t}(m) - r_{a_t,t}| \le B_{a_t,t}^{\theta}(m) + \Delta_L + \epsilon$ **then**
25: $\mathbf{A}_{t+1}(m) = \mathbf{A}_t(m) + \mathbf{x}_{a_t}\mathbf{x}_{a_t}^{\mathsf{T}}$, $\mathbf{b}_{t+1}(m) = \mathbf{b}_t(m) + \mathbf{x}_{a_t} r_{a_t,t}$
26: **else**
27: $\mathbf{A}_{t+1}(m) = \mathbf{A}_t(m)$, $\mathbf{b}_{t+1}(m) = \mathbf{b}_t(m)$
28: **end if**
29: $\hat{\boldsymbol{\theta}}_{t+1}(m) = \mathbf{A}_{t+1}(m)^{-1}\mathbf{b}_{t+1}(m)$
30: $\hat{\boldsymbol{\beta}}_{t+1}(m) = \mathbf{C}_{t+1}(m)^{-1}\mathbf{d}_{t+1}(m)$
31: **end for**
32: **end for**

$\mathbf{C}_t(m) = \lambda\mathbf{I} + \sum_{i\in\mathcal{I}_t^{\beta}(m)} \mathbf{x}_{a_i}\mathbf{x}_{a_i}^{\mathsf{T}}$ and $\mathbf{d}_t(m) = \sum_{i\in\mathcal{I}_t^{\beta}(m)} \mathbf{x}_{a_i} e_{a_i,i}(m)$. Intuitively, the bandit auditor for expert m evaluates whether an arm a at time t is change-invariant to the reward distributions specified by $\boldsymbol{\theta}_t^*$ and $\boldsymbol{\theta}_{t_m}^*$. The definition of badness requires us to update $e_{a,t}(m)$ of all observations in $\mathcal{I}_t^{\beta}(m)$ whenever $\hat{\boldsymbol{\theta}}_t(m)$ is updated or $\boldsymbol{\theta}_t^*$ is changed. But as the environment change is unknown to the learner, this update is infeasible. We decide to only accumulate the most recent τ observations in $\mathcal{I}_t^{\beta}(m)$ for auditor update, and prove this still provides us a high probability bound of each bandit auditor's badness estimation in our regret analysis,

$$|\hat{e}_{a,t}(m) - \mathbb{E}[e_{a,t}(m)]| \le B_{a,t}^{\beta}(m) \tag{1}$$

where $B_{a,t}^{\beta}(m) = \left(\sigma^2\sqrt{d\ln(\frac{\lambda+|\mathcal{I}_t^{\beta}(m)|}{\lambda\delta_2})} + \sqrt{\lambda}\right)\|\mathbf{x}_a\|_{\mathbf{C}_t^{-1}(m)}$.

Bandit Expert Selection. Based on Eq (1) and our badness definition, we have $|\hat{e}_{a,t}(m)| \le \mathbb{E}[e_{a,t}(m)] + B_{a,t}^{\beta}(m) \le |\mathbf{x}_a^{\mathsf{T}}\hat{\boldsymbol{\theta}}_t(m) - \mathbf{x}_a^{\mathsf{T}}\boldsymbol{\theta}_{t_m}^*| + |\mathbf{x}_a^{\mathsf{T}}\boldsymbol{\theta}_{t_m}^* - \mathbf{x}_a^{\mathsf{T}}\boldsymbol{\theta}_t^*| + B_{a,t}^{\beta}(m)$. The first part on the right-hand

side of this inequality is the reward estimation quality of bandit expert m, which can be bounded by,

$$|\mathbf{x}_a\hat{\boldsymbol{\theta}}_t(m) - \mathbf{x}_a\boldsymbol{\theta}^*_{t_m}| \leq B^{\theta}_{a,t}(m,a) \tag{2}$$

where $B^{\theta}_{a,t}(m,a) = \left(3\sigma^2\sqrt{d\ln(\frac{\lambda+|\mathcal{I}^{\theta}_t(m)|}{\lambda\delta_1})} + \sqrt{\lambda}\right)\|\mathbf{x}_a\|_{\mathbf{A}^{-1}_t(m)}$. We should note that this bound is different from those for classical linear bandit algorithms (e.g., [1]), since it also has to account for the possible contamination from change-invariant arms (as we do not restrict Δ_L to zero). The second part on the right-hand side can be bounded by Δ_L, if no change has happened since t_m or the arm a is change-invariant between t_m and t. As a result, the condition $|\hat{e}_{a,t}(m)| < B^{\theta}_{a,t}(m) + B^{\beta}_{a,t}(m) + \Delta_L$ in line 9 of Algorithm 1 determines if the bandit expert m is admissible to arm a at time t (supported by Lemma 1 and 2 in Section 3.3). When there is no admissible bandit expert for arm a, a new bandit expert needs to be created to account for the detected change of environment (line 13-15 in Algorithm 1).

Arm Selection. We appeal to the Upper Confidence Bound (UCB) principle [1, 20] to select an arm from the candidate arm pool (line 18 of Algorithm 1). With the above bandit expert selection strategy, for arm a at time t, we might collect a set of admissible bandit experts $\mathcal{M}^a_t$, and each admissible bandit expert m gives us an upper confidence bound of reward estimation for arm a: $\text{UCB}_{a,t}(m) = \mathbf{x}^{\intercal}_a\hat{\boldsymbol{\theta}}_t(m) + B^{\theta}_{a,t}(m)$. Therefore, we need to integrate $\text{UCB}_{a,t}(m)$ from multiple bandit experts (line 16 of Algorithm 1). We propose two strategies for this purpose, each of which has its own advantages; but both of them lead to the same upper regret bound (proved in Theorem 2 of Section 3.3).

Option 1: Average ensemble. For each arm, as in principle every admissible bandit expert is 'legitimate' to give a reward prediction for this arm, we compute an average upper confidence bound of reward based on all admissible expert models: $\text{UCB}_{a,t} = \frac{1}{|\mathcal{M}^a_t|}\sum_{m\in\mathcal{M}^a_t}\text{UCB}_{a,t}(m)$. This ensemble helps reduce variance in reward estimation among the admissible bandit experts, but might be disturbed by some least qualified bandit experts.

Option 2: Lower confidence bound of badness. Although every admissible bandit expert is guaranteed to have small enough badness to make an accurate reward prediction on the chosen arm, the uncertainty of their auditors' badness estimation may differ, which introduces another level of trade-off between exploitation and exploration in bandit expert selection. By applying the Lower Confidence Bound (LCB) principle (as we want to minimize the badness of chosen bandit experts), we select a bandit expert from $\mathcal{M}^a_t$ by the LCB of its auditor's estimated badness: $\tilde{m}_{a,t} = \arg\min_{m\in\mathcal{M}^a_t}\left(|\hat{e}_{a,t}(m)| - B^{\beta}_{a,t}(m)\right)$, and compute the UCB of arm a using the selected bandit expert $\tilde{m}_{a,t}$.

Model Update. Once the feedback $(\mathbf{x}_{a_t}, r_{a_t})$ is obtained from the environment on the selected arm a_t, we update the bandit experts and auditors in this arm's admissible model set (line 20-31 in Algorithm 1). In particular, we compare the acquired feedback against each bandit expert's estimation (line 24) to decide whether we should update the bandit expert to improve its reward estimation or the bandit auditor to improve its badness estimation. This decision comes from two factors that cause the observed reward estimation error: 1) large noise from the environment; 2) the arm is actually not change-invariant. Large noise may happen, but with a very small probability, as it follows a Gaussian distribution. Define $\epsilon = \sqrt{2}\sigma\text{erf}^{-1}(\delta_1 - 1)$, in which σ is the standard deviation of the Gaussian noise in reward feedback, and $\text{erf}(\cdot)$ is the Gauss error function. Violating the condition $|\hat{r}_{a,t}(m) - r_{a,t}| \leq B^{\theta}_{a,t}(m) + \Delta_L + \epsilon$ suggests that the chosen arm might not be change-invariant, such that the bandit expert should not be updated but the bandit auditor should be. This selective update strategy helps reduce erroneous observations in both bandit experts and auditors.

3.3 Regret Analysis

The accumulated (pseudo) regret of a bandit algorithm up to time T is formally defined as $R(T) = \sum_{t=1}^{T}(\mathbb{E}[r_{a^*_t,t}] - \mathbb{E}[r_{a_t,t}])$, in which a^*_t is the best arm according to the oracle at time t, and a_t is the arm selected by the algorithm to be evaluated. We first provide high probability bounds of bandit experts' reward estimation and bandit auditor's badness estimation in the following theorem.

Theorem 1 (Confidence Bounds). *We define S_{min} as the length of the shortest stationary period up to time T and $t_c(m)$ as the first change point in the environment after bandit expert m is created. When Assumption 1 is satisfied with $\Delta_H > 4\sqrt{\lambda} + \Delta_L$ and $\Delta_L \leq \frac{\sigma^2\sqrt{d\lambda\ln\frac{\lambda+T}{\lambda\delta_1}}}{T}$, and $1 < \tau \leq S_{min}\frac{\sigma^2\sqrt{d\lambda\ln\frac{\lambda+T}{\lambda\delta_1}}}{2\rho T}$, at time t for any $\delta_1 \in (0,1)$, $\delta_2 \in (0,1)$ and $\delta_3 = 1-(1-\delta_1)\left[(1-\delta_2)(1-\delta_1)\rho\right]^{\max\{t-t_c(m),0\}}$, with a probability at least $1-\delta_3$, for any arm a all the bandit experts in Algorithm 1 satisfy,*

$$|\mathbf{x}^{\intercal}_a\hat{\boldsymbol{\theta}}_t(m) - \mathbf{x}^{\intercal}_a\boldsymbol{\theta}^*_{t_m}| \leq B^{\theta}_{a,t}(m,a) \tag{3}$$

If there is no environment change in the past τ iterations, with a probability at least $1-\delta_2$, all bandit auditors at time t satisfy,

$$|\mathbf{x}^{\intercal}_a\hat{\boldsymbol{\beta}}_t(m) - \mathbf{x}^{\intercal}_a\boldsymbol{\beta}^*_t| \leq B^{\beta}_{a,t}(m,a) \tag{4}$$

And with a probability at least $1-\delta_3$, all the selected bandit experts in $\mathcal{M}^a_t$ for arm a satisfy,

$$|\mathbf{x}^{\intercal}_a\hat{\boldsymbol{\theta}}_t(m) - \mathbf{x}^{\intercal}_a\boldsymbol{\theta}^*_t| \leq \Delta_L + B^{\theta}_{a,t}(m) \tag{5}$$

This theorem specifies the threshold of minimum reward change for change-sensitive arms, i.e., Δ_H, which decides whether a change is detectable by our algorithm. We can further relax the threshold to $2B^{\theta}_{a,t}(m) + 2B^{\beta}_{a,t}(m) + \Delta_L$, which is shrinking over time and related to the current model uncertainties of the bandit expert and auditor. This would allow us to recognize more subtle reward changes across different stationary periods so as to improve the model estimation quality on the fly. On the other hand, Δ_L is the threshold deciding whether an arm is change-invariant with respect to two stationary periods. It is thus the resolution of our bandit experts in recognizing the ground-truth bandit parameters of their designated periods. Note, Δ_L is a parameter of the environment, rather than a parameter of our model. The parameter τ determines the number of most recent observations used for estimating the bandit auditors. Although a larger τ naturally leads to better badness estimation quality in the auditors, it cannot be arbitrarily large as it brings in out-of-date observations to the auditors. Theorem 1 imposes an upper bound of τ to guide practical use of our algorithm. Proofs this this theorem can be found in Appendix 7.1.

In the following two lemmas, we bound the probability of false negative and false positive selection of bandit experts, which proves the validity of our designed bandit expert selection strategy.

Lemma 1. *A false negative selection happens when the bandit expert m is not selected in its designated period or for the truly change-invariant arms to it in other periods. Denote the probability of a false negative selection as P_{FN}. At time t, we have $P_{FN} = \mathbb{P}\big(|\hat{e}_{a,t}(m)| > B^{\theta}_{a,t}(m) + B^{\beta}_{a,t}(m) + \Delta_L \,\big|\, |\mathbf{x}_a^\top \boldsymbol{\theta}^*_t - \mathbf{x}_a^\top \boldsymbol{\theta}^*_{t_m}| \le \Delta_L\big) \le (1-\delta_2)(1-\delta_3)$, in which δ_2 and δ_3 are defined in Theorem 1.*

Lemma 2. *A false positive selection happens when the environment has changed and the current arm is change-sensitive to a particular bandit expert m, but the bandit expert is mistakenly selected. Denote the probability of a false negative selection as P_{FP}. When Assumption 1 holds and $\Delta_H > 4\sqrt{\lambda} + \Delta_L$, we have at time $t > t_c(m)$, $P_{FP} = \mathbb{P}\big(|\hat{e}_{a,t}(m)| \le B^{\theta}_{a,t}(m) + B^{\beta}_{a,t}(m) + \Delta_L \,\big|\, |\mathbf{x}_a^\top \boldsymbol{\theta}^*_t - \mathbf{x}_a^\top \boldsymbol{\theta}^*_{t_m}| > \Delta_L\big) \le 1 - \big((1-\delta_1)(1-\delta_2)\rho\big)^{t-t_c(m)}$, in which δ_1 and δ_2 are defined in Theorem 1.*

Intuitively, a false negative selection of bandit experts happens when both the reward and badness estimations on a change-invariant arm exceed their confidence bounds; and a false positive selection happens when a change-sensitive arm undergoes substantial reward change but both the expert's reward estimation and the auditor's badness estimation still stay within their confidence bounds. Putting all these analyses together, we have the following regret bound for our proposed algorithm.

Theorem 2 (Regret bound of DenBand). *Under the same condition as stated in Theorem 1, and $(\delta_2 + \delta_3 - \delta_2\delta_3) \le \frac{1}{2S_{max}}$, using any bandit expert in $\mathcal{M}^a_t$ for UCB-based arm selection guarantees that with a probability at least $(1-\delta_3)(1-\delta_2)$ the expected accumulated regret of DenBand up to time T can be bounded as,*

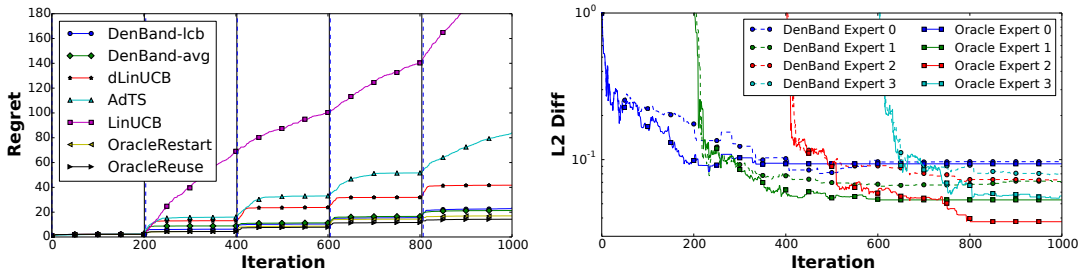
$$R(T) \le 2\Gamma_T\Big(3\sigma^2\sqrt{d\ln\frac{\lambda+U_T}{\lambda\delta_1}} + \sqrt{\lambda}\Big)\sqrt{S_{max}d\ln(\lambda + \frac{S_{max}}{d})} + (\frac{1}{\rho}+2)\sigma^2\sqrt{d\lambda\ln\frac{\lambda+T}{\lambda\delta_1}}$$

where S_{max} is the length of the longest stationary period up to time T, Γ_T is the total number of environment changes till T, and $U_T = \max\{|\mathcal{I}^{\theta}_T(m)|\}_{m\in\mathcal{M}_T}$.

U_T is the maximum number of updates taken among any of the bandit experts; and it is clearly smaller than T. Hence the accumulated regret is in the order of $O(\Gamma_T\sqrt{S_{\max}\ln T\ln S_{\max}})$, which is arguably a very tight upper regret bound without any further assumption about the environment. Detailed proof and interpretation of Theorem 2 can be found in Appendix 7.2.

Theorem 2 provides a general upper regret bound of our DenBand in the order of $O(\Gamma_T\sqrt{S_{\max}\ln T\ln S_{\max}})$. To better interpret this upper regret bound under different circumstances, we consider the following two special environment cases. **Case 1:** When the changes are evenly (or almost evenly) distributed, i.e., $S_{\max} = S = \frac{T}{\Gamma_T}$, the resulting regret bound can be rewritten as $O(\sqrt{\Gamma_T T}\ln T)$, which matches the general lower regret bound in an abruptly changing environment proved in [12] without further assumptions about the environment. **Case 2:** When the distribution of changes are highly unbalanced such that there is a single very long stationary period and many very short stationary periods, by denoting the short periods with a superscript 's', the final upper regret bound can be rewritten as $O(\sqrt{S_{\max}\ln T\ln S_{\max}} + \Gamma_T\sqrt{S^s_{\max}\ln T\ln S^s_{\max}})$ where $S^s_{\max} \ll S_{\max}$. For example, when $S^s_{\max} \ll \frac{S_{\max}}{\Gamma_T^2}$, the regret can be further upper bounded by $O(\sqrt{S_{\max}\ln T\ln S_{\max}})$, which matches and is better than the upper regret bound of running a single contextual bandit over the whole period (as $S_{\max} < T$).

Our regret analysis in those two special cases supports the validity of DenBand, and we can further generalize our analysis of it under other reward assumptions. In particular, our theoretical analysis supports that any contextual bandit algorithm can be used as a bandit expert in DenBand, as long as its reward estimation error is bounded with a high probability, which corresponds to $B^{\theta}_t(m,a)$ in Eq (3). The overall regret of DenBand will only be a factor of the actual number of changes in the environment, which is arguably inevitable without further assumptions about the environment.



4 EXPERIMENTS

We tested DenBand on a comprehensive set of evaluation datasets, which include a synthetic dataset and three real-world recommendation datasets. On all datasets, we compared against the following bandit baselines: LinUCB [20], a reference stationary linear contextual bandit algorithm; dLinUCB [35], AdTS [14], WMDUCB1 [38], and Meta-Bandit [15], which are state-of-the-art bandit algorithms for piece-wise stationary environment. For DenBand, we tested two variants of it: DenBand-lcb, which uses lower confidence bound of badness to select a bandit expert, and DenBand-avg, which takes the average reward UCBs from all admissible bandit experts.

4.1 Experiments on Synthetic Dataset

• **Simulation Settings.** In simulation, we generate a size-K (K = 1000) arm pool $\mathcal{A}$, in which each arm a is associated with a d-dimensional (d = 10) feature vector $\mathbf{x}_a \in \mathbb{R}^d$ with $\|\mathbf{x}_a\|_2 \le 1$. Similarly, we create a set of ground-truth bandit parameters $\boldsymbol{\theta}^* \in \mathbb{R}^d$ with $\|\boldsymbol{\theta}^*\|_2 \le 1$, which are not disclosed to the learners. The standard deviation of Gaussian noise σ on the reward is set to 0.05 by default. To simulate an abruptly changing environment, after every S rounds, we randomize $\boldsymbol{\theta}^*$ with respect to the constraint that at least ρ portion of arms in $\mathcal{A}$ satisfy $|\mathbf{x}_a^\top\boldsymbol{\theta}^*_{t_{c_j}} - \mathbf{x}_a^\top\boldsymbol{\theta}^*_{t_{c_{j+1}}}| > \Delta_H$. And by default, we set S to 200, Δ_H to 0.7, and ρ to 0.2.

• **Empirical Regret Comparisons.** Under this simulation setting, we execute all algorithms 1000 iterations and report their accumulated regret in Figure 3 (a). Because LinUCB imposes a stationary assumption about the environment, it suffers almost linearly increasing regret after the first change point. Both AdTS and dLinUCB can react to the environment changes, but they are slow in doing so and thus accumulate increasing regret. Both of our proposed algorithms, DenBand-lcb and DenBand-avg, can quickly identify the changes and create corresponding bandit experts to capture the new reward distributions. The solid and dashed vertical lines in Figure 3 (a) show the actual and detected change points by DenBand-lcb respectively. We can clearly notice that DenBand can almost immediately respond to the changes in the environment. To improve visibility of Figure 3 (a), WMDUCB and Meta-Bandit are excluded.

In addition, we also include two oracle algorithms in Figure 3 (a). One is to start a new bandit expert at each change point and only uses it in this period, named as *OracleRestart*. The other, named as *OracleReuse*, maintains one bandit expert for each stationary period, and uses all ground-truth reusable experts for reward estimation in change-invariant arms. DenBand performs very closely to such optimal algorithms, although it does not get access to the ground-truth environment changes. Figure 3 (b) shows the parameter estimation quality (i.e., the L2 difference between the estimated parameter and the ground truth parameter) for four dynamically created bandit experts in DenBand-lcb. For comparison, we also include the estimation quality of experts from the OracleReuse algorithm. The good estimation quality of each bandit expert in DenBand further verifies our conclusion in Theorem 1 about the confidence bound of admissible bandit experts' estimation quality.

• **Sensitivity to Environment Settings.** According to our regret analysis, the performance of DenBand depends on the environment settings: including standard deviation σ in the Gaussian noise, length S of stationary period, proportion ρ of change-sensitive arms, and magnitude Δ_H of reward change. We varied them in simulation to investigate their influence on the algorithms. We ran all algorithms for 10 times and reported the mean and standard derivation of obtained accumulated regret in Table 1. DenBand consistently achieved the best performance against all baselines in all environment settings. As expected, a larger noise level σ leads to worse regret in almost all algorithms. Since T is fixed in our simulation, a smaller S leads to a larger Γ_T, which linearly scales DenBand's regret. When Δ_H becomes smaller, the regret of the two variants of DenBand and AdTS are further reduced. This is because once Δ_H satisfies the requirement in Theorem 1, the change can be confidently detected; and in the meanwhile, because of a smaller Δ_H, the added regret from using a false-positive bandit expert becomes smaller. Lastly, ρ does not seriously affect the performance of DenBand, which indicates that the algorithm is robust to ρ as long as Assumption 1 is satisfied.

• **Sensitivity to Hyper-Parameters.** To verify the robustness of our proposed algorithm, we studied the effect of two important hyper-parameters in Table 2: τ, whic determines the number of most recent observations used in bandit auditors, and Δ_L, which introduces flexibility and accounts for the existence of change-invariant arms with infinitesimal reward shift. As a comparison, we also studied the effect of τ on dLinUCB and AdTS, which also use a sliding window for change detection. From Table 2 we can find that both variants of DenBand are robust to its parameter τ as long as it falls into the required range. This result verified our theoretical analysis about the role of τ in Theorem 1, which defines an upper and lower bound of τ for the proved confidence bound. On the contrary, the baselines, especially AdTS, are very sensitive to the setting of τ. For the parameter Δ_L, DenBand-lcb is very robust to it, but DenBand-avg is not. This can be explained from two perspectives: 1). As Δ_L accounts for the existence of change-invariant arms with infinitesimal reward shift, it should be upper bounded as required in Theorem 1. 2). When Δ_L is set too large, inadmissible bandit experts may be mistakenly selected. In this

(d) Effect of τ on Snapchat dataset

Figure 4: Effect of hyper-parameters on DenBand on two real-world datasets

case, DenBand-avg suffers from a contaminated average ensemble of bandit experts in reward prediction. DenBand-lcb reduces the risk by selecting a bandit expert by its lower confidence bound of estimated badness.

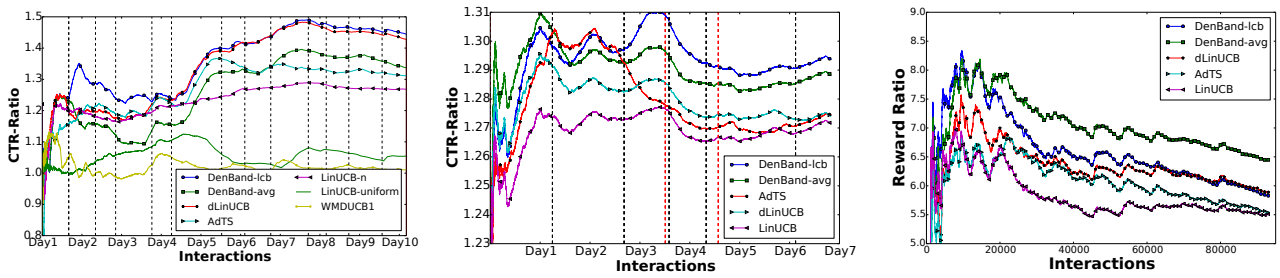
4.2 Experiments on Real-World Datasets

• **Datasets.** We tested all algorithms on the following three real-world recommendation datasets.

The first dataset is a large collection of Yahoo frontpage recommendation log, made available by the Yahoo Webscope program [20]. It contains 45,811,883 user visits to Yahoo Today Module in a ten-day period in May 2009. Unbiased offline evaluation is performed on this dataset following the offline evaluation protocol used in [20, 21].

The second dataset is a user click log collected from the Snapchat lens recommendation platform over a one-week period. This dataset contains hundred millions of anonymous observations related to 495 unique lenses and more than five hundred thousand randomly selected users. Each observation contains an anonymous user id, a lens id which is recommended by the logging policy, and corresponding user actions on this lens. Each lens is associated with an 8-dimensional feature vector constructed by historical click statistics. The sharing-related actions on items are considered as positive user click feedback. Due to the sparsity of observations, users are grouped into 22 groups according to their demographic information, and estimate one bandit model in each user group. The same offline evaluation protocol is used here as in the Yahoo news recommendation dataset.

The third data is extracted from the music streaming service Last.fm, which is made available on the HetRec 2011 workshop [2]. This dataset contains 1892 users and 17632 items (artists). We treat the 'listened artists' in each user as positive feedback. Following the settings in [8, 32, 36], we pre-processed the dataset in order to fit them into a contextual bandit setting. And we followed [15, 35] to simulate a non-stationary environment: we ordered observations chronologically inside each user, and built a single hybrid user by merging different users. Hence, the boundary between two consecutive batches of observations from two original users is treated as the preference change of the hybrid user.



• **Sensitivity of Hyper-Parameters.** To test the proposed algorithms' sensitivity to hyper-parameters and identify the best hyper-parameter setting, we perform parameter tuning using one day's data from yahoo dataset and two days' data from Snapchat dataset. We vary Δ_L and τ, and report the relative performance improvement compared with LinUCB in Figure 4. From Figure 4 (a) and (c), we notice that DenBand-lcb is very robust to the setting of Δ_L, while the performance of DenBand-avg can be bad when Δ_L is too large. As discussed in our study of hyper-parameters in Section 4.1, the reason is that for a larger Δ_L, DenBand is more likely to include false positive models as admissible bandit experts. In this case, the reward estimation quality may become inaccurate in DenBand-avg, which evenly trust all admissible experts' output. As for τ, in Figure 4 (b) and (d) we observed that AdTS is very sensitive to the choice of τ, while both variants of DenBand are quite robust to it as long as it is within a reasonable range.

• **Recommendation Quality** In Figure 5 (a), we report normalized Click-Through Rate (CTR) from different algorithms based on the corresponding logged random strategy's CTR on the Yahoo dataset. We set τ to 2,000 and Δ_L to 0.3 based on the hyper-parameter tuning results. From Figure 5 (a), we can find that DenBand-lcb achieves significant improvement compared with all baselines, especially at the beginning of the testing period. WMDUCB1 performs the worst as it cannot utilize any available context information. We also looked into the detected change points by DenBand-lcb, and found that it detected 25 changes in total, and we plotted 12 of them in Figure 5 (a) using vertical lines (to increase visibility of the figure). We can find close correspondence between its detected change points and its performance improvement.

Using the same evaluation protocol, we report the CTR ratio between different algorithms and the logging policy on Snap dataset in Figure 5 (b). We set τ to 500 and Δ_L to 0.1. On this dataset, the context-free algorithms perform significantly worse than the contextual ones, so that we excluded them from the comparisons. The results show that our algorithms achieve a 29% - 31% improvement comparing to the logging policy, and a 3.1% improvement against LinUCB in a per-user basis. Comparing to AdTS, although our proposed algorithm performs similarly at the beginning, it caught up very quickly later. We plot the detected change points for two largest groups of users (users in the same group share the same set of bandit experts) in Figure 5 (b) using vertical lines of different colors, which well correlate with performance improvement during the adaptive recommendation process.

The ratio between reward from the bandit algorithms and that from a random selection policy on LastFM dataset is reported in Figure 5 (c), where Δ_L is set to 0.1 and τ is set to 300. From this result, we can see that DenBand, especially DenBand-avg outperform all

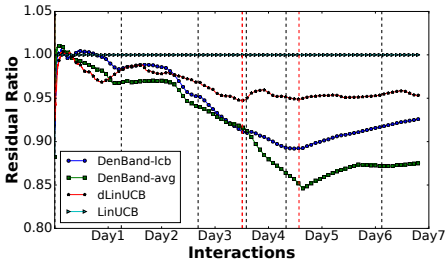

Figure 6: Residual ratio on Snapchat dataset

the baselines. LinUCB performs the worst as it failed to capture the non-stationarity of the environment. Since the distribution of items is highly skewed [8], the context-free bandits perform very poorly on this dataset. We therefore decide to exclude them from comparison in the figure.

• **Reward estimation quality and qualitative study.** In order to investigate the effectiveness of DenBand in reward estimation and illustrate the source of its performance improvement, we looked into its reward prediction error on the selected items on Snapchat dataset. In Figure 6, we normalize the accumulated residuals (i.e., reward prediction error) from different algorithms by that from LinUCB. It shows that both variants of DenBand have smaller reward estimation error on the selected items. In addition, we illustrate the detected change points for the two largest user groups using vertical lines. The detected changes correlate well with the turning points of residual ratio in DenBand. For example, at the first and last detected change points, the residual ratio is increasing, which indicates that the old bandit model is becoming bad; and thus new bandit experts are created to account for the new environment.

To reveal how DenBand recognizes the changes of users' interests in a context-dependent manner, we looked into the high reward items, change-invariant items, and change-sensitive items according to our sequentially created bandit experts and their corresponding auditors on the LastFM dataset. For each bandit expert and auditor pair, we used the learnt models in the bandit expert to get the top 500 high reward items, and used its auditor to get the top 500 change-invariant items and top 500 change-sensitive items separately. As each item is associated with some short text descriptions provided by the users, we then generated word clouds for each group of those selected items to summarize the learnt bandit models in Figure 7. It is interesting to find that the change-invariant items tend to be related with geographical regions. For example, the change-invariant items in group 1 are mostly about Brazilian

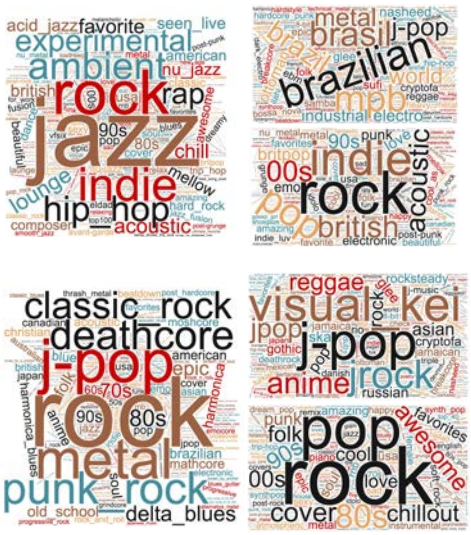

Figure 7: Word cloud visualization of two bandit experts and their auditors on LastFM. In each of the word cloud groups, the left one shows the tags from high reward items selected by the bandit expert; the upper right one shows tags from change-invariant items, and the lower right one shows tags collected from change-sensitive items according to the bandit auditor, respectively.

music, and those in group 2 are related to Japanese music. The change-sensitive items are mostly related to those more common genres of music. And the high reward items are a mix of these two types. Hence recognizing the changing and stable users' interest is essential in making satisfactory recommendations.

5 CONCLUSIONS & FUTURE WORK

We studied contextual bandits for adaptive recommendation in a piece-wise stationary environment. Capitalizing on the context-dependent property of environment changes, bandit models are dynamically ensembled and reused to conquer the non-stationary environment. Rigorous regret analysis validates the convergence of the proposed solution, and extensive empirical evaluations on simulation and three large real-world datasets verified the effectiveness and reliability of the proposed algorithm.

In this work, we treat bandit learners as independent from each other. As existing works have shed light on collaborative bandit

learning [13], it is meaningful to study non-stationary bandits in a collaborative manner, e.g., monitoring the change and reusing models across users. It is also important to study a continuously changing environment, such as Brownian motion or periodical changes, where the context-dependent changes help us better maintain and create bandit models.

7 APPENDIX

7.1 Proof of Theorem 1

Proof of Eq (3)**:** For the bandit expert m created at time t_m, we split its training instances in $\mathcal{I}_t^\theta(m)$ up to time t into two sets $\mathcal{H}_t(m)$ and $\tilde{\mathcal{H}}_t(m)$. The instances in $\mathcal{H}_t(m)$ are all from the reward distribution governed by $\boldsymbol{\theta}^*_{t_m}$, while the instances in $\tilde{\mathcal{H}}_t(m)$ are not. According to the first order optimum condition in ridge regression and the definition of $\mathbf{A}_t(m)$, the following equation can be obtained,

$$\hat{\boldsymbol{\theta}}_t(m) - \boldsymbol{\theta}^*_{t_m} = \mathbf{A}_t^{-1}\Big(\sum_{i\in\mathcal{I}_t^\theta(m)} \mathbf{x}_i\eta_i - \lambda\boldsymbol{\theta}^*_{t_m} - \sum_{i\in\tilde{\mathcal{H}}_t(m)} \mathbf{x}_i\mathbf{x}_i^\intercal(\boldsymbol{\theta}^*_{t_m} - \boldsymbol{\theta}^*_i)\Big)$$

Based on the self-normalized martingale bound in Theorem 1 of [1], for any $\delta_1 \in (0,1)$, with a probability at least $1-\delta_1$, we have

$$\|\hat{\boldsymbol{\theta}}_t(m) - \boldsymbol{\theta}^*_{t_m}\|_{\mathbf{A}_t} \le \sigma^2\sqrt{d\ln\frac{\lambda+|\mathcal{I}_t^\theta(m)|}{\lambda\delta_1}} + \sqrt{\lambda} + \|\sum_{i\in\tilde{\mathcal{H}}_t(m)} \mathbf{x}_i\mathbf{x}_i^\intercal(\boldsymbol{\theta}^*_t - \boldsymbol{\theta}^*_i)\|_{\mathbf{A}_t^{-1}}$$

To simplify notations, we define $F_t(m) = \sum_{i\in\tilde{\mathcal{H}}_t(m)} \mathbf{x}_i\mathbf{x}_i^\intercal(\boldsymbol{\theta}^*_t - \boldsymbol{\theta}^*_i)$. Then we have,

$$\begin{aligned}|\mathbf{x}_a^\intercal\hat{\boldsymbol{\theta}}_t(m) - \mathbf{x}_a^\intercal\boldsymbol{\theta}^*_{t_m}| &\le \|\hat{\boldsymbol{\theta}}_t(m) - \boldsymbol{\theta}^*_{t_m}\|_{\mathbf{A}_t}\|\mathbf{x}_{a_t}\|_{\mathbf{A}_t^{-1}} \qquad (6)\\ &\le \Big(\sigma^2\sqrt{d\ln\frac{\lambda+|\mathcal{I}_t^\theta(m)|}{\lambda\delta_1}} + \sqrt{\lambda} + \|F_t(m)\|_{\mathbf{A}_t^{-1}}\Big)\|\mathbf{x}_{a_t}\|_{\mathbf{A}_t^{-1}}\end{aligned}$$

According to the definition of $F_t(m)$ and $\tilde{H}_t(m)$, $F_t(m)$ can be understood as a form of contamination in bandit expert m's estimation of the ground-truth bandit parameter $\boldsymbol{\theta}^*_{t_m}$. Denote $t_c(m)$ as the time index of the first change point after the bandit expert m is created. When $t > t_c(m)$, essentially, the contamination in $F_t(m)$ comes from two sources: First, erroneous updates from change-sensitive arms, which is referred as false positive selection of bandit experts. In Lemma 2, we proved that with a high probability there will not be any false positive selection up to time t when the auditor's estimation is not contaminated (best case scenario). But we may have additional erroneous updates when the auditor's observations contain change-sensitive arms collected after the change points. Therefore, the possible erroneous updates are at most $2\frac{(t-t_m)}{S_{\min}}\tau$. This also explains why the sliding observation window τ of the bandit auditors cannot be arbitrarily large when we explained in the requirement of this Theorem. The second source of error is the small contamination from change-invariant arms, which can be bounded by $\big(t - t_c(m)\big)\Delta_L$, due to the fact that for change-invariant arms $|\mathbf{x}_a^\intercal(\boldsymbol{\theta}^*_{t_m} - \boldsymbol{\theta}^*_i)| \le \Delta_L$. As a result, we have $F_t(m) \le 2\frac{t-t_m}{S_{\min}}\tau\rho + \big(t - t_c(m)\big)\Delta_L$. Thus when $\Delta_L \le \frac{\sigma^2\sqrt{d\lambda\ln\frac{\lambda+|\mathcal{I}_t^\theta(m)|}{\lambda\delta_1}}}{t-t_c(m)}$ and $\tau \le S_{\min}\frac{\sigma^2\sqrt{d\lambda\ln\frac{\lambda+|\mathcal{I}_t^\theta(m)|}{\lambda\delta_1}}}{2\rho(t-t_m)}$, we have $\|F_t(m)\|_{\mathbf{A}_t^{-1}} \le 2\sigma^2\sqrt{d\ln\frac{\lambda+|\mathcal{I}_t^\theta(m)|}{\lambda\delta_1}}$. Substituting this inequaity into Eq (6) concludes the proof.

Proof of Eq (4)**:** The training instances for $\hat{\boldsymbol{\beta}}_t(m)$ are determined by the bandit expert's estimation about the ground-truth reward distribution in the environment. Every time when $\hat{\boldsymbol{\theta}}_t(m)$ gets updated, we will revise the historical training instances in $\hat{\boldsymbol{\beta}}_t(m)$, i.e., compute $e_{a,t}(m)$ by the updated reward estimation. In addition, the bandit auditors only accumulate badness observations in the most recent τ interactions. When there is no environment change in this time window, Eq (4) can be easily derived based on [1]. For the case in which there is environment change among the τ observations, wrong selection and update of bandit experts may happen but the number is relatively small, since the number of mistakes is at most τ in each stationary period. The effect of these mistakes will be taken into account in both the bandit expert's reward estimation and the final regret in Theorem 2.

Proof of Eq (5)**:** When $t \le t_c(m)$, Eq (5) is equivalent to Eq (3). When $t > t_c(m)$, we have $|\mathbf{x}_a^\intercal\hat{\boldsymbol{\theta}}_t(m) - \mathbf{x}_a^\intercal\boldsymbol{\theta}^*_t| \le |\mathbf{x}_a^\intercal\hat{\boldsymbol{\theta}}_t(m) - \mathbf{x}_a^\intercal\boldsymbol{\theta}^*_{t_m}| + |\mathbf{x}_a^\intercal\boldsymbol{\theta}^*_{t_m} - \mathbf{x}_a^\intercal\boldsymbol{\theta}^*_t|$, in which the first term can be bounded by $B^\theta_{a,t}(m)$ according to Eq (3). With Lemma 2, when the bandit expert m is selected for arm a, with a high probability the arm is change-invariant, which means that $|\mathbf{x}_a^\intercal\boldsymbol{\theta}^*_{t_m} - \mathbf{x}_a^\intercal\boldsymbol{\theta}^*_t| \le \Delta_L$. Putting them together concludes the proof.

7.2 Proof of Theorem 2

Proof of Theorem 2. According to the reward confidence bound proved in Eq (5) of Theorem 1, and the UCB arm selection strategy in Algorithm 1, the regret at time t can be upper bounded by,

$$\begin{aligned}\mathbb{E}[r_{a^*_t,t}] - \mathbb{E}[r_{a_t,t}] &\le \mathbf{x}_{a_t}\hat{\boldsymbol{\theta}}_t(m_{a_t,t}) + B^\theta_{t,a_t}(m_{a_t,t}) + \Delta_L - \mathbf{x}_{a_t}\boldsymbol{\theta}^*_t\\ &\le 2\Delta_L + 2B^\theta_{t,a_t}(m_{a_t,t}) \qquad (7)\end{aligned}$$

Combining with the additional regret caused by the events when a bandit auditor's most recent τ observations contain environment changes, the cumulative regret can be upper bounded by $R(T) \le 2\Gamma_T\tau + 2T\Delta_L + \sum_{m\in\mathcal{M}_T}\sum_{i\in\Omega_m} 2B^\theta_{i,a_i}(m)$, in which Ω_m is the set of time indices when the bandit expert m is used for arm selection up to time T. According to the proof of Theorem 3 in [1], we have,

$$\sum_{i\in\Omega_m} B^\theta_{i,a_i}(m) \le \Big(3\sigma^2\sqrt{d\ln\frac{\lambda+|\mathcal{I}_T^\theta(m)|}{\lambda\delta_1}} + \sqrt{\lambda}\Big)\sqrt{|\Omega_m|d\ln(\lambda + \frac{|\Omega_m|}{d})}$$

Since $\sum_{i\in\Omega_m} 2B^\theta_{a_i,i}(m)$ is a concave function with respect to $|\Omega_m|$, according to the Jensen's inequality $\sum_{m\in\mathcal{M}_T}\sum_{i\in\Omega_m} 2B^\theta_{i,a_i}(m) \le |\mathcal{M}_T|\Big(3\sigma^2\sqrt{d\ln\frac{\lambda+U_T}{\lambda\delta_1}} + \sqrt{\lambda}\Big)\sqrt{S_{\max}d\ln(\lambda + \frac{S_{\max}}{d})}$, in which $U_T = \max\{|\mathcal{I}_T^\theta(m)|\}_{m\in\mathcal{M}_T}$.

Regarding to the number of bandit experts in $\mathcal{M}_T$: denote the possible number of false negative detection as k_{FN}, which follows a binomial distribution $B(T, P_{FN})$. According to Lemma 1 and the tail bound of Binomial distribution, it can be proved that with a high probability, $|\mathcal{M}_T| \le \Gamma_T + k_{FN} \le \Gamma_T + 1$. Combining all the

conclusions above we have,

$$R(T) \leq 2\Gamma_T \tau + 2T\Delta_L + \sum_{m \in \mathcal{M}_T} \sum_{i \in \mathcal{S}_m} 2B^{\theta}_{i,a_i}(m) \leq (\frac{1}{\rho} + 2)\sigma^2 \sqrt{d\lambda \ln \frac{\lambda + T}{\lambda \delta_1}}$$

$$+ (\Gamma_T + 1)\Big(3\sigma^2 \sqrt{d \ln \frac{\lambda + U_T}{\lambda \delta_1}} + \sqrt{\lambda}\Big) \sqrt{S_T d \ln(\lambda + \frac{S_T}{d})}$$

which finishes the proof. □

Proofs of Lemma 1 and Lemma 2 are omitted here due to space limit. They will be provided in a longer version of this paper.

ABSTRACT

Social recommendation leverages social information to solve data sparsity and cold-start problems in traditional collaborative filtering methods. However, most existing models assume that social effects from friend users are static and under the forms of constant weights or fixed constraints. To relax this strong assumption, in this paper, we propose *dual graph attention networks* to collaboratively learn representations for two-fold social effects, where one is modeled by a user-specific attention weight and the other is modeled by a dynamic and context-aware attention weight. We also extend the social effects in user domain to item domain, so that information from related items can be leveraged to further alleviate the data sparsity problem. Furthermore, considering that different social effects in two domains could interact with each other and jointly influence users' preferences for items, we propose a new policy-based fusion strategy based on *contextual multi-armed bandit* to weigh interactions of various social effects. Experiments on one benchmark dataset and a commercial dataset verify the efficacy of the key components in our model. The results show that our model achieves great improvement for recommendation accuracy compared with other state-of-the-art social recommendation methods.

1 INTRODUCTION

Recommender systems, which aim at filtering and suggesting items of potential interests to targeted users, have extensive applications and can bring up a huge amount of commercial benefits, especially when the information overload problem has been pervasive with the rapid development of the World Wide Web. Conventional collaborative filtering (CF) methods for recommendation suffer from data sparsity and cold start problems. To this end, social recommendation, which attempts to leverage the social networks of users to incorporate more useful information, has been proposed to alleviate these two problems [5, 12, 19, 20].

Prior Works and Limitations. Nowadays, there are many composite platforms which integrate item recommendation and social network services (SNS). Users on these platforms can click on or

rate items as well as interact with their friends. A user's preference for one item could be impacted by her friends, which motivates us to probe into such social effect to improve recommendation quality. Previous studies for social recommendation attempt to model social effects in various ways, such as by trust propagation [5, 12, 22], regularization loss [20, 33, 40], matrix factorization [8, 18, 38], network embedding [17, 34], causal inference [16, 32], and graph neural network [36, 41].

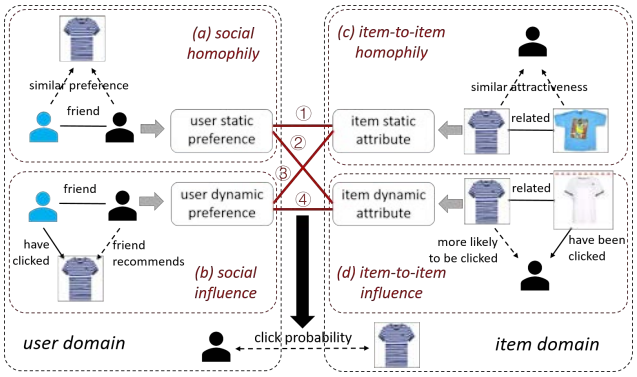

Figure 1: Illustration of the two-fold social effects, i.e., homophily effect and influence effect, in user social networks as well as among related items. The four social effects jointly affect a user's decision on one item. In this paper, we aim to build an unfied model to represent and weigh four effects given different user-item pairs.

However, these studies share several common limitations. **First**, most studies assume that linked users all share similar preferences. This assumption cannot suit well contemporary SNS since there could be various types of online friends, such as close friends, casual friends, and event friends [44]. Therefore, directly equating friendship on an SNS with preference similarity may not be sound. **Second**, most works model friends' influences statically under the forms of constant weights or fixed constraints. This assumption ignores the dynamic pattern of social effects. In fact, users could be influenced by a specific group of friends when it comes to specific items, which makes the social effect dynamic and dependent of specific contexts. **Third**, previous methods lack interpretability for social effects, i.e., they cannot explicitly indicate how a user's preference for one item is influenced by their friends.

Motivations and Rationales. In the real world, people's decisions could be influenced by various factors, and their behaviors are often the results of multifaceted causes. To this end, we probe into four different social effects in recommender systems, including two-fold effects in user domain and the other symmetric two-fold ones in item domain, as illustrated in Fig. 1. In user domain, friends could influence each other in two ways. For one thing, users tend to possess similar preferences to their friends, which is called as *social homophily* [24] (Fig. 1.(a)). Social homophily often leads to intrinsic effect for user preference which stays unchanged and independent of external contexts. For another, a user's friend who has purchased one item may recommend it to that user who then may be more likely to click such item, which is termed as *social influence* [21] (Fig. 1.(b)). Actually, social influence contributes to behavior-level effect for user preference which may change dynamically with specific contexts. *For example, a commercial analyst may be influenced by different communities of friends when it comes to an entertainment article or a commercial news.* Therefore, we can distinguish two components that may impact a user's preference: a static effect from social homophily and a dynamic effect from social influence[1], and we call corresponding user's preference as static and dynamic preference, respectively (left part of Fig. 1).

Moreover, in item domain, there exist analogous 'social effects'. For one thing, some related items tend to possess similar attractiveness when exposed to users. We term this as *item-to-item homophily*, and call the component of an item attribute affected by such effect as static attribute (Fig. 1.(c)). For another, if one item is popular among a certain community, then other related items would become more likely to be clicked by users in this social group. Such phenomenon can be termed as *item-to-item influence*, which depends on specific contexts (Fig. 1.(d)). *For example, a businessman and a researcher both read one article talking about the development of AI, but the businessman would prefer another article about financial information of AI companies, while the researcher would tend to click on another article about cutting-edge breakthroughs in AI.* We call the component of an item attribute affected by such effect as dynamic attribute. Finally, as shown by ①~④ in Fig. 1, the two-fold social effects in both user domain and item domain may jointly influence a user's decision on one item. Such phenomenon is pervasive on Epinion, Twitter, Facebook, and Netflix, etc.

Methodologies and Results. To these ends, in this paper, we propose *DANSER (Dual graph Attention Networks for modeling multifaceted Social Effects in Recommender systems)*, a novel architecture that extends graph attention networks (GAT) [31]. DANSER is composed of two dual GATs: one dual GAT for users—including a GAT to capture social homophily and a GAT to capture social influence—and the other dual GAT for items. Specifically, in user domain, one GAT to capture social homophily attentively aggregates adjacent users' embedding that reflects ones' preferences, and outputs representations for static user preference. Another GAT to capture social influence aims at convolution on adjacent users' context-aware preferences, which characterize relevance of users' rated items to candidate item, and outputs representations for dynamic user preference. In item domain, two analogous GATs as a dual architecture are designed to model items' static and dynamic attributes under effects of item-to-item homophily and influence, respectively, among related items. Such dual mechanism possesses two advantages: i) GATs to capture homophily and influence could collaboratively model two-fold social effects, taking advantage of both global and local views to investigate user-item interactions; ii) two GATs in item domain incorporate information from related items, which could further alleviate data sparsity problem.

Then, since user static (resp. dynamic) preference as well as item static (resp. dynamic) attribute could jointly affect a user's decision on one item (shown by ①~④ in Fig. 1) and the importance of these four interactions would vary for distinct user-item pairs, we propose a policy-based strategy to dynamically weigh the four interactions. Specifically, we model the problem as a contextual

[1]Previous studies tend to interchangeably use social homophily and social influence. In this paper, we discriminate these two notions to better investigate the dynamic social effect.

multi-armed bandit [1], and treat the weighing strategy as a policy conditional on the context (the targeted user-item pair). Then our goal is to optimize a reward (w.r.t predicted loss). For model training, we use stochastic policy gradient to update our neural network-based policy unit, and design a local-graph aware regularization technique to reduce computational cost for regularization. To verify our model, we conduct experiments on one benchmark datasets from *Epinions* and a commercial dataset from *WeChat Top Story*. The results show that DANSER outperforms state-of-the-art models under both explicit feedback settings (2.9% MAE improvement) and implicit feedback settings (4.5% AUC improvement).

Our contributions can be summarized as follows:

i) **General Aspects:** We distinguish the social homophily and social influence notions in view of static and dynamic effects. Also, we extend the two-fold social effects in user domain to item domain, and therefore investigate four social effects in recommender systems. These general aspects enable the model to capture more information and improve its capacity.

ii) **Novel Methodologies:** We propose DANSER with two dual GATs and a policy-based fusion unit. The dual GATs can collaboratively model four social effects in both user and item domains, while the policy unit, based on a contextual multi-armed bandit, dynamically weighs four interactions of social effects in two domains according to specific contexts.

iii) **Multifaceted Experiments:** We deploy DANSER on one benchmark dataset and a commercial dataset. The experiment results verify the superiority of DANSER over state-of-the-art techniques, the effectiveness of the proposed components, as well as its good interpretability for modeling social effects.

2 PRELIMINARY AND BACKGROUND

In this paper, we consider a user-item interaction matrix $\mathbf{R} = \{r_{ui}\}_{M\times N}$, where M and N are numbers of users and items respectively. For a recommender system with *implicit* feedback, $\mathbf{R}$ consists of 0 and 1, where $r_{ui} = 1$ if user u has clicked item i, and $r_{ui} = 0$ otherwise. For a recommender system with *explicit* feedback, r_{ui} represents the rating value given by user u on item i (In Epinions, rating values range from 1 to 5 and user could give a high rating if she likes the item), and $r_{ui} = 0$ if user u has not rated item i. We use $R_I(u)$ and $R_U(i)$ to respectively denote the set of items rated by user u and the set of users who have rated item i. Moreover, we assume the existence of a trust or friendship network for users, which is a graph $G_U = (V_U, E_U)$ where V_U is the set of users and E_U is the set of edges that connect two users. We use $F_U(u)$ to denote the set of nodes adjacent to u in G_U. Also, we consider interaction frequencies between user u and user v as edge features, denoted by $\mathbf{e}_{uv} \in \mathbb{R}^C$, where each element in $\mathbf{e}_{uv}$ denotes the frequency of one-type interaction between u and v, and C is the number of interaction types. The edge features reflect link strengths between two users.

Problem Formulation. The social recommendation problem can be defined as [28]: given observed interaction records in $\mathbf{R}$ and trust relationship G_U, we are to estimate unobserved interactions in $\mathbf{R}$, i.e., the probability of a targeted user u^+ clicking an unobserved candidate item i^+ (for implicit feedback) or the rating value user u^+ will score item i^+ (for explicit feedback).

3 METHODOLOGIES

We first introduce the model framework. For each part, we start from the motivations and intuitions, and then introduce the technical details. Secondly, we present some training techniques to improve the model performance. Finally, we discuss two key units in our model for justification.

3.1 Model Framework

Fig. 2 provides an overview of DANSER. We will go into the details of each part in order.

Raw Input and Item Implicit Network. The model requires user-item interaction matrix R and user social network G_U as input. Social recommendation methods focus on leveraging the user social network to solve the data sparsity problem in recommender systems. Most existing methods treat items independently since there is no prior information that explicitly expresses the relationship between items. One way to calculate the similarity or relevance between two items is by the common users who clicked or rated them [26]. For any item i and item j, we define their similarity coefficient s_{ij} as the number of users who clicked both items. These coefficients induce an equivalence relation over items as follows: item i is related to item j if $s_{ij} > \tau$ with τ a fixed threshold. We define the item implicit network as the graph $G_I = (V_I, E_I)$ where V_I is the set of items and E_I is the set of edges that connects two related items.

Embedding Layer. The raw input of each user (resp. item) is a one-hot vector with high dimension, and the embedding operation is to project each user to a low-dimensional representation. Inspired by [15] and [2], each user can be represented by a user-specific embedding and the items rated by her. The former representation reflects user's interests while the latter one (called *item-based user embedding*) captures implicit influence of her rated history on current decision. Such embedding could deal with false-negative samples and improve model accuracy [15]. Similarly, each item can be represented by an item-specific embedding and the users who rated it (called *user-based item embedding*).

For the user-specific embedding, we define $\mathbf{P} = \{\mathbf{p}_u\}_{D\times M}$, where D is the embedding dimension and $\mathbf{p}_u$ denotes the embedding vector for user u. For the item-based user embedding, we define another embedding lookup $\mathbf{Y} = \{\mathbf{y}_i\}_{D\times N}$, where $\mathbf{y}_i$ denotes the item latent factor. Then each item in $R_I(u)$ will be mapped via $\mathbf{Y}$ and outputs $\mathcal{Y}_u = \{\mathbf{y}_j | j \in R_I(u)\}$, which will be used to compute the item-based user embedding, a D-dimensional vector representation, in the next layer. The user embeddings reflect a user's inherent preference (the 'inherent' notion emphasizes that it contains no social information and only depends on the user oneself). Similarly, for the item-specific embedding, we define $\mathbf{Q} = \{\mathbf{q}_i\}_{D\times N}$, where $\mathbf{q}_i$ denotes the embedding vector for item i. For user-based item embedding, we define $\mathbf{X} = \{\mathbf{x}_u\}_{D\times M}$, where $\mathbf{x}_u$ is user latent factor, and each user in $R_U(i)$ will be mapped via $\mathbf{X}$ and outputs $\mathcal{X}_i = \{\mathbf{x}_v | v \in R_U(i)\}$, which will be used to compute user-based item embedding, a D-dimensional vector representation, in the next layer. Also, the item embeddings reflect item's inherent attribute.

Dual GCN/GAT Layer. Graph convolution network (GCN) [14] conducts local convolutional operation over neighbor nodes in graph and outputs a new representation for each node, in order to encode the graph structure information as low-dimensional node

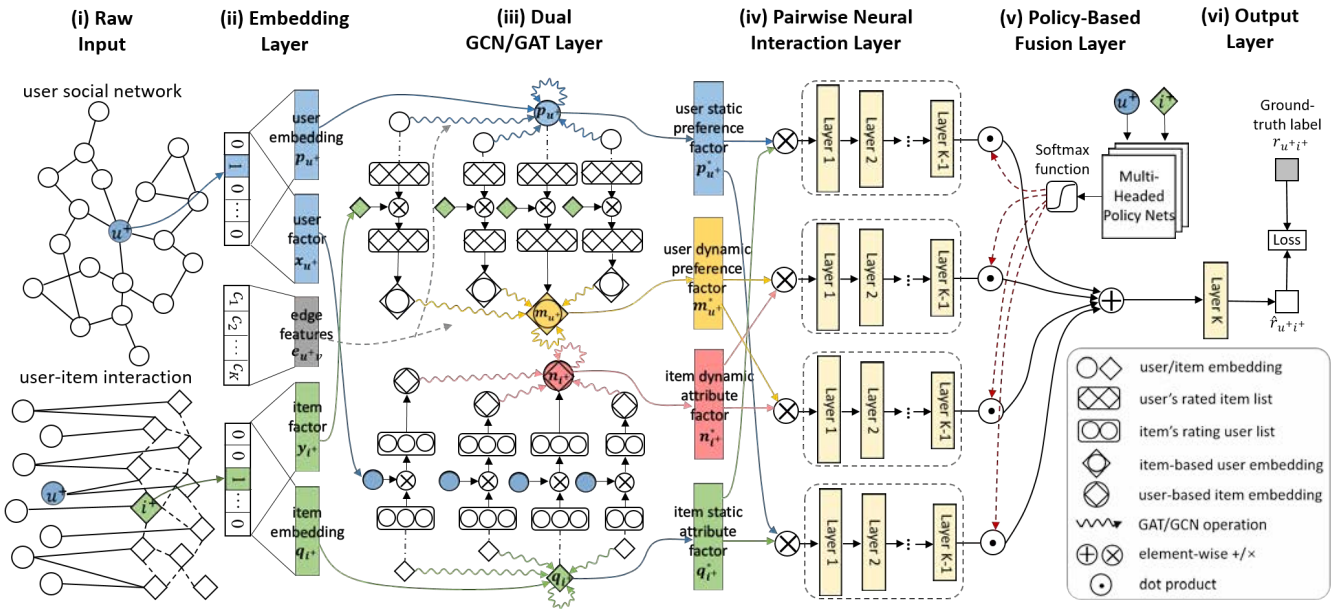

Figure 2: DANSER framework. Blue circles denote a targeted user u^+ while green rhombuses denote a candidate item i^+. i) The model requires user-item interaction records and user social network as raw input. We use common users who rate both items to calculate the item-item relevance and link the related items to form an item implicit network (the dotted lines between items). ii) In the embedding layer, we represent one user (resp. item) as a low-dimensional embedding vector and a latent factor. Besides, interaction frequencies between users are used as edge features. iii) In the dual GCN/GAT layer, four different graph attention networks are to capture the two two-fold social effects, where the upper (resp. lower) two of them output representations for user (resp. item) static and dynamic preferences (resp. attributes) under the effect of homophily and influence, respectively. iv) These four deep factors will be pairwisely combined as four interacted features, which are then fed into four independent neural networks to obtain more condensed representations. v) Then a policy net with the input of item i^+'s and user u^+'s embeddings as context information outputs weights for four interacted features, which will be aggregated as one synthetic vector. vi) Finally, the synthetic vector is input into the output layer to give the final predicted score $\hat{r}_{u^+i^+}$.

representations. Such operation can be viewed as an extension of convolution neural network (CNN) from a grid structure to general graphs. GCN equally aggregates the neighbors' embedding in each convolution and treats each neighbor nodes with equal importance. In contrast, Graph Attention Network (GAT) [31] leverages attention mechanism to consider different weights from neighbor nodes, which enables the model to filter out noises and focus on important adjacent nodes.

In order to exploit user social network G_U and item implicit network G_I, we propose dual graph attention networks, an extension of GCN/GAT as a means to non-linearly aggregate the embeddings of the neighbor nodes in both networks, so that the social effects from friends and related items can propagate to adjacent nodes through the graphs. As discussed in Section 1, we can distinguish two types of social effects for users (resp. items) in social recommender systems: *homophily* effect and *influence* effect. They jointly affect user preferences and item attributes in different ways. DANSER uses two dual GATs to collaboratively learn different deep representations for user static/dynamic preference and item static/dynamic attribute.

I. GAT to capture social homophily (marked as blue in Fig. 2). Firstly, via user embedding, we have $\mathbf{P}$ as representation of inherent user preference factor. Then the GCN/GAT operation could output a new representation, the user static preference factor $\mathbf{P}^*$, by

$$\mathbf{P}^* = \sigma(\mathbf{A}_P(G_U)\mathbf{P}\mathbf{W}_P^T + \mathbf{b}_P), \tag{1}$$

where $\sigma, \mathbf{W_P}, \mathbf{b_P}$ are activation function, weight matrix, bias vector respectively, and $\mathbf{P}^*$ is the updated representation of users, which incorporates social information by using the attention weights $\mathbf{A_P(G_U)} = \{\alpha^P_{uv}\}_{M\times M}$ obtained from G_U. Its elements are defined as follows:

$$\alpha^P_{uv} = \frac{attn_U(\mathbf{W}_P\mathbf{p}_u, \mathbf{W}_P\mathbf{p}_v, \mathbf{W}_E\mathbf{e}_{uv})}{\sum_{w\in\Gamma_U(u)} attn_U(\mathbf{W}_P\mathbf{p}_u, \mathbf{W}_P\mathbf{p}_w, \mathbf{W}_E\mathbf{e}_{uv})}, v \in \Gamma_U(u),$$

where $\mathbf{W}_E$ is weight matrix, $\Gamma_U(u) = \{u\} \cup F(u)$, $attn_U(x, y, z) = LeakyReLu(\mathbf{w}_U^T z \otimes (x||y))$, and $\mathbf{w}_U$ is weight vector. Here $\otimes$ and $||$ denote the element-wise product and concatenation, respectively. Note that the above GAT weight α^P_{uv} remains unchanged given user u and v, which means factor matrix $\mathbf{P}^*$ is fixed for users. This design conforms to the intuition that social homophily contributes to static effect for user's preference, this is why we call it static preference factor.

II. GAT to capture social influence (marked as yellow in Fig. 2). In contrast to social homophily, social influence effect is often context-aware, and the model needs to output different attention weights for friends w.r.t different candidate items. Through the embedding layer, we have $\mathcal{Y}_u$ as the embedding of the items clicked by user

u. Then we let each item clicked by user u interact with candidate item i^+,

$$\mathcal{Y}_u^{i^+} = \{\mathbf{y}_j \otimes \mathbf{y}_{i^+} | j \in R_I(u)\}.$$

This product operation can help to focus on the candidate item and model dynamic social influence under a specific context. We define the item-based user embedding $\mathbf{M}_{i^+} = \{\mathbf{m}_u^{i^+}\}_{D\times M}$, which depends on candidate item i^+ with max pooling to select the most dominating features for D dimensions:

$$m_{ud}^{i^+} = \max_{j\in R_I(u)} \{y_{jd} \cdot y_{i^+d}\} \quad \forall d = 1, \ldots, D$$

where $m_{ud}^{i^+}$, y_{i^+d}, and y_{jd} are the d-th feature of $\mathbf{m}_u^{i^+}$, $\mathbf{y}_{i^+}$, $\mathbf{y}_j$ respectively. The max pooling operation can help to focus on the most important value and alleviate noises in users' clicked history. The item-based embedding $\mathbf{m}_u^{i^+}$ includes two information: i) user u's context-aware preference (w.r.t candidate item i^+), and ii) inherent representation for u (independent of social information). In order to define the user dynamic preference factor $\mathbf{M}_{i^+}^*$, we proceed to incorporate the social information from friend users,

$$\mathbf{M}_{i^+}^* = \sigma(\mathbf{A}_M(G_U)\mathbf{M}\mathbf{W}_M^T + \mathbf{b}_M), \mathbf{A}_M(G_U) = \{\alpha_{uv,i^+}^M\}_{M\times M},$$

$$\alpha_{uv,i^+}^M = \frac{attn_U(\mathbf{W}_M\mathbf{m}_u^{i^+}, \mathbf{W}_M\mathbf{m}_v^{i^+}, \mathbf{W}_E\mathbf{e}_{uv})}{\sum_{w\in\Gamma_U(u)} attn_U(\mathbf{W}_M\mathbf{m}_u^{i^+}, \mathbf{W}_M\mathbf{m}_w^{i^+}, \mathbf{W}_E\mathbf{e}_{uv})},$$

for $v \in \Gamma_U(u)$. Note that the above attention weight α_{uv,i^+}^M depends on the user's history of rated items as well as specific candidate item i^+, which indicates that factor matrix $\mathbf{M}_{i^+}^*$ would change dynamically with different contexts. This design conforms to the intuition that social influence contributes to context-aware effect for a user's preference, so we term it as dynamic preference factor.

III. GAT to capture item-to-item homophily (marked as green in Fig. 2). Similarly, we use the item embedding $\mathbf{Q}$ as representation of inherent item attribute factor, and then leverage GAT to incorporate social information,

$$\mathbf{Q}^* = \sigma(\mathbf{A}_Q(G_I)\mathbf{Q}\mathbf{W}_Q^T + \mathbf{b}_Q), \mathbf{A}_Q(G_I) = \{\alpha_{ij}^Q\}_{N\times N},$$

$$\alpha_{ij}^Q = \frac{attn_I(\mathbf{W}_Q\mathbf{q}_i, \mathbf{W}_Q\mathbf{q}_j)}{\sum_{k\in\Gamma_I(i)} attn_I(\mathbf{W}_Q\mathbf{q}_i, \mathbf{W}_Q\mathbf{q}_k)}, j \in \Gamma_I(i),$$

where $attn_I(x, y) = LeakyRelu(\mathbf{w}_I^T(x||y))$, and $\mathbf{w}_I$ is a weight vector. The GAT weight α_{ij}^Q remains unchanged given item i and j. Correspondingly, item-to-item homophily contributes to static effect for item's attribute, and we call it static attribute factor.

IV. *GAT to capture item-to-item influence (marked as red in Fig. 2).* We now model item-to-item influence, which is context-aware and depends on the specific targeted user. Hence, our model needs to output different attention weights for distinct related items w.r.t different targeted users. Similarly to social influence, the user-based item representation $N_{u^+} = (n_i^{u^+})_{D\times N}$ for a given targeted user u^+ can be defined as follows:

$$\mathcal{X}_i^{u^+} = \{\mathbf{x}_v \otimes \mathbf{x}_{u^+} | v \in R_I(i)\},$$

$$n_{id}^{u^+} = \max_{v\in R_U(i)} \{x_{vd} \cdot x_{u^+d}\} \quad \forall d = 1, \ldots, D,$$

where $n_{id}^{u^+}$, x_{u^+d}, and x_{vd} are the d-th feature of $\mathbf{n}_i^{u^+}$, $\mathbf{x}_{u^+}$, $\mathbf{x}_v$ respectively. Then the representation for item dynamic attribute $\mathbf{N}_{u^+}^*$ can be computed as follows:

$$\mathbf{N}_{u^+}^* = \sigma(\mathbf{A}_N(G_U)\mathbf{N}_{u^+}\mathbf{W}_N^T + \mathbf{b}_N), \mathbf{A}_N(G_U) = \{\alpha_{ij,u^+}^N\}_{N\times N},$$

$$\alpha_{ij,u^+}^N = \frac{attn(\mathbf{W}_N\mathbf{n}_i^{u^+}, \mathbf{W}_N\mathbf{n}_j^{u^+})}{\sum_{k\in\Gamma_I(i)} attn(\mathbf{W}_N\mathbf{n}_i^{u^+}, \mathbf{W}_N\mathbf{n}_k^{u^+})}, j \in \Gamma_I(i).$$

Pairwise Neural Interaction Layer. Since user's decision on one item often depends on both user preference and item attribute, we can let two preference factors and two attribute factors pairwisely interact with each other. Then we borrow the idea from [11], feeding the four results into different neural networks indexed by $a \in \{1, 2, 3, 4\}$:

$$\mathbf{s}_a = \phi_K^a(\cdots\phi_2^a(\phi_1^a(\mathbf{z}_0[a]))),$$
$$\phi_k^a(\mathbf{z}_{k-1}) = tanh(\mathbf{W}_k^a\mathbf{z}_{k-1}^a + \mathbf{b}_k^a), k \in [1, K-1],$$
$$\mathbf{z}_0 = [\mathbf{p}_u^* \oplus \mathbf{q}_i^*, \mathbf{p}_u^* \oplus \mathbf{n}_i^*, \mathbf{m}_u^* \oplus \mathbf{q}_i^*, \mathbf{m}_u^* \oplus \mathbf{n}_i^*],$$

Here we employ a tower structure for each network, where higher layers have smaller number of neurons [11].

Policy-Based Fusion Layer. We further fuse the four interacted features $\mathbf{s}_a$ into a synthetic one. Note that homophily effect and influence effect could jointly affect user preference and item attribute, but for distinct users and items, the importance of the two-fold social effects could be different. To this end, we propose a new policy-based fusion strategy to dynamically allocate weights to the four interacted features according to specific user-item pairs.

We model the weight allocation as a contextual multi-armed bandit problem[1],where an action, denoted by $\gamma \in \{1, 2, 3, 4\}$, indicates which feature to choose, a context is a user-item pair and the reward after playing an action represents a recommendation loss. In this problem, a stochastic policy can be written as the conditional probability $p(\gamma|\mathbf{p}_u, \mathbf{q}_i)$, which could characterize the selecting probability or importance weights for different combinations of social effects given a specific pair (u, i).

To make the problem solvable, we approximate $p(\gamma|\mathbf{p}_u, \mathbf{q}_i)$ by a neural network (called policy network):

$$e_\gamma = \mathbf{W}_F^2 \tanh(\mathbf{W}_F^1(\mathbf{p}_u||\mathbf{q}_i) + \mathbf{b}_F^1) + \mathbf{b}_F^2.$$

$$p(\gamma|\mathbf{p}_u, \mathbf{q}_i) = \frac{\exp(e_\gamma)}{\sum_{a=1}^4 \exp(e_a)}.$$

Then the synthetic representation can be expressed as

$$\mathbf{s} = \mathbb{E}_{\gamma\sim p(\gamma|\mathbf{p}_u,\mathbf{q}_i)}(\mathbf{s}_\gamma) = \sum_{\gamma=1}^4 p(\gamma|\mathbf{p}_u, \mathbf{q}_i) \cdot \mathbf{s}_\gamma.$$

We call the above strategy *single-headed* policy-based fusion. Inspired by [30], we can extend it to a *multi-headed* version. We harness L different independent policy networks and the final weights are given by the averaged weights given by each policy net. The training of policy networks is by stochastic policy gradient, which will be discussed in Section 3.2.

Output Layer. Then probability of user u clicking item i can be predicted by

$$\hat{r}_{ui} = nn(\mathbf{s}).$$

If a clicking probability is required (for implicit feedback), $nn(\cdot)$ can be a fully-connected layer with a sigmoid activation function.

If a rating value is needed (for explicit feedback), $nn(\cdot)$ can be a fully-connected layer without activation function.

Loss Function. The loss function measures the discrepancy between predicted value and ground-truth value. For implicit feedback, the most widely adopted loss function is the cross-entropy defined as

$$\mathcal{L}_1 = -\sum_{(u,i)} r_{ui} \log \hat{r}_{ui} + (1 - r_{ui}) \log(1 - \hat{r}_{ui}).$$

For explicit feedback, we adopt the mean square loss

$$\mathcal{L}_1 = \sum_{(u,i)} \|\hat{r}_{ui} - r_{ui}\|^2.$$

Here, we concentrate on pointwise loss. Also, other pairwise loss functions can be used and we leave them for future investigation.

3.2 Training

In this subsection, we introduce some training techniques to improve the model performance.

Mini-Batch Training. We also leverage mini-batch training to calculate the gradient. For each iteration, we consider B user-item pairs. For each pair (u, i), the neighbor nodes $F_U(u)$, $F_I(i)$ in two networks as well as the rated history $R_I(v)$, $v \in \Gamma_U(u)$, and $R_U(j)$, $j \in \Gamma_I(i)$ will be together input into the model to compute the gradient. Once an epoch is finished, the batch partition will be randomly reset to incorporate enough noise during optimization. In each mini-batch, since numbers of friends are different for users, we need to pad zeros and input a matrix with dimension of max friend number in one batch. We observe that number of friends tends to obey a long-tail distribution, so the padding would lead to both high space and time complexity. Therefore, we use a sample technique: 1) for friend number more than F, we uniformly sample F friends as input data; 2) for friend number less than F, we pad zeros to obtain a F-dimensional vector. We also experiment other sample methods like random walk with restart (RWR) [29] on a sub-graph near central node, but we find that uniformly sampling over adjacent nodes can achieve competitive performance. This observation could be justified by one argument in sociology research that influence from users always propagates to adjacent users in social networks [7]. Thus we adopt the simpler method to reduce time complexity. In experiment part, we will investigate the impact of sample size F on the performance.

Local-Graph Aware Regularization. The other issue is regularization to avoid over-fitting problem. In our model, we adopt L1 regularization to constrain the embedding parameters to sparse forms. The regularization loss can be expressed as

$$\mathcal{L}_2 = \sum_u (\|p_u\| + \|x_u\|) + \sum_i (\|q_i\| + \|y_i\|).$$

However, the above loss introduces high computational complexity, since for each batch training we need to calculate the gradient of regularization over all users and items. Such operation can not generalize to large-scale data set. A recent work [45] proposes a mini-batch aware regularization trick to solve this problem. In each batch training, only the embedding parameters for user-item pair (u, i) in the batch will be used to calculate the regularization loss. Here we extend this idea to graph structure and call it as local-graph aware regularization. In each batch training, we constrain the embedding parameters of users, items as well as their neighbor nodes in social network and item implicit network. The new regularization loss can be written as

$$\mathcal{L}_2 = \frac{1}{2} \sum_{(u,i)} \Big[\|\mathbf{p}_u\| + \|\mathbf{x}_u\| + \sum_{v \in \Gamma_U(u)} \frac{1}{|F_U(v)|} (\|\mathbf{p}_v\| + \|\mathbf{x}_v\|) + \|\mathbf{q}_i\| + \|\mathbf{y}_i\| + \sum_{j \in \Gamma_I(i)} \frac{1}{|F_I(j)|} (\|\mathbf{q}_j\| + \|\mathbf{y}_j\|) \Big].$$

In fact, the local-graph aware regularization is to split the regularization loss into small parts for each mini-batch and guarantees that once an epoch is finished, each user and each item can be regularized equally. To sum up, the final loss function is

$$\mathcal{L} = \mathcal{L}_1 + \lambda \mathcal{L}_2, \tag{2}$$

where λ is a trade-off parameter between accuracy and complexity.

Besides, for parameters in neural networks (weight matrix and bias vectors), we adopt dropout strategy to replace the traditional regularization. Our experiments will further discuss the influence of different dropout probabilities ρ.

Policy Gradient. In training stage, we train the policy networks in a stochastic way. Assume $p_l(\gamma|\mathbf{p}_u, \mathbf{q}_i)$ to be the active probability given by l-th policy network, and random variable γ obeys a multinomial distribution. For each policy network, we draw $\gamma \sim Multi(p_l(\gamma|\mathbf{p}_u, \mathbf{q}_i))$, and feed $\mathbf{s}_\gamma$ into output layer, which gives prediction and returns loss. We leverage the loss to train the policy network. This design can be formulated as an actor-critic terminology: i) given the environment (user u and item i), the l-th agent (policy net) needs to execute an action according to policy $(p_l(\gamma|\mathbf{p}_u, \mathbf{q}_i))$; ii) every action would generate a reward (recommendation loss) that could lead the training of policy network. We define the reward as subtraction of loss generated by selected interacted feature, i.e., $\mathcal{R}(p_u, q_i, \gamma) = -\mathcal{L}(\mathbf{s}_\gamma)$ (where $\mathcal{L}(\mathbf{s}_\gamma)$ denotes the loss when we input $\mathbf{s}_\gamma$ into the output layer). We aim at maximizing the expected reward $\mathbb{E}_{\gamma \sim p(\gamma|p_u, q_i)}(\mathcal{R}(p_u, q_i, \gamma))$. The policy gradient method REINFORCE [35] can be used to update parameters in one policy network (denoted as θ), and the gradient can be derived as follows:

$$\begin{aligned} &\nabla_\theta \mathbb{E}_{\gamma \sim p_\theta(\gamma|\mathbf{p}_u, \mathbf{q}_i)}(\mathcal{R}(\mathbf{p}_u, \mathbf{q}_i, \gamma)) \\ \simeq &\frac{1}{4} \sum_\gamma \nabla_\theta \log p_\theta(\gamma|\mathbf{p}_u, \mathbf{q}_i) \mathcal{R}(\mathbf{p}_u, \mathbf{q}_i, \gamma). \end{aligned} \tag{3}$$

Training Algorithm. The training of DANSER updates policy networks and feedforward networks (including embedding, dual GAT, pairwise neural interaction and output layers) iteratively, which is presented in Alg. 1. First, we update feedforward networks for n_p steps (one mini-batch for one step) by optimizing (2). Then we train L policy networks independently by conducting corresponding policy gradient (3).

3.3 Discussions

In this subsection, we discuss on effectiveness of our key units, dual GAT layer and policy-based fusion layer, in order to shed more insights on DANSER.

Algorithm 1: Training for DANSER

  for $i = 1, \cdots, n_p$ **do**
    Sample B user-item pairs.;
    For each pair (u, i), uniformly sample F neighbors from $F_U(u)$ and $F_I(i)$, respectively;
    Draw $\gamma_l \sim Multi(p^l_{\theta_l}|\mathbf{p}_u, \mathbf{q}_i), l = 1, \cdots, L$;
    $w \leftarrow \eta \nabla_w \sum_l L(\mathbf{s}_{\gamma_l})$;
  $\theta_l \leftarrow \zeta \nabla_{\theta_l} \mathbb{E}_{\gamma \sim p^l_{\theta_l}(\gamma|\mathbf{p}_u, \mathbf{q}_i)}(\mathcal{R}(\mathbf{p}_u, \mathbf{q}_i, \gamma)), l = 1, \cdots, L$;

Justification of Dual GATs. During the training process, the GAT to capture the homophily effect would give larger weights to friends whose preferences for items are globally similar to the targeted user (resp. related items whose attractiveness to users are globally similar to candidate item), so the static preference (resp. attribute) factor captures static effect of friend users (resp. related items) from a global view. Differently, the weights given by the GAT to capture the influence effect depend on the targeted user (resp. item), so the corresponding dynamic factor captures context-aware effects from a local view. In each domain, a dual GAT collaboratively models the two-fold effects and takes both global and local views to conduct a more accurate investigations into distinct users and items.

To put it more symbolically, we illustrate its effectiveness by considering the following two cases for the recommendation of candidate item i^+ to targeted user u^+: item i^+ is similar to item i_1 and i^+ is similar to i_2 (see left and right columns of Fig. 3). Here, we assume that user u^+ has only clicked on i_1 and i_2 (and no other items), and users u_1 to u_4 are u^+'s friends. Previous works for social recommendation consider static effect of friends in an average manner. As illustrated in Fig. 3.(a), for friend u_1 who clicked on both items, the attention weight would be large, and the opposite for friend u_4. For u_2 and u_3, their weights are medium since they are both partially similar to u^+. Therefore static weights cannot discriminate between the influence of user u_2 and u_3 when it comes to item i^+ even if it is known that it is similar to i_1 or i_2. In contrast, DANSER contains two different attention weights, where one captures user-specific static effect (for homophily) and the other can dynamically change under different contexts (i.e., for influence). When candidate item i^+ is similar to i_1 (resp. i_2), the social influence GAT would focus more on u_1 and u_2 (resp. u_1 and u_3). Then the resultant force of the two GATs would make u^+ pay more attention to u_2 when i^+ is similar to i_1 and to u_3 in the other case. The global and local views of DANSER work collaboratively for selecting the 'right' neighbors that are similar to the targeted user under a specific context, which improves model expressiveness. In Section 4.5, we will verify the above argument via a real-case study.

Justification of Policy-Based Fusion. The policy-based fusion layer acts like a stochastic network while training, and the REINFORCE algorithm can help to explore the optimal weights distribution over four interacted features. Since the interacted feature with larger active probability is more likely to be selected, it would be more frequent for the interaction neural layer that gives the 'best' feature to be trained. Such mechanism brings up two major benefits. Firstly, the policy networks can filter 'right' user-item samples for training of corresponding interaction neural layer as well as previous GCN/GAT and embedding layers. Second, the active probability introduces random pattern to the training process, which can help to escape from local optimums. Our ablation study in experiment part also validate the superiority of the policy-based fusion compared with other straightforward strategies.

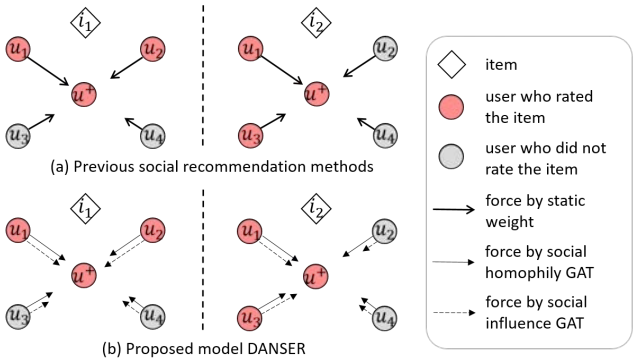

Figure 3: Illustration of effectiveness of dual GATs and comparison with previous social recommendation methods.

4 EXPERIMENTS

To comprehensively evaluate proposed model DANSER[2], we conduct experiments to answer the following research questions:
RQ1 How does DANSER perform compared with state-of-the-art models for recommendation and social recommendation?
RQ2 Are the key components in DANSER, such as dual GATs and policy-based fusion, necessary for improving performance?
RQ3 How do hyper-parameters in DANSER impact recommendation performance?
RQ4 How can DANSER interpret the four different social effects from real-world data?

4.1 Experiment Setup

4.1.1 Data sets. We apply our model to one public benchmark datasets for social recommendation *Epinions* and a commercial dataset *WeChat Top Story*. We provide some statistics of these two datasets in Table 1. The basic information about the two datasets is summarized as follows:

i) *Epinions:* Epinions is a consumer review websites, where users can rate some items and add other users in their trust lists. *Epinions* dataset [23] contains two parts of information: user-item interaction pairs, where items are rated from 1 to 5 (explicit feedback), as well as the directed trust relationships between users. The dataset has been widely used as benchmarks for social recommendation. Following other works [10, 17, 33, 38], we randomly choose 80% user-item interactions as training set and the remaining 20% as test set for each dataset.

[2]The codes are released at https://github.com/echo740/DANSER-WWW-19.

ii) *WeChat:* We also deploy our model on a real-world article recommender system, WeChat Top Story. This dataset is constructed by user-article clicking records on this platform. Different from *Epinions*, this dataset only contains implicit feedback, i.e., we only know whether a user clicked an article or not. Besides, the friend relationships are bidirectional. We chronologically order the user-article clicking records, and use the first 90% records to train our model and the remaining records to evaluate the prediction performance. Since the positive samples and negative samples are fairly unbalanced in this dataset, we uniformly sample the negative ones such that the numbers of positive and negative samples are the same for one user.

Table 1: Statistics of three datasets.

Dataset	#users	#items	#interactions	#relationships
Epinions	49,290	139,738	664,824	487,181
WeChat	~200,000	~100,000	~4,000,000	~2,000,000

4.1.2 Implementation Details. We use Tensorflow to implement our model and deploy it on GTX 1080 GPU with 8G memory. The hyper-parameter settings for *Epinions* are as follows: batch size $B = 64$, embedding dimension $D = 10$, dropout ratio $\tau = 0.5$, regularization coefficient $\lambda = 0.001$, sample size $F = 30$, truncation length $C_t = 30$, multi-head number $L = 4$, policy gradient period $n_p = 1000$. The learning rates $\eta = 0.1$, $\zeta = 0.01$. The Leaky ReLu slope is 0.2. In pairwise interaction neural layer, we adopt three-layer neural networks and neuron numbers are $10 - 16 - 8 - 4$.

4.1.3 Competitors. We choose several comparative methods, including some state-of-the-art models for recommendation and social recommendation, to evaluate the performance of our DANSER. The optimal hyper-parameter settings for each method are determined either by our experiments or suggested by previous works.

The recommendation models include *SVD++*[15] and *DELF*[2]. These two methods only leverage user-item interactions as model input. They can be used to evaluate the effectiveness of other models that use social information.

- *SVD++* [15] is a basic model-based recommendation method which use both user-specific and item-based user embedding to represent user's preferences.
- *DELF* [2] is a state-of-the-art CF method which proposes dual embedding for users and items, and adopts deep neural networks to capture complex non-linear information.

The social recommendation models include *TrustPro*, *TrustMF*, *TrustSVD*, *NSCR*, *SREPS*. These methods all leverage both user-item interactions and user friendships as input information.

- *TrustPro* [39] is a trust propagation method, using rating of friends to deduce rating of targeted user.
- *TrustMF* [38], as one matrix factorization method, optimizes user embedding to retrieve the trust matrix.
- *TrustSVD* [10] is another matrix factorization-based method, incorporating friends' embedding vectors into targeted user's predicted rating.
- *NSCR* [33], as a strong baseline for social recommendation, adopts deep neural networks to learn latent representations of users and items, and leverages graph regularization to constrain the embedding of adjacent users to be similar.
- *SREPS* [17] is another strong baseline, using a network embedding approach to encode social network.

We also construct several variants of DANSER as ablation study. To evaluate the necessity of dual GAT layer, we simplify our model as *DualEMB*, *DualGCN*, *userGAT*, and *itemGAT*. *DualEMB* removes the convolution over adjacent nodes, while *DualGCN* replace GAT by GCN. *userGAT* removes two GATs in item domain, and *itemGAT* removes two GATs in user domain. Moreover, to evaluate the necessity of policy-based fusion layer, we consider the following variants. *DANSER-m* and *DANSER-a* leverage max and average pooling to fuse four interacted features, respectively. *DANSER-c* concatenates the four interacted features as the input of output layer. *DANSER-w* removes the policy net, set four sharing fusion weights, and update the weights together with training of feed-forward networks.

4.1.4 Evaluation Protocol. We adopt different metrics to evaluate recommendation performance. Since two datasets possess different feedbacks, we consider different metrics for them. For *Epinions* with explicit feedback, we use *MAE* and *RMSE*, which are widely adopted by other works, as evaluation metrics. For *WeChat* with implicit feedback, we use *Precision@k* (short as P@k) and *AUC*, two universally acknowledged metrics for 0-1 classification, to evaluate the performance. We repeated each experiment ten times and report the average performance.

4.2 Comparative Results: RQ1

We report experiment results of DANSER and other comparative methods in Table 2. As we can see, our model DANSER outperforms other comparative methods and achieves great improvements, i.e., 2.87% MAE impv. for Epinions and 4.48% AUC impv. for WeChat. The results verify the superiority of proposed model for social recommendation. Also, there are some findings in these comparative experiments. First, matrix factorization methods like TrustMF and TrustSVD can achieve good accuracy in Epinions with explicit feedback, but perform poorly in WeChat with implicit feedback. Second, NSCR performs quite better than other linear methods, which indicates that neural network plays an important role in capturing complex non-linear information. Third, even though DELF has not leveraged any social information, it outperforms some social recommendation methods like TrustSVD and NSCR. This is possibly due to the facts: i) the dual embedding and neural interaction layer in DELF can better exploit information in user-item interactions; ii) other social recommendation methods like TrustSVD and NSCR do not make good use of social information. Indeed, TrustSVD assumes equal importance of each friend user while NSCR uses graph regularization that constrains representations for adjacent users in a static way. These settings resort to a prior assumption that friend users' preferences are all similar, which may not be true for contemporary SNS (also discussed in Section 1).

4.3 Ablation Study: RQ2

In order to verify the effectiveness of some components in our model, we do some ablation studies and the results are shown in

Table 2: Comparative results for Epinions and WeChat. For MAE, RMSE, the smaller value is better, and vice versa for P@10, AUC.

	Epinions		WeChat	
	MAE	RMSE	P@10	AUC
SVD++ [15]	0.8321	1.0772	0.0653	0.7304
DELF [2]	0.8115	1.0561	<u>0.0752</u>	<u>0.7818</u>
TrustPro [39]	0.9130	1.1124	0.0561	0.6482
TrustMF [38]	0.8214	1.0715	0.0625	0.7005
TrustSVD [10]	0.8144	1.0492	0.0664	0.7325
NSCR [33]	0.8044	1.0425	0.0736	0.7727
SREPS [17]	<u>0.8014</u>	<u>1.0393</u>	0.0725	0.7745
DANSER	**0.7781**	**1.0268**	**0.0823**	**0.8165**
Impv.[1]	2.87%	1.25%	9.33%	4.48%

[1]The improvement compares DANSER with the best competitor (underlined).

Table 3. We first compare DANSER with DualEMB and DualGCN. As we can see, GCNs can capture enough social information hidden in graph structure and improve recommendation accuracy (about 1.0% impv. for MAE over DualEMB), while GATs can further improve performance by differentiate importance weights for friend users (about extra 0.8% impv. for MAE over DualGCN). We secondly compare DANSER with userGAT and itemGAT. The results show that incorporation of user and item networks can both bring significant performance improvement, and the benefits brought by user social network are greater.

We also evaluate the necessity of policy-based fusion layer. The results show that our policy-based fusion and policy gradient method can improve the accuracy a lot. Also, for Epinions, the improvement is quite significant. One possible reason is that the social effects in Epinions are more heterogeneous than those in WeChat, so to dynamically weigh different social effects are more effective for Epinions. More importantly, since DualEMB can be seen as the extension of DELF [2], where we replace the concatenation of four embedding by our policy unit. Comparing DualEMB in Table 3 with DELF in Table 2, we find that the policy unit do help to improve its performance and is superior to straightforward concatenation.

In Section 1, we emphasized that social recommendation is proposed to solve the data sparsity and cold-start problem in recommender systems. Here we would like to investigate the performance of DANSER for cold-start users. Fig. 4 shows the results on Epinions and WeChat for users with different number of clicked items and friends. We present the median, the 75− and 25−percentile MAE/AUC. As we can see, with number of clicked items increasing, the gap between upper and lower bounds becomes narrow, which indicates that performance becomes better. Generally, DANSER can achieve better overall performance as well as lower variation of MAE/AUC. For users with different friend numbers, as depicted in the figure, when friend number goes up, the variation trends for three methods are different. For DualEMB, the performance improves a little. For DualGCN, there is an obvious performance decline, while performance of DANSER becomes better. This is

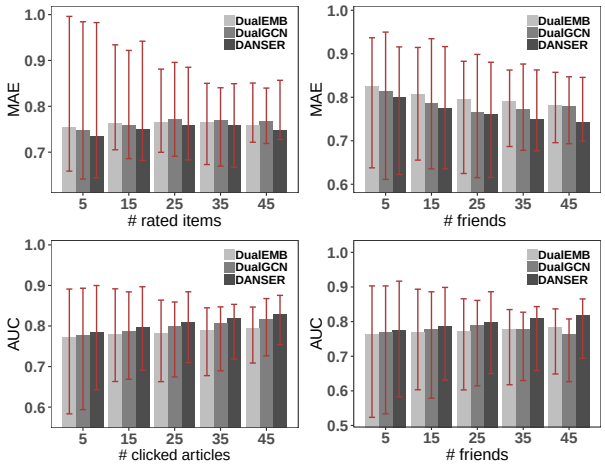

Figure 4: MAE/AUC of DANSER, DualGCN, DualEMB on Epinions/WeChat w.r.t users with different number of clicked items and friends.

Table 3: Ablation study of components in proposed method.

	Epinions		WeChat	
	MAE	RMSE	P@10	AUC
DualEMB	.7920(1.7%)[1]	1.0363(0.7%)	.0794(3.6%)	.7992(2.2%)
DualGCN	.7840(0.7%)	1.0335(0.4%)	.0814(1.1%)	.8102(0.8%)
userGAT	.7858(0.9%)	1.0364(0.7%)	.0813(1.2%)	.8136(0.4%)
itemGAT	.7919(1.7%)	1.0335(0.4%)	.0813 (1.2%)	.8138(0.3%)
DANSER-w	.8191(4.9%)	1.0659(3.4%)	.0820(0.4%)	.8151(0.2%)
DANSER-m	.8211(5.2%)	1.0681(3.6%)	.0815(1.0%)	.8144(0.3%)
DANSER-a	.8232(5.4%)	1.0710(3.9%)	.0814 (1.1%)	.8140(0.3%)
DANSER-c	.8091(3.8%)	1.0659(3.4%)	.0809(1.7%)	.8118(0.6%)
DANSER	**0.7787**	**1.0292**	**0.0823**	**0.8165**

[1]The ratio indicates the impv. comparing DANSER with corresponding variant.

possibly because for users with large number of friends, the GCN operation may incorporate more misleading information, and instead, GAT can attentively filter the noise and concentrate more on important neighbor nodes.

4.4 Parameter Sensitivity: RQ3

We study the performance variation for our model w.r.t some hyper-parameters including regularization parameter λ, dropout rate ρ, embedding dimension D, sample size F. (The other hyper-parameters have little impact on model performance, so we skip discussions on them for space limit.) The results are shown in Fig. 5 and enlighten us that. i) The regularization parameter plays an important role, and if it is too large, the model cannot focus on minimizing the recommendation loss. ii) If the dropout ratio is too large, the random pattern would hinder the training. If ρ is too small, it would lose the regularization efficacy. iii) A proper embedding size is needed. If it is too small, the model lacks expressiveness, while if it is too large, the representation vector would become so sparse, which leads to performance decline. iv) With the sample

size increasing, the accuracy improves but the computational cost increases as well. Hence an appropriate sample size can keep a good balance between complexity and accuracy.

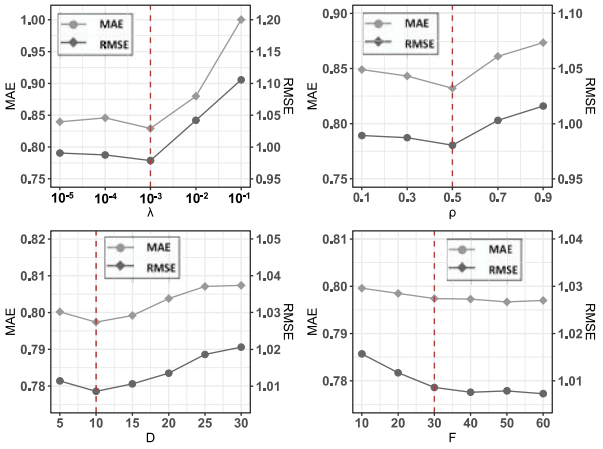

Figure 5: MAE of DANSER on Epinions w.r.t different hyper-parameters. The vertical dotted lines mark the values set in this paper.

4.5 Case Study: RQ4

We conduct a case study of four user-item pairs and show the weights given by four GATs by node size in Fig. 6. As we can see, the weights of two homophily GATs stay unchanged for the same user or item, while the weights of two influence GATs vary for different user-item pairs. Moreover, influence GATs incline to allocate larger weights to nodes with the same labels, which echoes the argument in Section 3.3 that the influence GATs tend to concentrate more on the similar nodes under a specific context. Also, the policy weights play a part in selecting the most dominant interacted features from four GATs representations.

More importantly, we can decompose the model interpretability for social effects in recommender systems by a two-level illustration: i) for a specific user-item pair (u, i), the policy weights first indicate the dominant combinations of social effects in user domain and item domain, ii) the corresponding GATs for four social effects further give out the influential degree of each friend given item i as well as the influential degree of each related item given user u.

5 RELATED WORKS

Social Recommendation. In online social networks, friends tend to have a large impact on users' decisions and behaviors [9, 27]. There are plenty of studies for social effects, such as homophily[24] and influence[21], over graph structures in social network analysis. For recommender systems, [13] is one of the pioneer who takes advantage of social networks to alleviate the data sparsity problem for item recommendation. Then many following studies begin to model social effects in recommender systems from various perspectives. [5, 12, 22] propose trust propagation methods by leveraging rating of friends to deduce rating of targeted user. This kind of approach is quite heuristic and is called *similarity-based* method. Then a more modern approach, *model-based* method, is proposed by other studies. [20, 40] use regularization to constrain the neighbor

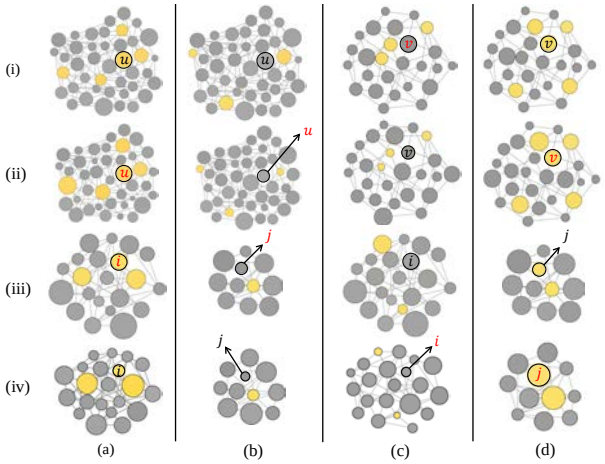

Figure 6: Visualization of the four GATs' weights for a case study. There are four user-item pairs: (a) (u, i), (b) (u, j), (c) (v, i), (d) (v, j). Row (i) and row (ii) are for social homophily and social influence GATs' weights, respectively, while row (iii) and row (vi) are for item-to-item homophily and item-to-item influence GATs' weights, respectively. Gray nodes are negative samples ($r_{ui} = 0$) while orange nodes are positive ones ($r_{ui} = 1$). In each line, the interacted feature of two factors with red symbol corresponds to the largest active probability given by policy networks.

users' embedding vectors to be similar and [8, 18, 38] adopt matrix factorization to incorporate the adjacent matrix into user embedding. Since the above methods can only capture linear information, some recent studies like [4, 33] and [17, 34, 43] leverage deep neural networks and network embedding approaches, respectively, to learn a more complex representation for graph structures. However, comparing with dual GATs used in this paper, the common limitations of existing studies lie in: i) they assume neighbors' influences to be equally important or statically constrained, ii) they ignore the social effects from related items, iii) modeling of social effects lacks interpretability.

Graph Convolution/Attention Network. GCN and GAT, as two powerful techniques to encode a complex graph into low-dimensional representations, are extensively applied into various problems involved with graph data since their proposals [3, 14, 31]. Using GCN and GAT to solve semi-supervised classification problem in graph could achieve state-the-of-art performance (GAT can be seen as an extension of GCN and provide better performance according to [31]), and its good scalability enables it to tackle large-scale dataset. Existing studies leverage GAT to tackle social influence analysis[25], graph node classification[6], conversation generation[46], relevence matching[43]. For recommendation, some recent studies like [42] adopt GCN to convolve on user-item network (a bipartite graph) to obtain better representations for items, and there are also some works using GCN to capture social information for recommendation [41][36]. We are the first to use GAT for social recommendation task, and our new architecture, dual GATs, can capture social information in both user and item networks.

Dual Mechanism. There are many dual phenomenons in real-life which inspire several dual structures in model design. [37] proposes a dual-model paradigm to merge the training of two dual tasks. [47] extends GCN to dual structures, combining global and local consistencies in graph. [2] proposes DELF conducting dual embedding for users and items in recommender systems. Compared to [2], our model possesses several key differences: i) for the item-based user embedding (resp. the user-based item embedding), DANSER considers dynamic embedding under specific candidate items (resp. targeted users), while DELF treats embedding statically given a user (resp. item); ii) in dual GCN/GAT layer, DANSER harnesses two dual GATs to capture social information in user social network and item implicit network, while DELF considers no user-to-user and item-to-item mutual influences; iii) in the policy-based fusion layer, DANSER dynamically weighs the importances of the four GAT representations, while DELF straightforwardly concatenates four embedding vectors.

6 CONCLUSION

In this paper, we proposed DANSER, which includes two dual graph attention networks, to learn deep representations for social effects in recommender systems. Our method is equipped with good expressiveness because: i) it can collaboratively model homophily and influence effects from both friend users and related items; ii) it can investigate heterogeneous importance distributions among different interactions of the two two-fold social effects for distinct user-item pairs. Our comparative experiments and ablation studies on a benchmark dataset and a commercial dataset showed that DANSER can learn effective representations of multifaceted social effects and leverage this information to significantly improve recommendation accuracy.

As extension of our work, we believe that the construction of item implicit network could leverage extra attribute features or distill more high-level connections through knowledge graphs if the information is available. More generally, one could extend DANSER to other information retrieval tasks, like question answering, where DANSER could model 'social effects' from related questions and similar answers given the corresponding networks of them.

ABSTRACT

Compared to general web search engines, web image search engines display results in a different way. In web image search, results are typically placed in a grid-based manner rather than a sequential result list. In this scenario, users can view results not only in a vertical direction but also in a horizontal direction. Moreover, pagination is usually not (explicitly) supported on image search search engine result pages (SERPs), and users can view results by scrolling down without having to click a "next page" button. These differences lead to different interaction mechanisms and user behavior patterns, which, in turn, create challenges to evaluation metrics that have originally been developed for general web search. While considerable effort has been invested in developing evaluation metrics for general web search, there has been relatively little effort to construct grid-based evaluation metrics.

To inform the development of grid-based evaluation metrics for web image search, we conduct a comprehensive analysis of user behavior so as to uncover how users allocate their attention in a grid-based web image search result interface. We obtain three findings: (1) "Middle bias": Confirming previous studies, we find that image results in the horizontal middle positions may receive more attention from users than those in the leftmost or rightmost positions. (2) "Slower decay": Unlike web search, users' attention does not decrease monotonically or dramatically with the rank position in image search, especially within a row. (3) "Row skipping": Users may ignore particular rows and directly jump to results at some distance. Motivated by these observations, we propose corresponding user behavior assumptions to capture users' search interaction processes and evaluate their search performance. We show how to derive new metrics from these assumptions and demonstrate that they can be adopted to revise traditional list-based metrics like Discounted Cumulative Gain (DCG) and Rank-Biased Precision (RBP). To show the effectiveness of the proposed grid-based metrics, we compare them against a number of list-based metrics in terms of their correlation with user satisfaction. Our experimental results show that the proposed grid-based evaluation metrics better reflect user satisfaction in web image search.

1 INTRODUCTION

Image search has been shown to be very important within web search. Existing work shows that queries with an image search intent are the most popular on mobile phone devices and the second most popular on desktop and tablet devices [27]. In web image search a different type of search result placement is used compared to general web search, which results in differences in interaction mechanisms and user behavior. Let us consider the image search search engine result page (SERP) in Figure 1 to highlight three important differences: (1) An image search engine typically places results on a grid-based panel rather than in a one-dimensional ranked list. As a result, users can view results not only vertically but also horizontally. (2) Users can view results by scrolling down without having to click on the "next-page" button because the image search engine does not have an explicit pagination feature. (3) Instead of a snippet, i.e., a query-dependent abstract of the landing page, an image snapshot is shown together with metadata

about the image, which is typically only available when a cursor hovers on the result.

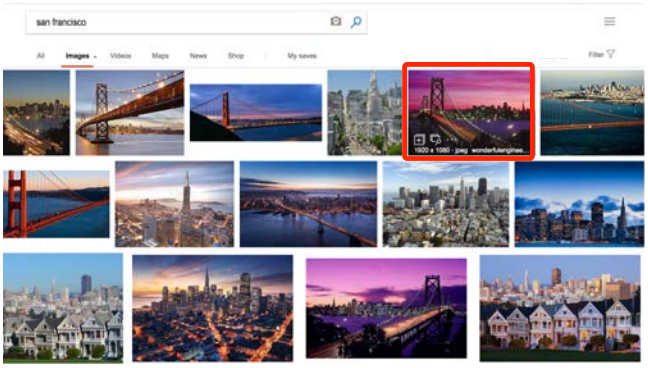

Figure 1: An example SERP from a popular image search engine. For the image that is highlighted using the red box, metadata is displayed when the user hovers over the image.

Evaluation metrics encapsulate assumptions about user behavior [10, 20] and, hence, differences in user behavior should lead to differences in the design of evaluation metrics in image search. Previous work on evaluation metrics [5, 15, 21] focuses on general web search scenarios where results are placed in a list manner. Among the evaluation metrics proposed, Rank-Biased Precision (RBP) [21] assumes that users will examine each result with a persistence probability p from top to bottom; users with a higher value of p are more patient to interact with search results. Discounted Cumulative Gain (DCG) [15] measures the gain of a document based on its position in the result list; the gain is accumulated from the top of the result list to the bottom and is discounted at lower ranks. Although these models work well to assess a result list in general web search, it is not obvious how to adapt them to image search where results are placed in a grid-based manner. Zhang et al. [39] show that the performance of these evaluation metrics is not promising in image search environments in the sense that they do not correlate well with user satisfaction. While the importance of different presentation formats has been recognized [23], there have been very few attempts to construct grid-based evaluation metrics.

As a first step towards designing better evaluation metrics for web image search, we conduct a comprehensive user behavior analysis using data from a lab-based user study so as to obtain a deeper understanding of the underlying user behavior, especially how users allocate their attention.

To summarize, we have three major findings through the analysis:

(1) Similar with the findings in [34], a middle position bias of users attention is observed in the user study data.
(2) The attention of image search users is not discounted monotonically and dramatically along with the rank positions, which means that more attention might not always be allocated to the higher rank positions. Also, the attention allocated to results within a row shows less variance than the attention among different rows.
(3) Users display row-skipping behavior on image SERPs. They may directly jump to results at some distance and ignore particular rows. A two-stage model can be used to depict this process in which users will judge the whole row first, and then decide to skip this row or view the details of results in this row.

Motivated by these observations, we propose corresponding user behavior assumptions to simulate users' interaction processes on SERPs. As shown in [3], evaluation metrics can be generalized as a function of gain and stopping probability, that is the sum over all ranks of the gain (e.g., relevance) accumulated by examining that far, times the probability that this is where the user stops examining the results. The basic idea of our proposed assumptions is to revise the stopping probability by incorporating grid-based position information. We show how we derive new evaluation metrics from these assumptions and how to adopt them to revise well-known list-based metrics.

We conduct extensive experiments to test the proposed assumptions. By using a large-scale commercial image search log, we show that incorporating grid-based features can help user behavior models to better predict the stopping position. We also use data from a field study, in which users' explicit satisfaction feedback and assessors' relevance judgments are available, to measure the performance of the grid-based evaluation metrics. We demonstrate that in image search, existing list-based metrics do not correlate well with user satisfaction while the proposed grid-based evaluation metrics can better reflect user satisfaction.

In summary, we make the following contributions:

- We thoroughly investigate how users allocate their attention on a grid-based interface in image search. We have three major findings of user behavior, i.e., "Middle bias," "Slower decay," and "Row skipping."
- Motivated by our findings on how attention is allocated, we propose corresponding user behavior assumptions to simulate users' search processes. We then derive new grid-based evaluation metrics based on these assumptions.
- We conduct extensive experiments to test the performance of our proposed grid-based evaluation metrics. Experimental results demonstrate that they better reflect user satisfaction and the assumptions behind them are closer to practical user behavior than the assumptions underlying competing models.

2 RELATED WORK

Related work comes in two areas: image search and evaluation metrics.

2.1 Image search

As result placement and interaction mechanisms in image search are different from general web search, user behavior in image search is different from user behavior in general web search. There exists a number of studies on user behavior analysis of image search engines. One line of prior research focuses on characterizing general user behavior based on search logs [2, 12, 28, 32]. Compared with general web search, important differences in user behavior (e.g., shorter queries, a tendency to be more exploratory, and to browse deeper) have been observed. Another line of research investigates more fine-grained user interactions with image SERPs. Xie et al. [34] observe a different browsing model on image SERPs and show a *middle position bias* of users' examination behavior. The observation "Middle bias" in this paper accords with their findings. Also,

interaction behavior such as cursor hovering has been shown to be a valuable additional signal for relevance [22, 35]. User behavior that is unique to image search has motivated various attempts at user behavior modeling that aim to improve the performance of image search engines [14, 35, 37].

Differences in user behavior also have an impact on evaluation. Previous work on evaluation of image search mainly adopts existing list-based evaluation metrics to measure the performance of models developed for image search by simply joining results together [11, 14]. Sanderson [24] introduces evaluation measures used in ImageCLEF, an evaluation forum for cross-language annotation and retrieval of images. However, these metrics still follow those in general web search. Zhang et al. [39] find that existing metrics in web search do not correlate well with user satisfaction in image search. The construction of evaluation metrics that do correlate well with user satisfaction in the context of grid-based interfaces for image search still remains an open question and deserves more attention.

2.2 Evaluation metrics

Evaluation sits at the center of IR research. In order to approximate the system's performance and users' search satisfaction, two components are needed. One is a search result collection labeled with query-dependent relevance levels and the other is a well-designed user model used to simulate the search process [25]. A number of effective evaluation metrics have been designed for general web search [7]. These metrics mainly follow the assumption that users scan ranked results from top to bottom before they stop [9]. One of these, RBP [21], assumes that users examine the $(i+1)$-th result after examining the i-th result with persistence p and will end their examination with probability $1-p$. Järvelin and Kekäläinen [15] propose a metric, DCG, that formalizes user gain from a result list as a discounting process. Besides considering the position impact, Expected Reciprocal Rank (ERR) [5] takes result relevance into consideration and defines the probability that a user is satisfied with a document to be related with relevance of the document. More sophisticated measures have been developed recently. Zhang et al. [38] try to model the search process based on upper limits for both benefit and cost, and propose a Bejeweled Player Model. Also, Wicaksono and Moffat [30] provide a detailed discussion of continuation probabilities (e.g., the persistence p in RBP) in user behavior models that underlie evaluation metrics.

In information retrieval, user satisfaction can be understood as the fulfillment of a specified desire or goal [16]. Satisfaction can be considered as the golden standard in search performance evaluation and is used to reflect users' actual feelings about the system [1, 13]. Correlation with actual user satisfaction is often taken to be the ultimate test for newly proposed evaluation metrics. Indeed, there exists a number of studies investigating different evaluation methods and the correlation between these methods and satisfaction [6, 19, 20, 26]. In this paper, we follow the same principle and also measure the performance of the proposed evaluation metrics by considering their correlation with actual user satisfaction.

What we add on top of the work discussed above is the following. List-based metrics have shown their effectiveness in estimating users' search satisfaction and measuring the performance of general web search engines – but they are list-based. However, in image search a grid-based result placement is adopted. We show that considering grid-based position information as part of the design of evaluation metrics can be beneficial. No previous research has investigated grid-based evaluation metrics for web image search.

3 IMAGE SEARCH USER BEHAVIOR PATTERNS

In order to gain a better understanding of user behavior in image search we examine the attention allocation mechanisms of search users in image search. The findings of this examination will help us to formulate an image search user model that will underlie our proposed grid-based evaluation metric.

We use two publicly available datasets, of image search and web search respectively, in this paper. The image search dataset has been created using data collected in a lab-based user study in image search scenarios [34]. A total of 40 participants have been recruited to complete 20 image search tasks in this study. A Tobbi eye-tracker with default settings has been used to record the examination behavior of participants; the participants' fixation points and fixation dwell time were recorded and certain image being examined was recorded by the built-in algorithms. The general web search dataset has been created using data collected in another user study conducted in general web search scenarios [18]. This dataset involves 32 participants who have been recruited to complete 30 web search tasks. Participants' fixation points on general web SERPs were recorded used the eye-tracker with the same settings and built-in algorithms as in the first dataset described above. Based on these two datasets, we cannot only investigate examination behavior in image search but compare image search with general web search.

We obtain three major findings of user examination behavior on image SERPs. They are "Middle bias," "Slower decay," and "Row skipping." The first one ("Middle bias") is mainly column-based and share the same observations with [34]. Starting from reviewing this finding, we introduce two new observations ("Slower decay" and "Row skipping") which are mainly row-based.

3.1 "Middle bias"

In image search, results are placed in a grid-like manner. Hence, users cannot only examine results vertically, as in web search, but also horizontally, within a row. It is important to investigate how users allocate their attention within a row. For the first dataset, similar to [34], we use the absolute position instead of the border of images to segment SERPs since the number of images in each row may be different (see the SERP example in Figure 1). Each SERP can be equally divided into 5 columns. We then draw a heat map with 10 rows and 5 columns of the distribution of examination durations (averaged over tasks and users); see Figure 2. Here, the examination duration of an image is defined as the dwell time during which a user gazes at the image. Gaze is the externally-observable indicator of human visual attention [17].

By examining the heat map in Figure 2 we re-confirm the observations from [34]: the middle positions in each row receive more attention than other positions, i.e., the leftmost or rightmost positions.

Based on these observations, we propose our first hypothesis:

Hypothesis 1 – Middle bias

Image search results in the middle position may attract more attention from search users than results in the left-most or rightmost position.

Figure 2: Distribution of examination duration (in seconds) in the first 10 rows in image search (0–9); rows are split into 5 columns (0–4).

Hypothesis 1 is not new: Xie et al. [34] already apply a linear mixed model to justify that the middle-position bias is significant statistically. That is, eye gaze behaviors are related to the location of an image within a row, and placing an image in the middle columns has a significant impact on fixation duration. However, they didn't adopt it to construct new image search evaluation metrics.

After Hypothesis 1, which concerns user examination behavior within a row, we introduce two other new observations and hypotheses that concern inter-row examination behavior patterns of image search users.

3.2 "Slower decay"

In image search, users can view results by scrolling down without having to click the "next page" button, which brings less cost to users and results in more exploratory search and deeper browsing depths [32]. We use the eye-tracking user study datasets to investigate how users examine SERPs in image search and general web search.

As shown in [35, 39], different within-row directions have little impact on user behavior modeling in image search. Define the *rank position* in a grid by following the top to bottom and left to right order. We calculate the examination duration for each cell in the grid (in the same way as was used in Section 3.1) and plot the distribution of the top 10 rank positions of image results in Figure 3. For the second dataset, we calculate the examination duration for each result and also plot the duration distribution in Figure 3 for comparison with image search.

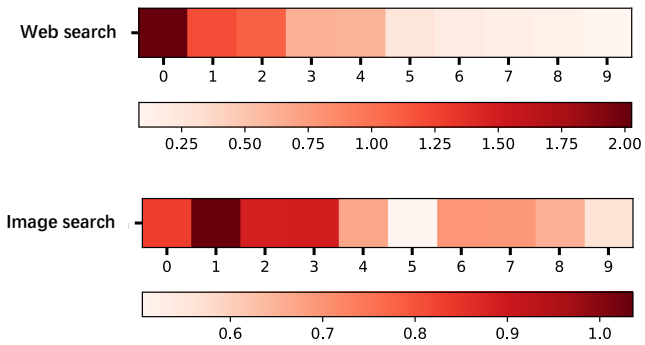

Figure 3: Distribution of examination duration (in seconds) in the first 10 rank positions of general web search and image search.

From Figure 3, the first observation is that users' examination duration does not decrease dramatically with the rank position in image search, especially within the same row (To note, there are five cells within a row.). Also, the difference of values between positions at different rows is smaller than the difference in web search. The second observation is that the change in examination duration in image search is not always monotonic, which is also different from web search. Position 7 (0.694s) receives a longer fixation than position 4 (0.671s) and position 5 (0.505s). In the case of web search, attention decreases in a monotonic way and at a higher speed than in the case of image search.

This leads to our second hypothesis:

Hypothesis 2 – Slower decay

Users' attention does not decrease monotonically and dramatically with the rank position. In the case of image search attention decays at a slower speed than in general web search.

To verify Hypothesis 2, we first take "two distributions in web search and Image search are similar" as the null hypothesis and then we use Pearson's chi-squared test, which is used to determine whether there is a significant difference between the expected distribution and the observed distribution, to determine whether the null hypothesis is true. The result shows that the p-value is less than 0.001. Hence, we can reject the null hypothesis and say that the difference in examination duration distribution between web search and image search in Figure 3 is significant. Also, we define "decay speed" as the result of dividing examination duration in position i by examination duration in position $i + 1$. We calculate the average decay speed based on the data shown in Figure 3. Results show that the average decay speed of image search (1.06) is much lower than of general web search (1.48).

3.3 "Row skipping"

We look deeper into examination sequences of search users using the eye-tracking data. We find that users will not examine every row one-by-one from top to bottom, which means they will skip rows and examine results at some distance. This "Row skipping"

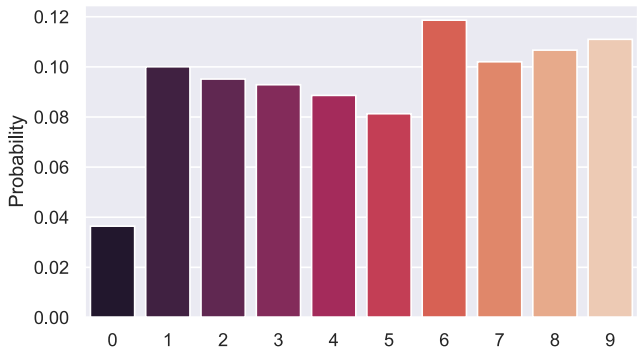

Figure 4: Probability of row-skipping behavior in different rows.

behavior can be formalized as: Right after a user examines results in the i-th row, she/he examines results in the j-th row where $j > i+1$. We define the probability of row-skipping behavior in a certain row (row i) as:

$$P(i) = \frac{S(i)}{S(i) + E(i)}. \tag{1}$$

Here, $E(i)$ is the number of cases where row i is being examined right after row $i-1$ has been examined. And $S(i)$ is the number of cases that users examine results at a row with a row number larger than i after examining row $i-1$. We define "search begin" as the row before row 0. That is, row 0 being skipped means the first examined row is not row 0. We show the probability of row-skipping behavior in the first 10 rows in Figure 4. There exists row-skipping behavior in image search. The highest probability is about 12% in the 6-th row in the first dataset. Also, the row-skipping probability in the 0-th row is much smaller than in later rows, which means users rarely skip the first row in image SERPs. Assuming that participants in a lab-based user study are more patient than users in real-life environments, the probability of row-skipping in real-life can be even higher.

Thus, we propose our third hypothesis:

Hypothesis 3 – Row skipping

Users may ignore particular rows and directly jump to results at some distance.

We take "the frequency of cases that row i being examined after row $i-1$ has been examined (i.e., E(i)) accords with the frequency of all cases that previous examined row is $i-1$ (i.e., S(i)+E(i))" as the null hypothesis. We also perform a chi-squared test and find that the p-value is less than 0.001. Therefore, we can reject the null hypothesis and say that row-skipping behavior does exist in user examination process.

To sum up, we have presented three hypotheses concerning user behavior in image search based on the observations made during eye-tracking user studies. Statistical tests have been conducted to verify the hypotheses and show the significance.

Although our first observation (i.e., "Middle bias") is not new, it has not been adopted in the design of image search evaluation metrics. we devote our attention to it as well as to two other, new observations, since considering both interaction processes in the horizontal direction ("Middle bias") and in the vertical direction ("Slower decay" and "Row skipping") as part of the construction of a grid-based evaluation metrics is beneficial in this two-dimensional environment.

4 GRID-BASED EVALUATION METRICS

In this paper, we construct grid-based evaluation metrics based on the user behavior hypotheses proposed in Section 3. We first introduce a uniform framework from which existing list-based evaluation metrics can be instantiated. We then propose three modeling assumptions motivated by the hypotheses in Section 3. Based on these assumptions, we derive new grid-based metrics by making revisions on the uniform structure.

4.1 Evaluation framework

Given a result set generated in response to a query, we can estimate users' satisfaction based on the relevance score of each query-result pair and a particular user model followed by users when they interact with this result set. Existing list-based evaluation metrics mainly follow an interaction process where users scan ranked results one-by-one from top to bottom before they stop. This interaction process can be regarded as a *cascade model* [9]. Following the cascade assumption, Moffat et al. [20] define a framework that captures a user's expected utility to generalize arbitrary list-based evaluation metrics (M) as:

$$M = \sum_{i=0}^{\infty} W_i R_i, \tag{2}$$

where R_i is the relevance score of the i-th result, and W_i is the metric-specific weight at rank position i. For example, for RBP with persistence probability p, $W_i = (1-p)p^{i-1}$ and for DCG, the metric-specific weight W_i would be $1/\log_2(i+2)$. To note, W_∞ is set to 0 for existing metrics.

Similar to work reported in [3, 38], we construct a uniform framework by considering user continuation and stopping probability. That is, users have a continuation probability C_i at position i to examine the $(i+1)$-th result and with probability S_i they stop at position i and leave this search or issue another query. Thus, S_i can be represented as:

$$S_i = \prod_{j=0}^{i-1} C_j(1 - C_i). \tag{3}$$

As shown in [3], the conditional probability of continuing past the i-th result, i.e., C_i, relates to the metric-specific weight, which can be computed as:

$$C_i = \frac{W_{i+1}}{W_i}. \tag{4}$$

We can transfer the framework mentioned in Eq. 2 to uniform framework depicting user stopping behavior and accumulated gain (relevance) as:

$$\overline{M} = \sum_{i=0}^{\infty}\left(S_i \sum_{j=0}^{i} R_j\right) = \sum_{i=0}^{\infty}\left(\prod_{j=0}^{i-1} C_j(1 - C_i) \sum_{j=0}^{i} R_j\right). \tag{5}$$

We refer to $\overline{M}$ as the *total user expected utility*. Next, we show that $\overline{M}$ and M are equivalent (i.e., $\overline{M} \sim M$):

$$\begin{aligned}\overline{M} &= \sum_{i=0}^{\infty}\left(\prod_{j=0}^{i-1} C_j(1-C_i)\sum_{j=0}^{i} R_j\right)\\ &= \frac{1}{W_1}\sum_{i=0}^{\infty}\left((W_i - W_{i+1})\sum_{j=0}^{i} R_j\right)\\ &= \frac{1}{W_1}\sum_{i=0}^{\infty}\left(R_i\sum_{j=i}^{\infty}(W_j - W_{j+1})\right)\\ &= \frac{1}{W_1}\sum_{i=0}^{\infty} R_i W_i\\ &\sim M.\end{aligned} \tag{6}$$

The last equivalence holds because W_1 is a constant given a certain evaluation metric. The framework detailed in Eq. 5 can take the user interaction process into consideration more naturally than the framework depicted in Eq. 2 which mainly models the metric-specific weight and obtained gain for each rank. We therefore make revisions on this framework by incorporating grid-based assumptions. For convenience, we use a triple $(i, r(i), c(i))$ to represent the index of an image result. As we discuss in Section 3.2, we predefine the examination order of search users in image search to be from top to bottom and from left to right. Based on this order, we can obtain the rank position i of a certain image which is in the $r(i)$-th row and $c(i)$-th column.

We are now in a position to introduce the grid-based modeling assumptions which are among the contributions of our work. The order in which we propose our assumptions is the same as the order used to present observations of user behavior patterns in Section 3, i.e., "Middle bias" followed by "Slower decay" and "Row skipping."

4.2 Middle bias assumption

The first assumption, named "Middle bias," focuses on the interaction within a single row, i.e., it is column-based. As mentioned in Section 3.1, users have a higher probability to examine results in the middle position. In this paper, we simulate this bias by considering users' continuation examination, in which we increase the stopping probability in the middle position and lower it in the leftmost or the rightmost positions. We assume that users will have a higher probability to finally stop at the middle position within a row. Hence, we can use a column-based function $f(c)$ to modify the stopping probability S_i. For the image at rank position i with the column number $c(i)$, we design the function $f(c(i))$ as follows:

$$f(c(i)) = e^{g(c(i))}, \tag{7}$$

where $g(c(i))$ is a normal distribution with mean μ and standard deviation σ as:

$$g(c(i)) = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{(c(i)-MP-\mu)^2}{2\sigma^2}}, \tag{8}$$

where MP denotes the column index of the middle position in row $r(i)$. We leave explorations of other functions (such as, e.g., a quadratic function) as future work. In a normal distribution, the mean is the central tendency of the distribution; it defines the location of the peak for normal distributions. And the standard deviation is a measure of variability; it defines the width of the normal distribution. Since we simulate users' middle bias in this assumption, we set μ to be a constant number 0 to further simplify the parameter estimation process, which means the "location" of the normal distribution will be right in the middle of the column. Thus, σ is then the only parameter needed to estimate in Eq. 8. Hence, based on the middle bias assumption, the total user expected utility ($\overline{M}$) can be represented as:

$$\overline{M_{MB}} = \sum_{i=0}^{\infty}\left(\prod_{j=0}^{i-1} f(c(i))C_j(1-C_i)\sum_{j=0}^{i} R_j\right). \tag{9}$$

4.3 Slower decay assumption

As mentioned in Section 3.2, the "Slower decay" observation shows that users are more patient in image search than in web search. Their attention decreases more slowly, especially on results within a row. Thus, simply adopting existing evaluation metrics, developed for web search, to image search scenarios is not promising. In this paper, we utilize the row information of image results. We assume that users' stopping probability will increase along with the row. Hence, we can revise the stopping probability S_i in the proposed evaluation framework by multiplying S_i with a row-based function $I(r)$. Considering a result at rank position i with row number $r(i)$ and column number $c(i)$, the revised probability of stopping at this result can be computed as:

$$\overline{S_{i,r(i),c(i)}} = I(r(i)) \cdot S_{i,r(i),c(i)}, \tag{10}$$

where $S_{i,r(i),c(i)}$ is the original stopping probability of a certain list-based metric; $I(r)$ is a monotonically increasing function. In this paper, we define $I(r)$ as an exponential function with a base β larger than 1. Then, we can rewrite Eq. 5 as:

$$\overline{M_{SD}} = \sum_{i=0}^{\infty}\left(\prod_{j=0}^{i-1} \beta^{r(i)} C_j(1-C_i)\sum_{j=0}^{i} R_j\right). \tag{11}$$

Adding the parameter β can slow down the speed of decreasing the stopping probability along with rows, since users might still have a relatively high probability of examining results at a lower rank (see Figure 3). Also, the stopping probability of results within a row will multiply the same value according to Eq. 10, which attempts to control the variance between the stopping probability of results in the same row. When $\beta = 1$, Eq. 10 models the stopping probability of existing list-based metrics. We show how different values of β affect the estimated stopping probability distribution in Section 6.

4.4 Row skipping assumption

The third assumption is motivated by the "Row skipping" observation which suggests that users may skip particular rows and jump to results at some distance. In this paper, we model this process by considering a two-stage browsing process. In the first stage, users briefly browse the whole row; we can join image results within a row together to an imaginary "united image". By viewing this "united image," users will make a decision for the second stage where they either skip this row or examine results in this row in detail. We arrive at this two-stage browsing process motivated by a

neuroimaging study [36], which gives important hints about the multistage mechanisms of visual perceptual learning in the brain.

We are now in a position to describe our row skipping evaluation metric ($\overline{M_{RS}}$). We use a parameter γ to depict the probability with which users skip the next row after examining the current row; γ is also a trainable parameter with a value between 0 and 1. Then, the stopping probability of users at rank position i can be computed as follows:

$$S_{i(RS)} = \underbrace{\prod_{k=0}^{r(i)-1}\left((1-\gamma)\prod_{j=S(k)}^{S(k)+N(k)-1}C_j+\gamma\right)}_{\text{two-stage browsing assumption}}\cdot(1-\gamma)\prod_{j=S(r(i))}^{i-1}C_j(1-C_i), \tag{12}$$

where $N(k)$ is the number of images in the k-th row and $S(k)$ is the total number of images before the k-th row. The first part of Eq. 12, before the multiplication sign, depicts the two-stage browsing assumption. We simply assume that with a probability $(1-\gamma)$, users will examine all the image results within this row. Since users stop at row $r(i)$, they will not skip row $r(i)$. Thus, there is the probability $(1-\gamma)$ in the second part after the multiplication sign in Eq. 12.

The row skipping assumption also has an impact on the accumulated gain (i.e., $\sum_{j=0}^{i} R_j$). Since users have a probability γ to skip a certain row, the gain received from this row should be discounted by multiplying $(1-\gamma)$. Hence, the total user expected utility ($\overline{M}$) based on the row skipping assumption can be computed as:

$$\overline{M_{RS}} = \sum_{i=0}^{\infty} S_{i(RS)} \sum_{j=0}^{i}(1-\gamma)R_j. \tag{13}$$

In this section, we have proposed three grid-based assumptions. According to these assumptions, we revise the formula expressing the continuation probability, stopping probability and also the accumulated gain in the uniform evaluation framework (see Eq. 5). To sum up, we modify the stopping probability at different columns, increase the value in the middle position, by considering a normal distribution according to the "Middle bias" assumption. We modify the stopping probability at each rank by increasing the value of the probability along with the rank according to the "Slower decay" assumption. And based on the "Row skipping" assumption, we consider a two-stage browsing process in which users have a skipping probability to ignore a certain row. Thus, the accumulated gain of a certain row is also modified by multiplying the probability that users browse this row.

5 EXPERIMENTAL SETUP

We evaluate the proposed grid-based evaluation metrics using search logs from a commercial image search engine and data from a field study, in which query-level satisfaction feedback and assessors' relevance judgments for query-image pairs are available. Since there is a user behavior model, which depicts the stopping behavior of search users, behind each proposed assumption, we first perform a sanity check, that is, an experiment to test if incorporating grid-based features can help the underlying user behavior model to better predict the stopping position (in terms of mean log-likelihood). As mentioned in Section 2, user satisfaction can be considered as the golden standard in search performance evaluation. In the same way as in [19, 38], we compare our proposed grid-based evaluation metrics against existing list-based metrics in terms of their correlation with user satisfaction to show the effectiveness of proposed grid-based assumptions.

In this section we first introduce the datasets and then describe the design of the two main experiments in this paper.

Table 1: Statistics of the datasets used in our experiments ("#" refers to "number of").

Dataset	#Tasks	#Participants	#Queries	#Sessions
Search log	–	–	82,629	100,000
Field study	555	50	1,212	1,212

5.1 Datasets

Two image search datasets are used to conduct the experiments. Descriptive statistics of these two datasets can be found in Table 1.

The first dataset ("Search log") is randomly sampled from a search log in October 2017 from the Sogou image search engine, which is popular in China. In this dataset, the grid-based information (i.e., row and column number of image results) and user interaction behavior (i.e., click and cursor hovering) are available. We keep query sessions that have at least one click to make sure we can estimate the user's stopping position, since the last clicked rank can be used to approximate the users' actual stopping rank as shown in [3]. The number of search sessions used in this paper is 100K in total, with 80,000+ distinct queries. We split all query sessions into training and test sets at a ratio of 8:2.

The second dataset ("Field study") consists of data collected from a one-month field study, which is publicly available (see [31]). In this field study, participants are asked to provide explicit satisfaction feedback for their search experience. To note, they can decide which query sessions they want to give the explicit feedback on without having to annotate all search sessions and they are also asked to provide a description about the task they conduct when issuing a specific query. Query-level satisfaction scores on a 5 point scale are gathered. Besides user behavior data recorded using a browser extension and explicit feedback from participants, relevance scores of query-image pairs are annotated by assessors on a crowdsourcing platform. Each query-image pair has at least five relevance annotation scores in the range of 0 to 100. We use the average of these annotation scores in our experiment as the label of a certain query-image pair. Also, assessors are recruited to assign a user intent tag to each task (i.e., the "Locate, Learn, Entertain" taxonomy proposed by Xie et al. [33]). Since image search users usually have deeper browsing depths, we test the performance of evaluation metrics at depths of 5, 10 as in [39] and 15 as well. Thus, we keep query sessions in which the number of the last browsing row is not less than 15, which leads to 1,212 query sessions in total in our dataset.

5.2 Experiment 1: Behavior prediction

Experiment 1 is aimed at testing whether the proposed grid-based user behavior assumptions (considering the continuation and stopping behavior in a grid-based interface) are closer to real-life user

Table 2: Grid-search values of hyper-parameters that need to be estimated and the grid-based assumptions these parameters belong to for Experiment 1.

Parameter	Assumption	Grid-search values
p	–	$\{0.1, 0.2, \ldots, 0.9\}$
σ	Middle bias	$\{1, 2, \ldots, 10\}$
β	Slower decay	$\{1.1, 1.2, \ldots, 2.0\}$
γ	Row skipping	$\{0.1, 0.2, \ldots, 0.9\}$

behavior than list-based assumptions. As mentioned in Section 4, the proposed grid-based assumptions revise users' stopping probability at different rank positions by incorporating row and column information. To validate the user behavior assumptions underlying the proposed evaluation metrics, we test the performance of these assumptions on predicting users' actual stopping positions.

We use RBP as our baseline model that naturally takes users' continuation and stopping into consideration. In RBP, a persistence probability p is used to depict users' continuation probability at each rank. Based on formulas introduced in Section 4, we can calculate the stopping probability at different ranks, estimated by RBP as well as by grid-based RBPs with different proposed assumptions (i.e., "MD": Middle bias; "SD": Slower decay; "RS": Row skipping). For example, the stopping probability at rank position $(i, r(i), c(i))$ estimated by grid-based RBP with the "Slower decay" assumption according to Eq. 11 can be computed as:

$$S_i(RBP - SD) = \prod_{j=0}^{i-1} \beta^{r(i)} p(1-p). \tag{14}$$

We regard the last click position to be users' stopping position on SERPs in the same way as in [3]. And we use log-likelihood to show how well the stopping probability distributions estimated by different models approximate the actual user stopping behavior.

We use a grid-search algorithm to estimate the best parameter(s) for each model to minimize the mean log-likelihood of the training data (80%) in our first dataset. We then test the performance of these models with the pre-trained hyper-parameter(s) in the test data (20%). We show the details of the bounds and discretization of the different parameters needed to be estimated using grid-search in Table 2.

5.3 Experiment 2: Correlation with user satisfaction

In Experiment 2, we measure the performance of our grid-based assumptions by testing the correlation between grid-based evaluation metrics, derived from our assumptions, and user satisfaction. We first conduct experiments on RBP-based metrics. We show Pearson's correlation results of RBP with different assumptions (the original list-based and the proposed grid-based assumptions). We also construct a t-statistic to test the significance of the difference between two dependent correlation coefficients [8]. The p-value level is reported if a significant difference is observed. We then look deeper into the effect of different settings of our proposed assumptions (e.g., different starting rows to consider row-skipping assumption, different number of rows of results being modeled in the evaluation metrics). After that, we report results of the grid-based evaluation metrics, under the best settings, based on other list-based prototype metrics (i.e., ERR and DCG). Comparisons are also made between different prototype metrics.

6 RESULTS

We first report the results of Experiment 1, behavior prediction of user behavior models that are based on different grid-based assumptions. Then, in Experiment 2 we show the performance of grid-based evaluation metrics in terms of their correlation with user satisfaction. We compare the parameter selection in different tasks and discuss the optimal settings to perform our proposed grid-based evaluation metrics. Additional comparisons are made between different grid-based evaluation metrics based on different prototype list-based evaluation metrics.

6.1 Evaluation of behavior prediction

Table 3 shows the minimized mean log-likelihood of each user behavior model as well as the value of the best parameters and improvements over the baseline model (RBP). Here, the improvement of the log-likelihood of model A over model B is computed as $\frac{LL(B)-LL(A)}{LL(B)}$. We also perform pairwise t-tests to determine the significance of the observed difference between grid-based models and the baseline model.

Table 3: Outcomes of Experiment 1. Minimized mean Log-likelihood of user behavior models. **: significantly better than the RBP model with p-value < 0.01.

Model	Parameter(s)	Log-likelihood	Improvement
RBP	$p(0.8)$	-0.542	–
RBP-MB	$p(0.8)$, $\sigma(2)$	-0.513^{**}	5.4%
RBP-SD	$p(0.8)$, $\beta(1.9)$	-0.473^{**}	12.7%
RBP-RS	$p(0.5)$, $\gamma(0.2)$	-0.469^{**}	13.5%

Compared against the baseline model (RBP), our grid-based models with the proposed assumptions achieve better performance on behavior prediction, i.e., users' stopping behavior, in terms of mean log-likelihood. Also, all observed differences are significant. The best grid-based model RBP-RS obtains a 13.5% (significant) improvement over the list-based model RBP. Thus, incorporating grid-based information into the construction of a user behavior model is beneficial and results show that search user behavior in a grid-based environment differs from that in a list-based environment.

Compared to the "Slower decay" and "Row skipping" assumptions, both of which help RBP to better predict user stopping behavior, RBP with the "Middle bias" assumption has a smaller improvement over the baseline model on behavior prediction. The reason can be two-fold:

(1) The method used to depict middle position bias of search users may not be optimal. The practical distribution of users' stopping probability within a row may follow more complex distributions. We leave an investigation on methods to more accurately model "Middle bias" behavior as future work.
(2) Users' stopping behavior correlates more with row information than with column information. Thus, the row-based assumptions ("Slower decay" and "Row skipping") achieve better results

than the column-based assumptions ("Middle bias") on behavior prediction.

We also show the value of the best parameters in Table 3. We can see the performance of the baseline model with a fixed continuation probability is not promising, which indicates that in image search users' continuation probability may be affected by other factors like the position information of the current examined result.

When considering the "Middle bias" assumption, the value of the best parameter σ is 2. For a normal distribution, a small standard deviation (σ) produces a distribution that is more tight. Thus, a difference in stopping probability between middle position and other positions is observable.

By incorporating the additional parameter β (when considering the "Slower decay" assumption), we are able to consider the possibility that users' stopping probability will increase along with the row. In this setting, the probability of the results at lower ranks being examined will be higher than in the list-based setting, which might indicate that in image search users have deeper browsing depth (confirming [32]); the stopping probability will decrease slowly.

In RBP with the "Row skipping" assumption, we observe that the probability to ignore certain rows is 0.2. This observation accords with the results shown in Figure 4 while the row-skipping probability in the search log is slightly higher than in the user study data. This may be caused by the fact that participants in a lab-based user study may be more patient due to the phenomenon that their behavior will be recorded. Thus, the probability of row-skipping of real-life users can be higher.

In summary, Experiment 1 has shown that the grid-based assumptions proposed in this paper are closer to natural user behavior than list-based assumptions. User behavior models underlying the grid-based assumptions achieve better performance in predicting real-life user behavior, i.e., users' stopping behavior. The value of the estimated parameters of grid-based assumptions further confirms the observations introduced in Section 3.

6.2 Evaluation of user satisfaction correlation

As explained in Section 5.3, we first consider RBP-based evaluation metrics at top 10 rows, in the same way as in [39]. Table 4 shows the coefficients of Pearson's correlation between RBP-based metrics and user satisfaction. As shown in Figure 4, the row-skipping probability in the 0-th row is much smaller; we also compare the different settings of where we start to perform "Row skipping" in this table.

We can observe from Table 4 that with the help of the proposed grid-based assumptions, RBP-based evaluation metrics can achieve better correlation with user satisfaction than the original RBP that follows the list-based assumption.

Since the optimization target is different from the target in Section 6.1, we fit the best parameters of different evaluation metrics to gain the best correlation with users satisfaction in this experiment. We can observe from Table 3 and Table 4 that the best parameters in these two tasks are slightly different. The reason can be two-fold:

(1) We consider a fixed number of rows in this experiment to calculate the correlation, since a predefined scale of results being measured is required for offline evaluation metrics [15, 21]. However, in Experiment 1, we compute the log-likelihood based on the rank users stop at. Real users may have different depths of browsing due to their search dwell time.
(2) In the field study, participants can freely decide the feedback of which query session to be recorded by the browser extension. Thus, the search intent distribution may be slightly different between the field study data and the search log. This difference has previously been observed by [33]. Different search intents have an impact on user behavior and satisfaction [31].

Table 4: Outcomes of Experiment 2. Pearson's Correlation between RBP-based evaluation metrics (@top 10 rows) and user satisfaction in the field study dataset. "S@n": "Start performing Row skipping assumption at row n". ↑ (↓): the grid-based evaluation metric achieves better (worse) performance than the baseline model RBP. All correlations are significant at the $p < 0.001$ level.

Metric	Parameter(s)	PC coefficient	Performance
RBP	$p(0.7)$	0.333	–
RBP-MB	$p(0.7)$ $\sigma(1)$	0.341	↑
RBP-SD	$p(0.7)$ $\beta(1.2)$	**0.342**	↑
RBP-RS(S@0)	$p(0.8)$ $\gamma(0.1)$	0.322	↓
RBP-RS(S@1)	$p(0.7)$ $\gamma(0.2)$	0.336	↑
RBP-RS(S@2)	$p(0.7)$ $\gamma(0.2)$	0.334	↑
RBP-RS(S@3)	$p(0.7)$ $\gamma(0.2)$	0.333	–

Table 5: Outcomes of Experiment 2. Pearson's Correlation between RBP-based evaluation metrics at different number of rows (top 5, 10 and 15 respectively) and user satisfaction in field study dataset. "S@n" refers to "Start performing row skipping at row n". All correlations are significant at the $p < 0.001$ level.

Metric	Top 5 rows	Top 10 rows	Top 15 rows
RBP	0.331	0.333	0.333
RBP-MD	0.340	0.341	0.341
RBP-SD	0.342	0.342	0.342
RBP-RS(S@1)	0.331	0.336	0.337

We also investigate how the choice of different first rows to which to apply the "Row skipping" assumption affects the performance of the grid-based evaluation metrics. Results are shown in Table 4; they indicate that applying the "Row skipping" assumption at the very beginning is not promising. When we apply the "Row skipping" assumption at the second row (i.e., RBP-RS(S@1)), we observe a better result, with a higher correlation with user satisfaction than list-based RBP. We also show the results of other RBP-RSs with different starting rows (with a row number larger than 1) to apply the "Row-skipping" assumption in Table 4. We find that although these metrics are better than the list-based metric, the improvement of them over the baseline decrease along with the row number of the starting rows. RBP-RS(S@3) has no observable improvement. Thus, it is optimal to consider "Row skipping" starting from the second row. This finding accords with the results plotted in Figure 4, which shows that users rarely skip the first row on an image SERPs.

Since we need to define the number of rows of results being considered in the evaluation metrics before using a certain metric, we also discuss the optimal setting of the row scale. For each query

session, we test the performance of different RBP-based models at the top 5, 10 and 15 rows respectively. Results are shown in Table 5. We have two findings from this table:

(1) When only a small number of rows is considered, grid-based evaluation metrics with the "Row skipping" assumption, which mainly takes row-based information into consideration, cannot achieve improvements over the list-based competitor. However, the column-based evaluation metric (i.e, RBP-MD) is still better than the baseline model: RBP-MD mainly considers user behavior within a row: changes in the number of rows have less effect on it. For the "Row skipping" assumption, the reason that we only observe small differences may be that the stopping probability at a lower rank is too small to be affected. Thus, the improvement over RBP obtained by considering "Row skipping" is achieved mainly from the top rows.
(2) The more rows are being considered in the evaluation metrics, the better the correlation with user satisfaction that can be achieved, for all evaluation metrics (see, e.g., how "Top 10 rows" compares with "Top 5 rows"). However, the difference between "Top 10 rows" and "Top 15 rows" is small which indicates there exists an upper bound on the performance. Hence, considering the annotation expense, we regard "Top 10 rows" as the best setting of the row scale.

Armed with the best settings ("S@1", "Top 10 rows") observed from the experiments conducted on the RBP-based evaluation metrics, we further test the effectiveness of our proposed grid-based assumptions on other list-based prototype metrics. We perform experiments on two other list-based prototype metrics, i.e., DCG and ERR. Recall that DCG is also a position-based model, like RBP. The difference is that the continuation probability of the result at rank i in DCG is rank-dependent; it can be computed as:

$$C_i(DCG) = \frac{W_{i+1}}{W_i} = \frac{\log_2(i+2)}{\log_2(i+3)}. \tag{15}$$

In addition, we consider ERR. Unlike DCG and RBP, the stopping criterion of ERR is affected by the gain (G) of the currently examined result. Following [5], the probability that a user stops at rank i can be represented as:

$$S_i(ERR) = \prod_{j=0}^{i-1}(1-G_j)G_i, \tag{16}$$

where G_i is the gain that correlates with the relevance score of the current result at rank i, which has the following form:

$$G_i(ERR) = \frac{2^r - 1}{2^{r_{\max}}}. \tag{17}$$

where r is the relevance score of the i-th result. ERR and DCG have been used in previous evaluation tasks on image search [35, 39].

We are now in a position to test the performance of our grid-based assumptions on these two evaluation metrics. The results are presented in Table 6. The proposed grid-based assumptions can help ERR and DCG to achieve better correlation with user satisfaction, while an exception is observed (ERR with the MB assumption). All ERR-based evaluation metrics obtain a poor correlation with user satisfaction, confirming a similar result by Zhang et al. [39]. The reason may be that ERR focuses more on the user gain rather than the examined position. As shown in [11, 35], users' judgments about image results depend largely on image attractiveness. Only considering the effect of relevance on user stopping may not be promising. Furthermore, since position information is not explicitly modeled in the stopping probability in ERR, a grid-based version of ERR cannot achieve promising results.

Table 6: Outcomes of Experiment 2. Pearson's Correlation between evaluation metrics (DCG and ERR @top 10 rows) and user satisfaction in field study dataset. "(u@0.9)" refers to "Upper bound of continuation probability is 0.9". All correlations are significant at the $p < 0.001$ level. ‡ (†): the difference is significant comparing to the corresponding list-based metrics at the $p < 0.01$ (0.05) level.

Metric	List-based	MB	SD	RS(S@1)
ERR	0.169	0.152	0.169	0.180
DCG	0.225	0.260‡	0.224	0.295‡
DCG (u@0.9)	0.291	0.308‡	0.305†	0.303

For the DCG-based evaluation metrics, we can observe the expected results that most grid-based DCG metrics perform better than the list-based DCG, demonstrating the effectiveness of our grid-based assumptions. We also observe a similar performance of DCG and DCG-SD. This may be explained by the fact that the original continuation probability, which is shown in Eq. 15, approaches 1 quickly along with the rank which results in a small stopping probability approaching 0. Thus, the parameter β of "Slower decay" assumption has limited effect on the stopping probability. We also consider an upper bound of the continuation probability of DCG-based evaluation metrics. The results are also shown in Table 6 (last row). All grid-based DCG metrics obtain better correlation with user satisfaction than the list-based DCG. Also, setting an upper bound on the continuation probability improves the performance of all DCG-based metrics, which confirms the observation that users' attention decays at a slower speed. Simply adopting assumptions of list-based DCG is not promising in image search scenarios. Importantly, the best parameters of grid-based DCG are almost the same as for RBP shown in Table 4, i.e., $\sigma(1)$, $\beta(1.1)$ and $\gamma(0.2)$, where the different setting for β may be caused by the different continuation probability settings between RBP and DCG. The results shown in Table 6 indicate that the proposed grid-based assumptions help increase the correlation of position-based models of user satisfaction (e.g., RBP and DCG).

In summary, Experiment 2 has shown that the proposed grid-based assumptions can help existing list-based evaluation metrics, especially position-based evaluation metrics (e.g., RBP and DCG), to better reflect user satisfaction. We find that: (1) performing the "Row-skipping" assumption beginning at the second row rather than the first row can help RBP-RS to achieve better performance; and (2) a result grid limited to the top 10 rows in RBP-based evaluation metrics is optimal considering the trade-off between metric performance and annotation cost.

7 CONCLUSION AND FUTURE WORK

In this paper, we have conducted a comprehensive user behavior analysis using data from a lab-based user study so as to understand the attention allocation mechanisms of search users in image search.

We obtain three major findings through our analysis: (1) User attention follows a middle position bias within a row ("Middle bias"). (2) User attention in the case of image search decays more slowly than in general web search ("Slower decay"). (3) Users may skip particular rows and jump to results at some distance ("Row skipping").

We have proposed three grid-based assumptions. Our experimental results show that user behavior models underlying these grid-based assumptions are closer to real-life user behavior. Existing evaluation metrics (e.g., RBP and DCG) can achieve better performance in terms of correlation with user satisfaction by taking grid-based assumptions into consideration.

Our work is the first attempt to construct grid-based evaluation metrics for Web image search. The research outputs of this paper can guide the optimization of image search engines (e.g., in result ranking and UI design) and are also meaningful to inform user behavior modeling in grid-based environments (not only image search but also video search and e-commerce).

Limitations of the proposed grid-based assumptions which may guide future work: (1) The proposed grid-based assumptions mainly consider the effect of the position. It may be beneficial to also take appearance bias (the effect of image attractiveness) into consideration. (2) The way to model grid-based user behavior may not be optimal, e.g., using the normal distribution to simulate the "Middle bias." Methods to encode grid-based user behavior and combine different user behavior assumptions need further investigation [4]. (3) We test the performance of grid-based assumptions on a small group of evaluation metrics only. Experiments conducted on further evaluation metrics are called for. (4) As the effectiveness of evaluation metrics may vary with tasks [29], we will try to investigate the performance of proposed grid-based evaluation metrics across search tasks and intents.

Code

To facilitate reproducibility of our results, we share the code used to run our experiments at https://github.com/THUxiexiaohui/grid-based-evaluation-metrics.

ABSTRACT

Sarcasm is sophisticated linguistic expression and is commonly observed on social media and e-commerce platforms. Failure to detect sarcastic expressions in natural language processing tasks, such as opinion mining and sentiment analysis, leads to poor model performance. Traditional approaches rely heavily on discrete handcrafted features and will incur enormous human costs. It was not until recent that scholars began to employ neural networks to address these limitations and have achieved new state-of-the-art performance. In this work, we propose a novel self-matching network to capture sentence *"incongruity"* information by exploring word-to-word interactions. In particular, we calculate the joint information in each word-to-word pair in the input sentence to build a self-matching attention vector, based on which we attend the sentence and build its representation vector. Such a network allows sentence to match within itself word by word and cater to the words of conflict sentiments. In addition, we incorporate a bi-directional LSTM network into our proposed network to retain compositional information. We concatenate incongruity information and compositional information through a Low-rank Bilinear Pooling method to control for potential information redundancy without losing discriminative power. Experiment results on publicly available datasets demonstrate that our model significantly outperforms extant baselines on standard evaluation metrics including precision, recall, $F1$ score and accuracy.

1 INTRODUCTION

Sarcasm, which refers to *"a sharp and often satirical or ironic utterance designed to cut or give pain"*[1], is not unusual in online communities such as social media and e-commerce platforms. Sarcasm detection is significant for many language understanding tasks, such as opinion mining and sentiment classification [27]. According to Ghosh and Veale, human's ability to detect sarcasm mainly relies on social cues such as sentiment, scenario and people's intentions [10]. However, as a computational task, using learning models to detect such a complicated linguistic expression is challenging. The sophistication of automatic sarcasm detection mainly comes from the difficulty in identifying its proper context dependency, such as humorous scenario [11], or discriminating the contradictory between literal expression and author's underlying intention, such as irony and metaphor [35]. Following are some sarcastic examples collected from Twitter by Riloff et al. [34]:

- *"A wonderful day of starting work at 6am"*.
- *"I love finals week! #justkidding #stressed"*
- *"I am working hard to be this poor"*.
- *"Nothing makes me happier than getting on the highway and seeing break lights light up like a Christmas tree"*.
- *"Oh thank GOD, our entire office email system is down"*.

These examples demonstrate a strong disparity between authors' intended emotions and true contexts. For example, *"starting work at 6am"* and *"finals week"* are less likely to be enjoyed. Joshi et al. defines such a disparity as *"incongruity"*, referring to contradictory implications between words and phrases [16].

Sarcasm is a widely studied topic in cognitive science and linguistics [7, 8, 14]. However, the study of sarcasm in computational linguistics community is still at its nascent stage [10]. Traditional machine learning based sarcasm detection approaches typically consider it as a binary classification task and emphasize the importance of exploring predictive discrete features [42], including both content features (e.g. n-grams, sentiment lexicons, incongruity) [29, 33, 34], and contextual features (e.g. historical behavior, contextual environment) [2, 30]. These approaches incur nonnegligible research efforts on feature engineering and the modeling process is usually inefficient. In recent times, scholars began to explore neural features based on word embeddings [26, 28] and cultivate deep

[1]Defined by Merriam-Webster dictionary at https://www.merriam-webster.com.

networks, such as Convolutional Neural Networks(CNN), Gated Recurrent Units (GRU), Long Short Term Memory (LSTM) networks, and Attention networks to improve modeling efficiency as well as model performance [1, 10, 35, 42].

Current state-of-the-art sarcasm learning models mainly rely on identifying and exploiting the incongruity patterns embedded in sentences [34, 35]. For example, Riloff et al. address a common incongruity pattern that a sentence contains a positive sentiment which is adhere to a negative scenario or vice versa [34]. A few other studies utilize the incongruity information between target sentence and authors' historical behaviors [1] or contextual information[11]. Approaches utilizing historical information or contextual information rely on extra inputs other than the target sentence itself. In the most recent state-of-the-art model, Tay et al. suggest that the incongruity can be identified by comparing word-to-word interactions and they compute the embedding similarity between every word-to-word pair in the input sentence to search for conflict sentiments [35].

In this work, we aim to predict sarcasm by using sentence information exclusively to save data collecting efforts. We follow the word-to-word comparison approach suggested by Tay et al. [35] to search for incongruity within input sentence. However, Tay et al. compute the joint information between words simply by using the inner product between word embeddings [35]. In our proposed self-matching network, we improve the word-to-word comparison approach by proposing a novel self-matching network based on the "co-attention" mechanism suggested by Lu et al. [23]. The original co-attention mechanism is designed to attend two input feature maps simultaneously, and we employ a similar approach to attend embeddings simultaneously to capture the joint information between every word-to-word pair in the input sentence. Such a comprehensive comparison mechanism allows us to fully capture any potential incongruity information generated by the sentiment conflicts between words. In addition, as Tay et al. suggest, compositional and sequential information of sentence is also important for sarcasm detection and existing state-of-the-art models rely on deep and sequential neural networks such as GRU and LSTM [35]. Therefore, we also incorporate sentence compositional information as prediction input by employing a bi-directional LSTM encoder [13], to complement the self-matching network. Our proposed network generates two sentence representations separately: one captures incongruity information, the other captures compositional information. We do not input them directly into the final prediction layer because of potential information redundancy. Instead, we propose a bilinear pooling method based on Low-rank Bilinear Pooling (LRBP) [21] to reduce input dimension without losing sentence representation's discriminative power.

We evaluate model performance by conducting extensive experiments on several publicly available datasets. Experiment results demonstrate two major findings: first, our proposed self-matching network outperforms most of extant neural network based sarcasm detection models on standard evaluation metrics including precision, recall, $F1$ score and accuracy, and on some datasets, we notice that our model improves $F1$ score and accuracy of existing state-of-the-art performance by over 10%. Second, sequential networks such as LSTM are known for its power on capturing compositional and sequential information, we compare the self-matching network with and without the bi-directional LSTM encoder to evaluate the effectiveness of cultivating compositional information on sarcasm detection task. Experiment results demonstrate that in most circumstances, employing a sequential neural network encoder to complement the self-matching network helps improve model performance.

The rest of this paper is organized as follows: in section 2, we briefly review extant related studies; in section 3 we describe our proposed model architecture in detail, specifically, we illustrate how self-matching network, bi-directional LSTM and the low-rank bilinear pooling method works; in section 4 we demonstrate our experimental settings and discuss experiment results; we conclude this paper in section 5.

2 RELATED WORKS

Sarcasm is a widely studied linguistic phenomenon by cognitive science and linguistic scholars [7, 8, 14], the study of sarcasm in the computational linguistic community is still at the beginning[10]. Extant studies on sarcasm detection can be classified into three main streams: (1) rule based approaches; (2) machine learning approaches based on discrete features; and (3) neural network approaches.

Rule based approaches are the most straightforward methods for sarcasm detection. Researchers attempt to identify sarcastic expressions based on typical linguistic rules and representative indicators. Among these obvious rules and routines, hash-tags attached by authors themselves, such as *#sarcasm*, *#not true*, *#just kidding*, are widely explored by previous studies [9, 25, 37]. Veale and Hao suggest that some unique simile types, such as sentences containing the pattern of "as xx as a xx" (e.g., *"as private as a park-bench"*, *"as useful as a chocolate teapot"*), can be a strong predictor for ironic expressions [38]. In social contexts, sarcasm is usually expressed verbally with heavy tonal stress or certain body gestures such as eye rollings [5], these pieces of behavioral information are unable to be recovered in automatic sarcasm detection though, certain syntactic and semantic text patterns, such as hyperboles identification [5] and interjections and punctuations [8] can still be utilized.

Rule based approaches solely rely on fixed patterns. In order to make improvements, scholars began to exploit a wide range of discrete features including pattern features and semantic features. Pattern features such as n-grams features and occurrence patterns, usually relate to words' syntactic patterns without considering words' implications [3, 16, 17, 22, 31, 33]. For example, Reyes and Rosso use n-grams, which are sequences combining 2 up to 7 words, to search for a set of recurrent words carrying sarcasm information [31]; Barbieri et al. propose an Italian sarcasm detection model based on bag-of-words [3]. Semantic features rely on words' implications and meanings. For example, ambiguity is an important aspect of sarcasm because sarcastic expressions usually present words with ambiguous meanings [4, 32]. Scholar also explore the relationship between contexts and behaviors [19, 30, 40]. Among these various semantic features, incongruity based features are the most widely explored ones, incongruity information is usually identified by searching for negative words in positive context or vice versa [3, 6, 12]. It is worth pointing out that traditional machine learning approaches usually employ various pattern features and semantic

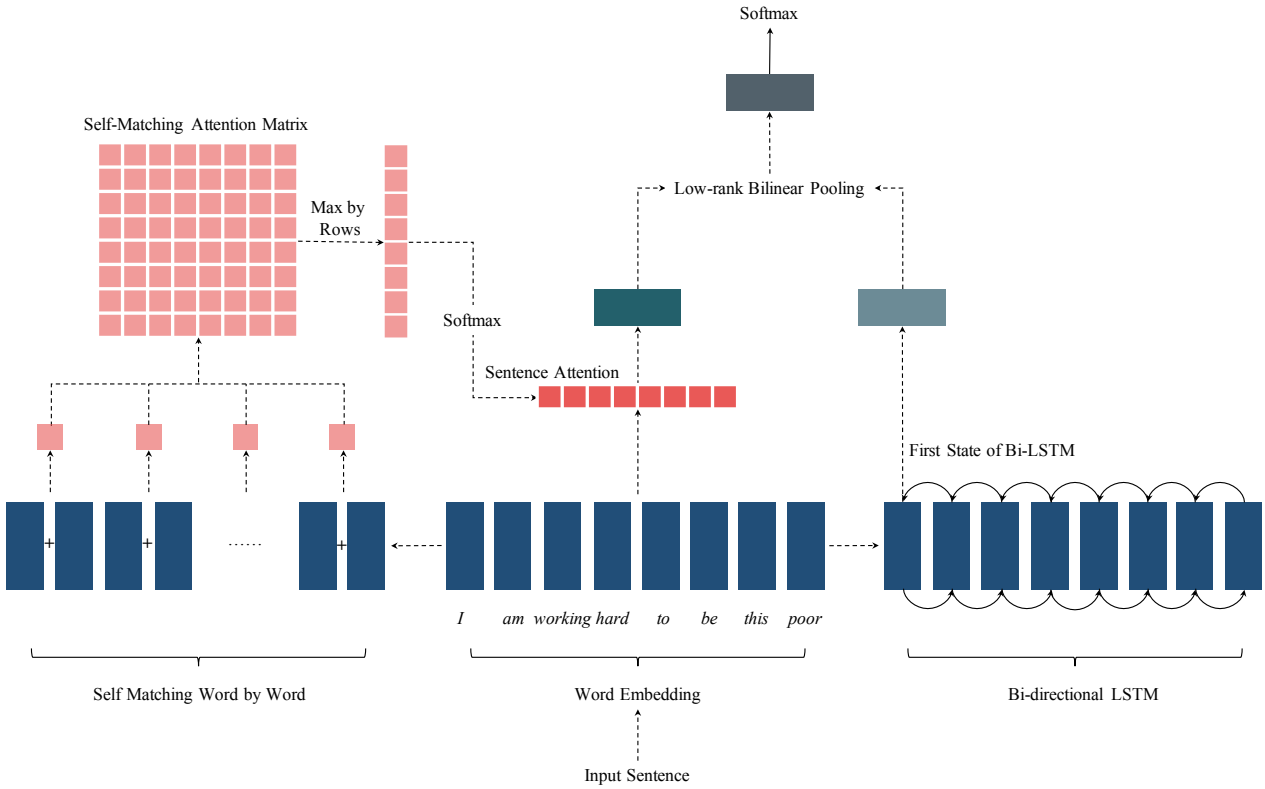

Figure 1: Model architecture. The left part is the self-matching network which is used to generate an attended sentence feature vector based on the self-matching process to search for incongruity information; and the right part is a bi-directional LSTM network used to capture sentence compositional information. We concatenate these two sentence feature vectors by using a low-rank bilinear pooling method to reduce the dimension of the final sentence representation vector.

features simultaneously. Joshi et al. provide a more comprehensive overview on studies based on feature engineering[15] .

Discrete feature based approaches incur nonnegligible research efforts on feature engineering. In recent years, scholars began to employ neural network approaches to detect sarcastic expressions. Joshi et al. are among the very first few studies demonstrating the effectiveness of word embeddings on sarcasm classification tasks [18]. Zhang et al. design a bi-directional Gated Recurrent Neural Network (GRNN) based on neural features, and they also explore how to automatically learn content and context embeddings to make improvements[42]. Amir et al. employ a Convolutional Neural Network (CNN) model to automatically learn *"user embeddings"* from users' historical behavior (e.g. previous tweets), and they detect sarcasm by searching for the incongruity between user embeddings and target content embeddings [1]. Ghosh and Veale combine Deep Neural Networks (DNN) with Long Short-Term Memory(LSTM) to capture sentences' sequential information[10]. In their following study, Ghosh and Veale incorporate user's mood information as well as contextual information into a neural architecture containing two CNN layers and one LSTM layer and achieve improved model accuracy [11] .

Neural network approaches achieve the state-of-the-art performance for sarcasm detection, according to Tay et al., sarcasm detection relies on semantic relationships between words and phrases, yet most sequential neural networks such as CNN, RNN and LSTM, still lack the capability to capture the incongruity and contrast between words, especially when those words are located relatively far from each other. Therefore, they propose a neural network to attend a sentence representation by comparing word-to-word embeddings, and an LSTM encoder to capture sequential information. The so-called *intra-attention* mechanism allows their model to search for conflict sentiments as well as maintain compositional information. This model achieves the new state-of-the-art performance on sarcasm detection [35].

Inspired by the concept of searching for words' contrast and incongruity [29, 33–35], we propose a novel Self-matching Sarcasm Detection model (SMSD) based on a modified "co-attention" mechanism [23]. The major difference between our approach and Tay et al. on capturing word-to-word information is that Tay et al. use inner product operation to capture the joint information between words [35], however, we believe that the inner product operation dilutes information across different words and it only captures words' co-occurrence patterns without considering their sentiment information. As an improvement, we calculate the joint information by introducing a parameter matrix between two word embedding vectors, it helps capture the correlation between words

and is more sensitive on attending sentiment conflicts. We will compare our experiment results with [35] to validate our model performance.

3 MODEL DESCRIPTION

In this section, we describe our proposed model in detail. Model architecture is depicted in Figure 1.

3.1 Sentence Representation

We begin by training a word embedding space $\mathbf{E} \in \mathbb{R}^{V \times k}$, where V is the size of vocabulary and k is the size of dimension for each word vector. For any word in our vocabulary, we assign a vector $\mathbf{e} \in \mathbb{R}^k$ as its feature vector. Feature vectors are associated with rows in the embedding space $\mathbf{E}$. For any sentence s, we build a feature map by combining its word embeddings: $\mathbf{S} = [\mathbf{e}_1^{\mathrm{T}}, \mathbf{e}_2^{\mathrm{T}}, \ldots, \mathbf{e}_n^{\mathrm{T}}]$, $\mathbf{S} \in \mathbb{R}^{k \times n}$, where n is the number of words in the input sentence.

3.2 Self-matching Network

The purpose of our proposed self-matching network is to generate a attended feature vector for the input sentence: $\boldsymbol{f}_a = \mathbf{S} \cdot \boldsymbol{a}$, where $\boldsymbol{a} \in \mathbb{R}^n$ is the self-matched attention vector. As previous studies have found that semantic incongruity is a strong predictor for sarcasm [16], therefore, attention vector $\boldsymbol{a}$ is designed to capture sentence incongruity. In this section, we discuss the specifics of how we calculate the self-matched attention vector.

In the recent state-of-the-art model, Tay et al. propose that the incongruity embedded in a sentence mainly comes from conflict sentiments between words, and they take a deep exploration into this concept by considering the interaction between every word-to-word relationship. In their proposed *"intra-attention"* network, they calculate inner product value for every word-to-word pair as the interaction information. For example, the interaction information $w_{i,j}$ between word i and j is computed as:

$$w_{i,j} = \mathbf{e}_i \cdot \mathbf{e}_j^{\mathrm{T}} \tag{1}$$

where $\mathbf{e}_i$ and $\mathbf{e}_j$ are word embeddings for i and j [35]. In our self-matching network, we employ a similar approach to search for potential incongruity by comparing word-to-word information. However, using inner product operation to compute joint information absorbs and dilutes too much information across different words. Arithmetically, inner product operation aims to compare the similarity between two feature vectors, it lacks the ability to take sentiment information into consideration. Word embedding aims to capture the occurrence patterns between words, not exclusively cater to the sentiment. For example, in a pre-trained word embedding space, the inner product between the vector for *"Loud"* and the vector for *"Silent"* usually is larger than the inner product between *"Loud"* and *"Noisy"*, yet the inner product between *"Loud"* and *"New"* also is likely to be significant because these two words are less likely to have similar occurrence patterns. Therefore, the simple inner product operation might not be able to fully capture sentiment conflicts between words. In the self-matching network, we introduce a parameter matrix based on "co-attention" approach to address this limitation.

Lu et al. propose a "co-attention" network to address the Visual Question Answering (VQA) task [23]. In particular, they introduce an affinity matrix $\mathbf{C}$ to attend input picture feature map $\mathbf{V}$ and text question representation $\mathbf{Q}$. $\mathbf{C}$ is calculated by:

$$\mathbf{C} = tanh(\mathbf{Q} \cdot \mathbf{W}_a \cdot \mathbf{V}) \tag{2}$$

where $\mathbf{W}_a$ contains attention weights based on which Lu et al. adopt a joint activation approach (e.g. maximize by rows and columns) to adjust attention weights for $\mathbf{V}$ and $\mathbf{Q}$ simultaneously. We modify this approach by introducing a weight matrix between word-to-word pair to improve the flexibility of capturing joint information between words.

Specifically, for word pair $(\mathbf{e}_i, \mathbf{e}_j)$, we compute the joint feature vector $w_{i,j}$ as follows:

$$w_{i,j} = tanh(\mathbf{e}_i \cdot \mathbf{M}_{i,j} \cdot \mathbf{e}_j^{\mathrm{T}}) \tag{3}$$

where $\boldsymbol{w}_{i,j} \in \mathbb{R}$ measuring the joint information between word i and word j, and $\mathbf{M}_{i,j} \in \mathbb{R}^{k \times k}$ is a parameter matrix.

We build a self-matching information matrix $\mathbf{W}$ based on all joint information $w_{i,j}, i, j \in (1, 2, ..., n)$:

$$\mathbf{W} = \begin{pmatrix} w_{1,1} & w_{1,2} & \cdots & w_{1,n} \\ w_{2,1} & w_{2,2} & \cdots & w_{2,n} \\ \vdots & \vdots & \ddots & \vdots \\ w_{n,1} & w_{2,2} & \cdots & w_{n,n} \end{pmatrix} \tag{4}$$

After having $\mathbf{W}$, we use a maximization activation approach to calculate the self-matched attention vector $\boldsymbol{a}$. We first calculate an intermediate vector $\boldsymbol{m} \in \mathbb{R}^n$ by maximizing elements in $\mathbf{W}$ by rows:

$$m_i = max(w_{i,1}, w_{i,2}, \ldots, w_{i,n}), \forall i \in (1, 2, \cdots, n) \tag{5}$$

and we input $\boldsymbol{m}$ into a standard softmax function to calculate $\boldsymbol{a}$: $\boldsymbol{a} = Softmax(\boldsymbol{m})$. Softmax function is adopted for the purpose of normalization.

3.3 Bi-direction LSTM

In our experiment we first propose an approach by inputing the attended sentence feature vector generated by the self-matching network $\boldsymbol{f}_a$ into the prediction layer (denoted as SMSD). However, we notice that the self-matching network only aims to capture incongruity information contained in sentence, it lacks the ability to cultivate sentence's compositional information, which as suggested by previous studies, is also critical for sarcasm detection [35]. Therefore, as a complement to the self-matching network, we propose a second approach which employs a standard Bi-directional LSTM encoder (Bi-LSTM)[13] to capture the compositional information for each input sentence (denoted as SMSD-BiLSTM). Bi-LSTM contains a forward LSTM operation ($\overrightarrow{LSTM}$) which reads the clause information from word 1 to word n; and a backward LSTM operation ($\overleftarrow{LSTM}$) which reads the clause information from word n to word i. Hidden states generated from forward LSTM and backward LSTM are concatenated as the hidden states for Bi-LSTM [2].

For each input sentence, we feed its original word embeddings into the Bi-LSTM encoder and we define the hidden state at the ith

[2]LSTM is based on a non-linear parameterized gating mechanism, as it's one of the most popular neural networks in NLP community, we skip the technical detail of LSTM and Bi-LSTM in this paper for brevity.

time step as:

$$\boldsymbol{h}_i = [\overrightarrow{LSTM}(\mathbf{e}_i), \overleftarrow{LSTM}(\mathbf{e}_i)], \forall i \in (1, 2, \cdots, n) \tag{6}$$

where n is the maximum number of words in the input sentence, $\mathbf{e}_i$ is the feature vector for the corresponding word and $\boldsymbol{h}_i \in \mathrm{R}^d$ is the hidden output of the bi-directional LSTM encoder at time-step i. Hyperparameter d is the dimension of the output vector.

Instead of using all hidden states generated from the Bi-LSTM encoder, we follow the approach proposed by Tay et al. and only adopt the first hidden state as the output of the Bi-LSTM encoder [35][3]. We define the sentence feature vector generated by Bi-LSTM encoder as follows:

$$\boldsymbol{f}_l = \boldsymbol{h}_1 \tag{7}$$

where $\boldsymbol{f}_l \in \mathbb{R}^d$, and d is a hyperparameter.

3.4 Low-rank Bilinear Pooling

We have two sentence feature vectors: $\boldsymbol{f}_a$ generated by the self-matching network, and $\boldsymbol{f}_l$ generated by the Bi-LSTM encoder. We can simply concatenate these two feature vectors for the final prediction. Self-matching network aims to capture word-to-word interactions and it is not intended to capture sequential information, but it might still contain compositional information because of the self-matching operation between adjacent words. Therefore, the two feature vectors $\boldsymbol{f}_a$ and $\boldsymbol{f}_l$ are of high possibility to have redundant sentence information and it is unnecessary to input all of them into the final prediction. In this case, we employ a Low-rank Bilinear Pooling (LRBP) method based on Hadamard product to reduce the dimension of the final input vector to control for potential information redundancy without reducing feature vector's discriminative power [21].

Considering the two feature vectors $\boldsymbol{x} \in \mathbb{R}^N$ and $\boldsymbol{y} \in \mathbb{R}^M$, standard bilinear pooling method uses a quadratic expansion of linear transformation to pool information from input vectors [21] as follows:

$$f_i = \boldsymbol{x}^{\mathrm{T}} \cdot \mathbf{W}_{p,i} \cdot \boldsymbol{y} + g_i \tag{8}$$

where $\mathbf{W}_{p,i} \in \mathbb{R}^{N \times M}$ is a weight matrix for output f_i and g_i is the bias. If L is the number of the output features, the total number of parameters including bias is $L \times (N \times M + 1)$. As an improvement, Kim et al. propose a Low-rank Bilinear Pooling (LRBP) method to reduce the rank of the weight matrix $\mathbf{W}_p$ with less parameters to be learned. Specifically, they decompose the matrix $\mathbf{W}_{p,i}$ as $\mathbf{W}_{p,i} = \mathbf{U}_i \cdot \mathbf{V}_i^{\mathrm{T}}$, where $\mathbf{U}_i \in \mathbb{R}^{N \times d}$ and $\mathbf{V}_i \in \mathbb{R}^{M \times d}$. Based on this concept, they propose the following equation to calculate a output feature vector $\boldsymbol{f} \in \mathbb{R}^c$:

$$\boldsymbol{f} = \mathbf{P}^{\mathrm{T}} \cdot (\mathbf{U}^{\mathrm{T}} \cdot \boldsymbol{x} \circ \mathbf{V}^{\mathrm{T}} \cdot \boldsymbol{y}) + \boldsymbol{g} \tag{9}$$

where $\circ$ represents the Hadamard product, the input of which are two matrices of the same dimension, and it produces another matrix of the same dimension where each element (i, j) in the output matrix is the arithmetic product of elements (i, j) in the original two matrices. $\mathbf{P} \in \mathbb{R}^{d \times c}$, $\mathbf{U} \in \mathbb{R}^{k \times c}$ and $\mathbf{V} \in \mathbb{R}^{d \times c}$ are parameters to be learned and $\boldsymbol{g} \in \mathbb{R}^c$ is bias, c and d are hyperparameters.

[3]Tay et al. adopts standard LSTM encoder in their network and use the last hidden state as the output. In this paper we adopt the Bi-LSTM encoder, therefore, the first hidden state contains the final information of the Bi-LSTM operation.

Table 1: Descriptive statistics

Dataset	Train	Test	Total
Reddit(/r/movies)	13,515	1,504	15,019
Reddit(/r/technology)	12,136	1,349	13,485
IAC-V1	1,794	200	1,794
IAC-V2	4,078	454	4532
Tweets(Riloff)	1,368	588	1,956
Tweets(Ghosh)	51,189	3,742	54,931

In this work, we follow the concept of LRBP to pool information from two input feature vectors: $\boldsymbol{f}_a \in \mathbb{R}^k$ and $\boldsymbol{f}_l \in \mathbb{R}^d$. Considering the fact that sentence representation vector usually doesn't employ very large number of dimensions, we simplify the approach by removing the parameter matrix $\mathbf{P}$ in equation (9) to reduce the parameters to be learned and do not further reduce the input dimension. We calculate the final projection feature vector for the input sentence as:

$$\boldsymbol{f} = \mathbf{U}^{\mathrm{T}} \cdot \boldsymbol{f}_a \circ \mathbf{V}^{\mathrm{T}} \cdot \boldsymbol{f}_l + \boldsymbol{g} \tag{10}$$

where $\boldsymbol{f} \in \mathbb{R}^c$, and c is a hyperparameter.

We use $\boldsymbol{f}$ as the final feature vector for the input sentence and we input $\boldsymbol{f}$ into a standard softmax classification layer to make the sarcasm prediction:

$$\boldsymbol{p}_i = Softmax(\mathbf{W}_f \cdot \boldsymbol{f} + \boldsymbol{b}), \tag{11}$$

where $\boldsymbol{p}_i \in \mathbb{R}^2$ representing the probability of whether the input sentence is sarcastic or not, and $\mathbf{W}_f \in \mathbb{R}^{2 \times c}$, $\boldsymbol{b} \in \mathbb{R}^2$ are parameters to be learned.

3.5 Training Objective

For the final sarcasm classification task, we optimize a standard cross-entropy loss function:

$$J(\theta) = -\sum_{i=1}^{N} [y_i \cdot log p_i + (1 - y_i) \cdot log(1 - p_i)] + \lambda \cdot R \tag{12}$$

where N is the size of training dataset, y_i is the true label for sentence i. $\theta = \{\mathbf{M}_{i,j}, \mathbf{U}, \mathbf{V}, \boldsymbol{g}, \mathbf{W}_f, \boldsymbol{b}\}$ are model parameters. $R = \|\theta\|_{L2}$ is the standard L2 regularization term and λ is a hyperparameter measuring the weight of regularization term. d is the hyperparameter in the bi-directional LSTM encoder referring to the number of dimension of the output feature vector. c is the hyperparameter in the low-rank bilinear pooling process referring to the number of dimension of the final sentence representation vector.

4 EXPERIMENTS

4.1 Datasets

To validate our model performance and make it comparable with baseline models, we follow previous studies and evaluate our model on two datasets collected from Reddit and another two datasets collected from IAC (Internet Argument Corpus) [10, 35, 42]. In addition, we notice that existent studies also test models on two popular Twitter datasets provided by Riloff et al. [34] and Ptáček et al. [29]. However, these two studies only provide Tweets IDs, and we are only able to recollect a comparable dataset with Riloff et al.[34]

but fail to match the dataset provided by Ptáček et al [29] [4]. As a complement, we test our model on a recent collected Twitter dataset provided by Ghosh and Veale [11]. Reddit and Twitter datasets mainly contain short texts, while IAC datasets focus on long texts. Descriptive statistics for all six datasets are summarized in Table 1.

- **Reddit**: Reddit is one of the world's largest online communities with millions of users and hundreds and thousands of topics. Provided by Khodak et al. [20], posts in Reddit dataset are annotated based on the '/s' tag left by authors themselves. We use two subsets: */r/movies* and */r/technology* that are tested by Tay et al. [35] to make our experiment results comparable [5].
- **IAC**(Internet Argument Corpus): the original corpus was collected by Walker et al. [39] from the online debate forum *4forums.com* to study political debates on online communities, Lukin and Walker annotate this corpus for sarcasm detection [24]. We test our model on the same two versions of the dataset used by Tay et al. [34], denoted as IAC-V1 and IAC-V2 respectively[6].
- **Tweets**: Twitter is the world's biggest microblogging platform where users can share any of their news, ideas and thoughts with their followers. Two twitter based datasets are widely used by NLP scholars: Riloff et al. provide a dataset with sentences manually annotated and checked, it is also known as the very first public tweets sarcasm dataset [34]; Ghosh and Veale collect a dataset in which tweets are labeled by hash-tags such as *#sarcasm*, *#sarcastic* and *#ironie* [29], and they also employ a feedback-based system which allows them to contact tweet authors to examine the validity of the sarcasm labels.

4.2 Baseline Models

We compare our model with following neural network based models to evaluate our model:

- **NBOW** is a baseline model using the average of word embedding vectors as sentence representation, which is adopted as the input of a standard logistic regression.
- **ATT-LSTM** is an attention based LSTM network proposed by Yang et al. [41], it employs an attention mechanism on all hidden states of the LSTM encoder. Although this model is not exclusively designed for sarcasm detection, it achieves outstanding performance on this task.
- **GRNN** is a bi-directional gated recurrent neural network model proposed by Zhang et al. [42], it employs a gated pooling method to extract content features from a gated recurrent neural network, and also employs a standard pooling method to extract contextual features. This model is among the very first models utilizing neural features for sarcasm detection and demonstrates improved model accuracy compared to traditional discrete feature engineering approaches.
- **CNN-LSTM-DNN** is proposed by Ghosh and Veale [10], it combines Convolutional Neural Network(CNN), Long Short-Term Memory(LSTM) and Deep Neural Network(DNN) into its model architecture. It employs two CNN layers with 1D convolution and two LSTM layers for feature engineering and employs a DNN layer for prediction. it was once the state-of-the-art model for sarcasm detection before Tay et al. [35].
- **SIARN** and **MIARN** are the state-of-the-art models for sarcasm detection [35] . It utilizes an intra-attention mechanism to overcome limitations from sequential neural networks and could better capture words' incongruities. **SIARN** employs a single-dimension intra-attention network and **MIARN** employs a multi-dimension intra-attention network.

4.3 Experimental Settings

To make our experiment results comparable with existent models, we align our experimental settings with Tay et al. [35]. We preprocess our datasets by removing words that appear only once in datasets, and sentences and documents with less than 5 tokens or contain hyper-links are also removed. Word embedding space in our model is generated by GloVe [28] with the dimension of word feature vector k fixed at 100 and we fine-tune the embedding during the training process. Considering the typical length of reviews and documents contained in our six datasets, we fix the length of each input sentence at (20, 20, 60) for datasets from Reddit, Twitter and IAC respectively.

All models are developed using TensorFlow and are trained on a GTX 1080Ti GPU. For the training process, we use the RMSProp optimizer[36] to optimize model parameters with learning rate equals to 0.01 and we train maximum 200 epochs for each model. The training batch size for all datasets is tuned amongst {64, 256, 512}. The L2 regularization is set to 10^{-5} for short texts contained in Reddit and Twitter datasets, and 10^{-3} for long texts covered in IAC datasets. Hyperparameter d in the Bi-LSTM encoder and hyperparameter c in the LRBP process are both fixed at 100.[7]

4.4 Experiment Results

We compare our model with baselines based on standard evaluation metrics including precision, recall, $F1$ score and the accuracy[8]. Experiment results on different datasets are reported in Table 2, 3 and 4.

On the two datasets collected from Reddit, we observe our models improve the state-of-the-art performance substantially. SMSD and SMSD-BiLSTM dominate previous baselines in precision, recall, $F1$ score and accuracy. The specific improvements differ in terms of evaluation metrics and datasets: on the Reddit(/r/movies) dataset, compared with the best performing baseline model, SMSD and SMSD-BiLSTM improve model precision by around 13%, improve recall by around 15-16%, improve the $F1$ score by around 11%

[4]We find the original Riloff dataset on a personal Github page and the dataset can be downloaded at https://github.com/przhang/Sarcasm-Detection. However, we are unable to find the Ptáček dataset from any reliable sources, and after 4 years passed, a substantial amount of original tweets are deleted and we are unable to collect them from Twitter.

[5]We download Reddit datasets from http://nlp.cs.princeton.edu/SARC/2.0/.

[6]We download IAC datasets from https://nlds.soe.ucsc.edu/sarcasm1 and https://nlds.soe.ucsc.edu/sarcasm2 respectively.

[7]As an important baseline, models proposed by Tay et al. [35] are not open-sourced yet, therefore, we align most of our hyperparameters with Tay et al. to make experiment results comparable.

[8]Precision, recall, $F1$ are calculated based on positive samples and accuracy is calculated by averaging both the accuracies in positive and negative samples.

Table 2: Experiment results on Reddit datasets. Best result in previous baselines is in *italic*, and best result in our approach is in bold. Experiment results of baseline models are collected from Tay et al. [35].

and model accuracy by 8-9%. On the Reddit(/r/technology) dataset, SMSD and SMSD-BiLSTM achieve around 10-11% increasing on precision, 12-13% increasing on recall, 16% increasing on $F1$ score and 11% increasing on model accuracy.

On the two datasets collected from IAC, SMSD and SMSD-BiLSTM also achieve outstanding performance. On the IAC-V1 dataset, MIRAN proposed by Tay et al. [35] has the highest recall though, SMSD-BiLSTM achieves around 11% increasing on precision, 3% increasing on $F1$ score and 1% increasing on model accuracy. On the IAC-V2 dataset, MIARN has higher recall and accuracy, yet SMSD has higher precision and $F1$ score. In addition, we also notice that our models are more robust in model performance across two different IAC datasets. For example, the difference of model accuracy between these two datasets is 4.4% for the SMSD, 4.7% for SMSD-BiLSTM, while the difference for SIARN and MIARN are over 9%. Among these baselines, only GRNN has similar stability with our model, while its $F1$ score and accuracy are much lower than ours.

Moreover, SMSD and SMSD-BiLSTM achieve state-of-the-art performance on the two datasets collected from Twitter. On the Rillof dataset, SMSD and SMSD-BiLSTM almost achieve perfect model performance, the accuracy and $F1$ score for both of our

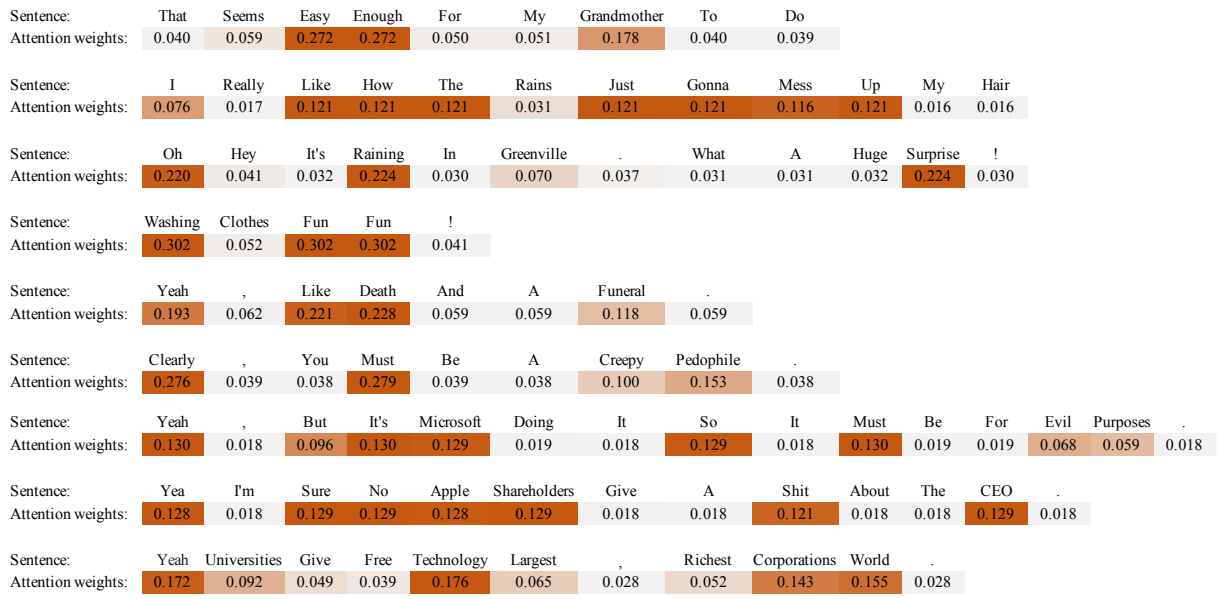

Figure 2: Visualization of Self-matching Results. For each sample, the first sentence shows the original input sentence, and the second sentence demonstrates the attention weights generated from the self-matching network, the darkness of the background varies according to the value of the corresponding attention weight.

models are over 97% [9]. The Ghosh dataset is not widely tested by extant studies yet, we only compare our model performance with the original paper [11] and we still find that our models outperform it, the SDSM-BiLSTM improves precision by around 5%, and SMSD improves recall, $F1$ score by 1% and 2% respectively.

As we have discussed in model description section, we design a self-matching network to compare word-to-word information aiming to search for potential incongruity information; and we also incorporate a bi-directional LSTM encoder to help capture sequential information. We report model performance with and without the Bi-LSTM separately to help us discriminate the value of these two components. As experiment results have demonstrated, in most circumstances, incorporating a bi-directional LSTM encoder will improve model performance. We test our models on six datasets and we find that on the IAC-V1 dataset, the SMSD-BiLSTM outperforms SMSD on four evaluation metrics. SMSD-BiLSTM generally have better performance than SMSD on two Reddit datasets except that SMSD has better precision on Reddit(/r/movies) and better recall on Reddit(/r/technology). These two models have comparable results on IAC-V2 and Tweets(Riloff) considering four evaluation metrics, except that SMSD-BiLSTM has higher accuracy and recall on IAC-V2. We notice that SMSD outperforms SMSD-BiLSTM on Tweets(Ghosh) in terms of recall, $F1$ score and accuracy. These comparison results indicate that the a bi-directional LSTM encoder indeed enriches model input by capturing sentence compositional information, and it helps to generate better sarcasm detection result.

4.5 Model Visualization

In this section we use a few model prediction results to showcase the mechanism of the self-matching network. The self-matching network attends word-to-word information simultaneously and the joint information are captured to attend the original sentence feature map. Therefore, words of conflict sentiments are more likely to be attended by our proposed model. In Figure 2 we depict a few sample sentences with their self-matched attention weights reported. We also demonstrate some bad cases in the prediction result to better understand under what circumstances our models would fail (see Figure 3)[10].

Examples demonstrate that the self-matching network is highly effective on attending words of incongruity information. For example. in the sentence *"That seems easy enough for my grandmother to do"* we notice that the phrase *"easy enough"* and the word *"grandmother"* have the highest attention weights; in sentence *"I really like how the rains just gonna mess up my hair"*, *"like"* and *"mess up"* have relatively high attention weights. These most attended words are usually of opposite sentiments compared to each other and are less likely to be found simultaneously in non-sarcastic expressions. The same pattern can be found across all the examples we provide in Figure 2. Therefore, the self-matching network has a strong power on capturing word pairs of incongruity information that can be taken as a strong indicator for the appearance of sarcasm.

[9]Indeed, the significant improvements on this dataset is beyond our expectation. As aforementioned, Rillof dataset is not provided officially and we collect the Rillof dataset from a personal Github link (as provided in previous section). We test the reliability of the dataset by checking the descriptive statistics of our collected dataset with the statistics reported in previous studies, such as Tay et al. [35] and we find no significant difference between these two datasets. We also notice that the Rillof dataset is unbalanced and evaluation metrics might be biased by prediction result on the dominant class. Therefore, we further examine the values of evaluation metrics from positive samples and negative samples respectively, and we find the results are highly similar.

[10]The authors want to thank two anonymous reviewers for the suggestion of providing a qualitative bad case analysis.

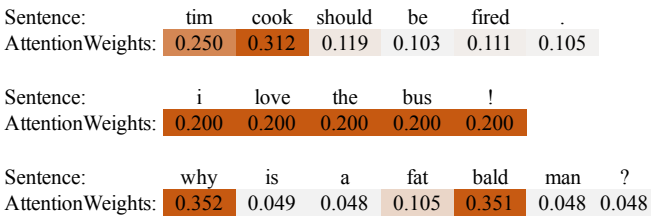

Figure 3: Bad case analysis. Three model prediction bad cases are reported, the first two samples are false negative, and the third sample is false positive.

In Figure 3 we report three bad cases: the first two are false negative and last one is false positive. The first case shows that our model fails to capture *tim cook* as a celebrity name and the sarcasm embedded in this sample replies heavily on external knowledge. In the second case, there are no conflict sentiments between those four words, and we have not further input to know that the author actually hates bus. In addition, the third false positive case *"why"* and *"bald"* have the highest attention weights, this sample sentence is a rhetorical question expression, which is highly similar with sarcastic expression. Therefore, our model is most likely to fail when the sarcasm relies on external knowledge or when the expression is a rhetorical question.

5 CONCLUSION

In this work we propose a novel self-matching network based on a modified co-attention mechanism to cater to sentence incongruity. The self-matching network allows us to capture the interaction between words to search for potential conflict sentiments. We also incorporate a bi-directional LSTM encoder to utilize sentence's compositional information. We conduct extensive experiments on six publicly available datasets. Experiment results demonstrate a strong evidence that our proposed model outperforms most of extant baselines in terms of standard evaluation metrics including precision, recall, $F1$score and accuracy. Our model even improve the state-of-the-art performance on some datasets dramatically. In addition, we also find supportive empirical evidence on utilizing sequential neural networks and low-rank bilinear pooling method can help improve sarcasm prediction result.

ABSTRACT

To bridge the knowledge gap between research and practice, we present the first empirical study on 16,500 the most popular Android apps, demystifying how smartphone apps exploit deep learning in the wild. To this end, we build a new static tool that dissects apps and analyzes their deep learning functions. Our study answers threefold questions: what are the early adopter apps of deep learning, what do they use deep learning for, and how do their deep learning models look like. Our study has strong implications for app developers, smartphone vendors, and deep learning R&D. On one hand, our findings paint a promising picture of deep learning for smartphones, showing the prosperity of mobile deep learning frameworks as well as the prosperity of apps building their cores atop deep learning. On the other hand, our findings urge optimizations on deep learning models deployed on smartphones, protection of these models, and validation of research ideas on these models.

1 INTRODUCTION

Smartphones are undoubtedly among the most promising platforms for running deep learning (DL) based applications [3, 6, 8, 27]. Such a huge market is driven by continuous advances in DL, including the introduction of latest neural-network (NN) hardware [45, 47, 57, 103], improvements in DL algorithms [53, 77, 82, 89], and the increased penetration in huge information analytics [49, 54, 79, 81]. The research community has built numerous DL-based novel apps [44, 68, 69, 76, 83, 102]. The industry has also tried to utilize DL in their mobile products. For example, in the latest released Android 9 Pie OS, Google introduces a small feed-forward NN model to enable Smart Linkify, a useful API that adds clickable links when certain types of entities are detected in text [38].

The year 2017 marked the dawn of DL for smartphones. Almost simultaneously, most major vendors roll out their DL frameworks for smartphones, or *mobile DL framework* for short. These frameworks include TensorFlow Lite (TFLite) from Google [37] (Nov. 2017), Caffe2 from Facebook [9] (Apr. 2017), Core ML from Apple [12] (Jun. 2017), ncnn from Tencent [35] (Jul. 2017), and MDL from Baidu [24] (Sep. 2017). These frameworks share the same goal: executing the DL inference task solely on smartphones. Compared to offloading the DL inference from smartphones to the cloud [2, 19, 21], the on-device DL inference better protects user privacy without uploading sensitive data, continues to operate in the face of poor Internet connectivity, and relieves app authors from affording the cost of running DL in the cloud [45, 63, 66, 67, 67, 69, 74, 100, 103].

Following the DL framework explosion, there emerges the first wave of smartphone apps that embrace DL techniques. We deem it crucial to understand these apps and in particular how they use DL, because the history has demonstrated that such *early adopters* heavily influence or even decide the evolution of new technologies [86] – smartphone DL in our case.

To this end, we present the first empirical study on how real-world Android apps exploit DL techniques. Our study seeks to answer *threefold* questions: *what are the characteristics of apps that have adopted DL, what do they use DL for*, and *what are their DL models*. Essentially, our study aims findings on how DL is being used by smartphone apps *in the wild* and the entailed implications, filling a key gap between mobile DL research and practice.

For the study, we have examined an extensive set of Android apps from the official Google Play appstore. We take two snapshots of the app market in early Jun. 2018 and early Sep. 2018 (3 months apart), respectively. Each snapshot consists of 16,500 the most popular apps covering 33 different categories listed on Google Play. We derive

insights by inspecting individual apps as well as by comparing the two snapshots. To automate the analysis of numerous Android apps, we build a new analyzer tool that inspects app installation packages, identifies the apps that use DL (dubbed "DL apps"), and extracts DL models from these apps for inspection. To realize such a tool, we eschew from looking for specific code pattern and instead identify the usage of known DL frameworks, based on a rationale that most DL apps are developed atop DL frameworks.

Our key findings are summarized as follows.

Early adopters are top apps (§4.2) We have found 211 DL apps in the set of apps collected in Sep. 2018. Only 1.3% of all the apps, these DL apps collectively contribute 11.9% of total downloads of all the apps and 10.5% of total reviews. In the month of Sep. 2018, the 211 DL apps are downloaded for around 13,000,000 times and receive 9,600,000 reviews. DL apps grow fast, indicating a 27% increase in their numbers over the 3 months in our study.

DL is used as core building blocks (§4.3) We find that 81% DL apps use DL to support their core functionalities. That is, these apps would fail to operate without their use of DL. The number of such DL apps grow by 23% over the period of 3 months.

Photo beauty is the top use (§4.3) DL is known for its diverse applications, as confirmed by the usage discovered by us, e.g. emoji prediction and speech recognition. Among them, photo beauty is the most popular use case: 94 (44.5%) DL apps use DL for photo beauty; 61 (29%) DL apps come from the photography category.

Mobile DL frameworks are gaining traction (§4.4) While full-fledged DL frameworks such as TensorFlow are still popular among DL apps due to their momentum, DL frameworks designed and optimized for constrained resources are increasingly popular. For instance, the number of DL apps using TFLite has grown by 258% over the period of 3 months.

Most DL models miss obvious optimizations (§5.2) Despite well-known optimizations, e.g. quantization which can reduce DL cost by up to two orders of magnitude with little accuracy loss [58], we find only 6% of DL models coming with such optimizations.

On-device DL is lighter than one may expect (§5.3) Despite the common belief that the power of DL models comes from rich parameters and deep layers, we find that DL models used in apps are rather small, with the median memory usage of 2.47 MB and the inference computation of 10M FLOPs, which typically incurs the inference delay of tens of milliseconds. These models are not only much lighter than full models designed for cloud/servers (e.g. ResNet-50 with 200 MB memory and 4G FLOPs inference computations) but also lighter than well-known models specifically crafted for smartphones, e.g. MobileNet with 54 MB memory and 500M FLOPs inference computations.

DL models are poorly protected (§5.4) We find that only 39.2% discovered models are obfuscated and 19.2% models are encrypted. The remaining models are a bit trivial to extract and therefore subject to unauthorized reuse.

Summary of implications: Overall, our findings paint a promising picture of DL on smartphones, motivating future research and development. Specifically, the findings show strong implications for multiple stakeholders of the mobile DL ecosystem. **To app developers:** our findings show that DL can be sufficiently affordable on smartphones; developers, especially individuals or small companies, should have more confidence in deploying DL in their apps; interested developers should consider building DL capability atop mobile DL frameworks; a few app categories, notably photography, are most likely to benefit from DL techniques. **To DL framework developers:** our findings encourage continuous development of frameworks optimized for smartphones; our findings also show the urgent need for model protection as the first-class concern of frameworks. **To hardware designers:** our findings motivate DL accelerator designs to give priority to the layers popular among mobile DL models. **To DL researchers:** our findings suggest that new proposal for optimizing DL inference should be validated on lightweight models that see extensive deployment on smartphones in the wild.

In summary, our contributions are as follows.

- We design and implement a tool for analyzing the DL adoption in Android apps. Capable of identifying the DL usage in Android apps and extracting the corresponding DL models for inspection, our tool enables automatic analysis of numerous apps for DL.
- We carry out the **first** large-scale study of 16,500 Android apps for their DL adoption. Through the empirical analysis, we contribute new findings on the first wave of apps that adopt DL techniques. In the dawn of DL explosion for smartphones, our findings generate valuable implications to key stakeholders of the mobile ecosystem and shed light on the evolution of DL for smartphones. We also publicize our tools and datasets[1].

2 BACKGROUND

DL models and frameworks DL has revolutionized many AI tasks, notably computer vision and natural language processing, through substantial boosts in algorithm accuracy. In practice, DL algorithms are deployed as two primary parts. The first one is *DL models*, which often comprise neuron layers of various types, e.g. convolution layers, pooling layers, and fully-connected layers. Based on the constituting layers and their organizations, DL models fall into different categories, e.g., Convolutional Neural Network (CNN) containing convolution layers, and Recurrent Neural Network (RNN) processing sequential inputs with their recurrent sub-architectures. The second part is *DL frameworks* that produce DL models (i.e. training) and execute the models over input data (i.e. inference). Since a commodity DL framework often entails tremendous engineering efforts, most app developers tend to exploit existing frameworks by major vendors, such as *TensorFlow* from Google.

Deploying mobile DL As training models is intensive in both data and computing [73], smartphone developers often count on cloud servers for modeling training offline prior to app deployment. At app installation time, the trained models are deployed as part of the app installation package. At runtime, apps perform inference

[1] https://github.com/xumengwei/MobileDL

with the trained models by invoking DL frameworks, and therefore execute AI tasks such as face recognition and language translation.

Inference: on-cloud vs. on-device Towards enabling DL on smartphones, model inference can be either offloaded to the cloud or executed solely on smartphones. Offloading to the cloud is a classical use case of Software-as-a-Service (SaaS), and has been well studied in prior work [43, 62, 85, 101]. The mobile devices upload data and retrieve the inference results, transparently leveraging rich data center resources as server-class GPU. Yet, we have observed that the on-device DL inference is quickly gaining large popularity due to its unique advantages of stronger privacy protection, resilience against poor Internet connectivity, and lower cloud cost to app developers. We will present more evidence in the paper. In this work, we focus our empirical study on such on-device deep learning for smartphones.

3 GOAL AND METHODOLOGY

3.1 Research Goal

The goal of our study is to demystify how smartphone apps exploit DL techniques in the wild. Our study focuses on two types of subjects: i) smartphone apps that embrace DL, and ii) the DL frameworks and models used in practice. Accordingly, we characterize the apps, the frameworks, and the models. We will present the results in Section 4 and Section 5 respectively.

Scope We focus our analysis on Android apps, as Android represents a dominant portion of smartphone shipment (88% in the second quarter of 2018) and hence serves a good proxy for the entire smartphone app population [18].

Datasets We retrieve from the Google Play store the full dataset used in this work. We select 16,500 apps in total, which consist of the top 500 free apps with most downloads from each of the 33 categories defined by Google Play[2]. We have crawled two datasets at different moments, June 2018 and September 2018, which are three months apart. The two app datasets have more than 2/3 overlapped apps. For each app, we download its apk file and crawl its meta information (e.g. app description and user rating) from the Google Play web page for analysis. Our analysis primarily focuses on the newer dataset, i.e., Sep. 2018, and the difference between the two data sets, unless specified otherwise.

3.2 Workflow Overview

We design and implement an analyzing tool to enable our research goal on large-scale Android apps. The tool runs in a semiautomatic way, as illustrated in Figure 1.

The very first step of the analyzing tool is identifying DL apps among a given set of Android apps as input. This is achieved via the module named DL Sniffer. The core idea of DL Sniffer, is detecting the usage of popular DL frameworks, instead of directly finding the usage of DL. After identifying DL apps, it performs analysis on those apps. During analysis, we use the manifest files extracted from DL apps via tool aapt [4] and the meta information crawled from the corresponding Google Play web page. The manifest files include information such as package name, app version, required permissions, etc. The web pages include information such as app description, user rating, app developer, etc.

The analyzing tool further extracts DL models from those DL apps. This extraction is achieved via a module called Model Extractor. After extracting DL models, it performs analysis on them. However, we here face the challenge that the models are mostly in different formats. Although developers are investing substantial efforts in integrating different model formats, such as designing a standardized one [25], the ecosystem of DL frameworks is still broken and fragmented nowadays. Thus, when looking into the internal structures of DL models, we substantially leverage the available tools and source of different frameworks. Fortunately, most of the frameworks we investigated (details in Table 2) are open-source and well-documented.

We discuss more details of DL Sniffer and Model Extractor in Section 4.1 and Section 5.1, respectively.

4 APPLICATION ANALYSIS

This section presents our analysis of smartphone DL apps. We first describe our methodology in Section 4.1 and then the following three major aspects of the DL apps:

- The characteristics of DL apps (§4.2): their popularity, their difference from non-DL apps, and their developers.
- The role of DL (§4.3): the popular usage of DL in apps, the categories of DL apps, and evidence that DL is already used as core building blocks of apps.
- An analysis of DL frameworks (§4.4): which frameworks are used, the cost, and their adoption trend over time.

4.1 Methodology: finding DL apps

As a part of our analyzing tool (Section 3.2), DL Sniffer takes apk file(s) as input, and outputs which of them use DL technique. Detecting DL usage is difficult, instead DL Sniffer mainly detects the usage of popular DL frameworks with Android support. Currently, DL Sniffer supports the detection of 16 popular DL frameworks, including *TensorFlow, Caffe, TFLite,* etc, and the details of those frameworks will be presented later in Section 4.4 & Table 2. DL Sniffer uses two ways to mine the usage of DL frameworks: (1) For those who provide native C++ APIs, DL Sniffer first decomposes the apk files via Apktool [5], and extracts the native shared libraries (with suffix ".so"). DL Sniffer then searches for specific strings on the *rodata* section of those libraries. Those strings can be regarded as identifications of corresponding frameworks, and are pre-defined by us. For example, we notice that the shared libraries that use *TensorFlow* always have *"TF_AllocateTensor"* in its *rodata* section. (2) For those who only support Java APIs, DL Sniffer first converts the apk file into smali code via dex2jar [14]. The smali code, which is a disassembled version of the DEX binary used by Android's Davik VM, enables us to carry out static program analysis. DL Sniffer statically goes through the class/method names of smali code and checks whether certain APIs exist. For example, the class *MultiLayerConfiguration* is used in almost every app that embeds DeepLearning4J framework.

Besides detecting the usage of DL frameworks, we also try to identify DL apps that don't use the frameworks listed in Table 2 (called "*no lib*" in this work). Similarly, this is achieved by searching

[2]Different app categories on Google Play can be visited via url https://play.google.com/store/apps/category/XXX, where XXX can be GAME or other category names.

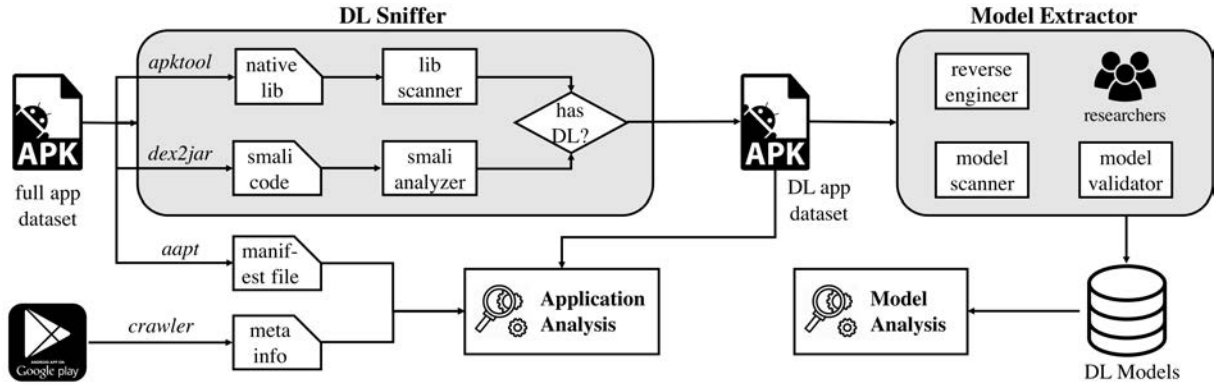

Figure 1: The overall workflow of our analyzing tool.

specific strings on the *rodata* section of native libraries as mentioned above, but the strings we use here are pre-defined such as *"neural network", "convolution", "lstm"*, etc, rather than extracted from existing frameworks. We then manually check the detection correctness through reverse engineering, filtering those don't really have DL usage (false positive). This manual check is also performed on other DL apps detected using the aforementioned approach, to ensure good accuracy in DL identification.

4.2 Characteristics of DL apps

• **Is DL gaining popularity on smartphones?** Our study shows: over our investigation period (June 2018 – Sept. 2018), the total amount of DL apps has increased by 27.1%, from 166 to 211. We further investigate the new downloads and reviews of DL apps within one month of Sept. 2018: in that period, the 211 DL apps are downloaded for around 13,000,000 times and receive 9,600,000 new reviews. The results indicate that a substantial amount of smartphones are running DL apps nowadays.

• **How are DL apps different from non-DL apps?** We investigate the following three aspects with results illustrated in Figure 2.

Downloads and Reviews are typical signal of apps' popularity [75]. As observed, the median number of downloads and reviews of DL apps are 5,000,000 and 41,074 respectively, much larger than non-DL apps, i.e., 100,000 and 1,036 respectively. We also count the download rankings of each DL apps within the corresponding category. The median number of such ranking is 89 among total 500 apps for each category. We deem the above statistics as strong evidences that *top apps are early adopters in deploying DL in mobile apps.* Such phenomenon can be explained that making DL work in the wild, though appealing, takes a lot of engineering efforts. The cycle of developing DL functionality on smartphones includes model construction, data collection, model training, offline/online testing, etc. Thus, many small companies or individual developers lack the resources to exploit DL on their apps.

Ratings show how much appreciation users give to apps. The Figure shows that DL apps and non-DL apps have similar ratings from users, with the same median number 4.3.

App size: as shown in Figure 2, DL apps have much larger apk files than non-DL apps (median number: 35.5MB vs 12.1MB). This

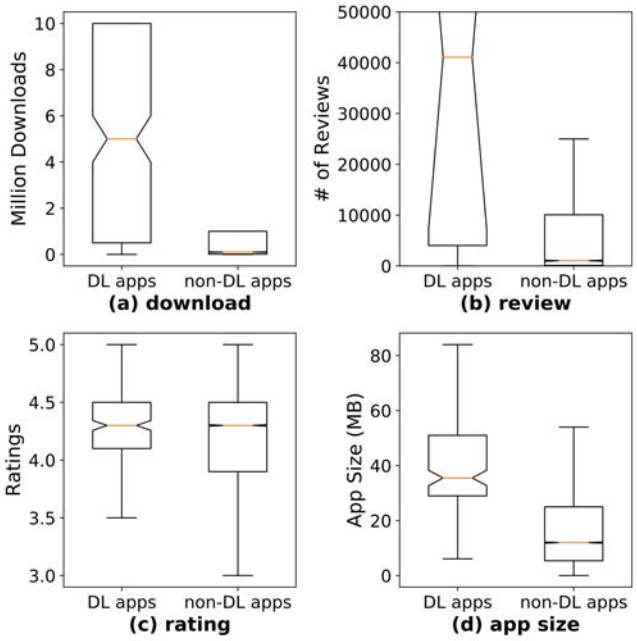

Figure 2: Comparisons between DL apps and non-DL apps on various aspects (a)–(d). Each box shows the 75th percentile, median, and 25th percentile from top to bottom. We manually set the y-axis limits for better presentation in (b): the missed out 75th percentile of DL apps is 324,044.

is reasonable since having DL not only adds DL frameworks and models to the apps, it also confidently indicates that the apps have much richer features.

• **Who are the developers of DL apps?** We also study the developers of DL apps. The results show that the identified 211 DL apps belong to 172 developers (companies), among which 27 developers have more than one DL apps. The developers with most DL apps are "Google LLC" (10) and "Fotoable,Inc" (6). We observe many big companies own more than one DL app, including Google, Adobe, Facebook, Kakao, Meitu, etc. This suggests that those big

Table 1: The DL usage in different apps. Note: as one app may have multiple DL uses, the sum of detailed usage (column 2) might exceed the corresponding coarse usage (column 1).

usage	detailed usage	as core feature
image: 149	photo beauty: 97	94 (96.9%)
	face detection: 52	44 (84.6%)
	augmented reality: 19	5 (26.3%)
	face identification: 8	7 (87.5%)
	image classification: 11	6 (54.5%)
	object recognition: 10	9 (90%)
	text recognition:11	4 (36.3%)
text:26	word&emoji prediction: 15	15 (100%)
	auto-correct: 10	10 (100%)
	translation: 7	3 (42.8%)
	text classification: 4	2 (50%)
	smart reply: 2	0 (0%)
audio: 24	speech recognition: 18	7 (38.9%)
	sound recognition: 8	8 (100%)
other: 19	recommendation: 11	2 (18.1%)
	movement tracking: 9	4 (44.4%)
	simulation: 4	4 (100%)
	abnormal detection: 4	4 (100%)
	video segment: 2	1 (50%)
	action detection: 2	0 (0%)
total: 211		171 (81.0%)

companies are pioneers in adopting DL into their products. We also notice that DL apps from the same developer often have identical DL frameworks. For example, four products from Fotoable Inc use the exactly same native library called *libncnn_style.0.2.so* to support DL technique. This is because that DL frameworks and even the DL models are easily reusable: a good nature of DL technique that can help reduce the engineering efforts of developers.

Implications: *The popularity of DL among top smartphone apps, especially ones developed by big companies, should endow smaller companies or independent developers with strong confidence in deploying DL in their apps.*

4.3 The roles of DL in apps

• **What are the popular uses of DL?** To understand the roles played by DL, we manually classify the usage of DL on different apps. This is achieved by looking into the app description and app contents. The results are shown in Table 1. Each app has one or more usages, and the usage is represented in two different levels (coarse and detailed). 10 apps are left out since we cannot confirm their DL usage.

Overall, image processing is the most popular usage of DL on smartphones, far more than text and audio processing (149 vs. 26 & 24). This is not surprising since computer vision is the field where DL starts the revolution [64], and the progress on this field has been lasting since then [72]. In more details, photo beauty (97) and face detection (52) are mostly widely used in DL apps, usually found in photo editing and camera apps to beautify pictures. In text field, word & emoji prediction (15) and auto-correct (10) are also

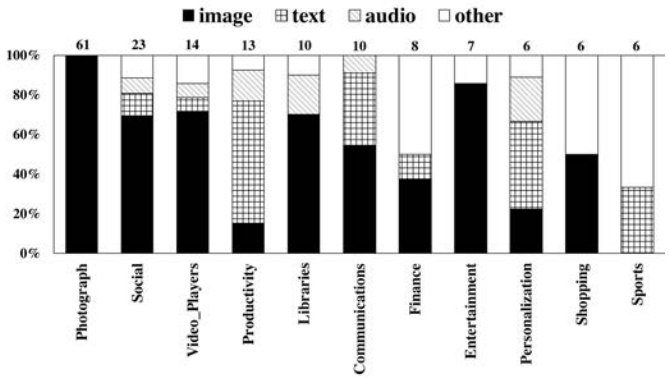

Figure 3: Distributions of DL apps over categories defined by Google Play. Numbers on top: the counts of DL apps in the corresponding categories. Apps in each category are further broken down by DL usage (see Table 1 for description). Categories with fewer than 5 DL apps are not shown.

popular, usually found in input method apps like GBoard. For audio processing, DL is mainly used for speech recognition (14). Besides, there are other types of usage such as recommendation (11) which is often found in shopping apps.

• **Which categories do DL apps come from?** Figure 3 summarizes the number of DL apps in different categories. As observed, almost 29% DL apps (61 out of 211) are in category photograph, all of which use DL for image processing. Social category is another hotspot with 23 DL apps in total, 78% of which use DL for image processing while others use it for text, audio, etc. The category of productivity also contains 13 DL apps, but most of them (62%) use DL for text processing. Overall, we can see that the DL usage is somehow diverse, with 11 categories has more than 5 DL apps among the top 500. Such diversity gives credits to the good generality of DL technique.

Implications: *Our findings encourage developers of certain types of apps, notably the ones with photo beauty, to embrace DL. Our findings also motivate encapsulating DL algorithms within higher level abstractions that cater to popular uses in apps. For instance, companies such as SenseTime already starts to ship DL-based face detection libraries to app developers. Masking the details of DL models and frameworks, such abstractions would make DL more friendly to developers.*

• **Is DL a core building block?** We also manually tag each DL usage as core feature or not. We define the DL functionality as apps' core feature if and only if two conditions are satisfied: (1) *hot*: the DL functionality is very likely to be invoked every time the apps are opened and used by users, (2) *essential*: without the DL functionality, the apps' main functionality will be severely compromised or even become infeasible. For example, DL on *text recognition* is treated as core feature in a scanner app (Adobe Scan) that helps users translate an image into text, but not in a payment app (Alipay) that uses it to scan ID card for identification. Similarly, DL on *photo beauty* is treated as core feature in a camera app (Meitu), but not in a social app (Facebook Messenger Kids).

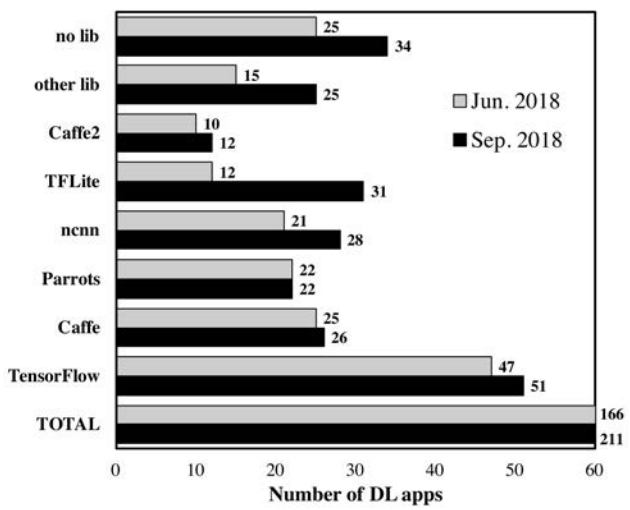

Figure 4: Numbers of DL apps using various mobile DL frameworks. "other lib": the DL apps developed on the frameworks in Table 2 but not itemized here, e.g. *mace, SNPE, and xnn*. "no lib": apps with DL functions but using no DL frameworks from Table 2. Note that the number in "TOTAL" is lower than the sum of others since some DL apps have integrated multiple frameworks.

Overall, 171 out of 211 (81%) apps use DL to support core features. Specifically, since photo beauty (96.9%) and face detection (84.6%) are primarily used in photo & camera apps, their usage is essential. Similarly, word & emoji prediction (100%) and auto-correct (100%) are treated as core features in keyboard apps, helping users input more efficiently and accurately. However, recommendation (18.1%) is often provided as complementary feature to others such as shopping apps, thus not treated as core feature.

Implications: *Our findings support future investment on R&D of mobile DL, as the core user experience on smartphones will probably depend on DL performance [67] and security [80, 92].*

4.4 DL frameworks

As mentioned in Section 2, DL frameworks are critical to DL adoption, as most developers use those frameworks to build their DL apps. In this subsection, we investigate into how those frameworks are used in DL apps: the numbers, the sizes, the practice, etc.

• **A glance over popular DL frameworks** We first make an investigation into popular DL frameworks, and the results are summarized in Table 2. We select those 21 frameworks for their popularity, e.g., forks and stars on GitHub, gained attention on StackOverflow and other Internet channels. Among those 21 frameworks, 16 frameworks support Android platform via Java (official language on Android) and/or C++ (native support via cross-compilation). Most of them are open-source, while others are either provided to public as a binary SDK (*SNPE, CoreML*), or only accessible by the providers' (collaborators') own products (*xNN, Parrots*). Most of them use customized format to store and represent the model files, but some

Figure 5: The number of check-in and check-out DL apps.

leverage existing approaches, such as ProtoBuf [28]. We also notice a trend on lightweight DL inference frameworks, which are designed specifically for mobile apps but have no training-support back-end (*ncnn, FeatherCNN, MACE*, etc). Those frameworks cannot train DL models, but can predict with pre-trained models via other frameworks such as *TensorFlow* or *Caffe*. Note that our later analysis substantially relies on the openness of DL frameworks: it enables us to use the existing tools to analyze or even visualize the DL models such as *TensorFlow*, or build our own interpreting scripts to analyze them based on the open code such as *ncnn*.

• **What is the adoption of DL frameworks?** As summarized in Figure 4, the most popular DL frameworks used in Sep. 2018 are *TensorFlow* (51), *TFLite* (31), and *ncnn* (28), as they contribute to almost 50% of the total number of DL apps. Other popular frameworks include *Caffe*, *Parrots*, and *Caffe2*. We have made several observations from those 6 dominant frameworks as following.

(1) All these frameworks are developed by big companies (e.g. Google), AI unicorns (e.g. SenseTime), or renowned universities (e.g. Berkeley).
(2) 5 out of these 6 frameworks are open-source, except *Parrots* which is provided as SDK to consumers. In fact, it is believed that openness is already an important feature in machine learning, especially DL society, as it supposes to [91]. It helps developers reproduce the state-of-the-art scientific algorithms, customize for personal usage, etc. As a result, for example, *TensorFlow* has more than 1,670 contributors up to Oct. 2018, going far beyond the community of Google.
(3) Most (4 out of 6) frameworks are optimized for smartphones, except *Caffe* and *TensorFlow*. Those mobile DL frameworks are designed and developed specifically for mobile devices, usually without training back-end, so that the resulted libraries can be faster and more lightweight. As an example, *TFLite* stems from *TensorFlow*, but is designed for edge devices and reported to have lower inference time and smaller library size than *TensorFlow* [106]. Besides those popular frameworks, we identify 34 (16.1%) DL apps that don't use any framework in Table 2. These apps use self-developed engines to support DL functionality.

• **Are mobile DL frameworks gaining traction?** As shown in Figure 4, DL frameworks optimized for smartphones, such as *TFLite* and *ncnn*, quickly gain popularity: the number of *TFLite*-based DL apps has increased from 12 to 31; that of *ncnn* increases from 21 to 28. We deem it as the trend of mobile DL ecosystem: *To train a model offline, use large, mature, and generic frameworks that focus on developer friendliness and feature completeness. To deploy a model on edge devices, switch to mobile-oriented frameworks that focus on performance (inference latency, memory footprint, and library size).*

Table 2: An overview of popular deep learning frameworks and their smartphone support at the time of writing (Nov. 2018).

Framework	Owner	Supported Mobile Platform	Mobile API	Is Open-source	Supported Model Format	Support Training
TensorFlow [36]	Google	Android CPU, iOS CPU	Java, C++	✓	ProtoBuf (*.pb, .pbtxt*)	✓

PyTorch [29]	Facebook	/	/	✓	customized, pickle (*.pkl*)	✓

We also investigate into the DL check-in and check-out behavior in mobile apps. We define the check-in DL apps as those that have no DL usage in earlier version (Jun. 2018) but add the DL usage in newer version (Sep. 2018), and the check-out vice versa. Note that the app list of our two datasets are not identical since we crawl the most popular ones, but the popularity is changing. So we only consider the apps that exist in both lists (11,710 in total), and conclude the results in Figure 5. As observed, 48 out of the 190 (25.3%) DL apps in newer version are checked in between Jun. 2018 and Sep. 2018. We also notice that some DL apps in old version checked out, but the number is much smaller (5). The reasons of check-out can be that the developers remove the corresponding functionality or just replace the DL with other approaches. Overall, the statistics support the fact that DL technique is increasingly adopted in mobile apps.

• **What is the storage overhead of frameworks?** Figure 6 shows the sizes of DL libs, i.e. the physical incarnation of DL frameworks. As shown, the average size of DL libs is 7.5MB, almost 6 times compared to the non-DL libs. Here, we only use the non-DL libs found within DL apps. The results show that DL libs are commonly heavier than non-DL libs, because implementing DL functionality, even without training backend, is quite complex. Looking into different frameworks, using *TensorFlow* and *Caffe* results in larger DL libs, i.e., 15.3MB and 10.1MB respectively, while others are all lower than 5MB. The reason is that mobile supports of *TensorFlow* and *Caffe* are ported from the original frameworks and substantially reuse the code base from them. However, these two frameworks are designed for distributed on-cloud DL. As comparison, other frameworks in Figure 6 are specifically designed for mobile devices to the purpose of good performance.

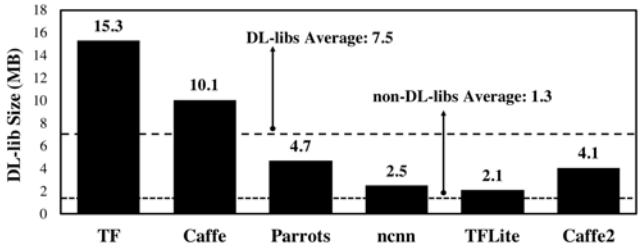

Figure 6: The binary library sizes of DL frameworks.

One app may incorporate multiple DL frameworks. Surprisingly, we find that 24 DL apps integrate more than one DL framework. For example, AliPay, the most popular payment app in China, has both *xnn* and *ncnn* inside. We deem such multi-usage as (potentially) bad practice, since it unnecessarily increases the apk size and memory footprint when these frameworks need to be loaded simultaneously. According to our statistics, the overhead is around 5.4MB, contributing to 13.6% to the total apk size on average. Such overhead can be avoided by running different tasks based on one framework, since most DL frameworks are quite generic and can support various types of DL models. Even if not, they can be easily extended to support the missing features [1]. The reason of such multi-usage behavior can be twofold. First, one app might be

developed by different engineers (groups), who introduce different frameworks for their own DL purpose. Second, the developers may just reuse existing code and models for specific tasks, without merging them together in one DL implementation.

Implications: *Our findings highlight the advantages and popularity of mobile DL frameworks, encouraging further optimizations on them. Our findings also motivate app developers to give these frameworks priority considerations in choosing the incarnation of DL algorithms.*

5 MODEL ANALYSIS

This section focuses on the model-level analysis of DL technique. We first describe the methodology details, e.g., the design of Model Extractor in Section 5.1. Then, we show the analysis results on those DL models from three main aspects.

- The structures of DL models: the model types, layer types, and optimizations used (Section 5.2).
- The resource footprint of DL models: storage, memory, execution complexity, etc (Section 5.3).
- The security of DL models: using obfuscation and encryption to protect models from being stolen (Section 5.4).

5.1 Model Extractor: finding DL models

As a part of our analyzing tool (Section 3.2), Model Extractor takes DL apps which we have already identified as input, and outputs the DL model(s) used in each app. Model Extractor scans the *assets* folder of each decomposed DL apps, tries to validate each model file inside. Since DL frameworks use different formats to store their model files, Model Extractor has a validator for each of supported framework. However, we observe that many models are not stored as plaintext inside apk files. For example, some of them are encrypted on storage, and decrypted when apps running on devices. For such cases, Model Extractor tries to reverse engineer the apps, and extract the analyzable models.

Overall results We extract DL models based on the most popular frameworks, i.e., *TFLite*, *TensorFlow*, *ncnn*, *Caffe*, or *Caffe2*. In summary, we successfully extract 176 DL models, which come from 71 DL apps. The reasons why we cannot extract models from the other DL apps could be (i) the models are well protected and hidden in the apk files; (ii) the models are retrieved from Internet during runtime. Among the extracted models, we can analyze 98 of them, which come from 42 DL apps. The other extracted models cannot be parsed via our framework currently because (i) the models are in format which we have no insights into, such as *Parrots*-based models, since the corresponding frameworks are not open-source; (ii) the models are encrypted.

5.2 Model Structures

• **DL model types** Among the DL models extracted, 87.7% models are CNN models, 7.8% models are RNN models, while others are not confirmed yet. The CNN models are mostly used in image/video processing and text classification. The RNN models are mostly used in text/voice processing, such as word prediction, translation, speech recognition, etc. The results are consistent with the conventional wisdom: CNN models are good at capturing visual characteristics from images, while RNN models are powerful at processing sequential data with temporal relationships such as text and audio.

Table 3: Layers used in DL models. "% of models" shows how many models contain such layer, while "# in each model" shows the median/mean numbers of occurrences in each model that contains such layer. "conv" and "fc" are short for convolution and fully-connect.

Layer type	% of models	# in each model	Layer type	% of models	# in each model
conv	87.7	5 / 14.8	relu	51.0	6 / 16.3
pooling	76.5	2 / 2.8	split	46.9	1 / 7.5
softmax	69.1	1 / 1.1	prelu	32.1	4 / 4.6
fc	60.5	3 / 5.6	reshape	28.4	2 / 24.1
add	56.8	9.5 / 23.8	dropout	21.0	1 / 1.0

Table 4: Optimizations applied on DL models.

	1-bit Quan.	8-bit Quan.	16-bit Quan.	Sparsity
TF	unsupported	4.78%	0.00%	0.00%
TFLite	unsupported	66.67%	unsupported	unsupported
Caffe	unsupported	0.00%	unsupported	unsupported
Caffe2	unsupported	0.00%	unsupported	unsupported
ncnn	unsupported	0.00%	unsupported	unsupported
Total	*0.00%*	*6.32%*	*0.00%*	*0.00%*

• **DL layer types** We then characterize different types of layers used in DL models. As shown in Table 3, convolution (conv) is the most commonly used type. 87.7% models have at least one convolutional layer, and the median (mean) number of convolutional layers used in those models is 5 (14.8). This is not surprising since convolution is the core of CNN models, and CNN is the dominant model architecture used in vision tasks. Our previous analysis already demonstrates that image processing is the most popular use case of mobile DL. Similarly, pooling is also an important layer type in CNN models, included in 76.5% DL models. Besides, softmax is also frequently used (69.1%), but don't repeatedly show up in one single model. This is because softmax layer usually resides at the end of DL models to get the probabilities as output. As a comparison, fully-connected (fc) layers are less common, only used in 60.5% DL models. A possible reason is that fully-connected layer is known to be very parameter- and computation-intensive, and can be replaced by other layers such as convolution [17]. Other frequently used layer types include add, split, relu, prelu, dropout, and reshape.

Implications: *Our findings motivate framework and hardware vendors who are interested in optimizing mobile DL to focus on the popular DL layers that we discovered in deployed models, e.g. convolution.*

We also notice that a small number (5) of DL models contain customized layer types. Such customization is made as an extension to existing DL frameworks [1]. The result indicates that the functionalities of current DL frameworks are mostly complete enough.

• **Model optimizations** Various techniques have been proposed to optimize the DL models in consideration of their sizes and computation complexity. Here, we study the usage of two most popular techniques in the wild: quantization and sparsity. **Quantization** compresses DL models by reducing the number of bits required

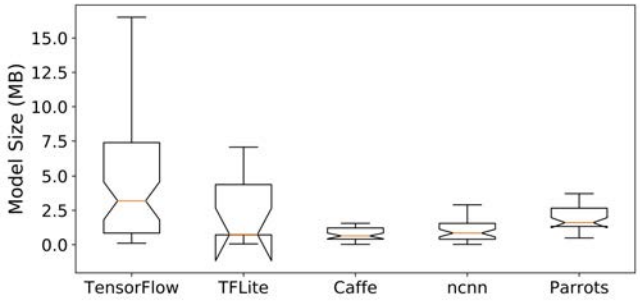

Figure 7: The size of DL models in different frameworks. We leave out *Caffe2* since we only successfully extract one model in *Caffe2* format.

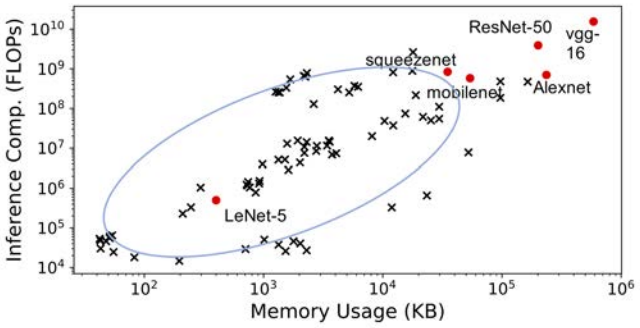

Figure 8: The cost of memory and computation of DL models extracted from apps. Red dots: classical CNN architectures as references. Black crosses: extracted DL models.

to represent each weight. The quantization has different levels, including 16-bit [56], 8-bit [95], and even 1-bit [48, 84], while the original models are usually presented in 32-bit floating points. **Sparsity** [71, 96] has also been extensively studied in prior literatures as an effective approach to make compact DL models. It's mainly used in matrix multiplication and convolutional layers to reduce parameters. Such optimizations are known to reduce DL cost by up to two orders of magnitude without compromising model accuracy [58].

Table 4 summarizes the optimizations applied on DL models. Here we focus on the DL models for 5 popular frameworks, i.e., *TensorFlow (TF), TFLite, Caffe, Caffe2*, and *ncnn*. Overall, most of these frameworks only support 8-bit quantization, except *TensorFlow* who has 16-bit quantization and sparsity support. However, only a fraction of DL models apply the optimization techniques: 6.32% models are quantized into 8-bit, while others are non-optimized.

Implications: *The findings that well-known DL optimizations are missing in real-world deployment suggest the efficiency potential of mobile DL is still largely untapped. The findings also urge immediate actions to fix the missing optimizations.*

5.3 Model Resource Footprint

• **Model size.** Figure 7 illustrates the size of DL models (in storage). Overall, we find that the extracted DL models are quite small (median: 1.6MB, mean: 2.5MB), compared to classical models such as VGG-16 [90] (around 500MB) and MobileNet [63] (around 16MB). The models in *TensorFLow* format (median: 3.2MB) are relatively larger than the models in other formats such as *TFLite* (median: 0.75MB) and *ncnn* (median: 0.86MB).

• **Runtime overhead.** We then study the runtime performance of DL models. Here, we focus on two aspects: memory and computations. The memory usage includes both the model parameters and the generated intermediate results (feature maps). For computation complexity, we use floating point operations (FLOPs) during one inference as the metric. Here we use only part of models in *TensorFlow* and *ncnn* formats since some others don't have fixed input sizes, e.g., image size, so that the computation complexity can only be determined at runtime [15]. We also include the performance of some other classical CNN models such as AlexNet, MobileNet, etc.

As illustrated in Figure 8, the black crosses represent the DL models we have extracted, while the red dots represent the classical CNN architectures. Overall, the results show that *in-the-wild DL models are very lightweight in consideration of memory usage and computation complexity, with median value of 2.47 MB and 10M FLOPs respectively.* Running such models on mobile processors is inexpensive. For example, as estimated on the CPU of Snapdragon 845[3], the execution time of 80% models are less than 15ms which is translated to 67 FPS [32]. To be compared, ResNet-50, one of the state-of-the-art models in image classification task, has around 200MB memory usage and 4GFLOPs computations. Even MobileNet and SqueezeNet, which are designed and optimized for mobile scenarios, require more memory usage and computations than 90% those mobile DL models that we have discovered.

Implications: *Our findings of dominant lightweight DL models on smartphones give app developers a valuable assurance: DL inference can be as cheap as a few MBs of memory overhead and tens of ms execution delay. Our findings challenge existing research on DL inference, which are typically centered on full-blown models (e.g. VGG) and validated on these models. Given the significance of smartphones as DL platforms, future DL algorithm proposals should consider applicability on lightweight models and resource constraints concern.*

5.4 Model Security

Finally, we investigate into how DL models are protected. We deem model protection as an important step to AI system/app security, because if attackers can acquire the model, they can (i) steal the intellectual property by reusing the model file or re-train a new model; (ii) easily attack the DL functionality via adversarial attack [80]. We focus on two practical protection mechanisms.

- **Obfuscation** is a rather shallow approach to prevent attackers from gaining insights into the model structures by removing any meaningful text, e.g., layer names.
- **Encryption** is better in security by avoiding attackers from getting the model structures/parameters, but also causes inevitable overhead for apps to decrypt the models in memory. Here, we deem encrypted models as always obfuscated too.

We investigate into how obfuscation and encryption are employed on DL models that we have extracted. We analyze the DL models

[3] A typical mobile chip used by many popular smartphones such as Galaxy S8.

extracted from apps using *TensorFLow, TFLite, ncnn, caffe*, and *Caffe2*. In total, we confirm the security level of 120 DL models. Note that here encryption doesn't necessarily mean encryption algorithm, but also includes cases where developers customize the model format so that the model cannot be parsed via the DL framework.

The results show that among the 120 DL models, we find 47 (39.2%) models are obfuscated and 23 (19.2%) models are encrypted. Note that these two sets of apps are overlapped: encrypted apps are also obfuscated. The results indicate that *most DL models are exposed without protection, thus can be easily extracted and utilized by attackers.* In fact, only few frameworks in Table 2 support obfuscation, e.g., *ncnn* can convert models into binaries where text is all striped [33], and *Mace* can convert a model to C++ code [11]. What's worse, no framework provides help in model encryption as far as we know. Thus, developers have to implement their own encryption/decryption mechanism, which can impose non-trivial programming overhead.

Implications: *The grim situation of model security urges strong protection over proprietary models in a way similar to protecting copyright digital contents on smartphones [41, 78, 87, 104]. This necessitates a synergy among new tools, OS mechanisms and policies, and hardware mechanisms such as ARM TrustZone [7].*

6 DISCUSSIONS

Limitations of our analyzing tool Although we carefully design our analyzer to capture as many DL apps as possible, and involve a lot of manual efforts to validate the results, we can still have false identifications. For example, those DL apps that neither depend on any popular DL frameworks, nor have any string patterns in the native libraries, will be missed out. In addition, the apps that have integrated DL frameworks but don't really use them will be falsely classified as DL apps. For the first case, we plan to mine the code pattern of DL implementation and use the pattern to predict more DL apps that might involve DL. For the second one, we plan to further enhance our analyzer with advanced static analysis technique [42] so that it can detect whether the API calls (sinks) of DL libraries will be invoked or not. Our tool can be further enhanced via dynamic analysis, e.g., running the extracted models on smartphones and inspecting the system behavior.

More platforms In this work, we only analyze the adoption of DL on Android apps. Though Android is quite representative of the mobile ecosystem, more interesting findings might be made by expanding our study on other platforms such as iOS and Android Wear. We believe that comparing the DL adoption on different platforms can feed in more implications to researchers and developers.

7 RELATED WORK

Mobile DL Due to their ubiquitous nature, mobile devices can create countless opportunities for DL tasks. Researchers have built numerous novel applications based on DL [44, 68, 69, 76, 83, 98]. Besides, various optimization techniques have been proposed to reduce the overhead of DL on resource-constrained mobile devices, e.g., model compression [50, 59, 67, 74, 97], hardware customizations [45, 47, 57, 103], and cloud offloading [61, 66, 99, 105]. These studies are usually carried out under lab environments, based on classical models such as VGG and ResNet, in lack of real-world workloads and insights. Thus, our work is motivated by those enormous efforts that try to bring DL to mobile devices, and fill the gap between the academic literature and industry products.

ML/DL as cloud services Besides on-device fashion, the DL functionality, or in a broader scope of Machine Learning (ML), can also be accessed as cloud services. The service providers include Amazon [2], Google [19], Microsoft Azure [21], etc. There are some prior analyzing studies focusing on such MLaaS (machine learning as a service) platforms. Yao *et al.* [101] comprehensively investigate into effectiveness of popular MLaas systems, and find that with more user control comes greater risk. Some other literature studies [52, 88, 94] focus on the security issues of those platforms towards different types of attacks.

Empirical study of DL Prior empirical analysis mainly focuses on assisting developers to build better DL apps/systems/models. Zhang *et al.* [107] characterize the defects (bugs) in DL programs via mining the StackOverflow QA pages and GitHub projects. Consequently, the results are limited in only open-source, small-scale projects. Fawzi *et al.* [51] analyze the topology and geometry of the state-of-the-art deep networks, as well as their associated decision boundary. These studies mostly focus on classical and small-scale DL models proposed in previous literature, while our study mine the knowledge from large-scale in-the-wild mobile apps.

DL Model protection Some recent efforts have been investigated in protecting DL models. For example, various watermarking mechanisms [41, 78, 87, 104] have been proposed to protect intellectual property of DL models. This approach, however, cannot protect models from being extracted and attacked. As a closer step, some researchers [55, 60, 93] secure the DL systems/models based on secure execution environments (SEE) such as Intel SGX [20]. Some DL frameworks also provide mechanisms for model protection. For example, *Mace* [23] supports developers to convert models to C++ code [11]. However, our results show that a large number of DL models are exposed without secure protection.

8 CONCLUSIONS

In this work, we have carried out the first empirical study to understand how deep learning technique is adopted in real-world smartphones, as a bridge between the research and practice. By mining and analyzing large-scale Android apps based on a static tool, we have reached interesting and valuable findings. Our findings also provide strong and valuable implications to multiple stakeholders of the mobile ecosystem, including developers, hardware designers, and researchers.

ABSTRACT

Detecting local graph clusters is an important problem in big graph analysis. Given seed nodes in a graph, local clustering aims at finding subgraphs around the seed nodes, which consist of nodes highly relevant to the seed nodes. However, existing local clustering methods either allow only a single seed node, or assume all seed nodes are from the same cluster, which is not true in many real applications. Moreover, the assumption that all seed nodes are in a single cluster fails to use the crucial information of relations between seed nodes. In this paper, we propose a method to take advantage of such relationship. With prior knowledge of the community membership of the seed nodes, the method labels seed nodes in the same (different) community by the same (different) color. To further use this information, we introduce a color-based random walk mechanism, where colors are propagated from the seed nodes to every node in the graph. By the interaction of identical and distinct colors, we can enclose the supervision of seed nodes into the random walk process. We also propose a heuristic strategy to speed up the algorithm by more than 2 orders of magnitude. Experimental evaluations reveal that our clustering method outperforms state-of-the-art approaches by a large margin.

1 INTRODUCTION

The graph/network is a natural representation of real-world relations. Graph clustering (or community detection) is a fundamental problem and is the base of many applications, such as online recommendation, medical diagnosis, social network and biological network analysis [11, 14, 15, 18]. The clustering of a graph aims to find groups of nodes that are closely related to each other in each group. Unlike global graph clustering which retrieves all clusters/communities from a graph, local graph clustering focuses on the subgraph within the neighborhood of the seed/query nodes and is applicable to very large data [17]. With the increasing size of networks, recently local clustering has attracted lots of research interest [6, 8, 9, 22].

The seed nodes of local graph clustering can be single or multiple. Existing local graph clustering methods do not accept multiple seed nodes (e.g., Random Walk with Restart [19]), or simply assume that all these seeds are from the same cluster (e.g., Personalized PageRank [1]). We argue that knowing the relations of seed nodes (in the same community or not) are important, as the network data may be noisy or lossy to be clustered accurately. Furthermore, it is a relatively easy task to label the seed nodes by users or domain experts, since the number of seed nodes is small.

Knowing seeds nodes are in the same community can help to merge divided subgroups to a whole community. Fig. 1 is part of a collaboration network used by a conference program committee (PC) member recommendation system. Given that Dr. Ke Wang and Dr. Kitagawa are prospectively favorable PC members, we want the system to recommend more researchers as candidates.

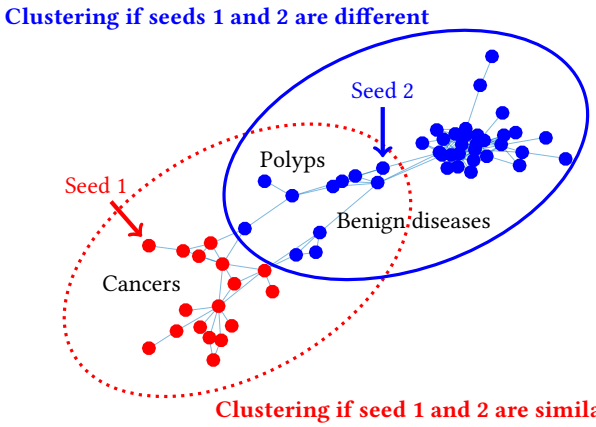

Figure 2: Example of a stomach disease similarity network. Vertices are diseases and edges are similarities between diseases. Red nodes are malignant diseases and blue nodes are benign ones. The dotted red circle contains diseases detected by a single querying seed 1. The solid blue circle encloses clustering result by knowing seed 1 and seed 2 are from different communities.

However, local clustering from either Dr. Wang or Dr. Kitagawa returns their own collaboration subgroup, which is not appropriate due to diversity concerns. On the other hand, assuming Dr. Wang and Dr. Kitagawa are in the same research community and querying jointly from both of them may return a larger community with diverse researchers relevant to them. The final recommendation can be decided by the proximity score of each researcher with respect to the two query seeds.

More importantly, knowing that seed nodes are different can separate a dense subgraph into semantically meaningful communities. Fig. 2 is a network of stomach diseases where red nodes are malignant tumors and blue nodes denote benign stomach diseases such as gastritis and ulcer. By conventional local clustering method, either query from seed 1 or from both seed 1 and 2 will enclose polyps into group of malignant diseases, which is not correct. On the contrary, with domain knowledge that seed 2 is benign and different from seed 1, stomach polyps can be well divided from malignant tumors by our proposed method. This helps the automatic medical diagnosis system to correctly identify a specific disease [13].

Generally, existing local graph clustering methods cannot take advantage of seed node labels, and prefer well-structured networks [8]. For networks without clear community structures, the performance of such methods is limited. In this paper, we introduce a method to leverage supervision of labeled seed node. If a clustering task has multiple seed nodes, we assume that the relationships of seed nodes are already known: we know that which seeds should be in the same community, and which should not. We name this local graph clustering problem with labeled seed nodes as constrained local graph clustering.

To solve the constrained local graph clustering problem, we propose a colored random walk (CRW) algorithm, which is motivated by random walk based local graph clustering [1]. In addition to using random walkers to explore a network, we label seed nodes and random walkers by colors, where seed nodes believed to be in the same community are marked with identical color. The algorithm launches colored random walkers for each color starting from the seed nodes with the corresponding color.

Unlike previous random walk methods [3, 20] where walkers change nothing to the graph, the colored random walker will leave colors to every node it visited. The colors on each node will affect the transition probability of subsequent walkers. In general, a walker is more likely to visit nodes with the same color. In other words, walkers are attracted by nodes with the same color and repulsed by nodes with different colors. The attraction and repulsion are affected by the amount of colors accumulated on each node. By this means, communities with different color of seed nodes are divided, even in unclear network structures.

For local graph clustering with single seed node, the proposed colored random method still outperforms the traditional approaches. This is due to the attraction of walkers by the community members which are assigned with the same color, especially by the central influential nodes with large degrees in each community. These nodes cumulate a higher amount of color by being visited more frequently (Fig. 9), and the cumulative color, in turn, prevents the random walkers from fleeing their community. Due to the same reason, our method is robust to the position of the seed nodes. No matter where is the seed node, the influential nodes remain the same, and so do the corresponding communities. This is different with the previous approaches, in which the performance degrades if seed nodes are close to cluster boundaries. Please refer to Section 5 for more details.

We formulate the colored random walk algorithm by power iterations, and introduce a heuristic speedup strategy to reduce the running time. By the nature of local graph clustering, nodes far away from seeds are not important. The strategy can speed up the searching process by more than 100 times while increasing the local clustering accuracy at the same time. Experiments show that the proposed algorithm outperforms the state-of-the-art baseline methods on both accuracy and speed.

The rest of the paper is organized as follows. Related works are discussed in Section 2. Section 3 explains the detail of our method. In Section 4, extensive experimental results are presented and analyzed. Section 5 provides two case studies for deeper insight of the proposed method, and finally Section 6 draws the conclusion.

2 RELATED WORK

The current local graph clustering methods have no restriction on seed nodes. Random Walk with Restart [20] uses Markovian random walkers to explore the networks. With certain probability, the walkers jump back to seed nodes. The local clusters are cut from nodes frequently visited by the walkers. Heat Kernel Diffusion [8] instead adopts values diffused from seed nodes to evaluate how close the nodes are to the seeds. Query-biased Densest Connect Subgraph method [22] weights nodes by random walk. Then the local community is selected to minimize a predefined goodness function. All these methods assume seed nodes are from a single cluster.

Semi-supervised learning, including semi-supervised clustering with constrains, gained success as they do not require a large amount of human annotations [4]. In semi-supervised learning, the labels are propagated from labeled seed instances by random-walk-like mechanisms through the similarity graph, and then a classifier is trained to categorize all other instances [24, 25]. However, traditional semi-supervised learning focuses more on classification than clustering, and is a heavy framework since it considers both local and global consistency during the learning process.

The colored random walk is also relevant to the Vertex-reinforced Random Walk (VRW), which views graph nodes as urns [16]. Each time the random walker visits a node, it puts a ball with its color into the corresponding urn. The further visiting probability of the random walker is reinforced by the numbers and colors of balls in each node. Though it is proved that single-color VRW is guaranteed to converge to a distribution [2], the converged distribution is not unique due to the randomness of the walker, which diminishes the performance of VRW in local graph clustering. Moreover, the theories of multi-color VRW are still underdeveloped.

3 OUR PROPOSAL

Local graph clustering requires proximity measurement to decide which nodes should be in a local cluster. Random walk based approaches such as Random Walk with Restart (a.k.a. Personalized PageRank) are commonly used to evaluate the node proximity in graphs [20]. Compared with other methods, random walk takes advantage of local network structure and reports better performance [9]. In this work, we extend the random walk method to colored random walk to solve the problem of local graph clustering with constrains.

3.1 Preliminaries

The local graph clustering targets on a graph $G = (V, E)$, where V is the node set and E is the edge set. The adjacency matrix of graph G is denoted by $\mathbf{A}$, whose element $\mathbf{A}_{ij}$ is the edge weight between node V_i and node V_j. $\mathbf{P}$ is the transposed column-stochastic transition matrix with entries $\mathbf{P}_{ji} = \mathbf{A}_{ij} / \sum_j \mathbf{A}_{ij}$. The main symbols and their definitions can be found in Table 1.

The core function of local graph clustering is to measure the proximity of each node with the seed node(s). In Random Walk with Restart (RWR), a random walker starts from the seed node q, and randomly walks to a neighbor node according to edge weights. At each time point $(t + 1)$, the walker continues walking with probability α or returns to the query node q with probability $(1-\alpha)$. The proximity score of node p with respect to node q is defined as the converged probability that the walker visits node p:

$$\mathbf{c}^{(t+1)} = \alpha \cdot \mathbf{P} \cdot \mathbf{c}^{(t)} + (1 - \alpha) \cdot \mathbf{s} \tag{1}$$

where $\mathbf{s}$ is the column vector of the initial distribution with q^{th} entry as 1 and all other entries 0, and $\mathbf{c}$ is the current distribution vector whose p^{th} entry is the visiting probability of node p.

RWR can be extended to accommodate multiple seed nodes. For n seed nodes, the initial vector $\mathbf{s}$ consists of entries with value $1/n$ for each seed node. However, if seed nodes are from multiple clusters, RWR cannot use such information. One may run RWR multiple times, each for a single seed node, yet this approach fails to take full advantage the prior knowledge of cluster membership of the seed nodes. For example, if two seed nodes are known from different clusters, walkers of each seed node should avoid walking into the other seed's cluster. We give the formal definition of constrained local graph clustering as follows.

Table 1: Main symbols

Symbol	Definition
$G = (V, E)$	graph G with node set V and edge set E
$\mathbf{A}, \mathbf{P}$	adjacency matrix and transition matrix
$\mathbf{c}, \mathbf{s}$	current and initial color distributions
α, θ	forward probability and color threshold
$\psi(t)$	decaying factor at time t
λ_1, λ_2	attraction and repulsion coefficient

Definition 3.1 (Constrained local graph clustering). Given graph $G = (V, E)$ and seed node set with K different colors, the constrained local graph clustering aims to find K local communities containing seed nodes of each color.

3.2 The Colored Random Walk

To solve the constrained local graph clustering problem, we propose a Colored Random Walk (CRW) method in this section, which takes advantage of seed node labels. Seed nodes of the same cluster are assigned with identical color, and seed nodes from different clusters have different colors. For each color, the algorithm sends out a colored walker from the corresponding seed nodes to explore the network. During the exploration, the walker leaves a certain amount of colored values to the visited nodes, similar to the RWR method in Eq. 1.

The main difference between CRW and conventional RWR is that the movement of walkers is affected by existing colors of nodes. Generally, a walker is more likely to visit nodes with identical colors, and is less likely to visit nodes with distinct colors. Since color values are changed at each time point t, the transition matrix $\mathbf{P}$ should be updated accordingly.

For a constrained local graph clustering task with K colors, the CRW algorithm maintains K transition matrix $\mathbf{P}^{(k,t)}$ for color k at time t. Then the Eq. 1 expands to a new power iteration formula

$$\mathbf{c}^{(k,t+1)} = \alpha \cdot \mathbf{P}^{(k,t)} \cdot \mathbf{c}^{(k,t)} + (1 - \alpha) \cdot \mathbf{s}^{(k)} \tag{2}$$

where $\mathbf{c}^{(k,t)}$ is the distribution of color k at time t, and $\mathbf{s}^{(k)}$ is the initial vector of color k, respectively.

3.3 Transition Matrix Reinforcement

The transition matrix $\mathbf{P}^{(k,t)}$ in Eq. 2 is based on the original transition matrix $\mathbf{P}$, and is reinforced by all current color distributions $\mathbf{c}^{(\ell,t)}$, $1 \le \ell \le K$. The reinforcement is done by

$$\mathbf{P}^{(k,t)} = \mathbf{P} \circ (1 + \mathbf{R}^{(k,t)}) \tag{3}$$

where operator $\circ$ is the Hadamard (entry-wise) product of two matrices with the same size [7]. By Hadamard product, we avoid adding new edges to graph G, and the reinforcement is done by weight adjustment of existing edges. In the Eq. 3, '1' is used to keep the original transition matrix $\mathbf{P}$ as part of the reinforced transition

matrix $\mathbf{P}^{(k,t)}$. $\mathbf{R}$ is a coefficient matrix defined by its entry

$$\mathbf{R}_{ij}^{(k,t)} = \sum_{\ell} \mathbf{c}_i^{(\ell,t)} \cdot \lambda_{k\ell}, \quad \lambda_{k\ell} = \begin{cases} \lambda_1 & k = \ell \\ -\lambda_2 & k \neq \ell \end{cases} \tag{4}$$

In Eq. 4, if the factor $\lambda_{k\ell}$ is defined as positive when color k equals color ℓ, and negative otherwise. This definition increases the likelihood of a walker going to the node with identical color, and decreases the likelihood of walking to the node with different colors. The mechanism can be understood as that, a walker is attracted by nodes with the same color, and repulsed by nodes with different colors. Here we denote by λ_1 the attraction coefficient and by λ_2 the repulsion coefficient.

By Eq. 3 and 4, the entries of $\mathbf{P}^{(k,t)}$ are possibly negative. To make $\mathbf{P}^{(k,t)}$ as a transition matrix meaningful, it is normalized before used in Eq. 2. The normalization includes two parts. First, the negative entries of $\mathbf{P}^{(k,t)}$ are set to be zero: $\mathbf{P}_{ij}^{(k,t)} \leftarrow 0$ if $\mathbf{P}_{ij}^{(k,t)} < 0$, and then each entry of the matrix is divided by the sum of its column to make the matrix column stochastic: $\mathbf{P}_{ij}^{(k,t)} \leftarrow \mathbf{P}_{ij}^{(k,t)} / \sum_i \mathbf{P}_{ij}^{(k,t)}$.

3.4 Convergence

Unlike the traditional random walk methods which have stationary transition matrix $\mathbf{P}$, the transition matrix $\mathbf{P}^{(k,t)}$ of colored random walk varies at each time t. To guarantee the convergence of Eq. 2, we introduce a decaying mechanism changing $\mathbf{P}^{(k,t)}$ to $\mathbb{P}^{(k,t)}$ (Eq. 5), where the value of function $\psi(t)$ approaches to 0 when t increases. Then the colored random walk is adapted to Eq. 6.

$$\mathbb{P}^{(k,t)} = \begin{cases} \mathbf{P} & t = 0 \\ \psi(t) \cdot \mathbf{P}^{(k,t)} + (1 - \psi(t)) \cdot \mathbb{P}^{(k,t-1)} & t \geq 1 \end{cases} \tag{5}$$

$$\mathbf{c}^{(k,t+1)} = \alpha \cdot \mathbb{P}^{(k,t)} \cdot \mathbf{c}^{(k,t)} + (1 - \alpha) \cdot \mathbf{s}^{(k)} \tag{6}$$

Here the definition of $\mathbf{P}$ remains the same with Eq. 3 and Eq. 4. Intuitively, when $\psi(t) \to 0$, $\mathbb{P}^{k,t} \to \mathbb{P}^{k,t-1}$, meaning that $\mathbb{P}^{k,t}$ converges. With a converged $\mathbb{P}^{k,t}$, the proximity score vector $\mathbf{c}^{(k,t)}$ converges, similar to the conventional random walk. The formal proof of convergence of $\mathbf{c}^{(k,t)}$ is given by Theorem 3.2.

Theorem 3.2 (Convergence of colored random walk). *Both $\mathbb{P}^{(k,t)}$ and $\mathbf{c}^{(k,t)}$ in Eq. 5 and Eq. 6 converge if $\psi(t) = \Omega(\alpha^t)$.*

Proof. To ease the description, we combine distributions, reinforced transition matrices, and initial vectors of all color at time t by

$$\mathbf{c}^{(t)} = \begin{bmatrix} \mathbf{c}^{(1,t)} \\ \mathbf{c}^{(2,t)} \\ \vdots \\ \mathbf{c}^{(K,t)} \end{bmatrix}, \mathbf{P}^{(t)} = \begin{bmatrix} \mathbf{P}^{(1,t)} & & & 0 \\ & \mathbf{P}^{(2,t)} & & \\ & & \ddots & \\ 0 & & & \mathbf{P}^{(K,t)} \end{bmatrix}, \mathbf{s} = \begin{bmatrix} \mathbf{s}^{(1)} \\ \mathbf{s}^{(2)} \\ \vdots \\ \mathbf{s}^{(K)} \end{bmatrix}$$

Evidently, Eq. 7 equals to Eq. 6 for all color $1 \leq k \leq K$. Similarly we define $\mathbb{P}^{(t)}$ as diagonal combination of all $\mathbb{P}^{(t,k)}$.

$$\mathbf{c}^{(t+1)} = \alpha \cdot \mathbb{P}^{(t)} \cdot \mathbf{c}^{(t)} + (1 - \alpha) \cdot \mathbf{s} \tag{7}$$

For convergence of decayed transition matrix $\mathbb{P}^{(t)}$, it is easy to know that for $t \geq 1$,

$$\|\mathbb{P}^{(t)} - \mathbb{P}^{(t-1)}\|_1 = \psi(t)\|\mathbf{P}^{(t)} - \mathbb{P}^{(t-1)}\|_1 \leq 2\psi(t)$$

Algorithm 1: The Colored Random Walk

Input : $\mathbf{P}, \mathcal{S}, \alpha, \lambda_1, \lambda_2, T, \psi(t)$
Output: $\mathbf{c}$

```
K ← |S|;
for k ← 1 to K do
    s^(k) ← 0;
    for each x ∈ S[k] do s_x^(k) ← 1/|S[k]| ;
s ← [s^(1); s^(2); ...; s^(K)];
c ← s;
P^(0) ← I_K ⊗ P;
ℙ ← P^(0);
Λ ← I_N · λ_1;
Set all non-diagonal entries of Λ as −λ_2;
Λ ← Λ ⊗ I_K;
for t ← 0 to T do
    c ← α · ℙ · c + (1 − α)s;
    r ← Λ · c;
    R ← r ⊗ 1^T_{N·K};
    P̂ ← P^(0) ∘ (1 + R);
    for each i and j do P̂_ij ← 0 for P̂_ij < 0;
    for each i and j do P̂_ij ← P̂_ij / Σ_x P̂_xj;
    ℙ ← ψ(t) · P̂ + (1 − ψ(t)) · ℙ;
```

For convergence of the color distribution $\mathbf{c}^{(t)}$, we define $\Delta^{(t)} = \|\mathbf{c}^{(t)} - \mathbf{c}^{(t-1)}\|_1$. Then

$$\begin{aligned}
\Delta^{(t+1)} &= \|\mathbf{c}^{(t+1)} - \mathbf{c}^{(t)}\|_1 = \|\alpha\mathbb{P}^{(t+1)}\mathbf{c}^{(t)} - \alpha\mathbb{P}^{(t)}\mathbf{c}^{(t-1)}\|_1 \\
&= \alpha\|\mathbb{P}^{(t+1)}\mathbf{c}^{(t)} - \mathbb{P}^{(t)}\mathbf{c}^{(t-1)}\|_1 \\
&= \alpha\|\mathbb{P}^{(t+1)}\mathbf{c}^{(t)} - \mathbb{P}^{(t+1)}\mathbf{c}^{(t-1)} + \mathbb{P}^{(t+1)}\mathbf{c}^{(t-1)} - \mathbb{P}^{(t)}\mathbf{c}^{(t-1)}\|_1 \\
&= \alpha\|\mathbb{P}^{(t+1)}(\mathbf{c}^{(t)} - \mathbf{c}^{(t-1)}) + (\mathbb{P}^{t+1} - \mathbb{P}^{t})\mathbf{c}^{t-1}\|_1 \\
&\leq \alpha\|\mathbb{P}^{(t+1)}(\mathbf{c}^{(t)} - \mathbf{c}^{(t-1)})\|_1 + \alpha\|(\mathbb{P}^{(t+1)} - \mathbb{P}^{(t)})\mathbf{c}^{t-1}\|_1 \\
&\leq \alpha\|\mathbb{P}^{(t+1)}\|_1\|\mathbf{c}^{(t)} - \mathbf{c}^{(t-1)}\|_1 + \alpha\|\mathbb{P}^{(t+1)} - \mathbb{P}^{(t)}\|_1\|\mathbf{c}^{t-1}\|_1 \\
&\leq \alpha\|\mathbf{c}^{(t)} - \mathbf{c}^{(t-1)}\|_1 + \alpha\|\mathbb{P}^{(t+1)} - \mathbb{P}^{(t)}\|_1 \\
&\leq \alpha\Delta^{(t)} + 2\alpha\psi(t+1) \leq \alpha^2\Delta^{(t-1)} + 2\alpha^2\psi(t) + 2\alpha\psi(t+1) \\
&\leq \alpha^t\Delta^{(1)} + 2\sum_{\tau=1}^{t} \alpha^\tau\psi(t-\tau+2)
\end{aligned}$$

To make $\Delta^{(t+1)}$ converge to 0, a sufficient condition is that $\psi(t) = \Omega(\alpha^t)$, which means $0 \leq c\psi(t) \leq \alpha^t$ for any $t > t_0$ and $c > 0$. Given $\psi(t) \leq 2\alpha^{t-1}$ for $t > t_0$,

$$\begin{aligned}
\Delta^{(t+1)} &\leq 2\alpha^t + 2\sum_{\tau=t+2-t_0}^{t} \alpha^\tau + 2\sum_{\tau=1}^{t+1-t_0} \alpha^{t+1} \\
&< 2\alpha^t + 2(t_0 - 1)\alpha^{t-t_0+2} + 2(t - t_0 + 1)\alpha^{t+1} \\
&< 2t_0\alpha^{t-t_0+2} + 2(t - t_0 + 1)\alpha^{t+1} \to 0
\end{aligned}$$

□

3.5 The Algorithm

By Eq. 7, we can formulate the colored random walk as shown in Algorithm 1. The input of the algorithm includes original transition matrix $\mathbf{P}$, seed node sets $\mathcal{S}$ of all colors, penalty factor α, attraction coefficient λ_1 and repulsion coefficient λ_2, together with the number of iterations T and the decaying faction $\psi(t)$. The output of the algorithm is the color distribution vector $\mathbf{c}$ for all colors. The details of the algorithm are as follows.

Lines 1 – 11 initialize the algorithm. Specifically, in line 1 we get the number of colors K by the number of seed node sets in $\mathcal{S}$. Lines 3 and 4 prepare for the initial color vectors $\mathbf{s}^{(k)}$ for each color k. From line 5 to line 8 we combine initial distributions and transition matrix of all colors together by $\mathbf{s}$ and $\mathbf{P}^{(0)}$, as explained in Section 3.4, and initialize the color distribution vector $\mathbf{c}$ and the modified transition matrix $\mathbb{P}$.

To calculate the color reinforcement for each node, we create a $N \times N$ factor matrix $\mathbf{\Lambda}$ (lines 9 to 11), which originally has the value of λ_1 on all diagonal entries and $-\lambda_2$ on all non-diagonal entries. The size of matrix $\mathbf{\Lambda}$ is then amplified (line 11) by Kronecker Product [7] with an identity matrix $\mathbf{I}_K$, to multiply with vector $\mathbf{c}$ (line 14), which is a matrix-form equivalence to the operation in Eq. 4.

The for loop from line 12 to 19 is the power iteration process. We first generate the color distribution for next iteration (line 13), and then generate the reinforcement vector $\mathbf{r}$ (line 14). Vector $\mathbf{r}$ is repeated to form a matrix $\mathbf{R}$ (line 15), which means that the reinforcement is fair to every node. After generating new reinforced matrix $\hat{\mathbf{P}}$ (line 16), we remove negative entries (line 17) and normalize it to column stochastic (line 18), and update the decayed transition matrix for the next iteration (line 19).

The power iteration part of the algorithm is critical in analyzing the time complexity, where all operations including calculations of color distribution (line 13), reinforcement (line 14) and decayed transition matrix (line 19) take $O(K|E|)$, if we base the operations on sparse matrices. Therefore, the overall time complexity is $O(TK|E|)$. As empirically reported in [9], $T = 10$ is sufficient for the convergence of distribution $\mathbf{c}$.

With the distribution $\mathbf{c}$ for each color, we rank nodes by their colors and cut local communities by sweeping from the top-rank node and find a cluster with minimum conductance [1].

3.6 Speedup Strategy

Time complexity of the proposed colored random walk algorithm is proportional to the number of edges $|E|$, implying that the algorithm searches the entire graph for local clusters. This is undesirable as the task of local clustering focuses only on the nodes close to the seeds.

In this section, we propose a localized variant of Algorithm 1, with the basic idea that random walkers only search the influential nodes around the seed nodes. Unlike Algorithm 1 where the walkers go as far as T-hops from the seeds, we only consider nodes with colors above a given tolerance threshold θ.

As the random process in Eq. 2 can be viewed as the diffusion of colors from each node to its neighbors, the key point of Algorithm 2 is that only colors with values above a threshold θ will diffuse to next iteration. The intuition behind this is that small color amount will not affect colors of next iteration very much. When a walker reaches a node with color value less than θ, it stops there and does not go to the node's neighbors, which prevents the process from searching too many further nodes. We also neglect the decaying function $\psi(t)$ and reinforce the node on demand (with color value greater than θ) to accelerate the algorithm.

Algorithm 2: The Localized Colored Random Walk

```
   Input  : P, S, α, λ1, λ2, T, θ
   Output : c
1  for each color k do
2      c^(k) ← 0;
3      for each node i ∈ S[k] do c_i^(k) ← 1/|S[k]| ;
4  for t ← 1 to T do
5      ĉ^(k) ← 0;
6      for each color k do
7          for each c_i^(k) > θ do
8              p ← 0;
9              for each neighbor j of node i do
10                 p_j ← P_ij^(k,t);
11                 for each color ℓ do
12                     if ℓ = k then p_j ← p_j + λ1 · c_j^(ℓ) ;
13                     else p_j ← p_j − λ2 · c_j^(k) ;
14                 if p_j < 0 then p_j ← 0 ;
15             for each p_j > 0 do ĉ_j^(k) ← ĉ_j^(k) + α · c_i^(k) · p_j / Σ p ;
16         for each seed node i ∈ S[k] do
17             ĉ_i^(k) ← ĉ_i^(k) + (1 − α)/|S[k]|;
18     for each color k do c^(k) ← ĉ^(k) ;
```

In Algorithm 2, lines 1 – 3 initialize the color distribution according to seed nodes, and lines 4 – 18 simulate the power iteration in a heuristic way. In this heuristic algorithm, we remove the process of decaying, as it is shown that the result of experiments without decaying is similar. Specifically, at each iteration (line 4) the current color scores are in $\mathbf{c}^{(k)}$ for color k, and the new scores for next iteration are calculated and stored in $\hat{\mathbf{c}}^{(k)}$. Note that, $\mathbf{c}^{(k)}$ is changed to $\hat{\mathbf{c}}^{(k)}$ after the scores of all colors are updated (line 18). Note that the color scores are updated simultaneously.

By this strategy, though color values diminish at each iteration, the summation of colors remains its majority value. The difference turns out to be less than 1%.

4 EXPERIMENTAL VALIDATION

Extensive experiments are conducted on both synthetic and real-world data to evaluate the effectiveness and efficiency of the proposed algorithms. All experiments are performed on a server with Redhat OS, Xeon 2.6GHz CPU, and 64G memory. The core functions are implemented by C++.

Each experimental result is gathered on average of 10,000 trials. The querying seeds are randomly selected. The accuracy is measured by F1-score, which is defined as $2pr/(p + r)$, where p and r

are precision and recall, respectively.

4.1 Non-overlapping Clusters

We use the following networks with non-overlapping ground truth clusters to test the effectiveness of our proposed method. The clusters are large enough to test the searching ability of the colored random algorithm algorithm.

Disease networks. The networks contain a disease similarity network [13] with 9,721 diseases. For this network, there are two sets of clustering ground truth for the disease network, with 17 classes and 47 classes, respectively. We use both sets of ground truth, and denote the experiments by Disease 1 and Disease 2, accordingly. Disease 3 is a phenotype similarity network with 5,080 diseases in 20 categories [21].

Gene network. The gene network represents the functional relationship between 8,503 genes [21] with 200 pathway labels.

Author network. This network comprises 20,111 authors from 4 research areas: Data Mining, Data Base, Information Retrieval and Machine Learning. The edge of this network is the number of papers co-published by the authors.

Conference network. This is a full graph comprises 20 main conferences from the same 4 areas with the author network. The edges are cosine similarity of keywords from the publication of the conferences. We use research areas as the ground truth for both author network and conference network.

Since no previous method is designed for the constrained local graph clustering problem, we compare the proposed colored random walk (CRW) method with the following five state-of-the-art local clustering methods, which support multiple seed node querying: Random Walk with Restart (RWR) [20] uses Eq. 1 to calculate the proximity score of each node; Heat Kernel Diffusion (HKD) [8] measures node proximity by heat kernel network diffusion; Query-biased Densest Connect subgraph (QDC) [22] assigns weights to nodes using RWR scores and finds the query biased densest subgraph; Vertex-reinforced Random Walk (VRW) [12] reinforces the next-hop visiting probability by previous visiting counts. For our method CRW, we use the localized colored random walk (Algorithm 2) with $\alpha = 0.9$, $\lambda_1 = 1000$, $\lambda_2 = 10$, $\theta = 10^{-5}$.

Effectiveness evaluations are conducted on the selected networks. Since the accuracy difference between our two algorithms is small, we present the results of Algorithm 2 only. Table 2 shows the result of single seed node querying. By column "CRW" we only use one seed node with a single color, so there is no repulsion of different colors, which serves as a baseline of our method. From the results in Table 2, it can be seen that even the basic CRW can outperform the state-of-the-art methods in terms of clustering accuracy.

In Table 2 we add an extra column of CRW_1^1, which randomly picks up two seed nodes of different colors to examine the impact of color repulsion. Comparison of CRW and CRW_1^1 shows that resistance of distinct colors helps to improve the clustering accuracy significantly. On all datasets CRW_1^1 achieves the best performance.

Table 3 shows the result of 2-seed-node query on the same 6 datasets. For each method except CWR_2^2 we use two seed nodes from the same cluster. CWR_2^2 is similar to CWR_1^1 by choosing 2 colors, each having two seeds. Though initially VRW is not designed for multiple seed nodes, we make it work by adding extra random walkers that are reinforced by rules of the original VRW. Comparing Table 3 with Table 2, the conclusion is that almost all methods improve clustering accuracy by having more seeds. Furthermore, CWR gains more improvement on average. Again CRW_1^1 and CRW_2^2 have the best performance among all chosen methods.

Table 2: 1-query accuracy for non-overlapping clusters

F1-score	RWR	HKD	QDC	VRW	CRW	CRW_1^1
Disease 1	0.33	0.27	0.11	0.08	**0.34**	**0.37**

4.2 Overlapping Clusters

Intuitively colored random walk works with non-overlapping clusters. However, due to its color-agglomerating nature, it also works for detecting overlapping clusters. Table 4 lists the statistics 4 of networks with overlapping ground truth communities (Amazon, DBLP, YouTube, LiveJournal). These datasets are publicly available at http://snap.stanford.edu. For the quality of clusters, we select clusters with size larger than 10, and within $\pm 3\sigma$ range of the average cluster size. The last column of Table 4 shows the mean and standard deviation (σ) of the chosen clusters.

Table 4: Networks with overlapping communities

Name	$\lvert V\rvert$	$\lvert E\rvert$	# clusters	avg (σ)
Amazon	334,863	925,872	75,149	13.23 (11.24)
DBLP	317,080	1,049,866	13,477	10.87 (20.41)
YouTube	1,134,890	2,987,624	8,385	10.22 (18.81)
LiveJournal	3,997,962	34,681,189	287,512	23.67 (24.75)

Table 5: 1-query accuracy on overlapping communities

F1-score	RWR	HKD	QDC	VRW	CRW	CRW_1^1
Amazon	0.92	**0.93**	0.90	0.70	0.92	**0.93**

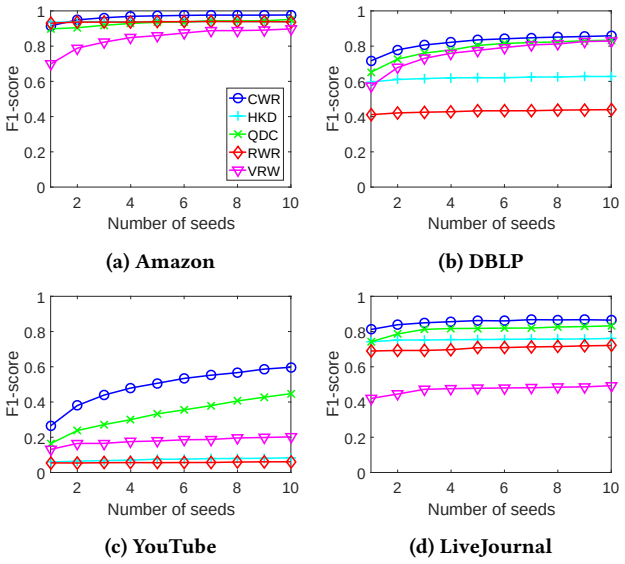
YouTube	0.05	0.06	0.19	0.13	**0.27**	**0.30**
LiveJournal	0.69	0.74	0.74	0.42	**0.81**	**0.84**

Table 6: 2-query accuracy on overlapping communities

F1-score	RWR	HKD	QDC	VRW	CRW	CRW_2^2
Amazon	0.93	0.94	0.91	0.79	**0.95**	**0.96**
DBLP	0.42	0.61	0.73	0.68	**0.78**	**0.81**
YouTube	0.05	0.06	0.21	0.16	**0.38**	**0.42**
LiveJournal	0.69	0.75	0.79	0.45	**0.84**	**0.86**

The clustering results are listed in both Table 5 and Table 6. It shows that 2-seed quires are generally better than single seed node. Among all methods HKD is relatively good since it is refined for the small overlapping communities. However, more seed nodes do not improve its performance very much (only 1% on average). The probability-reinforced methods VRW and CRW gain the biggest improvement by adding an extra seed. Once again our proposed method leads the accuracy measurements. For seed nodes more than 2, Fig. 3 shows that most methods perform better with more seeds. However, CRW, VRW and QDC take better advantage of more seed nodes, as they all have mechanisms of reinforcement on node weights.

Fig. 3 gives the results where seed nodes are from a single community. However, when seed nodes are from distinct communities, the other methods cannot use this relationship, so their performances are very low (Fig. 4). On the contrary, our method takes advantage of this cannot-link information, resulting in the increased accuracy with more communities (colors).

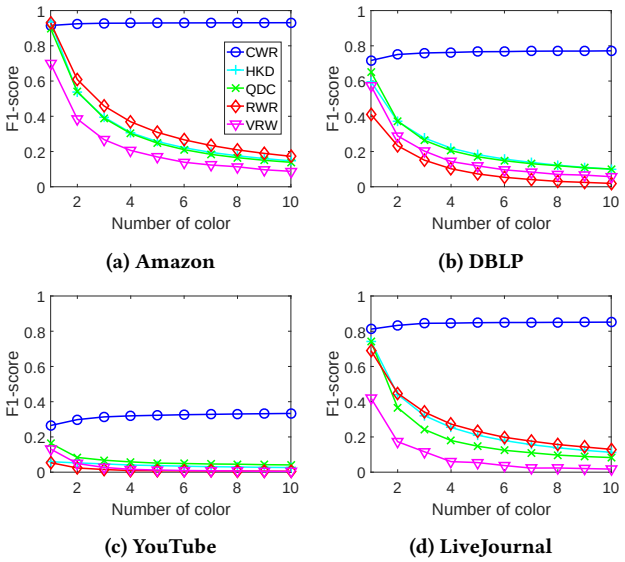


We also evaluate the efficiency of the selected methods on datasets provided in Table 4, since networks are relatively large. To be fair, the running time is measured on single color and single node on every method. Fig. 5 shows that CRW is one of the fastest methods of all, comparable to the HKD method, and is generally 100 times faster than the other approaches. Generally, CRW takes no more than 200 milliseconds in finding a target local cluster. For the scalability of colors and seed nodes, the running time of CRW does not increase with number of seed nodes, and is proportional with the number of colors.

4.3 Impact of Color Attraction and Repulsion

To analyze the sensitivity of the main parameters of our method (λ_1, λ_2, θ), we generate synthetic networks by the standard LFR benchmark [10].

We first test the impact of attraction and repulsion of Algorithm 1, by varying factor λ_1 and λ_2 on the synthetic graph of Fig. 6. The results are presented in Fig. 7, in terms of accuracy vs. attraction λ_1 and repulsion λ_2. We set $\psi(t) = 0.9^t$ is this experiment.



First we try our algorithm on the traditional problem of local graph clustering, where there is only one target community and accordingly only one color (Fig. 7a). We randomly choose 1 seed node (1×1) or 2 seed nodes (2×1) from a community, or 4 seed nodes from 2 different communities (2×2). Since there is no different color, we use attraction coefficient λ_1 only and set $\lambda_2 = 0$. In Fig. 7a the x-axis is the logarithmic value of λ_1 and y-axis is the F1-score. When λ_1 is close to 0, our algorithm degenerates into the conventional random walk based local clustering. By this means we can compare our methods with the basic random walk, as well as measuring the sensitivity of parameters λ_1 and λ_2.

(a) Amazon (b) DBLP

(c) YouTube (d) LiveJournal

Figure 3: Impact of adding more seed nodes

(a) Amazon (b) DBLP

(c) YouTube (d) LiveJournal

Figure 4: Impact of adding more colors

From curve of 1×1 we can see that the clustering accuracy increases obviously with the parameter λ_1. This indicates that even on traditional graph clustering problem, our algorithm still outperforms the basic random walk method. For curve 2×1, initially its accuracy is higher than 1×1 because of the information introduced by more seed nodes. However, the accuracy drops slightly after $\lambda_1 > 10^3$, because excessively strong attraction around the two individual seed nodes separates the target community. The attraction even works when seeds nodes are not from the same community, but labeled as the same color (curve 2×2).

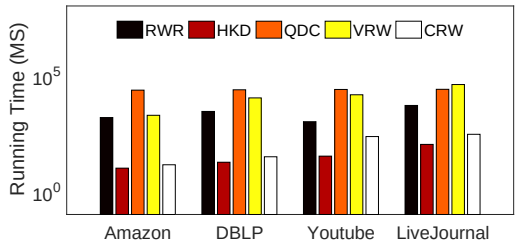


Figure 5: Running time comparison

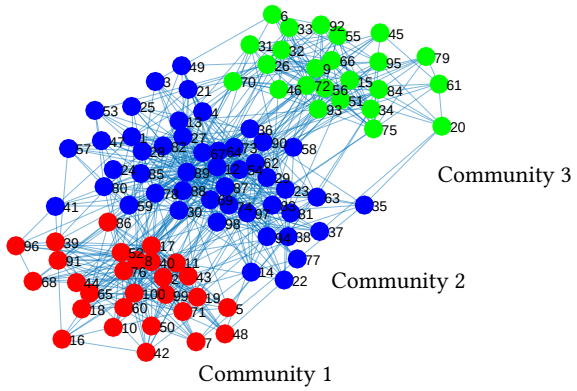

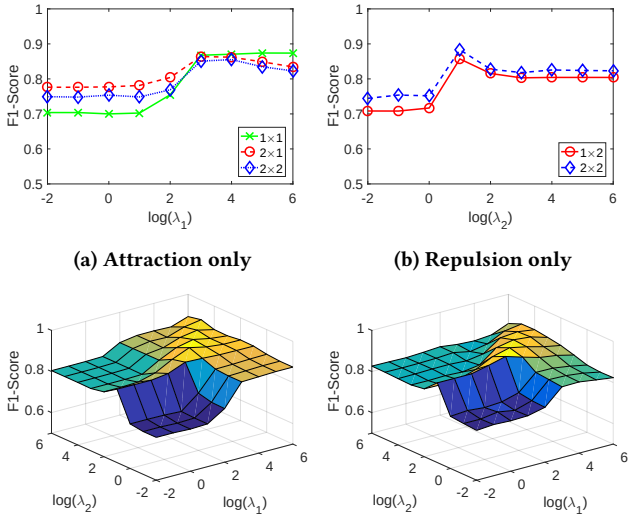

Figure 6: A 100-node graph generated by the LFR benchmark. The red, blue, green nodes are from 3 distinct ground-truth communities.

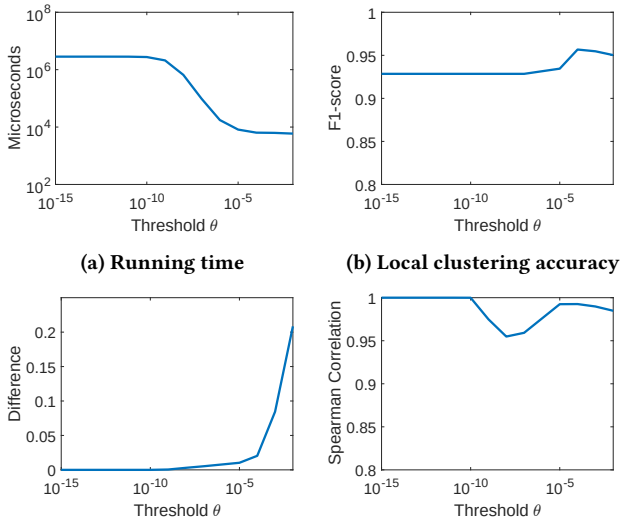
Similar results are observed by using repulsion force only and set $\lambda_1 = 0$. In experiments shown in Fig. 7b, we select 1 or 2 nodes from two adjacent communities and label them with different colors. The figures illustrate that the repulsion enhances clustering accuracy, as walkers from the two different communities are divided by distinct colors. However, overdose of repulsion ($\lambda_2 > 10$) drives walkers from the border of communities and decreases the accuracy.

Finally, we combine both attraction and repulsion forces together (shown in Fig. 7c and 7d). The best accuracy results come with $\lambda_1 = 10^4$ and $\lambda_2 = 10^2$, and the performance are maintained when these two parameters keep on increasing. The favorable λ_1 and λ_2 are large because of the stabilizer "1" in color reinforcement (Eq. 3), which requires large λ_1 and λ_2 to change the behavior of random walkers.

4.4 Evaluation of Speedup Strategy



We generate a network with 1 million nodes and 15 million edges by LFR benchmark to test the impact of threshold θ on Algorithm 2. The results are presented in Fig. 8. When the threshold θ rises from 10^{-15} to 10^{-5}, the average running time drops dramatically (Fig. 8a). Note that when $\theta \to 0$, Algorithm 2 reduces to a non-decaying version of Algorithm 1. The total speedup is more than 2 orders of magnitudes, when threshold increases to above 10^{-5}.

(a) Attraction only **(b) Repulsion only**

(c) 1×2 attraction and repulsion **(d) 2×2 attraction and repulsion**

Figure 7: Impact of color attraction and repulsion. λ_1 is the attraction coefficient and λ_2 is the repulsion coefficient.

(a) Running time **(b) Local clustering accuracy**

(c) Vector difference **(d) Spearman correlation**

Figure 8: Impact of threshold θ on Algorithm 2

In the meantime, the clustering accuracy remains intact and even increases from $\theta = 10^{-5}$. Looking closely, the recall of clustering remains stable while the precision rises after $\theta > 10^{-5}$. This is because the nodes of the target local clustering (true positive) are not faraway from seed nodes. Larger threshold θ makes the search more local: thus irrelevant nodes will not be enclosed, which reduces the false positive.

We also examine the difference between the output vectors from Algorithm 1 and Algorithm 2. From Fig. 8d, the summation of absolute difference value is only 1.03% at $\theta = 10^{-5}$ (Fig. 8c). Does

this difference substantially change the orders of nodes, which is crucial to clustering result? Spearman's rank correlation reveals that it is not the case (Fig. 8d). In calculating correlation, we only compare non-zero entries from both vectors. Though the correlation drops a little between 10^{-10} and 10^{-5} due to the noise introduced by the speedup strategy, it returns to above 0.98 after $\theta > 0.5$, where the correlation is limited to local clusters only. This indicates that the heuristic of Algorithm 2 has very little deflection on the order of nodes in the target local cluster.

In summary, the introduction of threshold θ largely reduces the running time of the proposed algorithm, and the clustering accuracy is enhanced. We adopt $\theta = 10^{-5}$ as a trade-off between running time and accuracy in our other experiments.

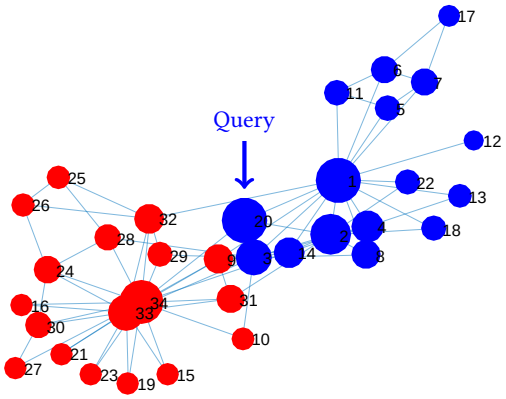
5 CASE STUDY

In this section we present two case studies to examine nature of the proposed colored random walk algorithm, explain why CRW works with even a single color, and provide more examples on how CRW divides dense subgraph into meaningful partitions.

5.1 Karate Club Social Network

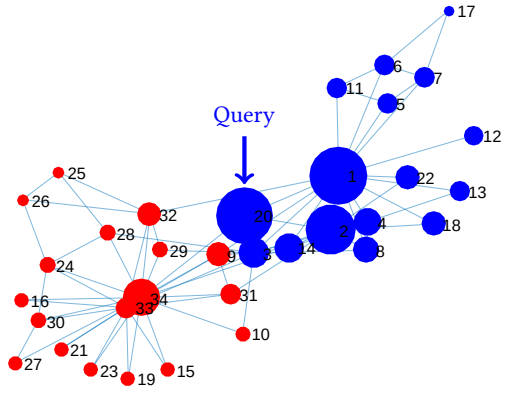
In this section we look into the colored random walk (CRW) method by the karate club network [23], to see how CRW improves the clustering accuracy even by a single seed node.

The karate club network contains 34 members (nodes) (Fig. 9). Edges are interactions among members. A conflict between the club instructor (node 1) and the president (node 34) divides the club into two separate groups (labeled by blue and red, respectively), which serves as clustering ground truth. It is obvious that node 1 and node 34 are influential nodes with large degrees in the two groups, connecting to many other members.



We choose node 20 as the seed node for both CRW and random walk with restart (RWR). It is a hard task as node 20 is on the border of these two clusters, though it is categorized to the blue cluster. The proximity scores are represented by size of nodes in Fig. 9.

From Fig. 9a, we can see that the proximity score distribution is relatively even on all nodes. This is not desirable since it is not easy to distinguish the node membership by the flat proximity scores. In contrast, proximity scores concentrate on the blue community, especially the central influential nodes 1 (Fig. 9b). These nodes accumulate more colors (proximity scores) and have more attraction to the colored walkers, and essentially helps to divide the two clusters.



5.2 Brain Activity Network

Fig. 10a depicts another example where prior knowledge about the difference of seed nodes is critical. It is part of a brain activity network where each node is a cortical area and edges are functional associations [5]. The nodes in this network are from Broadman area 6 (BA6) and Broadman area 13 (BA13). Since these two areas are closely connected with each other, conventional methods cannot divide these areas. Once knowing the difference of seed nodes (e.g., node 7 and 14), it becomes easier to separate the two Broadman areas. The clustering result can be viewed by 3D coordinates[1] in Fig. 10b.

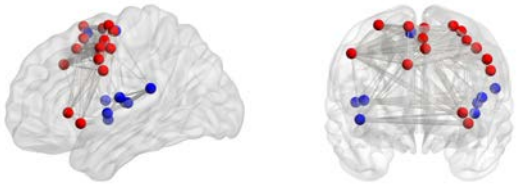
6 CONCLUSION



In this paper we advance a colored random walk method to solve the constrained local graph clustering problem, where the communities membership of seed nodes are known as prior knowledge. The proposed method dynamically adjusts node weights for each color during the random walk process, and the updated node weights help to trap the colored random walkers into the corresponding communities. Experiments show that the performance of our method is above the state-of-the-art approaches, even for conventional single-color and single-seed scenario. With more seed nodes and colors available, the performance of the proposed method is significantly better.

Revisiting User Mobility and Social Relationships in LBSNs: A Hypergraph Embedding Approach

{firstname.lastname}@unifr.ch

ABSTRACT

Location Based Social Networks (LBSNs) have been widely used as a primary data source to study the impact of mobility and social relationships on each other. Traditional approaches manually define features to characterize users' mobility homophily and social proximity, and show that mobility and social features can help friendship and location prediction tasks, respectively. However, these handcrafted features not only require tedious human efforts, but also are difficult to generalize. In this paper, by revisiting user mobility and social relationships based on a large-scale LBSN dataset collected over a long-term period, we propose LBSN2Vec, a hypergraph embedding approach designed specifically for LBSN data for automatic feature learning. Specifically, LBSN data intrinsically forms a hypergraph including both user-user edges (friendships) and user-time-POI-semantic hyperedges (check-ins). Based on this hypergraph, we first propose a random-walk-with-stay scheme to jointly sample user check-ins and social relationships, and then learn node embeddings from the sampled (hyper)edges by preserving n-wise node proximity ($n = 2$ or 4). Our evaluation results show that LBSN2Vec both consistently and significantly outperforms the state-of-the-art graph embedding methods on both friendship and location prediction tasks, with an average improvement of 32.95% and 25.32%, respectively. Moreover, using LBSN2Vec, we discover the asymmetric impact of mobility and social relationships on predicting each other, which can serve as guidelines for future research on friendship and location prediction in LBSNs.

1 INTRODUCTION

Understanding the correlation between human mobility and social relationships is crucial for studying human dynamics, which is also a key ingredient for friendship and location prediction tasks. Location Based Social Networks (LBSNs), such as Foursquare, have attracted millions of users and generated a considerable amount of digital footprints from their daily life. As such, they have become a primary data source to study the impact of mobility and social relationships on each other. Specifically, in LBSNs, users can share their real-time presences with their friends by checking-in at a Point of Interest (POI), such as a restaurant or a gym. In addition to such fine-grained and semantic user mobility information, the social network of the corresponding users is also available.

Based on LBSN data, empirical analyses have shown various socio-spatial properties of user activities, in particular the correlation between user mobility characteristics (e.g., distance, co-location rate, etc.) and social networks [8, 26–28, 42]. Based on these findings, two main applications have been investigated, i.e., friendship prediction (a.k.a. link prediction) and location prediction. *Friendship prediction* aims at recommending social relationships that are likely to be established in the future [28], while *location prediction* tries to predict which POI a user will go to in a given context (e.g., at a given time) [8]. Existing work has shown that considering the correlation between user mobility and social relationships can improve the performance of both friendship prediction [7, 25, 28, 32, 42] and location prediction [8, 12, 18, 21, 25]. More precisely, these approaches usually select a set of hand-crafted features either from user mobility data or from the corresponding social network, and then show the impact of one on the other. For example, social features usually involve different network proximity metrics including common neighbor, Adamic-Adar [1], Katz index [17], etc. For mobility features, co-location rate is a widely used metric to measure the homophily between two users in terms of mobility traces; it has different variations such as normalized/unnormalized, weighted/unweighted, spatial only/spatiotemporal [28, 33]. However, such a manual feature engineering process not only requires tedious efforts from domain experts, but also shows less generalizability [13] (see Section 5.2.2 and 5.3.2 for more detail).

To overcome the limitation of hand-crafted features, automatic feature learning (a.k.a. representation learning) has been proposed [3]. When applied to networks or graphs, this paradigm is typically known as *graph (or network) embedding* [5], which represents nodes of a graph in a low-dimensional vector space while preserving key structural properties of the graph (e.g., topological proximity of the nodes). Based on such embeddings, graph analysis tasks (e.g., link prediction) can then be efficiently performed. As shown in Figure 1, LBSN data in this context intrinsically form a hypergraph consisting of four key data domains, i.e., spatial, temporal, semantic and

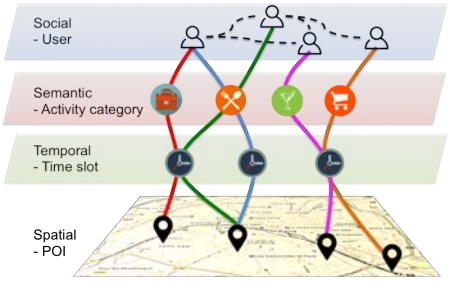

Figure 1: LBSN hypergraph containing both user mobility data (check-ins) and the corresponding social network. A friendship is represented by an edge (a black dotted line) linking two user nodes. A check-in is represented by a hyperedge (a colored thick line) linking four nodes, i.e., a user, an activity type, a time stamp and a POI.

social. This graph contains not only classical edges (i.e., friendships between two users in the social network), but also hyperedges (i.e., check-ins linking four nodes, one from each domain, representing a *user*'s presence at a *POI* at a specific *time* along with the *semantic* information about the user's activity there).

However, existing graph embedding techniques cannot fully grasp the complex data structure of LBSNs. First, most of the existing techniques were developed for classical graphs [6, 13, 22–24, 29, 30], where an edge links two nodes only; the node embeddings are then learnt such that the pairwise node proximity is preserved. However, preserving the pairwise node proximity cannot fully capture the information from the check-in hyperedges. Even though a hypergraph can be transformed into a classical graph by breaking each hyperedge into multiple classical edges, such an irreversible process causes a certain information loss, leading to degraded performance of the learnt node embeddings on different tasks (see Section 5.2 and 5.3 for more detail). Second, there are also a few techniques studying the hypergraph embedding problem, but they either focus on a n-uniform hypergraph (where all hyperedges contain a fixed number n of nodes) and thus capture only fixed-n-wise node proximity [2, 31, 44], or learn from hyperedges for heterogeneous events only (hyperedges linking nodes from different data domains) while ignoring edges within a data domain [14]. However, as shown in Figure 1, the LBSN hypergraph typically contains both classical friendship edges (n=2) within the user domain and check-in hyperedges (n=4) across all four data domains. Subsequently, these techniques cannot be directly applied to the full LBSN hypergraph. Even though these techniques could be applied on check-in hyperedges (n=4) only, ignoring social relationship indeed shows suboptimal performance for different tasks (see Section 5.3 for more detail).

Against this background, we revisit human mobility and social relationships in LBSNs in this paper and propose LBSN2Vec, a hypergraph embedding approach designed specifically for LBSN data with the special consideration of learning from *both* friendship edges *and* check-in hyperedges at the same time. Our contributions are three-fold:

- We collect a large-scale LBSN dataset over a long-term period and conduct a rigorous empirical analysis to systematically reveal the correlations between user check-ins and the corresponding social network. Specifically, existing publicly available LBSN datasets collected from Foursquare [12], Gowalla [8] or Brightkite [8], usually contain check-in data from a set of users over a period of time, and one snapshot of the corresponding user social network. However, it is often unclear when the social network snapshot is collected (e.g., before, during or after the check-in data collection period); such chronological information is important in studying the impact of user mobility and the corresponding social network on each other. For example, to investigate the impact of social networks on user mobility patterns, only friendship formed before a check-in should be considered. Therefore, our collected dataset contains not only check-ins of a set of users over a two-year period, but also two snapshots of the corresponding user social network before and after the check-in data collection period, respectively. Based on this dataset, we conduct a rigorous empirical analysis of the impact of user mobility and social network on each other, showing that each of the four data domains has a clear impact on both friendship and location prediction tasks.
- We propose LBSN2Vec, a hypergraph embedding approach that can efficiently learn node embeddings from both friendship edges and check-in hyperedges in a LBSN hypergraph. To this end, we first propose a random-walk-with-stay scheme to jointly sample friendship and check-ins from a LBSN hypergraph. To balance the impact of social relationships and user mobility on the learnt node embeddings, we incorporate a tunable parameter to control the portion of social relationships and check-ins in the learning process in a probabilistic manner. Moreover, to learn node embeddings from hyperedges containing n nodes, we design LBSN2Vec to preserve the n-wise node proximity by simultaneously optimizing the proximity of the n nodes from a hyperedge. More precisely, we first compute the best-fit-line of the n nodes in cosine space, and then iteratively maximize the cosine similarity between each node of the hyperedge and the best-fit-line.
- We conduct a thorough evaluation using our collected dataset. Our results show that LBSN2Vec outperforms state-of-the-art graph embedding techniques on both friendship and location prediction tasks, with an average improvement of 32.95% and 25.32%, respectively. Moreover, using LBSN2Vec, we discover the asymmetric impact of user mobility and social networks on predicting each other. We find that node embeddings learnt from 80% social and 20% mobility data results in the best performance on the friendship prediction task, while those learnt from 40% mobility and 60% social data give the best performance on the location prediction task. Such an observation can serve as guidelines for future research on friendship and location prediction.

2 RELATED WORK

2.1 Human Mobility and Social Relationships

The interaction between human mobility and social relationships has been widely studied using different data sources over the past decade. In the earlier stage, call detail records have been often used to study human mobility, social ties and link prediction problems

[8, 33]. Although these studies have revealed several interesting properties of human mobility and social ties, such data shows two obvious limitations. First, it contains only coarse-grained user location information on a cell tower level. Second, it does not contain actual information about social relationships between users; the corresponding social network are usually built from the users' communication activities based on certain heuristics. For example, a friendship is assumed between a pair of users when there is at least one call between them [33] (or 10 calls in [8]).

The emergence of Location Based Social Networks provides a novel opportunity to collect both large-scale user mobility data (i.e., check-ins) and the corresponding social network. Using LBSN data, positive correlations between social proximity and mobility homophily have been universally found [8, 33]. However, existing publicly available LBSN datasets (Foursquare [12], Gowalla [8] or Brightkite [8]) mainly contain check-in data of a set of user over a period of time, and one snapshot of the corresponding social network without mentioning when the social network is collected[1]; such chronological information is important in studying the impact of user mobility and the corresponding social network on each other. Therefore, in this paper, we collected our own dataset from Foursquare, containing not only check-ins of a set of users over about two years, but also two snapshots of the corresponding user social network before and after the check-in data collection period, respectively. Based on this dataset, we investigate the impact of user check-ins and the corresponding social network on both friendship and location prediction tasks.

First, friendship prediction is a classical problem in social network analysis. It predicts the potential friendship between two users based on the existing social network [19]. Using LBSN data, friendship prediction approaches [7, 25, 28, 32, 42] often combine social proximity and mobility pattern similarity to achieve better prediction performance. For example, Scellato et al. [28] investigated a set of hand-crafted features and showed that besides social proximity, mobility pattern similarity is also a strong indicator to predict future friendship. Sadilek et al. [25] manually combined features from social proximity, mobility similarity, and textual similarity extracted from users' Tweets for friendship prediction.

Second, location prediction is a typical problem in human mobility modeling, which predicts the location of a user under a certain context based on the user's historical mobility traces. Using LBSN data, location prediction approaches incorporate social factors in mobility models, showing an improved prediction performance [8, 12, 18, 21, 25]. For example, Gao et al. [12] combined check-in patterns and social ties by considering mobility similarity between friends (co-location rate measured by cosine distance). Noulas et al. [21] investigated the next place prediction problem and found that besides a user's own check-in history, a "social filtering" feature serves as an important predictor for the user's next location.

However, the manual feature engineering process adopted by the existing work not only requires a lot of human efforts, but also shows less generalizability [13]. In this paper, we propose LBSN2Vec, a hypergraph embedding approach to automatically learn the node embeddings from a LBSN hypergraph, based on which both friendship and location prediction tasks can be efficiently performed. Moreover, our LBSN2Vec can also model the impact of user mobility and social relationships on each other.

[1]Note that one of the existing work [28] used multiple social network snapshots to study the friendship prediction problem, but the dataset is not publicly accessible. Moreover, it used hand-crafted features for friendship prediction.

2.2 Graph Embeddings

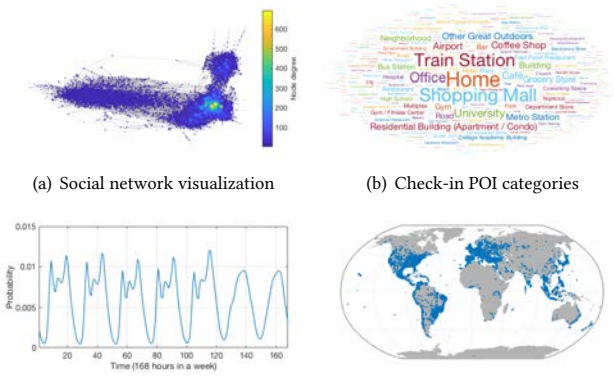
Most existing graph embedding approaches focus on preserving pairwise node proximity in a classical graph, which can be further classified into two categories according to the embedding learning process. First, *factorization based approaches* [6, 22, 24] measure pairwise node proximity as a matrix using a certain network proximity metric, such as common neighbor or Adamic-Adar, and then factorize this proximity matrix using matrix factorization techniques to learn the node embeddings. However, factorization-based approaches have an intrinsic scalability limitation, due to the quadratic complexity of matrix factorization algorithms [4]. Second, *graph-sampling based approaches* [13, 16, 23, 29, 30] sample node pairs (directly or via random walks) from a graph, and then design specific models to learn node embeddings from the sampled node pairs via stochastic optimization. These graph-sampling based approaches are able to scale up to large datasets, as their complexity mainly depends on the number of the sampled node pairs.

Moreover, there are also a few approaches studying the hypergraph embedding problem, but they either focus on a n-uniform hypergraph (where all hyperedges contain a fixed number n of nodes) and thus capture only fixed-n-wise node proximity [2, 31, 44], or learn from hyperedges for heterogeneous event only (hyperedges linking nodes from different data domains) while ignoring edges within a data domain [14]. However, in this paper, as shown in Figure 1, our LBSN hypergraph contains both classical friendship edges (n=2) within the user domain and check-in hyperedges (n=4) across all four data domains. Subsequently, these techniques cannot be directly applied to our full LBSN hypergraph. Even though they can be applied only on the check-in hyperedges (n=4) for example, ignoring social relationships indeed yields suboptimal performance (see Section 5.3 for more detail). Against this background, we propose LBSN2Vec to efficiently learn node embeddings from the LBSN hypergraph by preserving the n-wise node proximity encoded by the hyperedges (where $\{n \in \mathbb{Z}^+ | n \geq 2\}$).

We also note that there are several works exploited embedding techniques on LBSN data, but they mostly focus on check-in data only (without using social networks) for specific tasks, such as semantic annotation of POIs [34], POI recommendation [10, 35], next visitor prediction [11]. Only one recent work [43] used both social network and check-in data on LBSNs for learning embeddings for users and POIs, but it overlooks the temporal and semantic information of check-ins. Moreover, none of these works have investigated the correlations between human mobility and social relationships.

3 EMPIRICAL DATA ANALYSIS

In this section, we first present our dataset collection and its main characteristics, followed by empirical studies on the impact of mobility on the social network and vice versa.

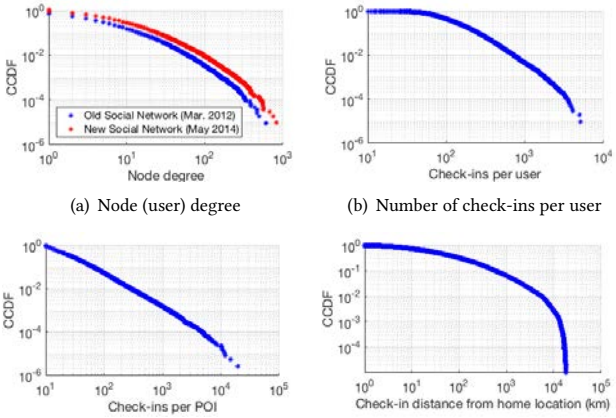


3.1 Dataset Collection and Characteristics

Our collected Foursquare dataset contains a set of global-scale check-ins over about two years (from Apr. 2012 to Jan. 2014), and two snapshots of the corresponding user social network before (in Mar. 2012) and after (in May 2014) the check-in data collection period. The check-in data is collected from Foursquare, which has been widely used as a key data source for studying location based services [39–41]. Specifically, as Foursquare user's check-ins can only be accessed from the user's social circle, they are not publicly available. However, many Foursquare users choose to also share their check-ins via Twitter [37]. Therefore, we collect global-scale check-in data by searching Foursquare-tagged Tweets from Twitter Public Streams for about two years (from Apr. 2012 to Jan. 2014). We keep only active users (who have performed at least one check-in per month). User social relationships are collected from Twitter, as Foursquare friendship information is not publicly available. Specifically, for each user, we first crawl her "followers" (users who follow this user) and "friends" (users who are followed by this user) on Twitter. We then build the corresponding user social network by keeping only reciprocal relationships [38], i.e., a friendship is assumed between two users if the two users follow each other. We collect two snapshots of such social network before (in Mar. 2012) and after (in May 2014) the check-in data collection period. After filtering out isolated users (i.e., users without social links), we keep only users appearing in both social network snapshots. In summary, our dataset contains 22,809,624 check-ins from 114,324 users on 3,820,891 POIs, and two snapshots of the corresponding user social network before (363,704 friendships) and after (607,333 friendships) the check-in data collection period. Our dataset is available here[2].

Figure 2 shows a series of visualizations of our dataset in all four data domains. For the social domain, Figure 2(a) shows the old social network with a color bar indicating user node degrees. We observe only a few nodes with high degrees, while most of the nodes are of low degrees, which suggests a heavy-tailed distribution. We do not show the new social network as its plot shows a very similar visual structure as the old one. For the semantic domain, Figure 2(b) shows the categorical distribution of check-in POIs, where we have a total number of 453 POI categories (i.e., activity categories). We find that daily-routine related activities including "Shopping Mall", "Home", "Train station" and "Office", are among the most frequent categories. For the temporal domain, Figure 2(c) plots the weekly temporal traffic pattern of check-ins over 168 hours in a week. We observe not only a clear daily periodicity, but also the difference between weekday (with three peaks in the morning, afternoon and evening, respectively) and weekend (with only one flat peak during the daytime). Based on this observation, we define the time granularity (time slot) as 168 hours (corresponding to a full week) for this study. For the spatial domain, we visualize the GPS coordinates of POIs on a world map in Figure 2(d). We observe POIs from our dataset spread all over the world, with urban areas concentrating many of the POIs.

In addition, we take a closer look at the dataset from a statistical point of view. Figure 3 shows the Complementary Cumulative Distribution Function (CCDF) of different statistics of the collected dataset. First, we observe a heavy-tailed distribution of all statistics,



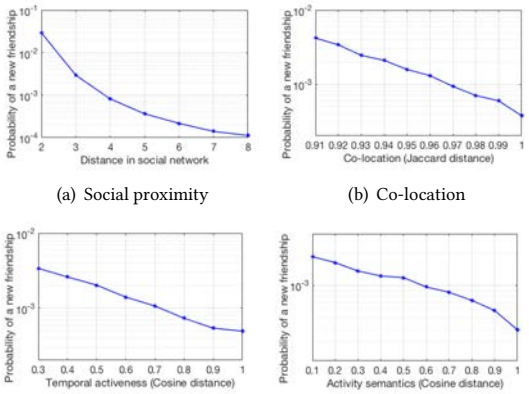
[2]https://sites.google.com/site/yangdingqi/home/foursquare-dataset

(a) Social network visualization (b) Check-in POI categories

(c) Temporal traffic of check-ins (d) World map of check-in POIs

Figure 2: Visualization of the collected LBSN data

(a) Node (user) degree (b) Number of check-ins per user



(c) Number of check-ins per POI (d) Check-in distance from home

Figure 3: Complementary Cumulative Distribution Function (CCDF) of various statistics in the collected dataset

including user node degrees in Figure 3(a), number of check-ins per user in Figure 3(b), number of check-ins per POI in Figure 3(c), and check-in distance from home location [8] in Figure 3(d), which implies a large variance in these statistics. For example, the heavy-tailed distribution of check-in distance from home shows that 70% of the check-ins happen less than 100km from home. Moreover, we observe that the user social network significantly expanded over the two years in Figure 3(a); the average degree increases from 3.38 to 5.56. In the following, we study the impact of mobility on the corresponding social network and vice versa.

3.2 Impact of Mobility on New Friendships

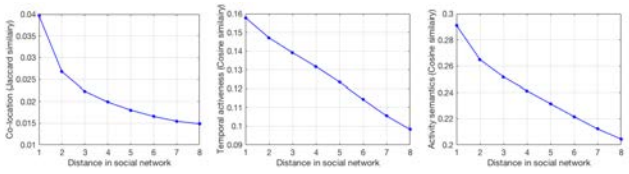
We investigate the probability of establishing a *new* friendship (appearing in the new but not in the old social network), w.r.t. various social and mobility factors in the old social network and user check-in data. Figure 4 shows the results. On one hand, the existing social network is unsurprisingly the primary predictor of future friendships [19]. Figure 4(a) shows the impact of the social proximity between users in the old social network. We observe that pairs of users at closer social distance are more likely to establish a new friendship. On the other hand, we use the following three metrics to

(a) Social proximity (b) Co-location

(c) Temporal activeness (d) Activity semantics

Figure 4: Impact of social and mobility factors on establishing new friendships

measure the similarity of user mobility patterns on spatial, temporal and semantic domains, respectively.



- **Co-location** [33]: By modeling each user's check-in data as a vector, where each element in the vector indicates whether the user has checked-in at the corresponding POI or not, we measure the Jaccard distance between two users' check-in vectors.
- **Temporal activeness** [36]: We model a user's check-in data by a vector encoding the user's check-in frequency over 168 hours in a week (as shown in Figure 2(c)), and then measure the Cosine distance between two users' temporal activeness vectors.
- **Activity semantics** [40]: We model a user's check-in data by a vector encoding the categorical distribution of a user's checked POIs (i.e., the distribution on POI categories as shown in Figure 2(b)), and then measure the Cosine distance between two users' activity semantic vectors.

Figure 4(b), 4(c) and 4(d) show the impact of the above three metrics on the probability of establishing a new friendship, respectively. We consistently observe that pairs of users with similar mobility patterns (measured in any of the three domains) are more likely to establish a new friendship in the future. *These observations suggest that all four data domains should be considered in the friendship prediction task. Note that we only use these metrics to investigate which data domains should be considered in the LBSN2Vec, yet none of these metric is required in our node embedding learning process.*

3.3 Impact of Friendship on Mobility

We investigate the similarity of user mobility patterns w.r.t. the social proximity between users in the *old* social network. Figure 5 shows the results. We consistently observe that pairs of users at closer social proximity are more likely to exhibit similar mobility patterns measured by all the three metrics, i.e., co-location, temporal activeness and activity semantics. Such an observation suggests that social relationships can be used to help predict user mobility.

In addition, we also investigate the impact of a user's historical mobility traces on her future mobility. To achieve this goal, we chronologically split our check-in data (of about two years) into

(a) Co-location (b) Temporal activeness (c) Activity semantics

Figure 5: Impact of social proximity on mobility factors

two parts of the same duration, i.e., a first-year check-in dataset and a second-year check-in dataset. Subsequently, we compute the similarity between each user's mobility patterns in the first and the second year, measured by the aforementioned three metrics. The average similarity is 0.12, 0.32 and 0.38 for co-location, temporal activeness and activity semantics, respectively. Compared to the mobility similarity between friends (the distance in the old social network is 1 in Figure 5, i.e., 0.04, 0.16 and 0.29 for co-location, temporal activeness and activity semantics, respectively), we find that a user's own mobility history is indeed the primary predictor of her future mobility. *Subsequently, we also consider all four data domains in our LBSN2Vec for node embedding learning in the location prediction task. We note again that as an automatic feature learning approach, LBSN2Vec does not involve any of the metrics defined in this section.*

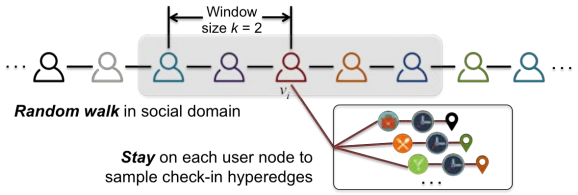
4 LBSN2VEC

In this paper, we adopt a graph-sampling based embedding paradigm due to its intrinsic scalability advantage as discussed in Section 2.2. Specifically, our method first uses a novel random-walk-with-stay scheme to jointly sample friendships and check-in hyperedges[3] from the LBSN hypergraph, and then learn node embeddings from these hyperedges to preserve the n-wise node proximity by optimizing the proximity of the n nodes from a hyperedge simultaneously.

4.1 Random Walk with Stay

As shown in Figure 1, the LBSN hypergraph consists of four data domains, i.e., spatial, temporal, semantic and social domain, and two types of edges, i.e., classical edges (friendships) linking pairs of user nodes and hyperedges (check-ins) linking four nodes, one from each domain. To sample (hyper)edges from this graph, we propose a random-walk-with-stay scheme to jointly sample friendship and check-in hyperedges. As shown in Figure 6, our random-walk-with-stay scheme performs classical random walk only on user nodes based on their friendships in social domain, while for each encountered user node, it stays on the user node to sample a set of hyperedges (check-ins) from the corresponding user. Subsequently, in the node embedding learning process, when iterating over each user node in a random walk sequence, we not only learn from two user nodes appearing with a context window of length k, but also stay on the corresponding user node to learn from its check-in hyperedges. In other words, the node embedding learning process alternates between these two types of edges (i.e., friendships and check-ins). To perform classical random walk on the user social

[3] A classical edge linking two user nodes (i.e., a friendship) can be regarded as a special case of a hyperedge consisting of only two nodes. In the following, besides the check-in hyperedges, we also use the term "hyperedge" to describe a pair of user nodes.



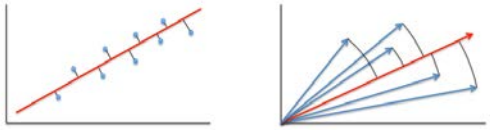


Figure 6: Random walk with stay on the LBSN hypergraph

(a) Euclidean space with perpendicular distance (b) Cosine space with cosine distance

Figure 7: Examples of the best-fit-lines in Euclidean and Cosine spaces. The given data points are represented in blue, while the corresponding best-fit-line is shown in red.

network, we use the same strategy as used by existing works [13, 23], generating r walks of length l rooted on each user node.

Moreover, in order to balance the impact of friendships and check-ins on the learnt node embeddings, LBSN2Vec incorporates a tunable parameter α to control the portion of learning edges of each type. Specifically, for a given context window of length k, we iterate over $2k$ contexts for each user node v_i (k context nodes on each side), resulting in $2k$ pairs of user nodes. Figure 6 shows an example where the context window size is 2. Subsequently, we sample for each user node the same number ($2k$) of check-ins. Afterwards, we learn from each check-in with a probability α, while from each user node pair with a probability $(1-\alpha)$, where α and $(1-\alpha)$ actually specify the impact of mobility and social network on the learnt node embeddings, respectively. In summary, for each node v_i in a random walk, the expected total number of learnt edges is $2k$, including an expected number $2k\alpha$ of check-ins and an expected number of $2k(1-\alpha)$ of user node pairs. A small value of α gives less importance on the check-in data and more on social network, and vice versa. In the following, we present our node embedding learning process preserving the n-wise node proximity for hyperedges.

4.2 Learning from Hyperedges

We design a novel embedding model in LBSN2Vec to preserve the n-wise node proximity by maximizing the similarity between the nodes of a hypergraph and their best-fit-line under cosine similarity. Specifically, our embedding model needs to learn from hyperedges linking either 2 or 4 nodes. We further generalize this problem to hyperedges containing n nodes, where $\{n \in \mathbb{Z}^+ | n \geq 2\}$, and design our model that can preserve the n-wise node proximity from those hyperedges. As the hyperedges are actually sampled and learnt one by one from a random walk, we focus in the following on the learning process for one hyperedge.

To learn node embeddings from a hyperedge containing n nodes, we borrow the idea of best-fit-line (a.k.a. line of best fit) from linear regression [15]. In general, a best-fit-line is a straight line that is the best approximation of the given data points. Figure 7(a) illustrates an example of the best-fit-line in Euclidean space that minimizes the sum of perpendicular distances, which can be computed via linear least squares. In this paper, following existing graph embedding techniques [6, 13, 22–24, 29, 30], we learn node embeddings in cosine space where the proximity between nodes are measured using cosine similarity (or dot product of the normalized embedding vectors). Moreover, we show below that the computation of the best-fit-line in cosine space can be significantly simplified. Formally, the best-fit-line of a set of node embeddings is the vector that minimizes the sum of cosine distances between each node embedding and the best-fit-line, as shown in Figure 7(b), which can be efficiently computed using Proposition 1:

Proposition 1. *For a set of nodes (in a hyperedge) $\{v_i | i = 1, 2, \ldots, n\}$, the corresponding best-fit-line can be computed as $\vec{v}_b = \sum_{i=1}^{n} \frac{\vec{v}_i}{\|\vec{v}_i\|}$, where $\vec{v}_i$ refer to the embedding vector of node v_i.*

Proof. The problem of finding the best-fit-line $\vec{v}_b$ that minimizes the sum of cosine distances can be formulated as follows:

$$\underset{\vec{v}_b}{\text{argmin}} \sum_{i=1}^{n} (1 - \cos(\vec{v}_i, \vec{v}_b)) \tag{1}$$

As minimizing the cosine distance is equivalent to maximizing the cosine similarity, we obtain:

$$\underset{\vec{v}_b}{\text{argmax}} \sum_{i=1}^{n} \cos(\vec{v}_i, \vec{v}_b) = \underset{\vec{v}_b}{\text{argmax}} \left(\sum_{i=1}^{n} \frac{\vec{v}_i}{\|\vec{v}_i\|} \right) \cdot \frac{\vec{v}_b}{\|\vec{v}_b\|} \tag{2}$$

Let $\vec{v}_a = \sum_{i=1}^{n} \frac{\vec{v}_i}{\|\vec{v}_i\|}$, we obtain:

$$\underset{\vec{v}_b}{\text{argmax}}\ \vec{v}_a \cdot \frac{\vec{v}_b}{\|\vec{v}_b\|} = \underset{\vec{v}_b}{\text{argmax}} \|\vec{v}_a\| \frac{\vec{v}_a \cdot \vec{v}_b}{\|\vec{v}_a\| \|\vec{v}_b\|} \tag{3}$$

where $\|\vec{v}_a\|$ is a constant for the given set of node. Subsequently, the above function actually maximizes the cosine similarity between $\vec{v}_a$ and $\vec{v}_b$. As the maximal cosine similarity between any two vectors is achieved if and only if the two vectors have the same orientation, the best-fit-line $\vec{v}_b$ can be simply computed as:

$$\vec{v}_b = \vec{v}_a = \sum_{i=1}^{n} \frac{\vec{v}_i}{\|\vec{v}_i\|} \tag{4}$$

This completes the proof. □

Therefore, we optimize the n-wise node proximity by iteratively maximizing the cosine similarity between each node embedding $\vec{v}_i$ from the hyperedge $\{v_i | i = 1, 2, \ldots, n\}$ and the best-fit-line $\vec{v}_b$.

$$\Theta = \sum_{i=1}^{n} \cos(\vec{v}_i, \vec{v}_b) \tag{5}$$

Note that here we keep using cosine similarity rather than dot product (which is widely used by existing techniques), because cosine similarity is not affected by the norm of the input vectors, in particular when the norm of the best-fit-line $\vec{v}_b$ computed by Eq. 4 has a large variance due to the variant number of the nodes n in different hyperedges ($n = 2$ or 4 in our LBSN hypergraph).

In addition, similar to other graph-sampling based embedding techniques [13, 23, 29, 30], we also adopt a negative sampling technique to maximize the cosine distance between each negative sample node v_N and the best-fit-line vector $\vec{v}_b$. Finally, we want

Table 1: Statistics of the selected datasets

Dataset	NYC	TKY	IST	JK	KL	SP
#User	4,024	7,232	10,367	6,395	6,432	3,954
#POI	3,628	10,856	12,693	8,826	10,817	6,286
#Check-ins	105,961	699,324	908,162	378,559	526,405	249,839
#Friendships(Before)	8,723	37,480	21,354	11,207	16,161	9,655
#Friendships(After)	10,545	51,704	36,007	16,950	31,178	14,402

to maximize the following objective function for one hyperedge $\{v_i|i = 1, 2, \ldots, n\}$:

$$\Theta = \sum_{i=1}^{n} (\cos(\vec{v}_i, \vec{v}_b) + \gamma \cdot \mathbb{E}_{v_N}[1 - \cos(\vec{v}_N \cdot \vec{v}_b)]) \tag{6}$$

where $\gamma \in \mathbb{Z}^+$ is the number of negative samples. Note that as the LBSN hypergraph contains four data domains, the negative samples for a node v_i from one data domain are uniformly sampled from the nodes in the same data domain.

The above objective function can be optimized using stochastic gradient descent techniques. Note that we only need to update $\vec{v}_i$ and $\vec{v}_N$ when learning from one specific hyperedge, as the best-fit-line vector $\vec{v}_b$ is fixed. The gradient of the above objective function with respect to $\vec{v}_i$ and $\vec{v}_N$ is computed as follows:

$$\frac{\partial \Theta}{\partial \vec{v}_i} = \frac{\vec{v}_b}{\|\vec{v}_i\|\|\vec{v}_b\|} - \frac{\vec{v}_i \cos(\vec{v}_i, \vec{v}_b)}{\|\vec{v}_i\|^2} \tag{7}$$

$$\frac{\partial \Theta}{\partial \vec{v}_N} = -\frac{\vec{v}_b}{\|\vec{v}_N\|\|\vec{v}_b\|} + \frac{\vec{v}_N \cos(\vec{v}_N, \vec{v}_b)}{\|\vec{v}_N\|^2} \tag{8}$$

In summary, to learn node embeddings from the LBSN hypergraph, we first sample a set of friendship and check-in hyperedges using our proposed random-walk-with-stay scheme, and then iteratively learn from each hyperedge $\{v_i|i = 1, 2, \ldots, n\}$ ($n = 2$ for friendships or $n = 4$ for check-ins) by optimizing the objective function in Eq. 6.

5 EXPERIMENTS

In this section, we evaluate LBSN2Vec on both friendship and location prediction tasks using our collected dataset. In the following, we first present our experimental setup, and then discuss the results on individual tasks, followed by a parameter sensitivity study.

5.1 Experimental Setup

5.1.1 Dataset. In this study, we investigate the friendship and location prediction at an urban scale. Without loss of generality, we select six cities with a large number of check-ins, while also considering the cultural diversity of the selected cities: New York City (**NYC**), Tokyo (**TKY**), Istanbul (**IST**), Jakarta (**JK**), Kuala Lumpur (**KL**), Sao Paulo (**SP**). We select users in the largest connected components of the old social network. Table 1 summarizes the statistics of the selected datasets.

5.1.2 Baselines. As our objective is automatic feature learning from LBSN data, we compare our method to the following state-of-the-art graph embedding methods.

- **DeepWalk** [23] first generates node sequences using random walks, and then feeds them to a SkipGram model to output node embeddings. We set the walk length to $l = 80$, the number of walks per node to $r = 10$, and the context window size for the SkipGram model to $k = 10$.
- **Node2vec** [13] extends DeepWalk by introducing a parameterized random walk method to balance the breadth-first search (return parameter p) and depth-first search (in-out parameter q) strategies, to capture richer graph structures. Following the suggestions in the original paper, we tune p and q with a grid search over $p, q \in \{0.25, 0.05, 1, 2, 4\}$. We keep the other parameters l, r, k similar as for DeepWalk.
- **LINE** [29] explicitly defines 1st and 2nd-order node proximity to learn graph embeddings. Specifically, to learn node embeddings of dimension d, it first learns two sets of $d/2$-dimension node embeddings preserving 1st and 2nd-order node proximity, respectively, and then concatenates them together.
- **HEBE** [14] learns node embeddings for *heterogeneous event data* using tensor modeling, where a heterogeneous hyperedge links nodes across different domains only and is modeled as an entry in an high-order tensor.
- **DHNE** [31] uses a deep autoencoder to learning node embeddings from a *n-uniform heterogeneous hypergraph*. It preserves both fixed-n-wise node proximity encoded by the hyperedges, and also the high-order node proximity defined as the similarity between nodes' neighborhood structures.

As the baseline methods cannot directly take the LBSN hypergraph as input graph, we propose three settings to adapt our LBSN hypergraph:

- **(S)**: Only the Social network is considered by keeping nodes in user domain and their friendship edges. This setting can be applied to classical graph embedding techniques (preserving pairwise node proximity), i.e., **DeepWalk**, **Node2vec** and **LINE**.
- **(M)**: Only the user Mobility is considered by keeping check-in hyperedges only. This setting can be directly applied to **HEBE** and **DHNE** which can take heterogeneous check-in hyperedges as input. In addition, we also apply this setting to **DeepWalk**, **Node2vec** and **LINE** by breaking each check-in hyperedge into multiple classical edges linking each pair of nodes in the hyperedge (e.g., user-time, time-POI, etc.).
- **(S&M)**: The full LBSN hypergraph containing both friendship edges and check-in hyperedges. This setting can be directly applied to our **LBSN2Vec**. In addition, we also apply this setting to **DeepWalk**, **Node2vec** and **LINE** by mapping the full LBSN hypergraph onto a classical graph by keeping friendship edges and also breaking each check-in hyperedge into multiple classical edges linking each pair of nodes in the hyperedge (same as for the M setting).

For our method LBSN2Vec, we keep the same random walk parameters as for DeepWalk and Node2vec ($l = 80$, $r = 10$, $k = 10$), and tune the parameter α within $[0, 1]$ with a step of 0.1 to balance the impact of social and mobility on the learnt embeddings (more discussion on this point in Section 5.4). The dimension of the node embeddings d is set to 128 and the number of negative samples γ is set to 10 for all methods in all experiments, if not specified otherwise. The implementation of LBSN2Vec is available here[4].

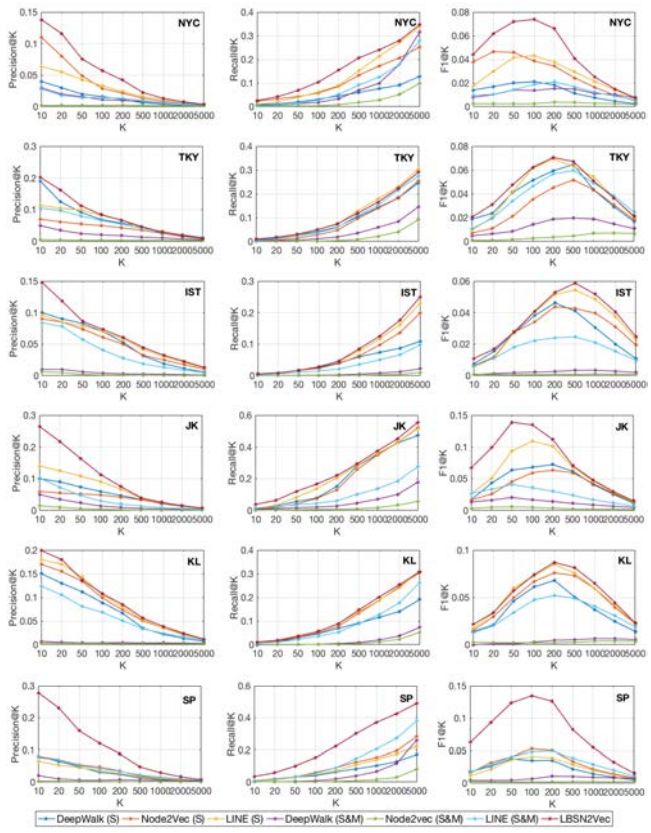

Figure 8: Friendship prediction performance comparison with other graph embedding methods. Each row shows the results on one dataset, while each column shows the results for one evaluation metric.

5.2 Friendship (link) Prediction

Friendship prediction recommends friendships that will probably be established in the future. In this study, we advocate an unsupervised friendship prediction approach [19, 20] which generates a ranking list of potential links between pairs of users. Specifically, after learning the node embeddings based on the *old* social network and check-ins, we rank pairs of user nodes (not being friends in the old social network) according to the cosine similarity between their embeddings. We then evaluate the obtained ranking list against the new friendships (appearing in the new but not in the old social network), using three common metrics for evaluating ranked results, i.e., precision, recall, and F1-score on the top K predicted friendships [19]. As the number of candidate pairs of nodes is too large, we randomly sample 1% pairs of nodes for the evaluation, and report the average results from 10 repeated trials.

5.2.1 Comparison with other graph embedding methods. We report only the methods including social networks (setting S and S&M), since the social proximity in the old social network is indeed the primary predictor of new friendships (see Figure 4(a) for more details) and since we found out that methods using setting M perform very poorly on this task. Figure 8 shows the results. We clearly observe that LBSN2Vec achieves the highest precision, recall and F1-score in general. For example, we find that LBSN2Vec outperforms all baselines with an average improvement of 32.95% on precision@10 over the best baselines across different datasets.

One interesting observation is that for all the baseline methods, considering both the social network and mobility (setting S&M) leads to worse performance than considering only the social network (setting S). In other words, for all baseline methods, adding user mobility information decreases the friendship prediction performance. Despite the counter-intuitive nature of this observation, we notice that these methods fail to balance the impact of social network and user mobility on the learnt node embeddings. More precisely, as the number of check-ins is usually much larger than the number of friendships, the S&M graph is dominated by the edges representing check-ins. When the baseline methods uniformly sample edges from the S&M graph to learn the node embeddings, the sampled edges are also dominated by the edges representing check-ins, which naturally imposes a strong impact of mobility on the learnt node embeddings. In fact, as mentioned for Figure 4(a) in Section 3.2, the social proximity in the old social network is indeed the primary predictor of new friendships (our parameter sensitivity study in Section 5.4 also verifies this point below). Therefore, the learnt node embeddings from those baseline methods (with setting M) result in the worst performance in friendship prediction.

5.2.2 Comparison with hand-crafted features. We compare LBSN2Vec with the following hand-crafted features suggested specifically for the friendship prediction task by previous work:

- *Katz Index (**Katz**)* [17] is the best performing social feature suggested by [33]. It is defined as the weighted sum of all paths between two users on the social networks, where the weight of a path decays exponentially with its length. $Katz(u,v) = \sum_{l=1}^{\infty} \beta^l \cdot |path^l_{u,v}|$, where $path^l_{u,v}$ is the set of all paths with length l from u to v. We set $\beta = 0.05$ as suggested by [33].
- *Adamic-Adar (**AA**)* [1] is the best performing social feature suggested by [28]. It is the weighted sum of the common neighbors between two users. The weight for each common neighbor is the inverse logarithm of its degree. $AA(u,v) = \sum_{z \in \Gamma(u) \cap \Gamma(v)} \frac{1}{\log |\Gamma(z)|}$, where $\Gamma(u)$ is the set of neighbors (friends) of user u.
- *Spatial Cosine Similarity (**SCos**)* is the best performing mobility feature suggested by [33]. It is defined as the cosine similarity between two users' check-in vectors C_u and C_v, i.e., $\cos(C_u, C_v)$, where each element $C_u(i)$ is u's check-in count on POI i.
- *Minimum place entropy (**Min_ent**)* is the best performing mobility feature suggested by [28]. It is defined as the minimum POI entropy (i.e., the entropy of the empirical distribution of check-ins at that POI over users) that two users share.

As combining social and mobility features is suggested by both [33] and [28], we consider all the combinations of the above social and mobility features, including **Katz+SCos**, **Katz+Min_ent**, **AA+Min_ent** and **AA+SCos**. Specifically, as these features have different value ranges, we first generate one ranking list of predicted friendships using each feature, and then merge two ranking

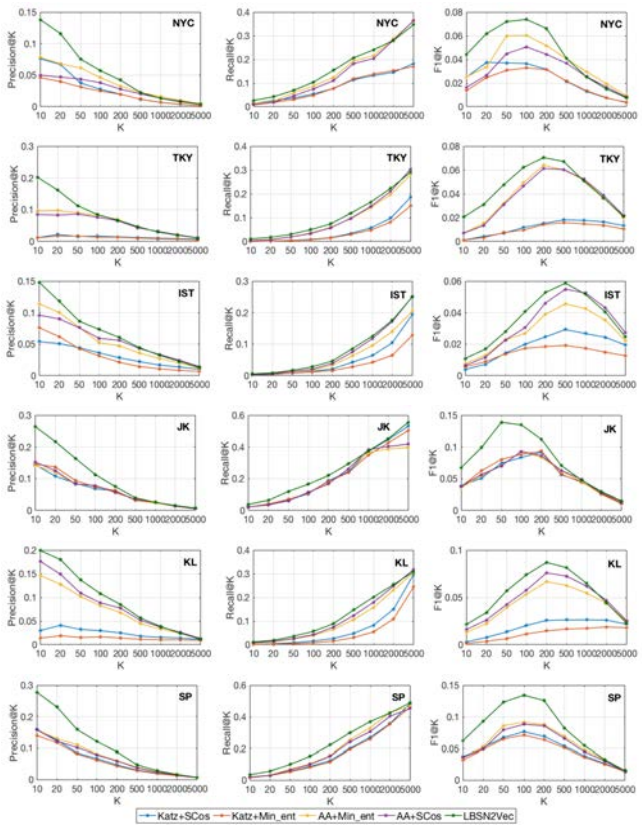

Figure 9: Friendship prediction performance comparison with hand-crafted features.

lists using reciprocal rank fusion [9], which is a popular rank fusion method widely used in information retrieval research. Figure 9 shows the results. We clearly observe that LBSN2Vec outperforms the hand-crafted feature based methods in general, and we find an average improvement of 66.44% on precision@10 over the best baselines across different datasets. Moreover, We observe that none of the four combinations can consistently outperform others over all datasets, which shows the generalization limitations of the hand crafted features across different datasets.

5.3 Location Prediction

Location prediction tries to predict the POI a user will be located in at a given time slot. To implement this task, we chronologically split our check-in data into two parts, i.e., the first 80% for training and the last 20% for testing. We then learn node embeddings from the old social network and the training check-in data. Based on the learnt node embeddings, for each test check-in (containing a user, a time slot and a POI), we rank all POIs according to the sum of two cosine similarities: one between the node embeddings of the user and a candidate POI, and one between the node embeddings of the time slot and the candidate POI. For DHNE, we use its own similarity function for ranking POIs. Subsequently, we evaluate the obtained POI ranking list against the actual POI in the test check-in. We report the average accuracy@10 over all test check-ins.

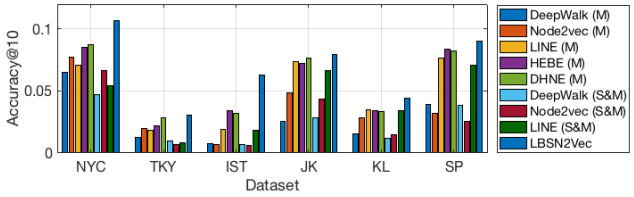

Figure 10: Location prediction performance comparison with other graph embedding methods on all test check-ins

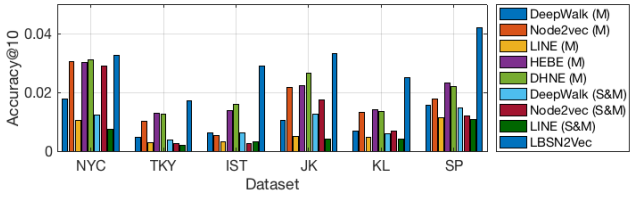

Figure 11: Location prediction performance comparison with other graph embedding methods on new POIs.

5.3.1 Comparison with other graph embedding methods. Figure 10 shows the results. Note that only settings involving check-in data (setting M and S&M) are eligible for this task. First, we observe that our LBSN2Vec consistently outperforms all baselines with an average improvement of 25.32% on accuracy@10 over the best baselines across different datasets. Second, we see that using setting M, hypergraph embedding techniques (HEBE and DHNE) achieve better performance than classical graph embedding techniques (preserving only pairwise node proximity) in general, as the irreversible process of transforming a hypergraph into a classical graph causes a certain information loss, leading to degraded performance for the location prediction task. Finally, similar to friendship prediction, we also find that for all baselines considering both the social network and mobility (setting S&M) results in worse performance than considering mobility (M) only, as the baseline methods fail to balance the impact of the social network and user mobility on the learnt node embeddings. However, the performance drop is relatively smaller than that of the friendship prediction task, as the S&M graph is actually dominated by the edges from the check-ins.

In addition, we also investigate the prediction performance on new POIs only, i.e., the POIs appearing in the test check-ins but not in the training check-ins. As historical (training) check-ins of a user are represented as hyperedges in the LBSN hypergraph, check-ins with new POIs actually refer to the non-observed hyperedges that will be established in the future. Therefore, this task is more difficult as it requires to explore the LBSN hypergraph structure for predicting potential hyperedges, rather than preserving the observed hypergraph structure. Figure 11 shows the accuracy@10 for only new POIs. We observe that compared to the case of all testing POIs, the improvement of our method over the baselines are much higher for new POIs. We observe an average improvement of 50.17% on accuracy@10 in the case of only new POIs, compared to an average improvement of 25.32% in the case of all test POIs. Such an observation demonstrates the strong advantage of LBSN2Vec in predicting potential check-in hyperedges.

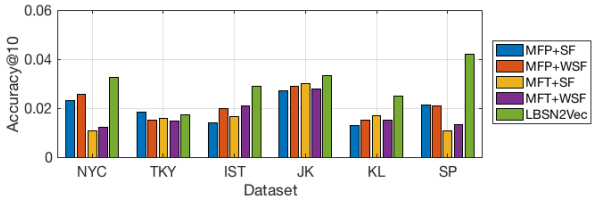

Figure 12: Location prediction performance comparison with hand-craft features on new POIs.

5.3.2 Comparison with hand-crafted features. We also compare LBSN2Vec with the following hand-crafted features suggested specifically for the location prediction task by previous work:

- *Most Frequent POI (**MFP**)* is the best performing mobility feature suggested by [21]. For each user, it ranks a POI according to the number of the user's check-ins at that POI in the training dataset.
- *Most Frequent Time (**MFT**)* is suggested by [40]. For each user and each time slot, it ranks a POI according to the number of user's check-ins at that POI and at that time slot in the training dataset.
- *Social Filtering (**SF**)* is suggested by [21]. For a user u and his friends $\Gamma(u)$, it ranks a POI according to the total number of check-ins that any friend v ($v \in \Gamma(u)$) of the user has performed at the POI.
- *Weighted Social Filtering (**WSF**)* is suggested by [12]. It is a weighted version of SF, where each friend's check-in count is weighed by the mobility similarity between the user and that friend. It ranks a POI according to the weighted sum of the number of check-ins that any her friend v, $v \in \Gamma(u)$, has performed at that POI.

Similar to the friendship prediction task, we combine the results from mobility and social features using reciprocal rank fusion [9], resulting in four combinations (i.e., **MFP+SF**, **MFP+WSF**, **MFT+SF**, **MFT+WSF**). Figure 12 shows the results on new POIs. We observe that our method outperforms the hand-crafted feature in most cases (expect for the TKY dataset where MFP+SF is slightly better). In addition, similar to the case of friendship prediction, none of the four combinations consistently achieve higher accuracy than others, showing the generalization limitations of hand-crafted features.

5.4 Parameter Sensitivity Study

5.4.1 Balance trade-off between social and mobility with α. We investigate the trade-off between the social network and mobility patterns on both the friendship and location prediction tasks by varying α within $[0, 1]$ with a step of 0.1. A small value of α gives more importance on the social network and less on check-in data when learning node embeddings, and vice versa. Figure 13 shows the results. We see a clear trade-off between the social network and mobility on all datasets. On one hand, when increasing α from 0, the friendship prediction performance slightly increases and reaches its peak around $\alpha = 0.2$, as considering mobility factors indeed helps the friendship prediction task. When further increasing α, the performance start to decrease, and we observe a sharp drop around $\alpha = 0.5$. On the other hand, when decreasing α from 1, the location prediction performance slightly increases and reaches its

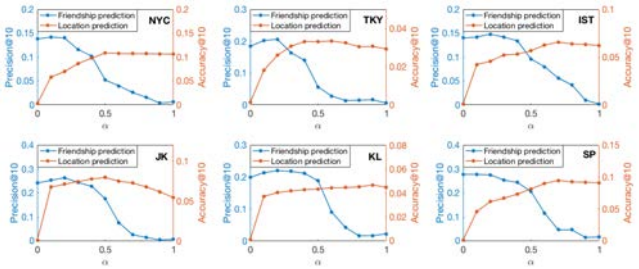

Figure 13: Impact of α on friendship and location prediction tasks

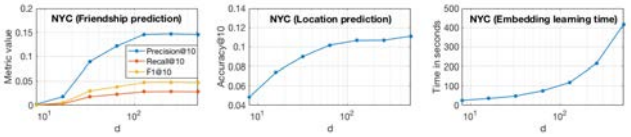

Figure 14: Impact of the node embedding dimension d on the NYC dataset

peak around $\alpha = 0.6$ in most cases (expect for KL dataset), meaning that considering social factors can also help the location prediction task. When further decreasing α, the performance start to decrease, but we observe a sharp drop around $\alpha = 0.1$ or 0.2. Interestingly, by comparing the values of α giving the peak performance in the two tasks, we find the asymmetric impact of social and mobility factor on each other, which seems to be universal across different datasets. More precisely, combining 80% social with 20% mobility data results in the best performance for the friendship prediction task, while combining 40% mobility with 60% social data gives the best performance for the location prediction task.

5.4.2 Dimension of the node embeddings d. We study the impact of the node embedding dimension d on both the friendship and location prediction tasks, as well as on the node embedding learning time on a commodity PC (Intel Core i7-4770HQ@2.20GHz, 16GB RAM, Mac OS X). Figure 14 shows the results on the NYC dataset. First, we see that a small d leads to poor performance on both tasks, as the resulting node embeddings cannot capture sufficient information from the LBSN hypergraph. Then, the performance increases with increasing d, and converges around $d = 128$, meaning that further increasing d leads to little performance improvement. In contrast, the embedding learning time always increases with increasing d, as a higher dimension of node embedding requires more computation in the node embedding learning process. Therefore, we select $d = 128$ for all previous experiments.

6 CONCLUSION

In this paper, by revisiting user mobility and social relationships in LBSNs, we propose LBSN2Vec, a hypergraph embedding approach designed specifically for LBSN data. First, by collecting a large-scale LBSN dataset over a long-term period, we conducted a rigorous empirical analysis to reveal the correlations between user check-ins and the corresponding social network. Then, we designed LBSN2Vec to learn node embeddings from the LBSN hypergraph. It performs random-walk-with-stay to jointly sample user mobility patterns and social relationships from the LBSN hypergraph,

and then learns node embeddings from the sampled hyperedges by preserving the n-wise node proximity captured by a hyperedge containing n nodes. Using the collected LBSN data, our extensive evaluation shows that LBSN2Vec consistently outperforms the state-of-the-art graph embedding methods on both the friendship and location prediction tasks, with an average improvement of 32.95% and 25.32%, respectively. Moreover, using LBSN2Vec, we discover the asymmetric impact of mobility and social relationships on predicting each other, which can serve as guidelines for future research on friendship and location prediction in LBSNs.

In the future, we plan to extend LBSN2Vec by further considering sequential patterns in the user check-in data.

ABSTRACT

This paper presents Scalpel-CD, a first-of-its-kind system that leverages both human and machine intelligence to debug noisy labels from the training data of machine learning systems. Our system identifies potentially wrong labels using a deep probabilistic model, which is able to infer the latent class of a high-dimensional data instance by exploiting data distributions in the underlying latent feature space. To minimize crowd efforts, it employs a data sampler which selects data instances that would benefit the most from being inspected by the crowd. The manually verified labels are then propagated to similar data instances in the original training data by exploiting the underlying data structure, thus scaling out the contribution from the crowd. Scalpel-CD is designed with a set of algorithmic solutions to automatically search for the optimal configurations for different types of training data, in terms of the underlying data structure, noise ratio, and noise types (random vs. structural). In a real deployment on multiple machine learning tasks, we demonstrate that Scalpel-CD is able to improve label quality by 12.9% with only 2.8% instances inspected by the crowd.

1 INTRODUCTION

The success of machine learning techniques — deep learning in particular — heavily relies on the quality and quantity of labeled training data [49]. While a growing body of research has addressed the data *quantity* issue [2, 9, 15, 31, 47], relatively little work has been focused on the data *quality* issue. Due to the lack of transparency and accountability of deep learning models [11, 19, 25], incorrect labels in the training data are generally difficult to identify when the prediction goes wrong; consequently, label noise has become a main obstacle for developing, deploying, and improving deep learning models. The significance of the problem is more obvious in critical domains such as health or justice [34]. For instance, in a medical context, models trained on drug instances that are wrongly labeled as successfully *treating* a certain condition would likely produce erroneous and damaging effects. We therefore argue that debugging noisy labels is of key importance for deep learning-based systems, both in terms of performance and security.

The main existing approach in that context leverages data distributions for debugging noisy labels (see Section 5 for more discussion on that point). The basic assumption is that data points distributed close to each other are more likely to have the same label. Existing methods [1, 35, 39], however, suffer from two major limitations. First, they only model data distributions in the *low-level* feature space with oversimplified structures (e.g., bag-of-words). As for most language and vision problems, the low-level distributions learned by these methods are limited compared to the true distributions that present complex dependencies among features. The second limitation, perhaps the most important one, is that all existing methods are automatic methods that rely on machine intelligence. As a result, the performance of such methods is limited by two factors: 1) the learning capability of the method, and 2) the predictive power of data distributions for true labels, a limiting factor of any data-driven method that relies on data distributions for debugging noisy labels.

Compared to machines, humans are more reliable in justifying decisions and verifying issues [3, 27]. We, therefore, advocate a *human-in-the-loop* approach to leverage both human and machine intelligence when debugging noisy labels. In such an approach, automatic methods can be used to identify data instances with potentially wrong labels in large training data and infer their latent classes, while crowd workers can be engaged to inspect data

instances for which the automatic method are insufficient. This approach can, therefore, exploit the complementary strength of humans and machines for debugging noisy labels. Despite its obvious potential, developing such an approach is however challenging. The first challenge is to develop a machine learning model that can learn high-quality data structures to capture data distributions with higher fidelity for identifying potentially wrong labels. Second, it is important to reduce crowd efforts in debugging large training data due to the difficulty of scaling out the crowd. This requires to select not only data points for which the inference is unreliable, but also those most *representative* data points, such that the labels verified or fixed by the crowd can be propagated to similar data instances.

This paper introduces `Scalpel-CD`, a new human-in-the-loop system that takes advantage of *deep* and *probabilistic* models for inferring the latent classes and human computation for improving the model's inference. Unlike existing probabilistic methods, our deep probabilistic model adopts deep neural networks to parameterize data distributions, thus is able to model complex feature relationships in the data and learn high-quality latent features. The model therefore benefits both from the flexibility of neural networks in learning the underlying data structure and from the expressiveness of probabilistic modeling in capturing data distributions. An additional advantage, which is of key importance when involving the crowd, is that the learned data structure and the reliability of model inference can be used to select the most representative data instances that need to be inspected by humans. To do so, `Scalpel-CD` employs a data sampler that considers both data representativeness and model reliability for data selection. To involve crowd workers, `Scalpel-CD` dynamically creates micro label inspection tasks and publishes them on a popular crowdsourcing platform. The collected results are distilled through aggregation algorithms and the corrected labels are propagated to similar data instances in the training data in order to scale out the contribution from the crowd.

A key design principle of `Scalpel-CD` is that each of its components seeks an optimal tradeoff between different factors that influence system performance on different types of machine learning datasets, in terms of the underlying data structure, noise ratio, and noise types (e.g., random vs. structural). These factors include 1) the level of trust to put in the data distribution and the existing noisy labels; 2) the importance between the representativeness of the data instances and the reliability of model inference in data sampling; and 3) the efficiency and the accuracy of label propagation. We model the tradeoffs between these important system factors as system parameters that are easy to understand; furthermore, we introduce a set of algorithmic solutions that allow to easily search for the optimal system configurations on different datasets. Our system is therefore, generic in the sense that it applies to a wide range of machine learning tasks.

In summary, we make the following key contributions:

- We introduce the notion of debugging noisy training data for learning tasks via a human-in-the-loop approach;
- We present a new system architecture that orchestrates both human and machine intelligence in debugging training data;
- We propose a deep probabilistic model that identifies potentially wrong labels and a set of algorithms for scaling out the contribution of the crowd while determining optimal system parameters.

To the best of our knowledge, we are the first to combine human and machine intelligence for debugging noisy labels. Extensive evaluation on multiple real-world datasets shows that our system is able to improve label quality by 12.9% (accuracy) and 15.8% (AUC) while requiring only 2.8% data to be inspected by the crowd.

2 ARCHITECTURE

In this section, we first give an overview of `Scalpel-CD`, and then describe in more detail some of its components.

2.1 System Overview

Figure 1 presents a simplified architecture of `Scalpel-CD`. It takes as input a noisy dataset, e.g., a corpus of documents each associated with a noisy label that represents the polarity (*sentiment*) of the text. The dataset is first passed to a *deep probabilistic model*, which infers the latent class for each data instance and a high-level latent feature representation of it. Both outputs are used as input for the *data sampler*, which calculates the reliability of the model's inference and the representativeness of the data instance. The data sampler then selects representative data instances whose labels need to be inspected the most. The selected data instances, together with the noisy labels, are passed to the *micro-task manager*, which dynamically creates human computation tasks and publishes them on a crowdsourcing platform.

The noisy label for each selected data instance is then examined by multiple human workers. Once workers complete their inspection, the results are passed to a *label aggregator*. The label aggregator aggregates multiple workers' annotations to obtain the true class for each inspected data instance. The data instances, together with their verified/fixed labels are then fed into a *label propagator*, which propagates the labels to similar data instances identified through their latent features (inferred by the deep probabilistic model). The data sampler and label aggregator can be seen as down-sampling and up-sampling methods to reduce crowd annotation efforts and amplify crowd contributions, respectively. Together, they help to scale out human contributions, which is of critical importance in a human-in-the-loop approach where human workers are often the bottleneck in terms of scalability or computational efficiency.

2.2 Components

C1: Deep Probabilistic Model. The deep probabilistic model receives a noisy dataset and simultaneously infers two types of latent variables, i.e., the latent class and the latent features. The latent class represents what the model believes is the true label for the data instance. The latent features, represented as low-dimensional vectors, essentially capture the underlying data structure. They are useful in identifying representative data instances for data sampling and in identifying similar data instances for label propagation. The inference relies on both the existing noisy label and the latent features. The basic idea is that data instances distributed close to each other in the latent feature space are likely to belong to the same class. Consider for example a data instance whose surrounding neighbors are all positively labeled; it is likely to be positive also, even when its existing noisy label is actually negative. In most cases, the surrounding neighbors are partially labeled as positive and partially as negative. The deep probabilistic model is able to

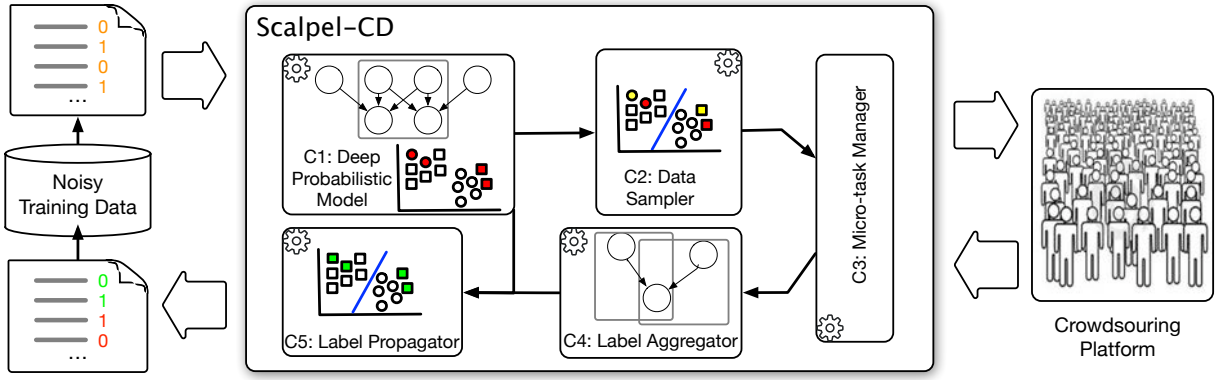

Figure 1: The architecture of `Scalpel-CD`: our system takes as input a noisy training dataset and identifies data instances with potentially wrong labels; it samples from the data representative instances and involves crowd workers to verify and fix wrong labels; the fixed labels are then propagated to similar data instances in order to scale out the contributions of the crowd.

strike a balance between the latent features and the noisy label to obtain a reasonable estimate of the latent class. This component is described in detail in Section 3.1 and 3.2.

C2: Data Sampler. The data sampler is critical in reducing the annotation effort of the crowd workers as it helps to select representative data instances for which the deep probabilistic model's inference is unreliable. The model reliability is approximated by the (inverse) uncertainty of the inference model. The representativeness of a data instance is estimated based on the underlying data structure. Specifically, the data sampler makes use of the latent features inferred by the deep probabilistic model to cluster the data instances. Within each cluster, data instances are supposed to be similar to each other. The data sampler then uses an algorithm to weight the importance of model reliability and data representativeness when selecting data. More details on the sampling algorithm are presented in Section 3.3.

C3: Micro-Task Manager. The micro-task manager is responsible for dynamically creating human computation tasks that are then published on a crowdsourcing platform. It takes as input data instances (together with their original noisy labels) selected by the data sampler, and builds a Web page to be published on the crowdsourcing platform using a templating engine. Once published, the micro-tasks can be selected by workers on the crowdsourcing platform, who are then asked to verify the noisy labels and fix them if deemed incorrect. The results are sent back to the micro-task manager, which in turns inserts them into the label aggregator.

C4: Label Aggregator. Label aggregation is a central problem in crowdsourcing. Given multiple human workers contributing to individual data instances, the label aggregator is designed to infer the true label through a probabilistic latent variable model. A large body of work can be found on this topic, e.g., the classic Dawid-Skene model [8] or the GLAD model [42] (see Section 5). Our work focuses more on addressing the scalability issue of the crowd rather than on quality issues. However, our system supports arbitrary label aggregation methods through a generic interface.

C5: Label Propagator. The label propagator transfers manually examined labels to similar data instances. This is achieved by exploiting the underlying data structure: the noisy labels of data instances identified by the deep probabilistic model are matched to the verified labels of the data instances in a cluster. For data instances with different verified labels in the same cluster, label matching is performed using a nearest neighbor search. Coupled with the data sampler, the label propagator serves as an amplifier for maximizing the utility of the crowd. The label propagator is designed to optimize two criteria: it propagates labels to as many data instances as possible while ensuring that the labels are propagated to the right instances. A detailed introduction to the propagation algorithm is given in Section 3.4.

3 DEEP PROBABILISTIC MODELING AND CROWDSOURCING TRADEOFFS

`Scalpel-CD` orchestrates human and machine intelligence via a set of components described in the previous section. These components intrinsically seek a tradeoff between different key factors of our system. In this section, we characterize the tradeoff space into three parts, relevant to the deep probabilistic model, the data sampler, and the label propagator, respectively; for each part, we introduce an algorithmic solution that simplifies the search for the optimal tradeoff as the search for a single system parameter. Note that the label aggregator is also concerned with a tradeoff: the number of crowd contributors involved and the accuracy of result aggregation. However, this has been extensively studied (see [2, 23]). In the following, we first briefly describe our deep probabilistic model, then introduce the algorithmic solutions to the three components.

3.1 Deep Probabilistic Model

To infer the latent class of a data instance, the basic intuition of our deep probabilistic model is that data instances similar to each other are more likely to belong to the same class. We consider a generative model to fully capture the data distribution of a large training dataset. Given a noisy dataset $\mathcal{D} = \{(\mathbf{x}_i, \hat{y}_i)\}_{i=1}^{N}$, where $\mathbf{x}_i$ is a data instance and $\hat{y}$ is its corresponding noisy label (we will omit the index i whenever it is clear that we are referring to a single data instance), the deep probabilistic model encompasses the generative modeling of both data and labels, described as follows.

- For each data instance $(\mathbf{x}_i, \hat{y}_i) \in \mathcal{D}$,

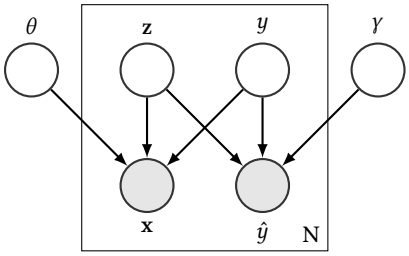

Figure 2: Graphical model of our deep probabilistic model. The data instance $\mathbf{x}$ and the noisy label $\hat{y}$ are both generated from distributions conditioned on the latent feature vector $\mathbf{z}$ and the latent class y. θ and γ are the parameters of the likelihood function for generating the data and noisy labels, respectively (priors of $\mathbf{z}$ and y are omitted).

- Draw a latent feature vector $\mathbf{z}_i \sim P(\mathbf{z})$ where $P(\mathbf{z}) = \mathcal{N}(0, \mathbf{I})$ is a standard Gaussian distribution;
- Draw a latent class $y_i \sim P(y)$ where $P(y) = \text{Cat}(y|\boldsymbol{\pi})$ is a Multinoulli distribution, where $\boldsymbol{\pi} = \{1/K, \ldots, 1/K\}^\top$ (K is the number of classes);
- Draw a data instance $\mathbf{x}_i \sim P_\theta(\mathbf{x}|\mathbf{z}, y)$;
- Draw a noisy label $\hat{y} \sim P_\gamma(\hat{y}|\mathbf{z}, y)$.

Our overall model is depicted in Figure 2. The data instance and the noisy label are both dependent on the latent feature vector $\mathbf{z}$ and the latent class y, which captures the class specification. $\mathbf{z}$ can contain both class and non-class related features. For example, for a sentence $\mathbf{x}$, the latent feature vector $\mathbf{z}$ can represent topics related to a certain class, and additionally, it can capture the author's writing style that are not class-related. The non-class related features, when mistaken as class-related, are likely to lead to wrong labels during the labeling process. $\mathbf{z}$ and y are conditionally dependent given the observed data instance $\mathbf{x}$ and the noisy label $\hat{y}$.

Formally, the deep probabilistic model is expressed by the following factorization:

$$P(\mathbf{x}, \hat{y}, \mathbf{z}, y|\theta, \gamma) = P_\theta(\mathbf{x}|\mathbf{z}, y)P_\gamma(\hat{y}|\mathbf{z}, y)P(\mathbf{z})P(y). \tag{1}$$

The likelihood functions $P_\theta(\mathbf{x}|\mathbf{z}, y)$ and $P_\gamma(\hat{y}|\mathbf{z}, y)$ are parameterized by deep neural networks to accurately capture the distributions of the data and the noisy labels. Depending on the specific form of the data, different likelihood functions are to be used for $P_\theta(\mathbf{x}|\mathbf{z}, y)$: Gaussian likelihood is suitable for image data, while Multinomial likelihood is more suitable for textual data (see [18, 29]). $P_\gamma(\hat{y}|\mathbf{z}, y)$ is represented by a Multinoulli likelihood.

Inference and Learning. The inference for the latent feature vector $\mathbf{z}$ and the latent class y is closely related to the learning of the deep probabilistic model parameters. The parameters are learned by maximizing the log likelihood of the observed data instances and the associated noisy labels:

$$\log P(\mathbf{x}, \hat{y}|\theta, \gamma) = \log \iint P(\mathbf{x}, \hat{y}, \mathbf{z}, y|\theta, \gamma)\, d\mathbf{z}dy. \tag{2}$$

Due to the intractability of the integral, we approximate the true posteriors of $\mathbf{z}$ and y with variational ones, denoted by $Q_\phi(\mathbf{z}|\mathbf{x}, y)$ and $Q_\psi(y|\mathbf{x})$, respectively. We use a Gaussian distribution for $Q_\phi(\mathbf{z}|\mathbf{x}, y)$ and a Multinoulli distribution for $Q_\psi(y|\mathbf{x})$. Given the complex dependencies among the low-level features of data instances and their relationships with the latent variables, these distributions are again parameterized by deep neural networks. The parameters, including those of the generation networks θ and γ and those of the inference networks ψ and ϕ, are then learned by maximizing the evidence lower bound (ELBO) [4] of the objective as follows:

$$\mathbb{E}_{Q_{\phi,\psi}(\mathbf{z},y|\mathbf{x})}[\log P_{\theta,\gamma}(\mathbf{x}, \hat{y}|\mathbf{z}, y)] - D_{KL}[Q_{\phi,\psi}(\mathbf{z}, y|\mathbf{x})\|P(\mathbf{z}, y)], \tag{3}$$

where $\mathbb{E}(\cdot)$ is expectation and $D_{KL}[\cdot\|\cdot]$ is the KL-divergence between two distributions.

3.2 Inferring the Latent Class

From a neural network perspective, the first part of the ELBO (Equation 3) can be interpreted as the sum of the (negative) reconstruction errors of the observed feature $\mathbf{x}$ and noisy label $\hat{y}$, while the second part is the (negative) regularization term preventing overfitting. Hence, we rely both on the data distribution and the existing noisy labels when inferring latent classes.

The original ELBO weights both types of reconstruction errors as equally important. While this can result in a powerful generative model for data and label generation, our goal is different: we are interested in inferring the latent classes, for which the data distribution and the existing noisy labels are likely to be differently important. Furthermore, their importance can vary across different datasets: for datasets whose data distributions are highly indicative of the true class and the noise ratio of the existing labels is high, the data distribution should be more trusted in the inference; otherwise, the existing label should be more trusted.

It is, therefore, natural to extend the ELBO by introducing a parameter β to weight the importance of the two types of reconstruction errors:

$$\begin{aligned}&\mathbb{E}_{Q_{\phi,\psi}(\mathbf{z},y|\mathbf{x})}[\log P_{\theta,\gamma}(\mathbf{x}, \hat{y}|\mathbf{z}, y)] = \\ &\mathbb{E}_{Q_{\phi,\psi}(\mathbf{z},y|\mathbf{x})}[\log P_\gamma(\hat{y}|\mathbf{z}, y)] + \beta \cdot \mathbb{E}_{Q_{\phi,\psi}(\mathbf{z},y|\mathbf{x})}[\log P_\theta(\mathbf{x}|\mathbf{z}, y)].\end{aligned} \tag{4}$$

In case $\beta \neq 1$, we are no longer optimizing the ELBO on the log marginal likelihood (Equation 2). If $\beta < 1$, we would trust more the existing labels than the data distribution; consequently, the model is less able to determine label noise by resorting to the data distribution. Otherwise, if $\beta > 1$, we are weakening our trust on the existing noisy labels while putting more trust on the data distribution in determining label noise. While this allows for more flexibility, it could also bring additional noise to the labels due to the non-class related features in the data distribution. Finding a proper value of β is important to achieve a good performance in inferring latent classes.

The resulting optimization algorithm is given in Algorithm 1. It iteratively goes over two steps, i.e., the forward and the backward step. In each iteration, the forward step (row 5) computes the latent variables given the current parameters; the backward step (row 6-8) then updates the parameters by backpropagating the gradients of the errors. In the calculation of the gradients (row 6), we use an adapted version of the ELBO (Equation 4).

3.3 Data Sampling

The data sampler selects representative data instances for which our deep probabilistic model's inference is most unreliable. The

Algorithm 1: Learning the Deep Probabilistic Model

Input: the set of N i.i.d. data instances $\mathcal{D} = \{\mathbf{x}_i, \hat{y}_i\}_{i=1}^{N}$, ELBO adapter β, and the maximum number of iterations $Iter$

1 Initialize ϕ, ψ, θ, γ;
2 **for** $t = 1; t \leq Iter; t++$ **do**
3 Sample a batch of data instances;
4 **forall** $\mathbf{x}_i \in$ *the batch* **do**
5 Compute y_i and $\mathbf{z}_i$;
6 Compute the noisy gradient $\Delta_{\phi,\psi,\theta,\gamma}\mathcal{L}$;
7 Average noisy gradients from batch;
8 Update ϕ, ψ, θ, γ with gradient descent;
9 **if** *ELBO has converged* **then**
10 break;

Algorithm 2: Data Sampling

Input: Data instances represented by latent features and inferred classes $\mathcal{D} = \{\mathbf{z}_i, P(y_i)\}_{i=1}^{N}$, budget B, #clusters c, validation instances with ground truth labels $\mathcal{V}$

Output: Data instances sampled $\mathcal{S} \subset \mathcal{D}$, clusters $\mathcal{C} = \{C_j\}_{j=1}^{c}$

1 $\mathcal{C} \leftarrow$ Cluster data instances $\mathcal{D}$ based on latent features;
2 $\mathcal{S} \leftarrow \emptyset$;
3 Decide the sampling strategy using $\mathcal{V}$;
4 **foreach** $C_j \in \mathcal{C}$ **do**
5 Rank data instances in C_j according to the sampling strategy;
6 $n_j \leftarrow \left\lfloor \frac{|C_j|}{N} \times B \right\rfloor$;
7 $\mathcal{S}_j \leftarrow$ Pick n_j top-ranking data instances;
8 $\mathcal{S} \leftarrow \mathcal{S} \cup \mathcal{S}_j$;

model reliability is approximated by the inverse of the model's *uncertainty*, measured by Shannon entropy [13, 37]:

$$H[y|x] = -\sum_{C=1}^{K} p(y = C|x) \log p(y = C|x) \tag{5}$$

where C is the class and K is the number of classes. We hypothesize that uncertainty sampling is effective for datasets with random noise: for data instances far away from the true decision boundary, the deep probabilistic model can take advantage of the majority label of data instances and provide correct inference; however for data instances close to the decision boundary, the deep probabilistic model will have a high uncertainty due to the mix of data instances from different classes and will likely result in some wrong inference.

However, for a dataset with structural noise, since there can exist certain regions of the data distribution where the majority of the labels are incorrect, the inference of the deep probabilistic model can be totally off while being highly probable according to the model. Therefore, we also consider random sampling, which is independent of the deep probabilistic model. The effectiveness of the two sampling methods can be evaluated using a set of validation instances with ground truth labels: a better sampling method is the one from which the sampled data instances covers more validation instances where the deep probabilistic model's inference is wrong.

An additional criterion for data sampling is the representativeness of the data instances, which is important for label propagation. We apply a clustering method to the data instances in the latent feature space as uncovered by the deep probabilistic model, i.e., $\mathbf{z}_i$ $(1 \leq i \leq N)$. Data instances falling into the same clusters are supposed to be more similar with each other.

We now describe our data sampling algorithm (see Algorithm 2). It starts by clustering data instances based on their latent features (row 1), then chooses a sampling strategy between uncertainty and random sampling based on the coverage of validation instances for which model inference is wrong (row 3). Then, given a budget B, i.e., the predefined number of data instances to be inspected by the crowd, the data sampler first ranks the data instances in each cluster according to the sampling strategy (row 5). It then selects from each cluster the top-ranking data instances (row 7). The number of data instances selected in each cluster is proportional to the size of the cluster (row 6). Note that for random sampling, selecting data from clusters proportionally is equivalent to stratified random sampling.

A key parameter of the algorithm is the number of clusters, denoted by $c \leq B$. By setting this parameter to different values, the data sampler weights the importance of data representativeness and model reliability differently. Consider the extreme case when $c = 1$, i.e., no data partitioning, the data sampler fully relies on uncertainty or random sampling for selecting data instances; when $c = B$, i.e., a single data instance is selected from each cluster, the data sampler relies more on data representativeness for selecting data instances. Our algorithm is not restricted to any specific clustering methods. The only requirement is the flexibility for users to specify the number of clusters c. As an example, we consider the widely used K-means method for clustering. Comparison of different clustering methods is left for future work.

3.4 Label Propagation

The label propagator amplifies the crowd contributions by propagating corrected labels to similar data instances. The similarity between data instances is calculated as the Euclidean distance between the latent feature vectors of the instances. A key parameter of the label propagating algorithm is the number of data instances to propagate the label to. Given that the size of the clusters are different and that data instances within each cluster are similar, we use a relative number for the parameter to represent the fraction of the data instances for label propagation in each cluster. We denote this parameter as p. A small value of p will affect fewer data instances, thus being less efficient in scaling out human contributions; on the contrary, a big value of p, while being efficient, might increase the noise ratio of the dataset as labels can get wrongly propagated. A proper setting of p is, therefore, of key importance for scaling out human contributions in a reliable way.

Our label propagation algorithm is presented in Algorithm 3. It performs label propagation in each cluster identified by the data sampler. For each inspected data instance in the cluster (row 1-2), the label propagator first ranks the data instances that have not been inspected by crowd workers according to their distance to the inspected instances (row 3-5). It then picks the top ranking instances with shortest distances (row 6). Finally, for each of the selected data instances in the cluster, the label of the nearest inspected data instance is propagated (row 7-8).

Algorithm 3: Label Propagation

Input: Data instances represented by latent features $\mathcal{D} = \{\mathbf{z}_i, \hat{y}_i\}_{i=1}^{N}$, data instances with fixed labels $\mathcal{S} = \{\mathbf{z}_h, y_h\}_{h=1}^{H}$, clusters $C = \{C_j\}_{j=1}^{c}$, propagation fraction p

Output: Fixed labels $\mathcal{D} = \{y_i\}_{i=1}^{N}$

foreach $C_j \in C$ **do**
  foreach $h \in \mathcal{S} \wedge h \in C_j$ **do**
    foreach $i \in C_j \wedge i \notin \mathcal{S}$ **do**
      $d_{i,h} \leftarrow$ distance between $\mathbf{z}_h$ and $\mathbf{z}_i$;
    Rank data instance i ($i \in C_j \wedge i \notin \mathcal{S}$) by $d_{i,h}$;
    $\mathcal{P}_h \leftarrow p \times |C_j|$ top ranking instances with smallest $d_{i,h}$;
  foreach $i \in \bigcup_{h=1}^{H} \mathcal{P}_h$ **do**
    $y_i \leftarrow y_{h^*}$ where $h^* = \arg\min d_{i,h}$ ($i \in \mathcal{P}_h$);

4 EXPERIMENTS AND RESULTS

This section presents experimental results for evaluating the performance of Scalpel-CD. We start by presenting an evaluation of each of its components by answering the following questions:

- **Q1:** How well does the deep probabilistic model perform when inferring the latent class from noisy data?
- **Q2:** How well do the uncertainty and random sampling perform on datasets of different noise types?
- **Q3:** How effective is label propagation (together with data sampling) in scaling out the contributions of crowd workers?

From a human computation perspective, while we mainly consider improving the scalability of the crowdsourcing process, we also investigate the quality of the work performed by the crowd, which we report when addressing Q3. Subsequently, we evaluate the system as a whole by considering the following issue:

- **Q4:** Does our proposed Scalpel-CD system outperform the state-of-the-art methods for debugging noisy labels?

In addition, we also investigate how much Scalpel-CD helps in improving the performance of a machine learning system. In the following, we start by introducing our experimental setup, before answering each of the above questions in a separate subsection.

4.1 Experimental Setup

Datasets. We experiment with three datasets created with different noise types, namely MovieReview (random noise), PoliDying (structural noise), and NYT (structural noise). These datasets are representative for sentiment analysis, event detection, and relation extraction, respectively. The MovieReview dataset [30] is a subjectivity classification dataset of movie reviews from Rotten Tomatoes. This dataset contains ground truth labels for all data instances; we, therefore, simulate wrong labels by randomly selecting a certain fraction (10% to 50%) of the data instances and flipping the ground truth labels. The PoliDying dataset is a tweet relevance classification dataset for detecting politician-dying events. Following previous studies [20, 36], the positive tweets were retrieved with detailed information on 11 seed events, including event name and date, while negative tweets were retrieved with "politician"- and "death"-related keywords. A set of 500 tweets were manually annotated for evaluation. The NYT dataset [33] is a relation extraction dataset for extracting relations from New York Times articles. We focus on the relation "location-contains". The dataset is labeled by distant supervision using Freebase as the labeling source. In this dataset, there are 395 manually annotated data instances.

Table 1: Statistics of the datasets in our experiments.

Dataset	MovieReview	PoliDying	NYT
#Data instances	10,000	17,030	125,267
#Test instances	2,000	500	395

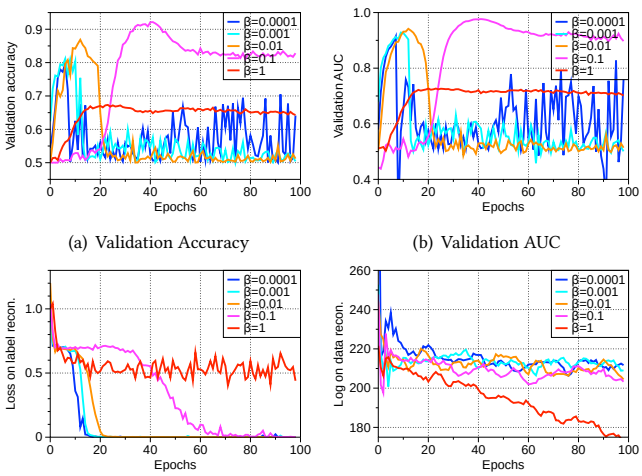
For each of the three datasets, the data sampler selects a number (i.e., the budget B) of data instances for crowdsourcing. We experiment with the budget varying in {50, 100, 200, 500, 1000}. Key statistics from these datasets are presented in Table 1.

Comparison Methods. Due to the lack of existing human-in-the-loop approaches in debugging training data, we compare the following automatic methods and our proposed system. 1) **Ratio** [5]: a ratio-based method that finds the most predictive features and identifies data instances with the most uncertain labels as those containing such features yet labeled differently from the label indicated by the features. The predictive power of a feature is calculated as the ratio between the number of data instances of a certain class containing such a feature and the overall number of data instances. 2) **Pattern** [39]: a generative model designed to capture the labeling process as a generative process from the latent classes. The model facilitates the inference of the posterior of the latent class given the observed features. However, unlike our deep probabilistic model that infers the latent class by exploiting the data distribution in the latent feature space, Pattern is a probabilistic model that directly models the generative process of low-level features. 3) **HierTopic** [1]: a hierarchical topic model that assumes a latent topic-word hierarchy for the data generation process. Unlike our probabilistic model which learns complex hidden data structures, HierTopic is only capable of learning a hierarchical structure. For our proposed system, we compare an automated variant and the full system involving human workers: 4) **DPM**, our proposed deep probabilistic model, which is used in isolation to automatically correct wrong labels. 5) **Scalpel-CD**, our proposed human-in-the-loop system which makes use of both the deep probabilistic model and crowd workers.

To demonstrate the effectiveness of our system on machine learning tasks, we compare the following training data configurations: 1) the original noisy training data; 2) training data denoised by the deep probabilistic model; and 3) training data denoised by Scalpel-CD. We apply and evaluate state-of-the-art machine learning models on these different data configurations: we use Convolutional Neural Network [16] for MovieReview and PoliDying and Piecewise Convolutional Neural Network (PCNN) [48] for NYT.

Parameter Settings and Model Training. We empirically set optimal parameters based on a held-out validation set that contains 10% of the test data. These include the hyperparameters of the deep probabilistic model and the parameters of the trade-off algorithms, i.e., β, c, and p. For the deep probabilistic model, we use a shared embedding layer as the first layer of the inference networks, i.e., Q_ϕ and Q_ψ, to encode the textual features. We apply a grid search in {32, 64, 128, 256, 512} for the dimension of the embeddings and that of the hidden layers, and we explore multi-layer perceptron

networks with 0, 1, and 2 hidden layers for both the generation and inference models, subject to the constraint that P_θ and Q_ϕ have a symmetric architecture (similar to an auto-encoder). We use Adam [17] for model training with mini-batches of 128 data samples for all datasets. The deep probabilistic model is trained for 200 epochs on each dataset and the one with the best performance on the validation set is kept for evaluation.



Evaluation Protocols. We separately evaluate the performance of `Scalpel-CD` on debugging noisy labels and its effect on the final machine learning tasks using different protocols. For the former task, we take the entire dataset as input. This includes the data instances in the test set together with their noisy labels. The system debugs labels in the whole dataset. The denoised labels of data instances in the test set are then compared against the ground truth. For the final machine learning tasks, our system debugs labels in the training set only. A state-of-the-art deep learning model is then trained on the denoised training set and evaluated on the test set. Two metrics are used to measure the performance of our proposed system in debugging noisy labels and its effect on the final machine learning tasks: accuracy and Area Under the ROC Curve (AUC). Higher accuracy and AUC values indicate better performance.

4.2 Inferring the Latent Class (Q1)

To understand the effectiveness of our deep probabilistic model in inferring the latent class, we analyze the relationship between capturing the data distribution and inferring the latent class. The analysis is carried out by comparing the performance of the deep probabilistic model with different settings of β, which controls the importance of the reconstruction errors of data instances and the noisy labels in the objective function. We analyze the dynamics of our deep probabilistic model on the validation set during the training process, with β selected from $\{0.0001, 0.001, 0.01, 0.1, 1\}$. Results on the MovieReview dataset with a noise ratio $NR = 20\%$ are shown in Figure 3. We discuss below the influence of different datasets and noise ratios on the performance of the model.

From Figures 3(a-b), we observe a general pattern across different settings of β: when the training proceeds, the performance of the deep probabilistic model first increases then decreases. The difference between the performance across β settings indicates that the optimal performance is hit at different performance levels and epochs during the training process: from $\beta = 0.0001$ to 0.1, the optimal performance grows and is reached later in the training process for larger values of β; then from $\beta = 0.1$ to 1, the optimal performance decreases and is reached earlier. Given such results, we speculate that $\beta = 0.1$ best infers the latent classes as it strikes a balance between minimizing the reconstruction errors of the data and the noisy labels. In addition, we further hypothesize that there is a consistent relationship between the level of optimal performance and the time at which it is reached in the training process.

These hypotheses are confirmed by Figures 3(c-d). For small values of β ($0.0001-0.01$), the deep probabilistic model quickly reaches the minimum reconstruction error of noisy labels. As a result, the inferred latent classes are biased towards existing noisy labels, which is evidenced by the optimal accuracy of $\beta = \{0.0001, 0.001\}$ being only slightly higher than 0.8 (Figure 3(a); the performance of $\beta = 0.01$ is slightly higher yet still not optimal). For $\beta = 1$, the

(a) Validation Accuracy (b) Validation AUC

(c) Loss on Label Reconstruction (d) Loss on Data Reconstruction

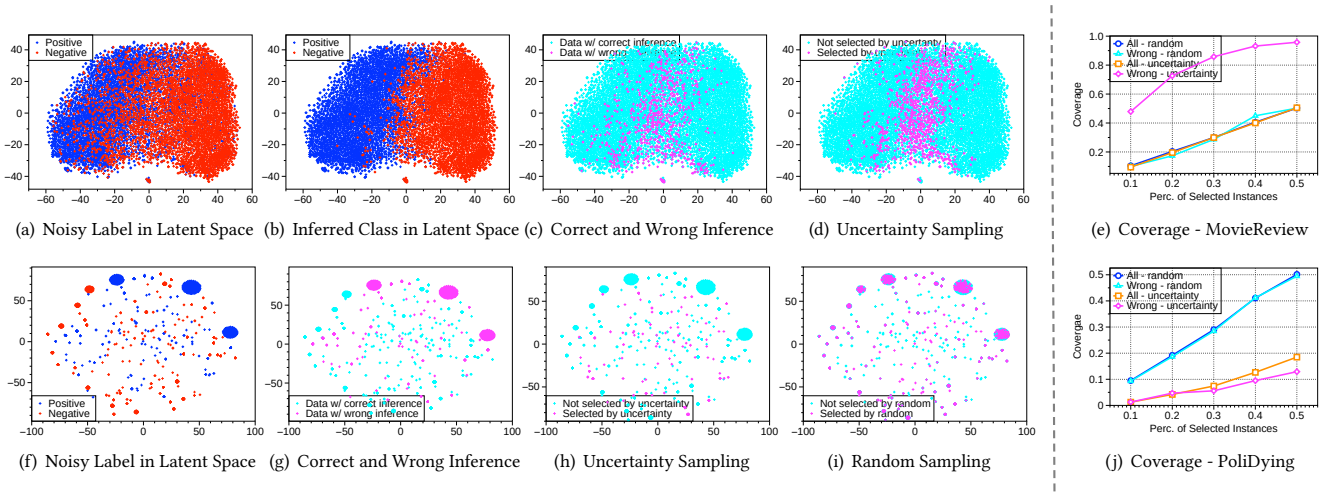


Figure 3: Comparison of performance against loss in data and label reconstruction with different settings of β on the MovieReview dataset. Upper figures are the dynamics of accuracy (a) and AUC (b) on the validation set during the training process; lower figures are the reconstruction loss (negative log-likelihood) of noisy labels (c) and data instances (d).

reconstruction error of the data is significantly reduced (more than for other settings, see Figure 3(d)); the reconstruction error of noisy labels is however not reduced as much as in the other settings (Figure 3(c)). The inferred latent classes therefore cannot benefit from those existing correct labels. To infer the latent class in an unbiased manner, sufficient model training has to be performed to reduce both types of reconstruction errors. This implies that the optimal setting of β is most likely the one that takes most of the time to reach the optimal performance during the training process.

Impact of Datasets and Noise Ratios. We observe similar results with the other datasets. The optimal settings of β are 1 and 0.01 for PoliDying and NYT, respectively. The variation across datasets implies different utility of the data distribution in inferring the latent class, which highlights the importance of searching for the optimal β separately for different datasets. Actual performance using these β values will be reported in Section 4.5. We note that our model is robust with respect to different noise ratios. It achieves accuracy scores > 0.9 even when the noise ratio of MovieReview goes up to 40%. Compared with noise ratios, model performance is more affected by the predictive power of the data distribution. We remark, however, that the model can always benefit from the data distribution and achieve better performance than $1 - NR$.

4.3 Uncertainty and Random Sampling (Q2)

The data sampling component of `Scalpel-CD` allows for two sampling strategies, i.e., uncertainty sampling and random sampling, which are model-dependent and model-independent, respectively. We therefore hypothesize that random sampling is more effective than uncertainty sampling for datasets with structural noise. To verify our hypothesis, we conduct a comparative analysis between the MovieReviews dataset and the PoliDying and NYT datasets,

(a) Noisy Label in Latent Space (b) Inferred Class in Latent Space (c) Correct and Wrong Inference (d) Uncertainty Sampling (e) Coverage - MovieReview

(f) Noisy Label in Latent Space (g) Correct and Wrong Inference (h) Uncertainty Sampling (i) Random Sampling (j) Coverage - PoliDying

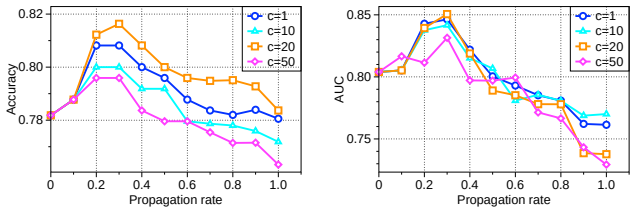

Figure 4: Effects of uncertainty and random sampling on the MovieReview dataset (upper figures) and the PoliDying dataset (lower figures). From left to right, upper figures are the visualization of the noisy label (a) and the inferred latent class (b) in the two dimensional latent feature space; visualization of the data instances with correct and wrong inference of the latent class (c) and those selected (top-10%) and not selected by uncertainty sampling (d). Lower figures are the visualization of the noisy labels (f) and the data instances with correct and incorrect inference of the latent class (g) in the latent feature space; visualization of the (top-)10% selected and not selected data instances by uncertainty sampling (h) and random sampling (i). Figures on the right part are the coverage of the uncertainty sampling and random sampling on the entire validation set and the subset where the inference is wrong for the MovieReview dataset (e) and the PoliDying dataset (j).

as the two types of noisy datasets. The comparison is carried out by 1) visually locating in the latent feature space the selected data instances using the two sampling strategies and the data instances where the inference of the latent classes is wrong, and 2) statistically comparing the coverage of the selected data instances on data instances where the inference is wrong. (For rigorousness, we use the validation set for comparison, however similar results are observed in the test set.)

We start by investigating the effectiveness of uncertainty sampling on the MovieReview dataset. We apply t-SNE [26] to embed the latent features of the data instances into a two-dimensional space, and then visualize the noisy label and the inferred latent class in Figures 4(a-b). Given our previous results (high performance of our deep probabilistic model in latent class inference in Figures 3(a-b)), we observe from Figures 4(a-b) that the inferred latent features are highly indicative of the latent class: data instances of different classes are located separately in the latent feature space. Figure 4(c) then shows the data instances for which the inference is correct and wrong in two colors, respectively. We observe that our model can effectively recover the true classes of data instances located far away from the model's decision boundary. In contrast, the majority of the data instances with wrong class inference are located close to the decision boundary. This is due to the fact that at the decision boundary, data instances of different classes are mixed with each other, leading to high model uncertainty. This is confirmed by Figure 4(d), which visualizes the top-10% data instances selected by uncertainty sampling. Comparing Figures 4(c) and 4(d), we observe that uncertainty sampling is a highly effective method in selecting data instances when the model inference is wrong.

For comparison, we show the effect of uncertainty sampling and random sampling on the PoliDying dataset created with structural noise. Figure 4(f) visualizes the noisy labels in the latent feature space and 4(g) shows the data instances with correct and wrong inference in two colors. We can observe that the deep probabilistic model can be totally wrong in its inference for a set of data instances close with each other (i.e., those about the same topic), e.g., the red clusters in Figure 4(g). Comparing such a result to Figure 4(f), we observe that the noisy labels for these data instances are almost all incorrect. These highly consensual yet wrong labels not only make the inference wrong, but also lead to high model confidence (i.e., low uncertainty). This is validated by Figure 4(h), which shows that uncertainty sampling can hardly identify data instances with structural errors. In contrast, Figure 4(i) shows a similar number of data instances (both 10%) selected by random sampling, which is able to cover data instances with wrong inference scattered at different regions of the latent feature space.

Impact of Noise Types. To quantitatively compare uncertainty and random sampling, Figures 4(e,j) show for both datasets the coverage of the selected data instances (from 10% to 50%) on the entire validation set and the subset where the model inference is wrong. On one hand, we observe that for MovieReview, uncertainty sampling is highly capable of selecting those data instances with wrong inference (80% covered by 20% selected instances). On the other hand, random sampling performs much better for PoliDying. These results highlight the distinct capabilities of uncertainty sampling at tackling random noise and of random sampling at tackling structural noise. Finally, we note that for the NYT dataset the two sampling strategies perform comparably well. This is likely due to the variety of the entity pairs (tens of thousands) in the external database used for labeling, which comes in contrast to the PoliDying dataset that uses a limited number of seed events and keywords as labeling sources.

(a) Expert - Accuracy (b) Expert - AUC

(c) Crowd - Accuracy (d) Crowd - AUC

Figure 5: Effect of label propagation with different settings of the propagation rate and the number of clusters on the PolyDying dataset. Upper figures are the results with expert-contributed labels measured by accuracy (a) and AUC (b); lower figures are the results with crowd-contributed labels measured by accuracy (c) and AUC (d).

4.4 Scaling out Human Contributions (Q3)

We now investigate the effectiveness of data sampling and label propagation for scaling out human contributions. The relevant system parameters are the number of clusters c, which controls the importance of the representativeness of data instances in data sampling, and the fraction of data instances p in each cluster to be considered for label propagation. We analyze the impact of different settings of p from 0 to 1 with a step of 0.1, and c selected from {1, 10, 20, 50}. Furthermore, we conduct a comparative study between labels verified by experts and crowd workers to understand the impact of imperfect human work. We report results on the PoliDying dataset with a budget $B = 500$. Similar results are observed on the NYT dataset; results for the MovieReview dataset and the impact of different budgets will be analyzed below.

Figures 5(a-b) show the results of expert verified labels. When p increases from 0 to 1, we observe inverse U-shaped curves across all different settings of c and the two metrics: the performance first increases then decreases, with optimal performance reached at $p = 0.3$. This indicates that label propagation does help in correcting more data instances not inspected by experts. The performance decreases from $p = 0.3$ to 1 since the propagation accuracy decreases when labels are propagated to data instances semantically different from the manually verified ones. Comparing the different settings of c, we observe that label propagation reaches its best performance at $c = 20$, which significantly outperforms other settings. This confirms the importance of finding an optimal setting for c to make the best partitioning of the data and the optimal tradeoff between the different criteria for data sampling.

For our crowdsourcing experiment, we solicit from the crowd three labels for each data instance. Results show that crowd labels match expert labels on 84.73% data instances. With such an accuracy, we do not observe consistent patterns of performance variation in label propagation. A simple filtering of data instances where all three crowd workers agree results in 81.50% remaining data instances, whose labels match expert labels 90.20% of the time. Figures 5(c-d) show the label propagation results on the filtered labels. We observe similar patterns with expert labels (Figures 5 (a-b)). Overall, label propagation enhances system performance by 3.5% (accuracy) and 4.6% (AUC) for expert labels and by 2.1% (accuracy) and 3.8% (AUC) for crowd labels.

Impact of Budgets and Datasets. We observe similar results for budget $B = 1000$ on both the PoliDying and NYT datasets. However, for $B <= 200$ no explicit patterns are observed. This is likely due to the under-representativenes of the inspected data instances. For MovieReview, crowd contributions improve the resulting accuracy from 0.925 to 0.956 and the AUC from 0.977 to 0.987. However, the performance gets worse for $p >= 0.1$. This is mainly due to the effectiveness of the deep probabilistic model in making use of data distributions to correct erroneous labels in a dataset with random noise (see Figures 3(a-b) and Section 4.5), which makes it difficult to further improve label quality through label propagation.

4.5 Performance on Debugging Labels (Q4)

We now compare the performance of our proposed system to state-of-the-art methods for debugging noisy labels. Table 2 ("Debugging") reports their performance on our three datasets. From these results, we make the following observations.

Ratio works well on the MovieReview dataset, however fails on PoliDying and NYT (compared to the original labels). Pattern, as a probabilistic method, is more robust: it improves label quality for both MovieReview and PoliDying. Yet, it still fails on the NYT dataset. Recall that both methods use the low-level features (i.e., words) for label inference. These results indicate that probabilistic methods that capture data distributions based on low-level features do not necessarily work for debugging noisy labels. In contrast, HierTopic, which models a hierarchical structure from the data using a probabilistic framework, consistently improves the label quality across all datasets. These results confirm the importance of considering data structures in debugging noisy labels.

Our proposed deep probabilistic model outperforms all the other methods by a large margin: it yields an average improvement of 7.0% in accuracy and 3.9% in AUC compared to HierTopic; compared with the original noisy labels, it improves the label quality by 9.1% in accuracy and 11.8% in AUC. These results clearly indicate the effectiveness of our model in debugging noisy labels. In particular, the improvements over HierTopic shows that deep neural networks are effective in learning the underlying data structure. Furthermore, the effectiveness of the model on PolyDying and NYT indicates that, overall, the model works well for datasets with structural noise, even if the inference can be unreliable for data instances distributed in certain regions of the latent feature space (Section 4.3).

`Scalpel-CD` achieves the best performance across all datasets. It outperforms the deep probabilistic model by 3.8% in accuracy and 3.9% in AUC on average. This highlights the value of human input in the process. Compared to the original noisy labels, our system improves label quality by 12.9% in accuracy and 15.8% in AUC, with only 2.8% data instances manually inspected by the crowd.

Table 2: Performance of the compared methods on two settings: debugging noisy labels and machine learning. Results on the MovieReview dataset are reported for $NR = 20\%$. Results of our proposed systems are obtained with a budget $B = 500$. The best performance for each dataset in each setting is boldfaced; the runner up is labelled with "*".

	Methods	MovieReview		PoliDying		NYT	
		Acc.	AUC	Acc.	AUC	Acc.	AUC
Debugging	Original labels	0.800	0.800	0.625	0.633	0.701	0.722
	Ratio	0.891	0.949	0.615	0.616	0.605	0.664
	Pattern	0.849	0.897	0.669	0.672	0.631	0.646
	HierTopic	0.852	0.929	0.629	0.693	0.706	0.770
	DPM	0.925*	0.977*	0.742*	0.742*	0.731*	0.791*
	Scalpel-CD	**0.956**	**0.987**	**0.812**	**0.831**	**0.745**	**0.810**
Learning	SOTA	0.798	0.902	0.608	0.670	0.665	0.733
	W/ DPM	0.845*	0.913*	0.746*	0.793*	0.690*	0.754*
	W/ Scalpel-CD	**0.883**	**0.949**	**0.828**	**0.896**	**0.719**	**0.765**

Impact on Learning Tasks. The benefits of using our system on machine learning tasks is shown in Table 2 ("Learning"). The performance of state-of-the-art learning methods improves significantly when using our deep probabilistic model or our system as a whole. On average, machine learning performance is improved by 12.0% in accuracy and 10.2% in AUC using Scalpel-CD. These results clearly highlight the benefits of debugging noisy labels and the effectiveness of Scalpel-CD on machine learning tasks.

5 RELATED WORK

This section gives an overview of relevant work from the emerging field of human-in-the-loop paradigm for artificial intelligence (HITL-AI) and from label noise reduction for training data.

HITL-AI. Human computation and machine learning are increasingly interweaving with each other [41]. The main intersection is crowdsourced training data creation, e.g., the ImageNet dataset for computer vision [10] and many crowd annotated datasets for various natural language processing tasks [14, 28]. A closely related line of work in the machine learning community is "learning from crowds", where researchers study models that can learn from noisy labels contributed by crowds [32, 40, 46, 47]. Unlike the conventional learning setting, models developed in this context are concerned with learning parameters of the annotation process (e.g., annotator expertise [32] and task difficulty [46]) and inferring true labels from noisy ones. Such an idea has been extended to incorporate (deep) active learning to reduce annotation efforts [12, 40, 45, 47].

In contrast to creating high-quality training data from scratch, e.g., through active learning from the crowd, fast creation of training data with noise tolerance is becoming more popular [2, 31]. Existing work on debugging machine learning systems mainly focuses on identifying the weakest component. Much fewer approaches have considered debugging training data, which is a key bottleneck for improving machine learning systems [6]. Existing work is mainly developed within the topic of interpretability and transparency of machine learning models [34]. These work mainly uses perturbation based approaches to identify data instances that are likely to cause incorrect predictions [7, 19, 24]. Unlike these work that requires incorrect predictions to be observed, our deep probabilistic method is a self-discovering method as the identification of erroneous labels only relies on data distributions; more importantly, our system involves humans for reliable label correction.

Label Noise Reduction. Existing methods have been developed separately for distant supervision and crowdsourcing. Methods in the former context mainly leverage data distributions in the low-level feature space, e.g., the factor graph model by Riedel et al. [35] and the generative model by Takamastu et al. [39]. Alfonseca et al. [1] introduce a hierarchical model to capture the data distribution in the topic space. In comparison, our deep generative model is flexible to capture data distributions with more complex data structures. In crowdsourcing, label noise reduction has been a central problem as worker annotations are often noisy. Typical methods assume a redundancy of worker annotations [22, 38], e.g., majority voting and those based on Expectation Maximization (EM) [8]. EM methods simultaneously estimate the true labels and parameters of the annotation process, e.g., worker reliability by Dawid and Skene [8] and task difficulty by Whitehill et al. [42]. These methods are, however, not applicable to most machine learning scenarios where each data instance is labeled only once. Our work is different in that we consider the broader scope of noisy training data, where labels are not necessarily redundant.

Finally, our work is also related to the broader domain of data cleaning, mainly studied by the database community [21, 43, 44]. Yakout et al. [44] study an approach to automatically generate data cleaning rules for relational databases. Krishnan et al. [21] specifically focus on cleaning training sets for convex statistical models (e.g., SVM, Logistic Regression). They introduce an SGD-like method that leverages expected model improvement to identify the most beneficial data instances to be cleaned. The method, however, does not apply to deep learning models. Most importantly, all existing work does not explicitly consider the human's role in data cleaning and does not address the potential issues of human involvement (e.g., scalability and work quality).

6 CONCLUSION

We presented Scalpel-CD, a new human-in-the-loop system that exploits the complementary strength of humans and machines for debugging noisy training data. Scalpel-CD leverages deep probabilistic modeling to identify data instances with potentially wrong labels and infer their latent classes, and engages humans to inspect specific data instances for which the model inference is of low reliability. Scalpel-CD is a generic system applicable to any type of training data and can be easily optimized for specific datasets. Our extensive evaluation on multiple machine learning datasets with different noise types demonstrates that Scalpel-CD significantly improves label quality and machine learning performance with minimum human involvement. As future work, we plan to study how to best involve humans to increase the explainability of the models and to reduce potential biases in automated decisions.

ABSTRACT

People's content choices are ideally driven by their intentions, aspirations, and plans. However, in reality, choices may be modulated by recommendation systems which are typically trained to promote popular items and to reinforce users' historical behavior. As a result, the utility and user experience of content consumption can be affected implicitly and undesirably. To study this problem, we conducted a 2×2 randomized controlled field experiment (105 urban college students) to compare the effects of intention informed recommendations with classical intention agnostic systems. The study was conducted in the context of spoken word web content (podcasts) which is often consumed through subscription sites or apps. We modified a commercial podcast app to include (1) a recommender that takes into account users' stated intentions at onboarding, and (2) a Collaborative Filtering (CF) recommender during daily use. Our study suggests that: (1) intention-aware recommendations can significantly raise users' interactions (subscriptions and listening) with channels and episodes related to intended topics by over 24%, even if such a recommender is only used during onboarding, and (2) the CF-based recommender doubles users' explorations on episodes from not-subscribed channels and improves satisfaction for users onboarded with the intention-aware recommender.

1 INTRODUCTION

People make choices about what content to consume on a day-to-day basis, such as selecting music or podcasts to listen to and identifying articles to read. Ideally, users make choices according to their intentions, plans, and aspirational preferences [31]. For example, a person may use a search engine to find an article or a piece of music with a specific title. However, choosing content on real world platforms is more complex, in part because users' choices are often sub-optimal and focus on the short-term [32], and these immediate choices then get reinforced by recommendation systems that expose users to biased sets of items. The bias of item presentations mainly comes from two sources: (1) recommenders often hold a partial and skewed view of users' preferences that are learned from observational interaction records [40, 51], and (2) recommenders are typically subject to popularity bias [51], which hinders the system from presenting relevant items. When subject to regular exposure to these biased item sets, users' original intention-related choices may be altered — on the one hand, users may explore more content, on the other hand, they may end up consuming trendy but mediocre or irrelevant content with low utility to them.

Prior recommendation systems literature was focused on *how many* [21, 41] and *what* [16, 46] items people choose but rarely addressed *why* people choose them. For example, are the choices a result of people's original intentions or their interactions with recommendation systems? In other words, how recommendations may change users' consumption from what they might have chosen, or aspire to choose? These under-explored questions are critical for recommender systems to listen to users and support users' needs, intentions, and desires [14, 26].

In this paper, we investigate the above mentioned questions, specifically, *how intention informed recommendations modulate users' choices, as compared to intention agnostic systems?* To answer this question, we designed a randomized controlled field study [27] in the domain of podcasts, where we leveraged the **topics of interest** as an indicator of user intentions. The field study is a 2×2 experiment where two factors are two stages of app usage, and two interventions within each factor are different recommendation algorithms. First, during onboarding, users expressed their topics of interest and subscribed to a set of podcast channels through a

website, where we compared a popularity-based recommender to a recommender that takes into account users' intentions (**intention-aware recommender**) in presenting channel candidates. Then, during the remainder of their participation (app usage in the field), users used a customized commercial mobile app without constraint. During this stage of the study, we compared a subscription-based recommender to a Collaborative Filtering (CF)-based recommender in populating the home feed that users interacted with everyday. Finally, participants were invited to complete a post-study survey where they gave ratings in terms of four aspects of satisfaction.

We choose podcasts as the study domain for two main reasons. First, traditional podcast content consumption is typically based on subscriptions and therefore clearly relates to user intentions — users subscribe to RSS feeds of the channels they plan to listen to and then regularly consume released episodes from those channels. Second, recommendation systems for podcasts is of growing importance but currently under-explored (Section 2.4).

We conducted the study with 105 urban college students, which consists of 52.5 hours of one-by-one onboarding, four weeks of field experiments with daily communications and weekly reminders, and a follow-up survey with each participant. Our key findings include:

- **Effects of onboarding recommendations:** Compared to commonly used popularity-based ranking of channels, intention-aware recommendations for user onboarding significantly raised the ratio of channel subscription and episode listening that were aligned with users' topic-wise aspirations (improvements: 72.1% and 36.5% in terms of subscriptions at onboarding and in the field, and 24.9% in terms of listening time).
- **Effects of field recommendations:** Home feeds that were populated by the CF-based recommendations significantly increased the ratio of episode listening to not-subscribed channels by 127.5%, as compared to the traditional home feeds that were filled purely with episodes from subscribed channels.
- **Interaction effects:** User satisfaction was jointly affected by the recommendation algorithms used in the two stages — the CF-based recommender improved satisfaction for users onboarded with the intention-aware recommender, whereas for others, the CF-based recommender was shown to have negative effects.

These findings suggest that recommendations can implicitly but significantly modulate users' intention-related choices — they can encourage or discourage users to pursue their aspirations and intentions. The positive modulation effects can be leveraged to support healthy behavior and benefit an individual's aspired long-term growth, as discussed in Section 5. Also, our study suggests a hybrid form of recommender for podcasts and subscription-based media, consisting of an intention-aware recommender for onboarding and a CF-based recommender for home feed generation. Together, these recommenders support user aspirations, encourage content exploration, and provide satisfying user experiences.

Through our study, we also find that signals regarding the utility of user engagement is not reflected in intention-agnostic statistics (e.g., total listening time and total number of subscriptions) that are commonly employed to understand user experiences (Section 4.1). This highlights the importance of using metrics conditioned on individual intentions to complement the understanding of recommendation effects (Section 5.5).

2 RELATED WORK

Our work builds on and contributes to four lines of research: (1) studying the effects of recommendations, (2) investigating user intentions in using intelligent systems, (3) building recommendation systems beyond optimizing for accuracy, and (4) analyzing and leveraging spoken word content on the web.

2.1 Effects of recommendations

Recommendation systems were shown to increase traffic and user engagement [41], but it was recently recognized in the research community that they can also significantly affect end users' behavior and the structure of a society. Prior work in studying the effects of recommendations mainly focused on the social network structures [11, 42, 43] and the filtering bubble problem [3, 7, 16, 20, 34, 36]. For example, the former line of research demonstrated that introducing friend-based recommendations into social network platforms exacerbates popularity bias (i.e., rich gets richer) [43] and establishes an algorithmic ceiling for minority groups of users [42]. The latter line of research illustrated how recommendations affect users' information exposure by either limiting users' information exposure to a biased scope [16, 36] or enabling users to explore ideologically diverse opinions [3, 16]. As a result, consumers and users may be fragmented [20]. Most recently, Chaney et al. [8] used a simulation to show that recommendations may lead to a homogenization of users' choices. For contextual-aware recommendations, prior work has raised the concern about their potential alternation of users' content consumption context [1].

Although prior research has revealed significant effects of recommendations in the global and individual levels, these effects are user intention-agnostic and are measured and interpreted from system designers' and experts' perspectives. It is unknown whether recommendations' effects are aligned with or deviated from users' own intentions. Our study measures effects from users' angle and contributes findings that are critical to the future user-centric recommendation systems [14, 21, 26].

2.2 User intentions

Understanding and leveraging user intentions is an important theme in designing intelligent systems. For example, in the context of web search, previous research [12, 29, 39, 44, 48] discovered diverse user intents in using search engines [44], e.g., for the same query, users may look for different information. The understanding and prediction of users' intents is an essential component for personalized search experience [12, 44, 48]. In other domains, such as arts and fashion [10], and psychology [15, 38], user intentions were also investigated and were shown to be predictable from behavior logs [10]. In the context of recommendation systems, prior work leveraged interactive systems to elicit signals about user intentions, such as conversation-based [25], survey-based [52], and critique-based [9] systems. Recently, Tomkins et al. [46] presented a system that recommends appropriate products for users who intend to maintain a sustainable behavior.

However, when incorporating users' intentions, the intelligent systems were often evaluated against intention-agnostic metrics, such as click-through rate, dwelling time, and etc., which do not answer the questions of how these systems alter users' choices from

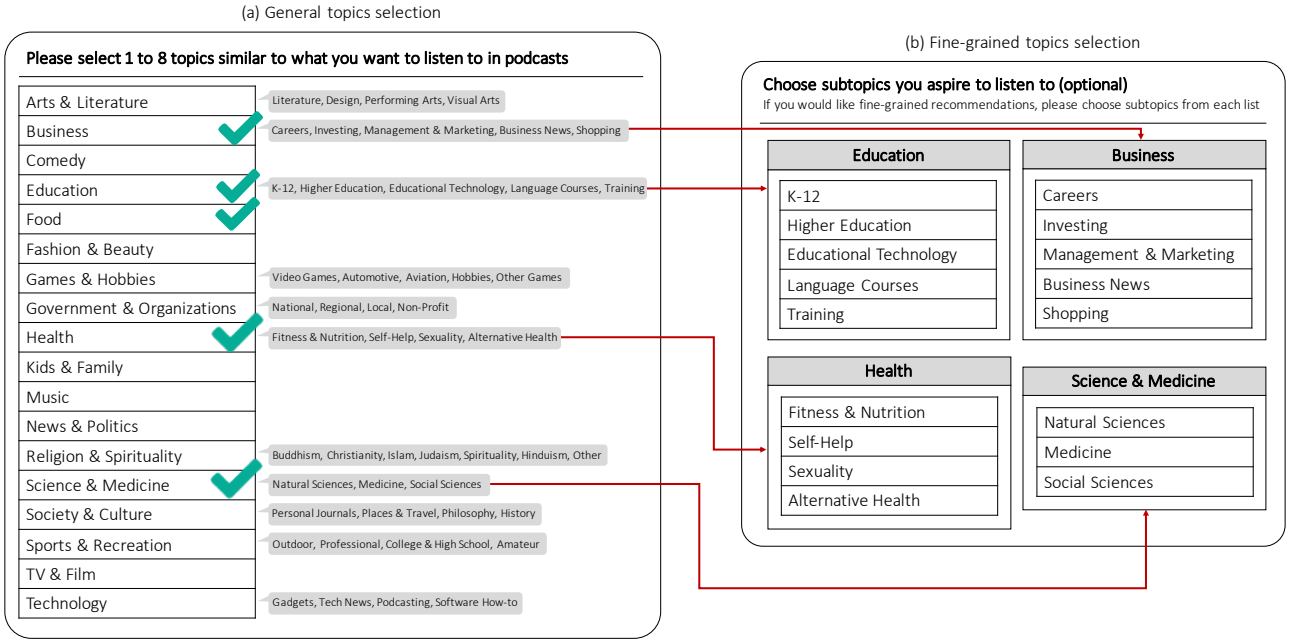

Figure 1: The web user interface designed for participants to indicate their topic-wise intentions. Participants first (a) select up to eight general topics they want to listen to and then (b) optionally select fine-grained topics. The topics are defined using podcast categories in iTunes.

what they might have chosen, and how much of users' intentions were satisfied. As argued by Knijnenburg et al. [26] and Ekstrand et al. [14], future recommenders should be able to satisfy *what users want* and *what they want to achieve*. Our research takes a step further and investigates how intention informed recommenders would in turn affect users' intention-related choices, which closes the feedback loop between choices and recommendation systems.

2.3 Recommendations beyond accuracy

Our work contributes to the increasing recognition and interests in building recommender systems for objectives beyond accuracy [14, 26, 50], such as diversity [21, 53], fairness [13], novelty [45], sustainability [46], and unbiasedness [40, 51]. These objectives were motivated by the observation that recommender systems purely optimized for accuracy may have various negative effects on end users, as reviewed in Section 2.1. These enable recommendations to serve users with different needs and intents. Nevertheless, similar to the limitations discussed in Section 2.2, prior work optimized these systems using hand-crafted or expert-designed metrics (such as categorical accuracy [13]), which may or may not be aligned with users' intentions and goals. Our study reveals the extent to which users' choices are related to their intentions, which can be used to inform future design of recommenders beyond accuracy.

2.4 Web spoken word content

We conducted the field study in the domain of spoken word content (podcasts) — an emerged channel for information and entertainment [37]. In the web community, prior research was mainly focused on building web search engines [5, 17, 19, 33, 35], which index podcast metadata and audio files so as to match given text queries to audio. However, there has been very little work addressing the podcast recommendation problem. The only work we recognized was from Tsagkias et al. [47] that predicted users' podcast preference using hand-crafted preference indicators, which can hardly be applied in the wild because of the heterogeneity of users and content. With the interests from major media companies to serve podcasts, research is needed to build recommenders that better expose users to content beyond passive receiving. Our study contributes a hybrid form of podcast recommender that serves users' intentions, encourages exploration and results in higher user satisfaction. Our paper also presents key guidelines for the design of podcast recommenders, which can be applied to other subscription-based media platforms as well.

3 STUDY DESIGN

Our study design included collecting consumption intentions from all participants and randomly assigning participants to four independent experimental conditions. This design allowed us to conduct within-subject comparisons to understand the discrepancy between users' content consumption and intentions, and between-subject comparisons to measure the effects of different recommendations. Specifically, our study consisted of two phases: an **one-by-one video onboarding** (30 minutes) and a **field study** (four weeks), corresponding to the prominent settings under which podcast listeners are exposed to recommendations in the wild (i.e., when they first begin to use an application, and during the daily usage). Our design for both phases of the study allowed participants to

interact with recommendations naturally. During onboarding, participants were instructed to subscribe to a set of podcast channels they wanted to listen to from a ranked list of candidates; and in the field, participants were provided with a customized commercial podcast mobile app (available on both Android and IOS) to listen to podcasts naturally and without study constraints. The experiment used a full 2×2 factorial design where the two factors were recommendations made in the two study stages, i.e., onboarding (**ONB**) and field (**FIE**) recommendations, and the two interventions within each factor were specific algorithms that presented channels or episodes in different orders. Below, we describe detailed design of each phase.

3.1 Onboarding (ONB)

We onboarded participants one-by-one using remote video conferencing software. Participants were instructed to complete two tasks during onboarding: (1) indicate their topic-wise intentions and interests, and (2) subscribe to channels that they want to listen to in the field. Participants were directed to use a website we developed to complete both tasks.

Indicating topic-wise intentions. We collected participants' listening aspirations in the form of podcast topics (Fig. 1). This topic selection approach is a common practice adopted by major content platforms (e.g., Pinterest and Medium) to elicit user preferences during onboarding. We used podcast categories defined by iTunes[1] as topics, which consists of two levels: general and fine-grained. Through the website, participants first picked 1-8 general topics (Fig. 1-a), and then optionally chose fine-grained topics within the selected general ones (Fig. 1-b). To help participants make sense of general topics, fine-grained topics were shown side-by-side.

Subscribing to channels. Each participant was then asked to subscribe to up to ten podcast channels from a list of recommendations (Fig. 2). The recommendation list was subject to the control or experimental setting, according to the participants' assignments in the study. The control intervention implemented a standard user onboarding strategy that ordered channels based on their popularity on iTunes (**POP**) (Fig. 2-a), whereas the experimental intervention ranked channels by the degree to which they related to participants' aspirations[2] (**ASP**) (Fig. 2-b). The relevance of a channel c for a user u is characterized by a score $s(c|u)$ calculated as follows.

$$s(c|u) = |\mathcal{S}_c \cap \mathcal{A}_u| + \mathbb{1}\left[m_c \in \mathcal{A}_u\right] \tag{1}$$

where $\mathcal{S}_c$ is the set of topics (general and fine-grained) that the channel c belongs to, m_c is the channel's primary topic ($m_c \in \mathcal{S}_c$), and $\mathcal{A}_u$ is the set of topics that users aspired to listen to. Both $\mathcal{S}_c$ and m_c were scraped via iTunes RSS API. As shown in the above equation, when calculating $s(c|u)$, we placed an additional weight on the primary topic.

For both groups, participants were instructed to browse the website freely and make decisions at any point of time. To prepare channels for recommendations, we scraped all top channels returned by the iTunes RSS feed, and made a join with our podcast database. Eventually, 2231 channels were used.

[1]Podcast directory: https://itunes.apple.com/us/genre/podcasts/id26?mt=2
[2]To break ties, channel popularity on iTunes was used.

3.2 Field Study (FIE)

After onboarding, each participant was provided with a podcast mobile app and a pre-registered account to use for four weeks in the field. The app was pre-loaded with the channels for which the participant subscribed during onboarding. We customized a popular commercial app for our study. The app (shown in Fig. 3 and Fig. 4) has three main pages: (1) a **home** page (Fig. 3-b,c) that presented a personalized list of new podcast episodes, and is the default page when opening the app, (2) a **library** page (Fig. 3-a) that showed the channels to which a user has subscribed, and (3) a **discover** page (Fig. 4) that listed channels based on categories and popularity, which were not personalized. In addition, the app allowed users to directly search for content (through the icon at the top-right corner), and users can also consume episodes from a channel's page (by clicking on the channel's thumbnail).

Similar to onboarding, the field intervention was applied to recommendations on the mobile home page, which chronologically listed episodes from a personalized set of channels and was refreshed daily for newly-released episodes. For the control group, the personalized set contained channels to which a user has subscribed (**SUB**); whereas for the experimental intervention, the set additionally mixed five not-subscribed channels (**MIX**). These channels were retrieved by a matrix factorization based recommendation model, which we built as follows:

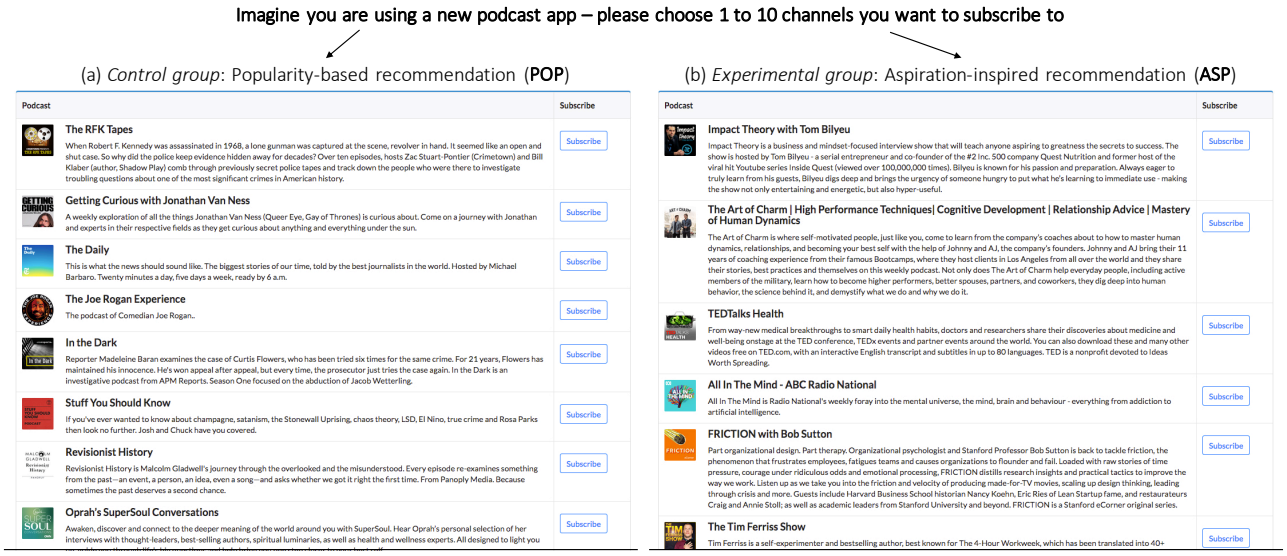
- **Dataset collection**. We scraped the most recent 500 reviews of 29K popular podcast channels on iTunes to train a recommendation model. In order to conduct recommendations based on users' channel subscriptions, which are binary signals, we disregarded rating scores and treated iTunes reviews as positive-only feedback. The final training dataset contained 702K user-channel interactions from 137K iTunes users.
- **Recommendation model**. We used OpenRec [50] to build a Weighted Regularized Matrix Factorization (WRMF) [22] based recommender, which is a representative implicit-feedback-based recommendation model and is optimized to minimize the following objective function:

$$\min_{x_*, y_*} \sum_{u \in \mathcal{U}, i \in \mathcal{I}} w_{ui}(p_{ui} - x_u^T y_i)^2 + \lambda \|\Theta\|^2 \tag{2}$$

  where Θ is a set of model parameters, x_u and y_i are latent factor representations for user u (among all iTunes users $\mathcal{U}$) and channel i (among all iTunes channels $\mathcal{I}$) respectively, and p_{ui} is a binary indicator for user preferences ($p_{ui} = 1$ if user u subscribed to channel i, and $p_{ui} = 0$ otherwise). In addition, WRMF uses w_{ui} to control models' confidence levels on p_{ui}. We set w_{ui} such that $w_{ui} = 1$ if $p_{ui} = 1$, and $w_{ui} = 0.01$ otherwise. These parameter settings achieved the best validation results in our dataset. When applying the WRMF model, we discarded x_u since it corresponds to users from iTunes, and fixed trained channel representations y_i. For a participant u', we derived an analytic expression of the optimal user representation $x_{u'}$ by differentiating the objective function (eqn. 2):

$$x_{u'} = \frac{1}{\lambda + \sum_i w_{u'i} y_i^T y_i} \sum_i w_{u'i} p_{u'i} y_i \tag{3}$$

- **Not-subscribed channel retrieval**. For any participant u' in the experimental group, we retrieved the top 5 not-subscribed



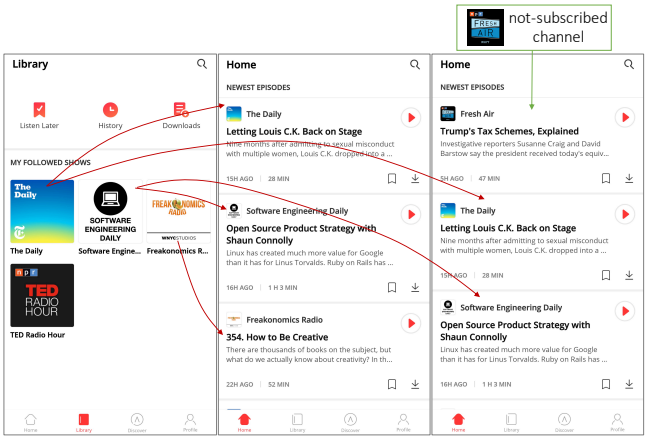


Figure 2: The web user interface designed for participants to subscribe to channels during onboarding. The interface presented a list of podcast shows, and participants were instructed to subscribe to up to ten of them. For the control group (POP), channels were ordered by their popularity on iTunes, whereas for the experimental group (ASP), the ordering was determined by channels' alignment to participants' topic-wise intentions. Both groups shared the same set of candidate content.

(c) Popular/Trending channels

Figure 4: The discover page of the customized podcast mobile app. The page grouped channels into topic-wise categories and presented a trending chart that ordered channels according to their popularity on iTunes. This page allowed users to readily explore and subscribe to new channels.

channels that had the highest dot product scores (i.e., $x_{u'}y_i, i \in \{i|p_{u'i} = 0 \wedge i \in \mathcal{I}\}$). Although the recommendation model was fixed throughout the study, retrieved channels were adaptively updated whenever participants subscribed to new shows.

3.3 Post-study Survey

After participants finished the 4-weeks field study, we conducted a post-study survey through email to elicit user satisfaction. The survey questions follow a template: "How satisfied were you with

Total number of participants: 105, **unreported:** 26	
Gender:	Female: 50 Male: 29
Age (years):	Max: 43 Min: 17 Mean: 21
Device:	IOS: 49 Android: 30
Major:	Computing and Information Science: 20 Arts & Sciences: 22 Life Sciences: 10 Medicine: 2 Business: 16 Engineering: 9

Table 1: Participants' demographic information including gender, age, primary mobile device, and college major.

___?", and the aspects we surveyed include *the app*, *the experiment*, *your current podcast channel subscriptions*, and *the home feed in the app*. For each question, participants were instructed to give a likert-scale rating (i.e., *not at all satisfied*, *slightly satisfied*, *neutral*, *very satisfied*, and *extremely satisfied*).

3.4 Participant Recruitment

We recruited 105 full-time undergraduate students who were studying in New York City and were from diverse background. The demographic information of the participants is summarized in Table. 1. Participants were compensated with $30 after completing both phases of the study. To encourage app usage in the field, we provided an additional $20 bonus for those who used the mobile app for at least five days a week, and reminded all participants to listen to new episodes weekly. Finally, participants were randomly assigned to one of the 2×2 conditions (POP-SUB: 25, POP-MIX: 26, ASP-SUB:29, ASP-MIX:25), and two research personnel who were blind to condition assignments managed and executed participants onboarding and the field study. The study was approved by the Institutional Review Board (IRB) under the protocol #1507005739.

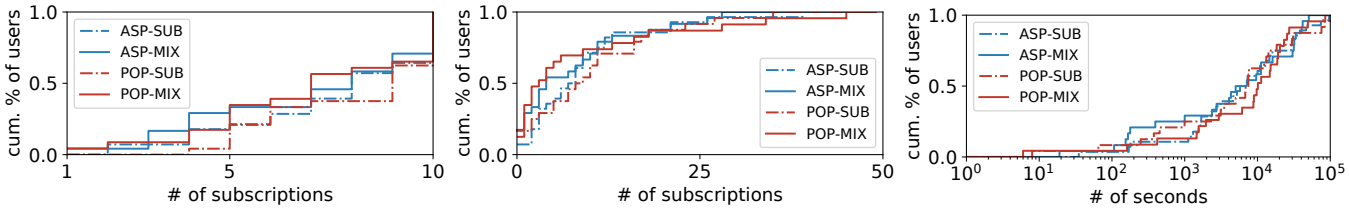
4 STUDY RESULTS

Our study recorded the choices that participants made at onboarding and in the field including both channel subscriptions and episode listening. In addition, we recorded satisfaction ratings that participants gave to questions in the final survey. Eventually, 99 out of 105 participants completed the study (POP-SUB: 24, POP-MIX: 23, ASP-SUB:28, ASP-MIX:24). We summarize and present our study results in four dimensions: general usage patterns (Section 4.1), choices related to topic-wise intentions (Section 4.2), exploratory choices (Section 4.3), and user satisfaction (Section 4.4).

4.1 General usage patterns

To understand the usability and user experience with our podcast content platform, we investigate a type of commonly used metrics, user activity level [28]. We count the number of subscriptions that each user made in the field, and the amount of time that each user spent listening to episodes. The distributions of these measures over users are illustrated in Fig. 5. Overall, participants were fairly active in using the mobile app in the field with 8.8 average number of subscriptions and 4.58-hour average listening time. Participants' activity level is also distributed within a range and has rare outliers (Fig. 5-b,c). In Fig. 5-a, we also plot the distribution of the number of onboarding subscriptions, which is shown to spread from one to ten (maximum allowance) with an average of 7.4. To test whether two experimental factors affect the three measures in Fig. 5, we conduct a general nonparametric factorial analysis using the Aligned Rank Transform (**ART**) [49] (by treating the three measures as responses). We use ART because our study contains more than one factor, and all the measures are not normally distributed over users[3]. In the rest of this paper, if not specified, the ART is used to conduct statistical significance tests (notations: $***$: $p < 0.001$, $**$: $p < 0.01$, $*$: $p < 0.05$). The ART reports no significant effect from ONB, FIE, or ONB×FIE for all the three measures. However, as shown in Section 4.2 and 4.3, ONB and FIE have significant effects on users' podcast consumption patterns, although they are not captured in the general user activity measures. We discuss the limitations of these traditional measures in Section 5.5.

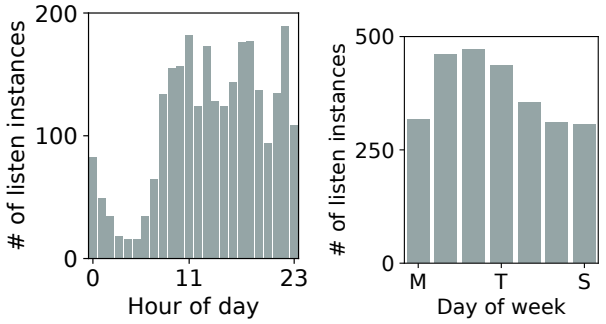
In addition to aggregate users' activities (subscriptions and listening time) on a per-user basis, we also cluster the activities into hour of day (Fig. 6-a), day of week (Fig. 6-b), and distinct channels (Fig. 7). Temporal distributions of listening instances (Fig. 6) reveal several diurnal and weekly listening patterns, such as decreased listening during night and over weekends. However, no statistical evidence shows significant effects of experimental factors on these temporal patterns. Regarding the channel-wise user activity distributions (Fig. 7), they demonstrate that (1) during onboarding (Fig. 7-a), participants' channel subscriptions manifested significant popularity bias under the POP treatment, i.e., the majority of user subscriptions were concentrated on a small number of channels, whereas under the ASP treatment, subscriptions were spread out to more channels and tended to be uniformly distributed, and (2) in the field, users interacted with a broader set of podcast channels than during onboarding, but both experimental factors have no significant effect on the number of interactions that each channel received. In the Appendix, we additionally visualize top channels subscribed by participants.



4.2 Choices related to topic-wise intentions

The distribution of the topics that participants intended to consume is shown in Fig. 8, which shows the diversity of the topics of interest chosen by participants — the intended topics in the population were spread across 53 distinct general and fine-grained categories, and most of the topics were selected by less than half of the population. Such a wide range of selected topics is partially attributable to the diverse background of our recruited participants (Table. 1). To show how users' choices related to topic-wise intentions may be modulated by two stages of recommendations, we define a topic-wise intention ratio $r_{\text{topic}}(c|u)$ of a channel c for the user u as follows:

$$r_{\text{topic}}(c|u) = \frac{|\mathcal{S}_c \cap \mathcal{A}_u|}{|\mathcal{S}_c|} \tag{4}$$



where we use the notations from eqn. 1. The value of $r_{\text{topic}}(c|u)$ corresponds to the proportion of a channel's content that aligns with a user's intended topics. Then using $r_{\text{topic}}(c|u)$, we calculate the average alignment of a user u's subscriptions, $P^{\text{sub}}_{\text{topic}}(u)$, as the

[3]The normality test is conducted via the Shapiro-Wilk normality test

(a) Onboarding subscriptions. (b) Field subscriptions. (c) Listening time.

Figure 5: The cumulative distributions of users over number of subscriptions and listening time. These figures show the extent to which participants were actively subscribing and listening to podcasts throughout the study. A vertical line in these figures represents a group of users with a similar activity level. We note that these commonly-used aggregated measures are not statistically different across the four groups. In other words, they do not reflect the different composition of content consumption across these groups (Section 4.2 and 4.3). These differences are critical to understand the effects of recommendations on individual growth and experience.

(a) Hour of day distribution. (b) Day of week distribution.

Figure 6: The distribution of podcast listening instances over hour of day and day of week. The aggregation is across all participants. Again we note that no statistical difference is observed across the four groups.

average $r_{\text{topic}}(c|u)$ over all followed channels $\mathcal{F}_u$, i.e.,

$$P^{\text{sub}}_{\text{topic}}(u) = \frac{\sum_{c\in\mathcal{F}_u} r_{\text{topic}}(c|u)}{|\mathcal{F}_u|} \tag{5}$$

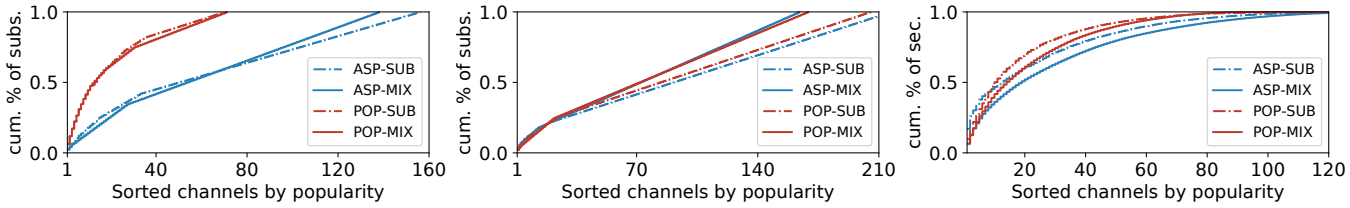
and calculate the average alignment of a user u's listening, $P^{\text{listen}}_{\text{topic}}(u)$, as the weighted average of $r_{\text{topic}}(c|u)$ over listened channels $\mathcal{L}_u$ with the weight proportional to the listening duration d_c, i.e.,

$$P^{\text{listen}}_{\text{topic}}(u) = \frac{\sum_{c\in\mathcal{L}_u} r_{\text{topic}}(c|u)d_c}{\sum_{c\in\mathcal{L}_u} d_c} \tag{6}$$

We show the cumulative distributions of users over $P^{\text{sub}}_{\text{topic}}(u)$ and $P^{\text{listen}}_{\text{topic}}(u)$ in Fig. 9, and the 2×2 groupwise averages in Fig. 10. These graphs and corresponding ART tests demonstrate that under all scenarios, the ASP intervention significantly improves the ratio of content consumption that matches users' topic-wise intentions — during onboarding, ASP increases $\overline{P}^{\text{sub}}_{\text{topic}}$ by 72.1% (ONB:**), and in the field, ASP improves $\overline{P}^{\text{sub}}_{\text{topic}}$ and $\overline{P}^{\text{listen}}_{\text{topic}}$ by 36.5% (ONB:***) and 24.9% (ONB:*) respectively. It is worth noting that although improvements are larger at onboarding when the intervention is directly applied, ASP is shown to have significant indirect effects on users' content consumption in the field as well. The statistical test does not show significant effects from the FIE factor and the interaction (i.e., ONB×FIE).

4.3 Exploratory choices

To investigate how participants' exploratory choices were affected by recommendations, we divided their podcast listening into subscribed listening (exploitation) and not-subscribed listening (exploration). We define the exploratory ratio $r_{\text{explore}}(c|u)$ as a counterpart for $r_{\text{topic}}(c|u)$ (Section 4.2). This exploratory ratio is calculated as follows.



$$r_{\text{explore}}(c|u) = 1 - \mathbb{1}\left[c \in \mathcal{F}^t_u\right] \tag{7}$$

where $\mathbb{1}$ is an indicator function, and $\mathcal{F}^t_u$ is the set of channels that the user u subscribed to at time t when the channel c was consumed. Essentially, $r_{\text{explore}}(c|u) = 1$ if the channel was not subscribed when consumed, otherwise $r_{\text{explore}}(c|u) = 0$. We then substitute $r_{\text{topic}}(c|u)$ in eqn. 6 with $r_{\text{explore}}(c|u)$ and derive an exploratory measure of a user u' s listening, denoted as $P^{\text{listen}}_{\text{explore}}(u)$. From another angle, $P^{\text{listen}}_{\text{explore}}(u)$ can be viewed as the percentage of time that the user u explored new information channels.

We show the distributions of users over $P^{\text{listen}}_{\text{explore}}(u)$ and the groupwise average scores in Fig. 11. Both figures and ART statistical tests demonstrate that the MIX intervention significantly increases $\overline{P}^{\text{listen}}_{\text{explore}}$ by 127.5% (FIE:*). In other words, the MIX feeds significantly encouraged participants to explore beyond existing and potentially narrow information channels. The onboarding recommendations (ONB) and the interaction between the two stages of recommendations (ONB×FIE) do not have significant effects.

4.4 User satisfaction

Four satisfaction indicators were surveyed and reported by participants after the study was over (Section 3.3). Among 99 valid participants, 89 of them responded to our email survey (Response rate: 89.9%). Both experimental factors and their interaction do not have significant effects on whether or not a participant responded to the survey. To quantitatively analyze survey results, following

(a) Onboarding subscriptions. **(b) Field subscriptions.** **(c) Listening time.**

Figure 7: The cumulative distributions of subscriptions and listening time over channels ordered by popularity. The popularity is defined as the number of subscription (a, b) and the amount of listening (c). These figures show the extent to which participants' content consumption was concentrated on a small set of popular items. A linear line in the figure represents uniformly distributed consumption over all channels. During onboarding, the POP intervention resulted in significant popularity bias in participants' subscriptions, but in the field, no significant effect from experimental factors is observed.

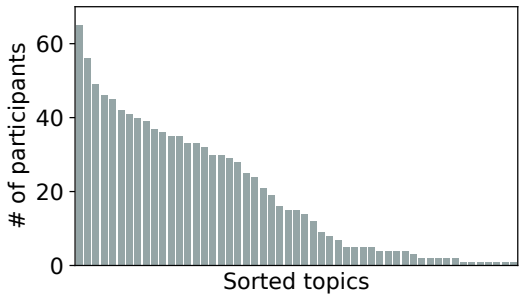


Figure 8: The distribution of user intentions over podcast topics (categories). Topics are sorted by their popularity in a descending order. Participants' intended topics were diversely spread across 53 categories, with most of the topics liked by less than half of the participants.

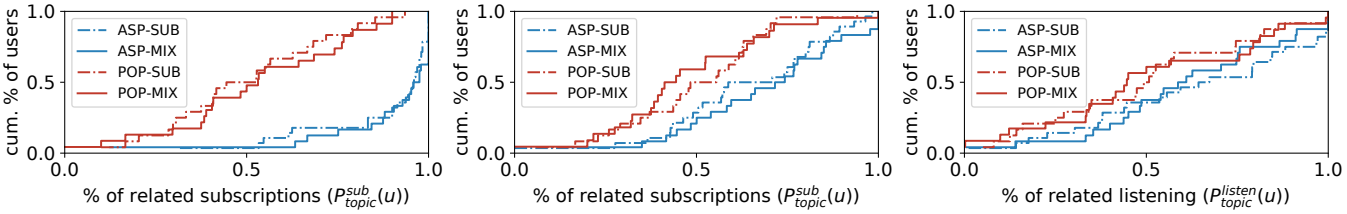
the common practice [21], we convert the five options in each survey question, i.e., *not at all satisfied*, *slightly satisfied*, *neutral*, *very satisfied*, and *extremely satisfied*, to 1–5 numerical ratings.

We found that satisfactions for all indicators are highly correlated. Therefore, we aggregated them into one factor by taking the average of the ratings. The distributions of the aggregated satisfaction ratings and the groupwise average values are shown in Fig. 12. Participants' satisfaction is significantly affected by the interaction between two factors (ONB×FIE: $*$); and the post-hoc differences of differences test [6, 30] confirms the effects of one factor given the other. In other words, if participants were onboarded with the popularity-based recommender, applying the CF-based recommender to populate users' home feeds significantly degraded users' satisfaction, whereas if participants were initially presented with a channel list ranked by their intentions, the CF-based recommender used in the field showed positive effects. These findings have important implications as to how the reinforcing nature of recommendations may improve or degrade utility and user experience, as discussed in Section 5.

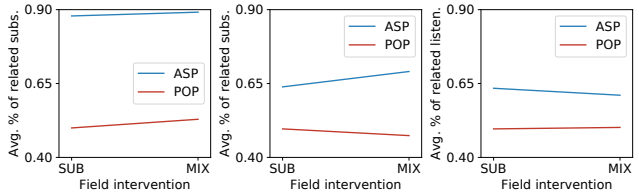
5 IMPLICATIONS AND DISCUSSIONS



Our study results indicate significant interactions between recommendations and intentions. We discuss our findings in light of theoretical and empirical research on human decision making and suggest directions for designing better recommendation systems that benefit end users.

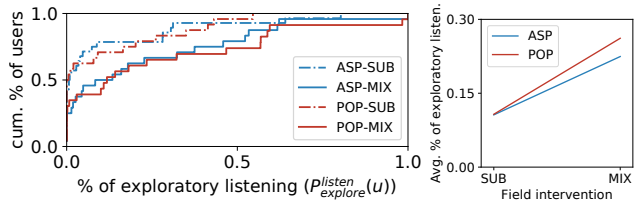
5.1 Employing planning and intentions

Individuals face self-control challenges when making decisions about content consumption, just as they do when managing diet or finance [32]. People have troubles translating their intentions and goals into actions when facing real-world decision-making problems. For example, prior research showed that people rent documentaries in line with their "aspirational self" but were less likely to actually consume this type of movie compared to more affective movies such as action films [32]. Filter bubbles [36] are another example in which users' long-term interests do not match with short-term consumption of news. To help people choose according to their long-term interests, our study suggests to employ a deliberative thinking via planning in the form of preference elicitation. As shown in Section 3.1, our onboarding system leveraged a preference elicitation-based interaction technique and an intention-aware recommender system that allowed for the explicit inclusion of user intentions. Such a design was shown to have significantly positive effects as users subscribed according to their elicited intentions during onboarding and later followed up on their plans when listening in the wild. Similar strategies were examined in behavioral science literature suggesting that people planning ahead are more likely to act on their intentions and to exhibit aspirational behavior in line with their long term interests [18].



5.2 Encouraging exploration

Classical recommendation systems based on collaborative filtering and click-based metrics are often criticized since they are likely to be overly optimized to reinforce past behavior and preferences [24]. As a result, measures such as novelty and diversity are increasingly explored both in research papers and industry practice in recent years [21, 45, 53]. Finding the right mix of novel and familiar items can be challenging as it is not clear to what extent a certain quality characteristic like novelty is truly desired in a given application for a specific user and at a certain time. In the social and behavioral science literature this is often formulated as the exploration-exploitation trade-off [2, 4, 23]. Our results demonstrate



(a) Onboarding subscriptions (ONB: $**$). **(b) Field subscriptions (ONB: $***$).** **(c) Listening time (ONB: $*$).**

Figure 9: Cumulative distributions of users over the percentage of the topicwise intention-related subscriptions and listening. In the above figures, an $x = 1.0$ curve denotes that all users' consumption is related to their topicwise intentions, while an $x = 0.0$ curve denotes that none are related. The ASP intervention during onboarding is shown to significantly increase the topic-related onboarding subscriptions, topic-related field subscriptions, and topic-related field listening. The FIE factor and the interaction ONB×FIE have no significant effect.

(a) Onboard. subs. (ONB:$**$) **(b) Field subs. (ONB:$***$)** **(c) Listening time (ONB:$*$)**

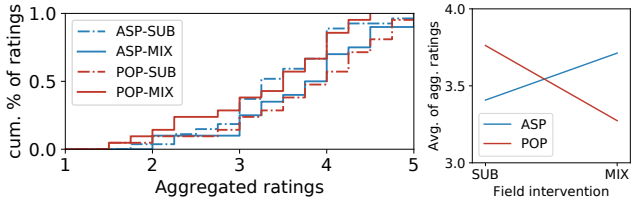


Figure 10: The groupwise average percentage of the topicwise intention-related subscriptions and listening. The ASP intervention significantly improves the topic-relatedness of onboarding subscriptions, field subscriptions, and field episode listening by 72.1%, 36.5%, and 24.9% respectively. The FIE and the interaction (ONB×FIE) have no significant effect.

(a) The cumulative distribution over users (FIE: $*$). **(b) The groupwise average (FIE: $*$).**

Figure 11: The percentage of subscriptions and listening from not-subscribed channels — (a) cumulative distributions over users, and (b) groupwise average. In (a), a $x = 1.0$ curve denotes that users do not listen to episodes from subscribed channels, while a $x = 0.0$ curve denotes that all listening comes from subscribed channels. The MIX intervention is shown to significantly increase the exploration rate by 127.5%. The ONB factor and the interaction (ONB×FIE) have no significant effect.

that introducing recommendation systems in content platforms that were mainly driven by user intentions provided benefits in the form of user exploration, because recommendations helped people find

(a) The cumulative distributions of aggregated ratings (ONB×FIE:$*$). **(b) The average ratings (ONB×FIE:$*$).**

Figure 12: Participants' satisfaction (the averaged ratings of all indicators) — (a) cumulative distributions of aggregated ratings, and (b) groupwise average ratings. The interaction between two factors (ONB×FIE) significantly affects satisfaction — MIX improves satisfaction if participants were onboarded with the ASP, otherwise MIX shows negative effects. No single factor alone has a significant effect.

choice alternatives that they were not aware of. However, how recommendation systems may influence the explore-exploit dilemma in the long term is an open question for future research.

5.3 Understanding user satisfaction

Our results show that users were satisfied when CF-based recommendations (MIX) were delivered based on intention-driven subscriptions (ASP) at onboarding. This can be explained by the benefits of reinforcing users' long-term interests. Whereas when users' initial subscriptions were only driven by channels' popularity and not aspirational, CF-based recommendations ignored their intentions and left them dissatisfied. Another possible explanation is the explainability and trust of recommendations. People are more likely to follow recommendations they trust, and explaining recommendations is shown to increase the trust [54]. Since the ASP-MIX hybrid recommender systems were informed by stated users' preferences, recommendations were implicitly explained and were easier to be perceived and understood by users. Whereas when the POP-MIX systems were used, the explainability and trust of field recommendations was expected to be low.

Additionally, as shown in Section 4.4, we also observe high user satisfaction under the POP-SUB interventions, in which users were

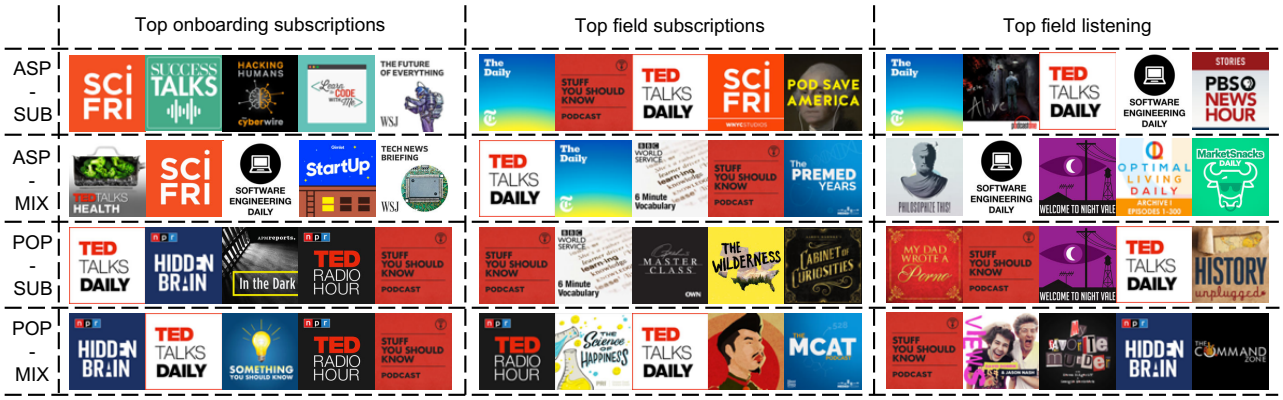

Figure 13: Top five most interacted content source during onboarding and in the field, categorized by 2×2 groups. Each square icon represents a podcast channel. These qualitative results further demonstrate how users' content consumption in the field was jointly affected by users' intentions and recommendation systems.

left in their information bubble populated with self-chosen popular items. This may be explained by people's inherent motivation to chase popular items [51] even if these items were misaligned with users' stated intentions; such content satisfies an important, if implicit, aspect of people's information needs and desires.

5.4 Optimizing for multiple objectives

Our study reveals benefits of jointly optimizing people's information consumption for multiple objectives. For example, for podcasts and other subscription-based media, service providers should consider a hybrid form of recommender that contains an intention-aware recommender for onboarding and a CF-based recommender for field listening. This combination can support users' intentions while encouraging them to explore beyond existing channels. As a result, users are likely to be more satisfied. More generally, with a global view of the recommendations that people are increasingly exposed to, we can jointly optimize recommendation systems to support an individual's aspirations and satisfaction in other domains such as diet and time management.

5.5 Limitations of intention-agnostic metrics

Commonly-used metrics that quantify user experiences are often agnostic to people's intentions. As a result, these metrics mainly reflect the extent to which recommendations engage people but overlook the utility of those engagements. For example, in our study, total listening time and total number of subscriptions show that people were equally active across different groups (Section 4.1), but in reality, people in certain groups were less exposed to new information, guided away from their aspirations, and less satisfied. Therefore, when probing and evaluating the performance of recommendation systems, it is important to condition metrics on individual intentions.

6 CONCLUSIONS AND FUTURE WORK

We presented a randomized controlled field experiment that studied the effects of recommendations on people's content choices related to intentions. Our study revealed how recommendations (1) modulated people's choices of topically relevant content, (2) affect the likelihood that people explore beyond their existing information sources, and (3) jointly affected user satisfaction. We discussed the implications and applications of our study findings on the design, evaluation and understanding of recommendation systems. Our study confirms the suspected importance of recommendations beyond discovering relevant information; in particular, that these systems implicitly alter online behavior in a manner that can have profound implications for individuals and society [1]. Future work is needed to study the generalization of these effects to wider demographic groups, and explore broader and longer term effects of recommendations through offline evaluation, simulations, and larger scale field experiments.

A QUALITATIVE USAGE RESULTS

We show the channels that were most-subscribed and listened during onboarding and in the field (Fig. 13). During onboarding, the subscriptions made in ASP-$*$ groups were much more diverse compared to the POP-$*$ groups. The subscriptions from POP-$*$ groups were mostly concentrated on trendy channels such as TED Talks Daily, TED Radio Hour, and Hidden Brain. However, in the field, all groups manifested diverse content consumption patterns, and the top subscribed and listened channels contained both trendy and long-tail items. These qualitative results further illustrate how users' podcast content consumption was driven by users' intentions and at the same time affected by recommendation systems.

ACKNOWLEDGMENTS

This research was supported by the National Science Foundation under grant IIS-1700832 and by Yahoo Research (via the Connected Experiences Laboratory at Cornell Tech). The work was further supported by the small data lab at Cornell Tech, which received funding from NSF, NIH, RWJF, UnitedHealth Group, Google, and Adobe. The City University of New York provided generous support in recruiting participants. We thank the anonymous reviewers for their insightful comments and suggestions.

ABSTRACT

Spatial-temporal prediction is a fundamental problem for constructing smart city, which is useful for tasks such as traffic control, taxi dispatching, and environment policy making. Due to data collection mechanism, it is common to see data collection with unbalanced spatial distributions. For example, some cities may release taxi data for multiple years while others only release a few days of data; some regions may have constant water quality data monitored by sensors whereas some regions only have a small collection of water samples. In this paper, we tackle the problem of spatial-temporal prediction for the cities with only a short period of data collection. We aim to utilize the long-period data from other cities via transfer learning. Different from previous studies that transfer knowledge from one single source city to a target city, we are the first to leverage information from multiple cities to increase the stability of transfer. Specifically, our proposed model is designed as a spatial-temporal network with a meta-learning paradigm. The meta-learning paradigm learns a well-generalized initialization of the spatial-temporal network, which can be effectively adapted to target cities. In addition, a pattern-based spatial-temporal memory is designed to distill long-term temporal information (i.e., periodicity). We conduct extensive experiments on two tasks: traffic (taxi and bike) prediction and water quality prediction. The experiments demonstrate the effectiveness of our proposed model over several competitive baseline models.

CCS CONCEPTS

• **Information systems → Data Mining**; • **Computing methodologies → Transfer learning**.

1 INTRODUCTION

Recently, the construction of smart cities significantly changes urban management and services [12, 13, 25, 28, 42, 43]. One of the most fundamental techniques in building smart city is accurate spatial-temporal prediction. For example, a traffic prediction system can help the city pre-allocate transportation resources and control traffic signal intelligently. An accurate environment prediction system can help the government develop environment policy and then improve the public's health.

Traditionally, basic time series models (e.g., ARIMA, Kalman Filtering and their variants) [10, 15, 19], regression models with spatial-temporal regularizations [6, 44] and external context features [30, 35] are used for spatial-temporal prediction. Recently, advanced machine learning methods (e.g., deep neural network based models) significantly improve the performance of spatial-temporal prediction [34, 35, 41] by characterizing non-linear spatial-temporal correlations more accurately. Unfortunately, the superior performance of these models is conditioned on large-scale training data which are probably inaccessible in real-world applications. For example, there may exist only a few days of GPS traces for traffic prediction in some cities.

Transfer learning has been studied as an effective solution to address the data insufficiency problem, by leveraging knowledge from those cities with abundant data (e.g., GPS traces covering a few years). In [29], the authors proposed to transfer semantically-related dictionaries learned from a data-rich city, i.e., a source city, to predict the air quality category in a data-insufficient city, i.e., a target city. The method proposed in [27] aligns similar regions across source and target cities for finer-grained transfer. However, these methods, transferring the knowledge from only a single source city, would cause unstable results and the risk of negative transfer. If the underlying data distributions are significantly different between cities, the knowledge transfer will make no contribution or even hurt the performance.

To reduce the risk, in this paper, we focus on transferring knowledge from *multiple source cities* for the spatial-temporal prediction in a target city. Compared with single city, the knowledge extracted from multiple cities covers more comprehensive spatial-temporal correlations of a city, e.g., temporal dependency, spatial closeness, and region functionality, and thus increases the stability of transfer. However, this problem faces two key challenges.

- **How to adapt the knowledge to meet various scenarios of spatial-temporal correlations in a target city?** The spatial-temporal correlations in the limited data of a target city may vary considerably from city to city and even from time to time. For example, the knowledge to be transferred to New York is expected to differ from that to Boston. In addition, the knowledge to be transferred within the same city also differs from weekdays to weekends. Thus a sufficiently flexible algorithm capable of adapting the knowledge learned from multiple source cities to various scenarios is required.
- **How to capture and borrow long-period spatial-temporal patterns from source cities?** It is difficult to capture long-term spatial-temporal patterns (e.g., periodicity) accurately in a target city with limited data due to the effects of special events (e.g. holiday) or missing values. These patterns as indicators of region functionality, however, are crucial for spatial-temporal prediction [33, 45]. Take the traffic demand prediction as an instance. The traffic demand in residential areas is periodically high in the morning when people transit to work. Thus, it is promising but challenging to transfer such long-term patterns from source cities to a target city.

To address the challenges, we propose a novel framework for spatial-temporal prediction, namely **MetaST**. It is the first to incorporate the meta-learning paradigm into spatial-temporal networks (ST-net). The ST-net consists of a local CNN and an LSTM which jointly capture spatial-temporal features and correlations. With the meta-learning paradigm, we solve the first challenge by learning a well-generalized initialization of the ST-net from a large number of prediction tasks sampled from multiple source cities, which covers comprehensive spatial-temporal scenarios. Subsequently, the initialization can easily be adapted to a target city via fine-tuning, even when only few training samples are accessible. Second, we learn a global pattern-based spatial-temporal memory from all source cities, and transfer it to a target city to support long-term patterns. The memory, describing and storing long-term spatial-temporal patterns, is jointly trained with the ST-net in an end-to-end manner.

We evaluate the proposed framework on several datasets including taxi volume, bike volume, and water quality. The results show that our proposed MetaST consistently outperforms several baseline models. We summarize our contributions as follows.

- To the best of our knowledge, we are the first to study the problem of transferring knowledge from multiple cities for the spatial-temporal prediction in a target city.
- We propose a novel MetaST framework to solve the problem by combining a spatial-temporal network with the meta-learning paradigm. Moreover, we learn from all source cities a global memory encrypting long-term spatial-temporal patterns, and transfer it to further improve the spatial-temporal prediction in a target city.
- We empirically demonstrate the effectiveness of our proposed MetaST framework on three real-world spatial-temporal datasets.

The rest of this paper is organized as follows. We first review and discuss the related work in Section 2. Then, we define some notations and formulate the problem in Section 3. After that, we introduce details of the framework of MetaST in Section 4. We apply our model on three real-world datasets from two different domains and conduct extensive experiments in Section 5. Finally, we conclude our paper in Section 6.

2 RELATED WORK

In this section, we briefly review the works in two categories: some representative works for spatial-temporal prediction and knowledge transferring.

2.1 Spatial-Temporal Prediction

The earliest spatial-temporal prediction models are based on basic time series models (e.g., ARIMA, Kalman Filtering) [10, 15, 19]. Recent studies further utilize external context data (e.g., weather condition, venue types, holiday, event information) [26, 30, 35] to enhance the prediction accuracy. Also, spatial correlation is taken into consideration by designing regularization of spatial smoothness [21, 31, 44].

Recently, various deep learning methods have been used to capture complex non-linear spatial-temporal correlations and predict spatial-temporal series, such as stacked fully connected network [24, 35], convolutional neural network (CNN) [23, 41] and recurrent neural network (RNN) [39]. Several hybrid models have been proposed to model both spatial and temporal information [7, 33, 34]. These methods combine CNN and RNN, and achieve the state-of-the-art performance on spatial-temporal prediction. In addition, based on the road network structure, another type of hybird models combines graph aggregation mechanism and RNN for spatial-temporal prediction [9, 38, 40]

Different from previous studies of deep spatial-temporal prediction which all rely on a large set of training samples, we aim to transfer learned knowledge from source cities to improve the performance of spatial-temporal prediction in a target city with limited data samples.

2.2 Knowledge Transfer and Reuse

Transfer learning and its related fields utilize previously learned knowledge to facilitate learning in new tasks when labeled data is scarce [16, 17]. Previous transfer learning methods transfer different information from a source domain to a target domain, such as parameters [32], instances [1], manifold structures [3, 4], deep hidden feature representations [22, 37]. Recently, meta-learning (a.k.a., learning to learn) transfers shared knowledge from multiple training tasks to a new task for quick adaptation. These techniques include learning a widely generalizable initialization [2, 11], optimization trace [18], metric space [20], transfer learning skills [36].

However, only a few attempts have been made on transferring knowledge on the space. [29] proposes a multi-modal transfer learning framework for predicting air quality category, which combines multi-modal data by learning a semantically coupled dictionary for multiple modalities in a source city. *However, this method works on multimodal features instead of spatial-temporal sequences we focus on. Therefore, it cannot be applied to solve the problem.* For predicting traffic flow, [27] leverages the similarity of check-in records/spatial-temporal sequences between a source city and a target city to construct the similarity regularization for knowledge transfer. *Different from this method that intelligently learns the correlation which could be linear or non-linear. Compared with both*

methods above, in addition, our model transfers the shared knowledge from multiple cities to a new city, which increase the stability of transfer and prediction.

3 DEFINITIONS AND PROBLEM FORMULATION

In this section, we define some notations used in this paper and formally define the setup of our problem.

Definition 1 (Region) Following previous works [34, 41], we spatially divide a city c into an $I_c \times J_c$ grid map which contains I_c rows and J_c columns. We treat each grid as a region r_c, and define the set of all regions as $\mathcal{R}_c$.

Definition 2 (Spatial-Temporal Series) In city c, we denote the current/latest timestamp as k_c, and the time range as a set $\mathcal{K}_c = \{k_c - |\mathcal{K}_c| + 1, ..., k_c\}$ consisting of $|\mathcal{K}_c|$ evenly split non-overlapping time intervals. Then, the spatial-temporal series in city c is represented as

$$\mathcal{Y}_c = \{y_{r_c,k_c} | r_c \in \mathcal{R}_c, k_c \in \mathcal{K}_c\}, \tag{1}$$

where y_{r_c,k_c} is the spatial-temporal information to be predicted (e.g., traffic demand, air quality, climate value).

Problem Definition Suppose that we have a set of source cities $C_s = \{c_1, ..., c_S\}$ and a target city c_t with insufficient data (i.e., $\forall s \in \{1, \cdots, S\}$, $|\mathcal{K}_{c_s}| \gg |\mathcal{K}_{c_t}|$), our goal is to predict the spatial-temporal information of the next timestamp $k_{c_t} + 1$ in the testing dataset of the target city c_t, i.e.,

$$y^*_{r_{c_t},k_{c_t}+1} = \arg\max_{y_{r_{c_t},k_{c_t}+1}} p(y_{r_{c_t},k_{c_t}+1} | \mathcal{Y}_{c_t}, f_{\theta_0}), \tag{2}$$

where f represents the ST-net which serves as the base model to predict the spatial-temporal series. Detailed discussion about ST-net is in given Section 4.1. More importantly, in the meta-learning paradigm, θ_0 denotes the initialization for all parameters of the ST-net, which is adapted from $\mathcal{Y}_{c_1}, \cdots, \mathcal{Y}_{c_S}$.

4 METHODOLOGY

In this section, we elaborate our proposed method **MetaST**. In particular, we first introduce the ST-net as the base model f for spatial-temporal prediction, and then present our proposed spatial-temporal meta-learning framework for knowledge transfer.

4.1 Spatial-Temporal Network

Recently, hybrid models combining convolution neural networks (CNN) [8] and LSTM [5] have achieved the state-of-the-art performances on spatial-temporal prediction. Thus, following [34], we adopt a CNN to capture the spatial dependency between regions, and an LSTM to model the temporal evolvement of each region.

In city c, for each region r_c at time k_c, we regard the spatial-temporal value of this region and its surrounding neighbors as an $N \times N$ image with v channels $\mathbf{Y}_{r_c,k_c} \in \mathbb{R}^{N \times N \times v}$, where region r_c is in the center of this image. For instance, when N=3, we are considering a center cell as well as 8 adjacent grid cells of the cell, which is a 3*3 size neighborhood. The number of channels v depends on a specific task. For example, in taxi volume prediction, we jointly predict taxi pick-up volume and drop-off volume, so that the number of channels equals two, i.e., $v = 2$. Taking $\mathbf{Y}_{r_c,k_c}$ as input $\mathbf{Y}^0_{r_c,k_c}$, a local CNN computes the q-th layer progressively:

$$\mathbf{Y}^q_{r_c,k_c} = \text{ReLU}(\mathbf{W}^q_r * \mathbf{Y}^{q-1}_{r_c,k_c} + \mathbf{b}^q_r), \tag{3}$$

where $*$ represents the convolution operation, $\mathbf{W}^q_r$ and $\mathbf{b}^q_r$ are learnable parameters. After Q convolutional layers, a fully connected layer following a flatten layer is used to infer the spatial representation of region r_c as $\mathbf{s}_{r_c,k_c}$ eventually.

Then, for predicting y_{r_c,k_c+1}, we model the temporal unfolding of region r_c by passing all the spatial representations along the time span $\{k_c - |\mathcal{K}_c| + 1, ..., k_c\}$ through an LSTM, which can be formulated as

$$\begin{aligned}
\mathbf{i}_{r_c,k_c} &= \sigma(\mathbf{U}_i[\mathbf{s}_{r_c,k_c}; \mathbf{e}_{r_c,k_c}] + \mathbf{W}_i \mathbf{h}_{r_c,k_c-1} + \mathbf{b}_i), \\
\mathbf{f}_{r_c,k_c} &= \sigma(\mathbf{U}_f[\mathbf{s}_{r_c,k_c}; \mathbf{e}_{r_c,k_c}] + \mathbf{W}_f \mathbf{h}_{r_c,k_c-1} + \mathbf{b}_f), \\
\mathbf{d}_{r_c,k_c} &= \sigma(\mathbf{U}_d[\mathbf{s}_{r_c,k_c}; \mathbf{e}_{r_c,k_c}] + \mathbf{W}_d \mathbf{h}_{r_c,k_c-1} + \mathbf{b}_d), \\
\hat{\mathbf{c}}_{r_c,k_c} &= \tanh(\mathbf{U}_c[\mathbf{s}_{r_c,k_c}; \mathbf{e}_{r_c,k_c}] + \mathbf{W}_c \mathbf{h}_{r_c,k_c-1} + \mathbf{b}_c), \\
\mathbf{c}_{r_c,k_c} &= \mathbf{f}_{r_c,k_c} \circ \mathbf{c}_{r_c,k_c-1} + \mathbf{i}_{r_c,k_c} \circ \hat{\mathbf{c}}_{r_c,k_c}, \\
\mathbf{h}_{r_c,k_c} &= \tanh(\mathbf{c}_{r_c,k_c}) \circ \mathbf{d}_{r_c,k_c},
\end{aligned} \tag{4}$$

where $\circ$ denotes Hadamard product, $\mathbf{U}_j$, $\mathbf{W}_j$, and $\mathbf{b}_j$ ($j \in \{i, f, d, c\}$) are learnable parameters, $\mathbf{i}_{r_c,k_c}$, $\mathbf{f}_{r_c,k_c}$, and $\mathbf{d}_{r_c,k_c}$ are forget gate vector, input gate vector, and output gate vector of the i-th context feature, respectively. $\mathbf{h}_{r_c,k_c}$ denotes the spatial-temporal representation of region r_c, and $|\mathcal{K}_c|$ is the number of time steps we use to consider the temporal information. Note that $\mathbf{e}_{r_c,k_c}$ represents other external features (e.g., weather, holiday) that can be incorporated, if applicable. By doing these, $\mathbf{h}_{r_c,k_c}$ encodes both the spatial and temporal information of region r_c. As a result, the value of the next time step of spatial-temporal series, i.e., $\hat{y}_{r_c,k_c+1}$, can be predicted by

$$\hat{y}_{r_c,k_c+1} = \tanh(\mathbf{W}_n \mathbf{h}_{r_c,k_c} + \mathbf{b}_n), \tag{5}$$

where $\mathbf{W}_n$ and $\mathbf{b}_n$ are learnable parameters. The output is scaled to (-1,1) via a $\tanh(\cdot)$ function, to be consistent with the normalized spatial-temporal values. We later denormalize the prediction to get the actual demand values. We formulate the loss function of ST-net for each city c as:

$$\mathcal{L}_c = \sum_{r_c} \sum_{k_c} (\hat{y}_{r_c,k_c+1} - y_{r_c,k_c+1})^2, \tag{6}$$

so as to enforce the estimated spatial-temporal value to be as close to the ground-truth y_{r_c,k_c+1} as possible. As introduced previously, we denote all the parameters of the ST-net as θ, and the ST-net parameterized by θ as f_θ. For better illustration, we visualize the structure of the spatial-temporal network (**ST-net**) in Figure 1.

4.2 Knowledge Transfer

Next, we propose a meta-learning framework that enables our ST-net model to borrow knowledge from multiple cities. The framework consists of two parts: adapting the initialization and learning the spatial-temporal memory. We present the whole framework in Figure 2.

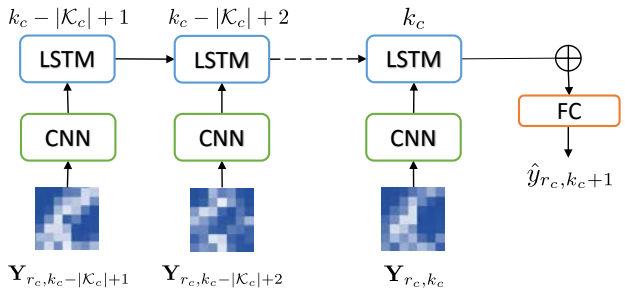

Figure 1: The framework of the ST-net. The heatmaps are exemplar spatial-temporal values. CNN is used to capture spatial dependency and then LSTM is used to handle temporal correlation.

4.2.1 Adapting the Initialization. As we described before, we are supposed to increase the stability of prediction by transferring knowledge from multiple source cities. Since the spatial-temporal correlation of limited data in a target city may vary considerably from city to city and even from time to time. For example, in traffic prediction, the knowledge to be transferred to Boston with limited weekend data is expected to differ from that to Chicago with limited weekday data. Thus, the extracted knowledge from multiple cities is expected to include comprehensive spatial-temporal correlations such as spatial closeness and temporal dependency, so that we can adapt the knowledge to a target city with limited data under different scenarios.

In ST-net, the parameters θ are exactly the knowledge which encrypts spatial-temporal correlations. To effectively adapt the parameters to a target city, as suggested in model-agnostic meta-learning (MAML) [2], initialization of θ from multiple source cities, i.e., θ_0, so that the ST-net initialized by θ_0 achieves the minimum of the average of generalization losses over all source cities, i.e.,

$$\theta_0 = \min_{\theta_0} \sum_{c_s \in C_s} \mathcal{L}'_{c_s}(f_{\theta_0 - \alpha \nabla_\theta \mathcal{L}_{c_s}(f_\theta)}). \tag{7}$$

Here we would note that $\mathcal{L}_{c_s}(f_{\theta_{c_s}})$ denotes the training loss on the training set of a city c_s sampled from C_s, i.e., $\mathcal{D}_{c_s}$ (refer to S-train in Figure 2). We illustrate the iterative update of the parameters θ_{c_s} during the training process (shown as the yellow solid arrow in Figure 2), by showing one exemplar gradient descent, i.e.,

$$\theta_{c_s} = \theta_0 - \alpha \nabla_\theta \mathcal{L}_{c_s}(f_\theta). \tag{8}$$

In practice, we can use several steps of gradient descent to update from the initialization θ_0 to θ_{c_s}. For each city c_s, the training process is repeated on batches of series sampled from D_{c_s}.

Since Eq. (7) minimizes the generalization loss, $\mathcal{L}'_{c_s}(\cdot)$ evaluates the loss on the test set of the city c_s, i.e., $\mathcal{D}'_{c_s}$ (refer to S-test in Figure 2). By optimizing the problem in Eq. (7) using stochastic gradient descent (shown as the purple solid arrow in Figure 2), we obtain an initialization which can generalize well on different source cities. Therefore, it is widely expected that transferring the initialization θ_0 to a target city c_t would also bring superior generalization performance, which we will detail in the end of this section.

4.2.2 Spatial-Temporal Memory. In spatial-temporal prediction, long-term spatial-temporal patterns (e.g., periodic patterns) play an important role [33, 45]. These patterns reflect the spatial functionality of each region and can be regarded as the global property shared by different cities. An example of spatial-temporal patterns and their corresponding regions are shown in Figure 3. In this figure, one region around NYU-Tardon in New York City and another one around Georgetown University in Washington DC are selected. The averaged 5-days' taxi demand distributions of both regions are daily periodic and similar, whose value are higher in the afternoon when students and faculties go back to home. The similarity of distributions between different cities verifies our assumption, i.e., spatial functionality is globally shared. However, in a target city, these patterns are hard to be captured with limited data due to missing values or the effects of special events (e.g., holidays). Thus, we propose a global memory, named **ST-mem**, to store long-term spatial-temporal patterns and further transfer to improve prediction accuracy in target cities. The framework of ST-Mem is illustrated in Figure 4.

Based on spatial-temporal patterns, we first cluster all the regions in source cities to G categories. The categories G of regions represent different region functionalities. For region r_c, the clustering results are denoted as $\mathbf{o}_{r_c} \in \mathbb{R}^G$. If region r_c belongs to cluster g, $\mathbf{o}_{r_c}(g) = 1$, otherwise $\mathbf{o}_{r_c}(g) = 0$. Then, we construct a parameterized spatial-temporal memory $\mathcal{M} \in \mathbb{R}^{G \times d}$. Each row of the memory stores the pattern representation of a category, and the dimension of the pattern representation is d.

Next, we utilize the knowledge of patterns stored in memory $\mathcal{M}$, and distill this knowledge for prediction via attention mechanism [14]. Since we only have short-term data in a target city, we use the representation of short-term data to query ST-mem. In particular, we linearly project the spatial-temporal representation $\mathbf{h}_{r_c,k_c}$ of ST-net to get the query vector for the attention mechanism, which is formulated as:

$$\mathbf{v}_{r_c,k_c} = \mathbf{W}_l \mathbf{h}_{r_c,k_c} + \mathbf{b}_l. \tag{9}$$

Then, we use the query vector $\mathbf{v}_{r_c,k_c} \in \mathbb{R}^d$ to calculate the similarity score between it and the pattern representation for each category g. Formally, the similarity score is defined as

$$\mathbf{p}_{r_c,k_c}(g) = \frac{\exp(\langle \mathbf{v}_{r_c,k_c}, \mathcal{M}(g) \rangle)}{\sum_{g'=1}^{G} \exp(\langle \mathbf{v}_{r_c,k_c}, \mathcal{M}(g') \rangle)}, \tag{10}$$

where $\mathcal{M}(g)$ means the g-th row of memory (i.e., for the g-th pattern category). We calculate the representation of spatial-temporal pattern $\mathbf{z}_{r_c,k_c}$ as:

$$\mathbf{z}_{r_c,k_c} = \sum_{g=1}^{G} \mathbf{p}_{r_c,k_c}(g) * \mathcal{M}(g). \tag{11}$$

Then, we concatenate the representation $\mathbf{z}_{r_c,k_c}$ of spatial-temporal patterns with the representation $\mathbf{h}_{r_c,k_c}$ of ST-net. And the input of the final layer $\mathbf{h}_{r_c,k_c}$ in Eq. (5) is replaced by the enhanced representation i.e.,

$$\hat{y}_{r_c,k_c+1} = \tanh(\mathbf{W}'_n[\mathbf{h}_{r_c,k_c}; \mathbf{z}_{r_c,k_c}] + \mathbf{b}'_n). \tag{12}$$

where $\mathbf{W}'_n$ and $\mathbf{b}'_n$ are learnable parameters.

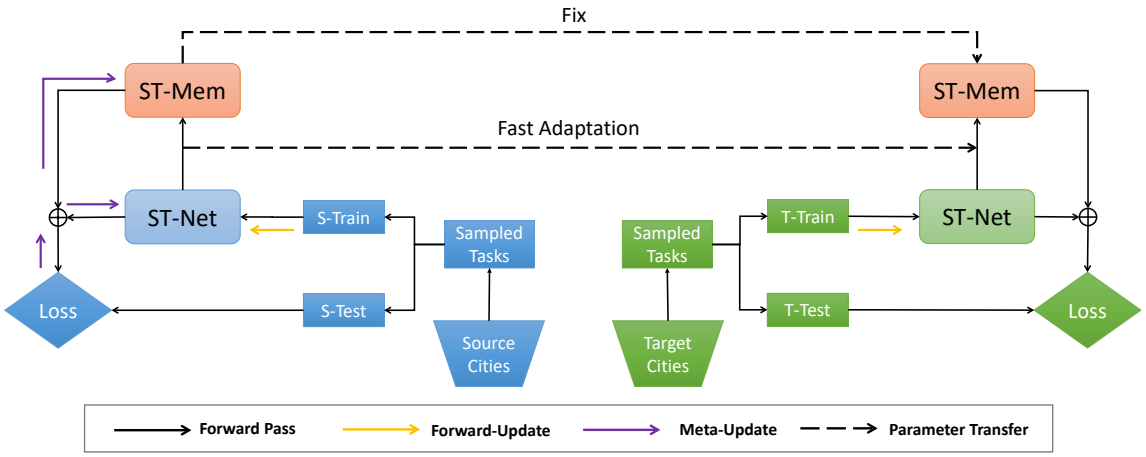

Figure 2: The framework of proposed MetaST. ST-net and ST-mem mean spatial-temporal network and spatial-temporal memory. S-train and S-test, T-train and T-test represent the training and testing set of source tasks (i.e., source cities) and target tasks (i.e., source cities), respectively. In the process of knowledge transfer, the parameters of ST-net will be updated by the training set in target city (i.e., T-train), while the parameters of ST-mem are fixed.

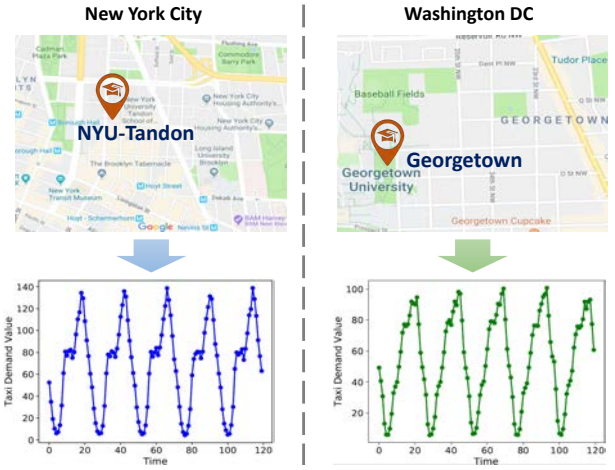

Figure 3: The illustration of spatial-temporal patterns of two regions and their corresponding region functionality.

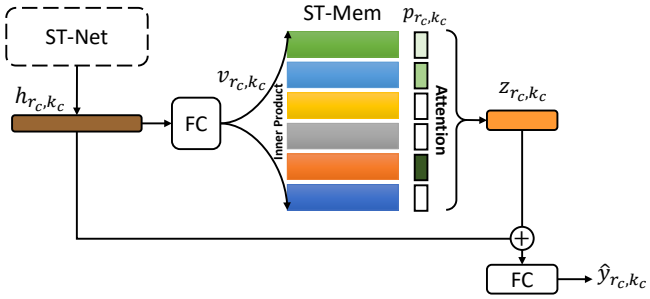

Figure 4: The stucture of ST-mem. The spatial-temporal representation $\mathbf{h}_{r_c,k_c}$ is projected as a query vector $\mathbf{v}_{r_c,k_c}$. Then, the attention mechanism is used to get the pattern representation $\mathbf{z}_{r_c,k_c}$. The short-term spatial-temporal representation and pattern representation are concatenated together for prediction.

In order to learn the memory $\mathcal{M}$, we construct the clustering loss of city c_s, which enforce the attention scores to be consistent with previous clustering results $\mathbf{o}_{r_c}$. The formulation of the clustering loss is as follows:

$$\mathcal{L}_{clu} = -\sum_{r_c}\sum_{k_c} \mathbf{o}_{r_c} \log(\mathbf{p}_{r_c,k_c}). \tag{13}$$

Additionally, the memory $\mathcal{M}$ is also updated when we train the MetaST framework, together with the initialization θ_0. Thus, we revise the loss function in Eq. (7) by adding the clustering loss. Then, our final objective function is:

$$\theta_0, \mathcal{M} = \min_{\theta_0, \mathcal{M}} \sum_{c_s \in C_s} \gamma \mathcal{L}_{clu}(f_{\theta_{c_s}}) + \mathcal{L}'_{c_s}(f_{\theta_{c_s}}), \tag{14}$$

where γ is a trade-off hypeparameter and is used to balance the effect of each part. $\theta_{c_s} = \theta_0 - \alpha\nabla_\theta \mathcal{L}_{c_s}(f_\theta)$ is defined in Eq. (8). By using testing set $\mathcal{D}'_{c_s}$ of each city c_s, the memory $\mathcal{M}$ and initialization θ_0 are updated by gradient descent. Note that, as we discussed before, the spatial-temporal patterns are common property between cities. We do not update memory $\mathcal{M}$ when training a specific task (i.e., Eq. (8)). In Figure 2, the purple solid arrow indicates the process of meta-update. In Eq. (14), the initialization θ_0 and memory $\mathcal{M}$ are mutually constrained. Since the memory $\mathcal{M}$ provides region-level relationship via spatial-temporal patterns, it can also help learn the initialization θ_0 of ST-net.

4.2.3 Transfer Knowledge to Target Domain. To improve the prediction in target cities, we transfer the ST-mem $\mathcal{M}$ and initialization θ_0 of ST-net. The black dotted line in Figure 2 shows the process of knowledge transfer. For each new city c_t sampled from C_t, the

Algorithm 1: Framework of MetaST

Input: Set of target cities C_t; Set of source cities C_s; hyperparameter γ
Output: Spatial-temporal predictions of each target city

Randomly initialize θ_0 and $\mathcal{M}$;
Cluster all regions in C_s and get $\mathbf{o}_{r_c}$ for each region r_c;
/* learning θ_0 and $\mathcal{M}$ on source cities */
while *not done* **do**
  Sample a batch of cities from C_s;
  for *each city* c_s **do**
    Sample a set $\mathcal{D}_{c_s}$ from c_s;
    Evaluate $\nabla\mathcal{L}_{c_s}(f_{\theta_{c_s}})$ using $\mathcal{D}_{c_s}$ by Eq. (6);
    Compute adapted parameters θ_{c_s} with gradient descent by Eq. (8);
    Sample a new set $\mathcal{D}'_{c_s}$ from c_s;
    Evaluate $\mathcal{L}'_{c_s}(f_{\theta_s})$, $\mathcal{L}_{clu}(f_{\theta_{c_s}})$ by $\mathcal{D}'_{c_s}$;
  end
  Update θ_0, $\mathcal{M}$ by gradient descent;
end
/* Evaluate our model on target cities */
for *each city* c_t *in* C_t **do**
  Sample a sample set $\mathcal{D}_{c_t}$ from c_t;
  Compute adapted parameters θ_{c_t} with gradient descent by Eq. (15);
  Sample new series $\mathcal{D}'_{c_t}$ and predict;
end

memory is fixed and the parameters θ_{c_t} are trained with initialization θ_0 and training samples $\mathcal{D}_{c_t}$ (i.e., T-train in Figure 2), which is defined as:

$$\theta_{c_t} = \theta_0 - \alpha\nabla_\theta\mathcal{L}_{c_t}(f_\theta), \tag{15}$$

where $\mathcal{L}_{c_t}$ is the loss function of training set in target city t and the formulation is:

$$\mathcal{L}_{c_t} = \sum_{r_t}\sum_{k_t}(\hat{y}_{r_t,k_t+1} - y_{r_t,k_t+1})^2. \tag{16}$$

The predicted value $\hat{y}_{r_t,k_t+1}$ is calculated via Eq. (12). Hence, we distill knowledge of spatial-temporal patterns from source cities to target city via ST-mem $\mathcal{M}$. Finally, we evaluate the model $f_{\theta_{c_t}}$ on testing set $\mathcal{D}'_{c_t}$ (i.e., T-test in Figure 2) of city c_t and get the prediction value of this city. The whole framework of MetaST is shown in Algorithm 1.

5 EXPERIMENT

In this section, we conduct extensive experiments for two domain applications to answer the following research questions:

- Whether MetaST can outperform baseline methods for inference tasks, i.e., traffic volume prediction in and water quality (pH value) prediction?
- How do various hyper-parameters, e.g., the dimensions of each cluster in ST-mem or trade-off factor, impact the model's performance?
- Whether ST-mem can detect distinguished spatial-temporal patterns?

Table 1: Data Statistics of Traffic Prediction

Data	City	Time Span (m/d/y)	Trips	Size
Taxi	NYC	1/1/15-7/1/15	6,748,857	10×20
	DC	5/1/15-1/1/16	8,151,077	16×16
	Porto	7/1/13 - 6/30/14	1,710,671	20×10
	CHI	9/1/13-11/1/14	124,820	15×18
	BOS	10/1/12 - 10/31/12	839,897	18×15
Bike	NYC	1/1/17-12/31/17	16,364,475	10×20
	DC	1/1/17-12/31/17	3,732,263	16×16
	CHI	1/1/17-2/1/17	106,165	15×18

5.1 Application-*I*: Traffic Prediction

5.1.1 Problem Overview. We first conduct experiments on two traffic prediction tasks, i.e., taxi volume prediction and bike volume prediction. Similar as the previous traffic prediction task in [33, 41], each individual trip departs from a region, and then arrives at the destination region. Thus, our task is to predict the pick-up (start) and drop-off (end) volume of taxi (and bike) at each time interval for each region. The time inveral of traffic prediction task is one hour. We use *Root Mean Square Error* (RMSE) to evaluate our model, which is defined as:

$$\text{RMSE} = \frac{1}{|N|}\sqrt{\sum_{r_t}\sum_{k_t}(\hat{y}_{r_t,k_t+1} - y_{r_t,k_t+1})_2^2}, \tag{17}$$

where $\hat{y}_{r_t,k_t+1}$ and y_{r_t,k_t+1} represent predicted value and actual value, respectively. $|N|$ means the number of all samples in testing set.

5.1.2 Data Description. For taxi volume prediction, we collect five representative mobility datasets from five different cities to evaluate the performance of our proposed model, i.e., New York City (NYC)[1], Washington DC (DC), Chicago (CHI), Porto[2], and Boston (BOS). We use NYC, DC, Porto as the source cities and CHI, BOS as the target cities. Note that the Boston data does not have drop-off records, and thus we only report the results on predicting pick-up volume.

For bike volume prediction, we collect three datasets from four cities, i.e., NYC[3], DC[4], and CHI[5]. NYC and DC are used as source cities, and CHI are used as target city. All trips in the above datasets contain time and geographic coordinates of pick-up and drop-off. For each city above, as discussed before, we spatially divide them to a grid map. The grid map size of NYC, DC, CHI, BOS, Porto is 10×20, 16×16, 15×18, 18×15, 20×10, respectively. Detailed statistics of these datasets are listed in Table 1.

In addition, for each source city, we select 80% data for training and validation, and the rest for testing. For each target city, we select the 1-day, 3-day and 7-day data for training, and the rest for testing.

[5] https://www.divvybikes.com/system-data

5.1.3 Compared Baselines. We compare our model with the following two categories of methods: non-transfer methods and transfer methods. Note that, for non-transfer baselines, we only use the training data of target cities (limited training data) to train the model and use the testing data to evaluate it. For transfer baselines, we transfer the learned knowledge from source cities to improve the prediction accuracy.

Non-transfer baselines:

- **Historical Average (HA)**: For each region, HA predicts spatial-temporal value based on the average value of the previous relative time. For example, if we want to predict the pick-up volume at 9:00am-10:00am, HA is the average value of all time intervals from 9:00am to 10:00am in training data.
- **ARIMA**: Auto-Regressive Integrated Moving Average (ARIMA) is a traditional time-series prediction model, which considers the temporal relationship of data.
- **ST-net**: This method simply use the spatial-temporal neural network defined in Section 4.1 to predict traffic volume. Both pick-up and drop-off volume are predicted together.

Transfer baselines:

- **Fine-tuning Methods**: We include two types of fine-tuning methods: (1) Single-source fine-tuning (**Single-FT**): train ST-net in one source city (e.g., NYC, DC or Porto in taxi data) and fine-tune the model for target cities; and (2) multi-source fine-tune (**Multi-FT**): mix all samples from all source cities and fine-tune the model in target cities.
- **RegionTrans [27]**: RegionTrans transfers knowledge from one city to another city for traffic flow prediction. Since we do not have auxiliary data, we compare the S-Match of RegionTrans. For each region in target city, RegionTrans uses short period data to calculate the linear similarity value with each region in source city. Then, the similarity is used as regularization for fine-tuning. For fair comparison, the base model of RegionTrans (i.e., the ST-net) is same as MetaST.
- **MAML [2]**: an state-of-the-art meta-learning method, which learns a better initialization from multiple tasks to supervise the target task. MAML uses the same base model (i.e., the ST-net) as MetaST.

5.1.4 Experimental Settings.

Hyperparameter Setting. For ST-net, we set the number of filters in CNN as 64, the size of map in CNN as 7×7, the number of steps in LSTM as 8, and the dimension of hidden state of LSTM as 128. In the training process of taxi volume prediction, we set the learning rate of inner loop and outer loop as 10^{-5} and 10^{-5} respectively. For bike volume prediction, we set the learning rate of inner loop and outer loop as 10^{-5} and 10^{-6} respectively. The parameter γ is set as 10^{-4}. The number of updates for each task is set as 5. All the models are trained by Adam. The training batch size for each meta-iteration is set as 128, and the maximum of iteration of meta-learning is set as 20000.

Spatial-temporal Clustering. In addition, since the pattern of traffic volume usually repeats every day. Thus, in this work, we use averaged 24-hour patterns of each region to represent its spatial-temporal pattern. We use K-means to cluster these patterns to 4 groups. Furthermore, in this work, we do not use other external features, which means that $[\hat{\mathbf{y}}_{r_c,k_c};\mathbf{e}_{r_c,k_c}]$ in Eq. (4) equals to $\hat{\mathbf{y}}_{r_c,k_c}$. We set the size of pattern representation in memory as 8.

5.1.5 Results. We implement our model and compare it with the baselines on taxi and bike-sharing datasets. We run 20 testing times and report the average values. The results are shown in Table 2 and Table 3, respectively. According to these tables, we draw the following conclusions.

- Comparing with ST-net and some single-FT models, in some cases (e.g., 1-day training data), traditional time-series prediction methods (i.e., HA and ARIMA) achieves competitive performance in this problem. The reason is that traffic data show a strong daily periodicity, so that if we only have limited traffic data, we can still use periodicity to predict traffic volume.
- Comparing with ST-net, all transfer learning models (i.e., fine-tune models (including Single-FT and Multi-FT models), MAML, RegionTrans, MetaST) significantly improves the performance (i.e., lower the RMSE values). The results indicate that (1) it is difficult to train a model from random initialization with limited data; (2) the knowledge transfer between cities is effective for prediction.
- In most cases, Multi-FT outperforms Single-FT. One possible reason is that Multi-FT increases the diversity of source domain. In other cases (e.g., Chicago pick-up prediction with 3-day training data), the best performance of Single-FT outperforms Multi-FT. The results implicitly indicates that if there exists a source city that is optimally transferable to the target city, simply mixing other cities may hurt the performance.
- RegionTrans models only slightly outperform their corresponding fine-tuning models (i.e., RegionTrans from NYC to Chicago v.s., Single-FT from NYC to Chicago). The results suggest that regional linear similarity regularization may not capture complex relationship between regions. In addition, since the data from different cities are collected from different time, regional similarity calculations may be inaccurate. Thus, it is not an effective and flexible way to transfer knowledge via regional similarity regularization.
- MAML and MetaST achieve better performance than fine-tuning methods and RegionTrans. This is because fine-tuning methods and RegionTrans cannot be adapted to different scenarios, and thereby decreasing the stability of transfer. However, MAML and MetaST not only learn the initialization based on multiple cities, but also achieve the best performance in every scenario sampled from these cities.
- Our proposed MetaST achieves the best performance in all experimental settings. Comparing with MAML, the averaged relative improvement is 5.0%. This is because our model can also capture and transfer long-term information, besides learning a better initialization. Moreover, the long-term pattern memory helps learn a further enhanced initialization. The stability of knowledge transfer increases to the highest degree.
- Finally, we compare the results under different training data size in target city (i.e., 1-day, 3-day, and 7-day data). For every learning models (except HA and ARIMA), the performance improves with more training data. Our proposed MetaST still outperforms all baselines.

Table 2: Comparing with baselines for taxi volum prediction

Taxi Data		Chicago						Boston		
		Pick-up			Drop-off			Pick-up		
		1-day	3-day	7-day	1-day	3-day	7-day	1-day	3-day	7-day
HA		2.83	2.36	2.18	2.67	2.28	2.13	11.07	9.13	7.71

MAML		1.85	1.87	1.62	1.85	1.79	1.56
MetaST		**1.76****	**1.73****	**1.45****	**1.83****	**1.71****	**1.46****

[1]Due to the space limitation, in this table, SFT, RT mean single-FT and RegionTrans respectively.

** (*) means the result is significant according to Student's T-test at level 0.01 (0.05) compared to MAML.

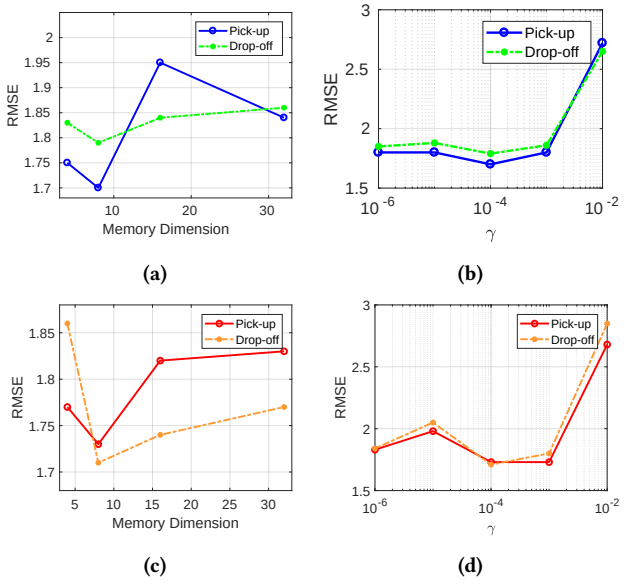

Figure 5: (a) (c) RMSE with respect to the dimension of spatial-temporal memory in Chicago taxi/bike volume prediction, respectively; (b) (d) RMSE with respect to the value of γ in Chicago taxi/bike volume prediction, respectively.

5.1.6 Parameter Sensitivity. MetaST involves a number of hyper-parameters. In this subsection, we evaluate how different selections of hyper-parameters impact our model's performance. Specifically, we analyze the impacts of two key parameters of spatial-temporal memory, i.e., the dimension d of pattern representation and the trade-off factor γ of two losses in the joint objective. All other hyperparameters are set as introduced in Section 5.1.4. We use the scenario of 3-day data for sensitivity analysis.

For the the dimension d of pattern representation, we change the dimension of pattern representation from 4 to 32 in spatial-temporal memory. The performance of Chicago taxi and bike volume prediction are shown in Figure 5a and Figure 5c, respectively. We find that the performance increases in the beginning but decreases later. One potential reason is that the spatial-temporal memory provides too little information when the dimension is too small, while it can

include too much irrelevant information when the dimension is too large. Both of the scenarios hurt the performance. Another experiment of trade-off factor γ also demonstrates similar assumption. We change the parameter γ in Eq. (14) from 10^{-6} to 10^{-2}. Higher value of γ means higher importance of spatial-temporal memory. The results of Chicago taxi and bike volume prediction are shown in Figure 5b and Figure 5d, respectively. We can see the similar change of the performance, increasing at first but decreasing later.

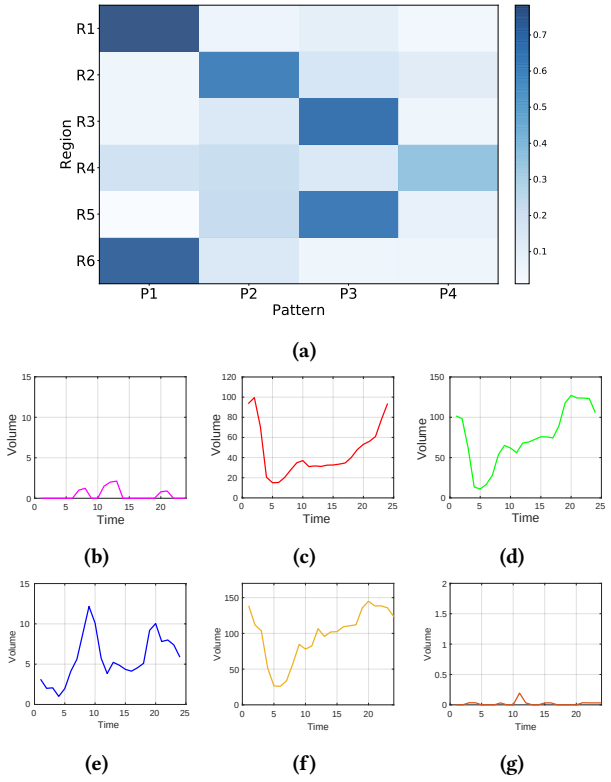

Figure 6: Spatial-temporal patterns detected by the memory $\mathcal{M}$ in Boston Taxi data. (a): probability of 4 pattern values of 6 regions; (b),(c),(d),(e),(f),(g) denote actual patterns of R1, R2, R3, R4, R5, R6, respectively.

5.1.7 Case Study: Visualization of Detected Patterns. To intuitively demonstrate the efficacy of the usage of the Spatial-temporal memory, we visualize patterns detected from Boston taxi pick-up volume prediction. We also use 3-day data for this case study. We randomly select six regions and show the similarity values with respect to each pattern category in the memory $\mathcal{M}$. The results are shown in Figure 6a. The corresponding actual patterns of each region are shown in Figure 6b, Figure 6c, Figure 6d, Figure 6e, Figure 6f, and Figure 6g respectively. We can see that the taxi pick-up volume of R1 and R6 is almost zero and their attention weights are also similar (Pattern 1 is activated). The volume distribution in R2, R3 and R5 have one peak. The peak time of R2 is around 1:00am - 2:00am (Pattern 2 is activated). The pattern and attention weights of R3 and R5 are similar and the peak time is around 8:00pm - 9:00pm (Pattern 3 is activated). In R4, the volume distribution has two peaks (Pattern 4 is activated). One peak is around 9:00am - 10:00am, another one is 8:00pm - 9:00pm. The results indicate that the memory can distinguish regions with different patterns.

5.2 Application-*II*: Water Quality Prediction

5.2.1 Problem Overview. The second application studied in this work is water quality prediction task. We also conduct a water quality prediction experiment. In this scenario, the water quality is represented by pH value of water, because pH value is easier to measure than other chemical metrics of water quality. We aim at predicting pH value in a specific location of next month (i.e., the time interval of water quality prediction is one month), as the changing of pH indicates the relative changes in the chemical composition in water. RMSE is still used as the evaluation metric in this task.

5.2.2 Dataset. The data used in this experiment is collected from the Water Quality Portal[6] of the National Water Quality Monitoring Council. It spans about 52 years from 1966 to 2017. Each record represents one surface water sample with longitude, latitude, date and pH value in a standard unit. The continental U.S. area is roughly split to six areas: Pacific, West, Midwest, Northeast, Southwest, South. Note that, in the water quality prediction task, the areas are treated as the cities in previous descriptions.

In addition, due to the sparsity of sampling points, we split each area into a grid region map, the size of each grid being 0.5°of latitude by 0.5°of longitude. Thus, the map sizes of all the six areas are 25×50, 30×25, 35×25, 30×25, 50×25, 45×25, respectively. The pH value of each region is represented by the median value of all sampling points in this region. We select Pacific, West, Midwest as source areas, and Northeast, Southwest, South as target areas.

5.2.3 Baselines. We use the same baselines as in the experiments for traffic prediction. Both non-transfer methods and transfer methods are used to evaluated our algorithm. Note that, when calculating HA, the relative time is monthly. For example, if we want to predict the water quality at May, HA is the average value of all pH values at May in training data.

5.2.4 Experimental Settings.

Hyperparameter Setting. Similar as the traffic prediction application, we do have external features in the water quality prediction task. For the learning process of spatial-temporal framework, we set the maximum of iterations as 5000, the number of filters in CNN as 32, the dimension of hidden states of LSTM as 64 and the size of memory representation as 4. Other hyperparameters are the same as traffic prediction.

Spatial-temporal Clustering. By analyzing the data, pH in the current month is strongly correlated with pH in the same month of previous year. Thus, we use the 12-month periodic pattern of each region. Similar as traffic prediction task, K-means is also used to cluster these patterns to 3 groups. DTW distance is used to measure the distance of K-means.

5.2.5 Results. We implement our model and compare with baselines on the water quality prediction task. We run 20 testing tasks and report the average values in Table 4. Most experiment results and their explanation are similar to traffic prediction. Besides, from this table, we observe that:

- Comparing with Multi-FT model, the performance of MAML only slightly improves in most cases. The potential reason is that the regions in the source areas may be homogeneous in short-term performance. Thus, compared to MAML which learning a initialization, simply mixing all samples (i.e., Multi-FT) may not significantly hurt the performance significantly.
- MetaST achieves the best performance compared with all baselines with the averaged relative improvement as 7.7%. Since MetaST provides more detailed long-term information by spatial-temporal memory and distills the long-term information to target city, which explicitly increases the diversity of regions in source domain.

5.2.6 Parameter Sensitivity. Following the same step of traffic prediction task, we investigate the effect of the dimension d of pattern representation and the trade-off factor γ of two losses in the joint objective on MetaST performance. The performance of d from 2 to 32 and γ from 10^{-7} to 10^{-2} on water quality value prediction is shown in Figure 7a and Figure 7b, respectively. Both Figure 7a and Figure 7b are evaluated on Northeast water quality prediction with 3-year training data. Accordingly, MetaST achieves the best performance when $d = 4$ and $\gamma = 10^{-4}$. Similar as the reasons in traffic prediction, the results indicate that suitable selection of d and γ lead to the best performance.

6 CONCLUSION AND DISCUSSION

In this paper, we study the problem of transferring knowledge from multiple cities for spatial-temporal prediction. We propose a novel MetaST model which leverages learned knowledge from multiple cities to help with the prediction in target data-scarce cities. Specifically, the proposed model learns a well-generalized initialization of spatial-temporal prediction model for easier adaptation. Then, MetaST a global pattern-based spatial-temporal memory from all source cities. We test our model on two spatial-temporal prediction problem from two different domains: traffic prediction and environment prediction. The results show the effectiveness and of our proposed model.

(a) (b)

Figure 7: (a) RMSE with respect to the dimension of spatial-temporal memory; (b) RMSE with respect to the value of γ.

For future work, we plan to investigate from two directions: (1) We plan to further consider network structure (e.g., road structure) and combine it with our proposed model. For example, a simple extension is that we can use graph convolutional network as our base model; (2) We plan to explain the black-box transfer learning framework, and analyze which information is transferred (e.g., spatial correlation, region functionality).

ABSTRACT

Recent advances in deep learning motivate the use of deep neural networks in Internet-of-Things (IoT) applications. These networks are modelled after signal processing in the human brain, thereby leading to significant advantages at perceptual tasks such as vision and speech recognition. IoT applications, however, often measure *physical phenomena*, where the underlying physics (such as inertia, wireless signal propagation, or the natural frequency of oscillation) are fundamentally a function of signal frequencies, offering better features in the *frequency domain*. This observation leads to a fundamental question: For IoT applications, can one develop a new brand of neural network structures that synthesize features inspired not only by the biology of human perception but also by the fundamental nature of physics? Hence, in this paper, instead of using conventional building blocks (*e.g.*, convolutional and recurrent layers), we propose a new foundational neural network building block, the Short-Time Fourier Neural Network (STFNet). It integrates a widely-used time-frequency analysis method, the Short-Time Fourier Transform, into data processing to learn features directly in the frequency domain, where the physics of underlying phenomena leave better footprints. STFNets bring additional flexibility to time-frequency analysis by offering novel nonlinear learnable operations that are spectral-compatible. Moreover, STFNets show that transforming signals to a domain that is more connected to the underlying physics greatly simplifies the learning process. We demonstrate the effectiveness of STFNets with extensive experiments on a wide range of sensing inputs, including motion sensors, WiFi, ultrasound, and visible light. STFNets significantly outperform the state-of-the-art deep learning models in all experiments. A STFNet, therefore, demonstrates superior capability as the fundamental building block of deep neural networks for IoT applications for various sensor inputs [1].

1 INTRODUCTION

Motivated by the needs of IoT applications, this paper presents a principled way of designing deep neural networks that learn (from IoT sensing signals) features inspired by the fundamental properties of the underlying domain of measurements; namely, properties of physical signals. We refer by IoT applications to those where sensors measure some physical quantities, generating (possibly complex and multi-dimentional) time-series data, typically reflecting some underlying physical process. The human brain (whose wiring inspires the structure of conventional neural networks) extracts features well-suited for *external perceptual* tasks, which explains the great success of such networks at those tasks. In contrast, the internal *physical processes* underlying sensor measurements in IoT systems have properties (such as physical intertia, characteristics of wireless signal propagation, and signal resonance) that depend more on signal *frequency*, motivating feature extraction in the *frequency domain*. It is no coincidence that much of classical signal processing literature works by transforming time-series data to the frequency domain first. To help capture signatures of internal physical processes the way a brain captures their externally perceived properties, this paper develops a new neural network block designed specifically for learning in the frequency domain.

The design of neural network structures greatly influences efficiency of signal modelling and ease of extraction of hidden patterns. Convolutional neural networks (CNNs) for image recognition, for example, align perfectly with biological studies of the visual cortex [13] and with domain knowledge in digital image processing [7]. We thus ask a fundamental question: what structures are well-suited for the domain of physical sensor measurements, which we henceforth call the domain of IoT?

Previous research on customizing deep learning models to the needs of IoT applications [16, 26, 31] mainly focused on designing neural network structures that integrate conventional deep learning components, such as convolutional and recurrent layers, to extract spatial and temporal properties of inputs. On the other hand, since the

physics of measured phenomena are best expressed in the frequency domain, decades of research on signal processing developed powerful techniques for time-frequency analysis of signals, including motion sensor signals [12, 23], radio frequency signals [19, 25], acoustic signals [3, 8], and visible light signals [17]. A popular transform that maps time-series measurements to the frequency domain is the Short-Time Fourier Transform (STFT). We, therefore, propose a new neural network model, namely, Short-Time Fourier Neural Networks (STFNets) that operate directly in the frequency domain.

One potential approach for learning in the frequency domain might simply be to convert sensing signals into the frequency domain first, and then apply conventional neural network components, possibly extending them to support operations on complex-numbers so they can represent frequency-domain quantities [24]. These approaches miss two key opportunities for improvement, described below, that we take advantage of in this work. As a result, our work leads to more accurate results, as shown in the evaluation section. The two reasons that account for our improvements are as follows.

First, different from traditional neural networks, where the internal representations constitute features with no physical meaning, the internal representations in STFNet leverage frequency domain semantics that encode time and frequency information. All operations and learnable parameters we propose are explicitly made compatible with the basic properties of spectral data, and align corresponding frequency and time components. In our design, we categorize spectral manipulations into three main types: filtering, convolution, and pooling. Filtering refers to the general spectral filtering and global template matching operation; convolution refers to the local motif detection including shift detection and local template detection; and pooling refers to dimension reduction over the frequency domain. We then design the spectral-compatible parameters and operating rules for these three manipulation categories respectively, which have shown superior performance in evaluations compared to the application of *conventional* neural networks in the domain of complex-numbers.

Second, transforming signals to the frequency domain is governed by the *uncertainty principle* [22]. The transformed representation cannot achieve both a high frequency resolution and a high time resolution at the same time. In STFT, the time-frequency resolution is controlled by the length of the sliding window (the length of the part of the time-series being converted at a time). With a longer window, we can obtain a finer-grained frequency representation. However, we then cannot achieve a time resolution smaller than the window size. The uncertainty principle causes a dilemma in traditional time-frequency analysis. One often needs to guess the best time-frequency resolution using trial and error. In STFNet, we circumvent this dilemma by simultaneously computing multiple STFTs with different time-frequency resolutions. The representations with different time-frequency resolutions are then mutually enhanced in a data-driven manner. The network then automatically learns the best resolution or resolutions, where the most useful features are present. STFNet defines a formal way to extract features from multiple time-frequency transformations with the same set of spectral-compatible operations and parameters, which greatly reduces model complexity while improving accuracy.

We demonstrate the effectiveness of STFNet through extensive experiments with various sensing modalities. During the evaluation, we focus on device-based and device-free human activity recognition with a broad range of sensing modalities, including motion sensors (accelerometer and gyroscopes), WiFi, ultrasound, and visible light. The experimental results validate the design settings of STFNets and illustrate their superior accuracy compared to the state-of-the-art deep learning frameworks for IoT applications.

Broadly speaking, the main contributions of this paper to the general research landscape of deep learning and IoT are twofold:

(1) STFNet presents a principled way of designing neural networks that reveal the key properties of physical processes underlying the sensing signals from the time-frequency perspective.
(2) STFNet unveils the benefit of incorporating domain-specific analytic modelling and transformation techniques into the neural network design.

The rest of paper is organized as follows. Section 2 introduces related work on deep learning in the context of mobile sensing as well as deep learning for spectral representations. We introduce the detailed technical design of STFNet in Section 3. The evaluation is presented in Section 4. Finally, we discuss the results in Section 5 and conclude in Section 6.

2 RELATED WORK

The impressive achievements in image classification using deep neural networks at the turn of the decade [15] precipitated a re-emergence of interest in deep learning. Deep neural networks have achieved significant accuracy improvements in a broad spectrum of areas, including computer vision [11, 21], natural language processing [1, 4], and network analysis [14, 18].

Recent efforts applied deep learning in the context of IoT. In order to improve the predictive accuracy of IoT applications, researchers employed deep learning to model complicated sensing tasks [16, 26]. In order to improve system efficiency at executing neural networks on low-end IoT devices, efforts have been made to compress model parameters and/or structures in a manner that does not entail (almost any) accuracy loss [2, 10, 27, 32]. Recent work in the context of IoT also addressed mathematical foundations for quantifying confidence in deep learning predictions to support mission-critical applications. The work produced deep neural networks that offer well-calibrated uncertainty estimates in results [5, 6, 28, 30]. Finally, the challenge of insufficient labeling of IoT data was addressed by introducing semi-supervised approaches for deep learning that allow neural network training using mostly *unlabeled* data [29]. However, none of the aforementioned IoT-inspired efforts addressed the customization of learning machinery to a different signal space inspired by the physics of measured processes; namely, the frequency domain.

To fill the above gap, recent work in machine learning focused on extending deep neural networks to complex numbers and spectral representations. Trabelsi et al. propose deep complex networks, investigating the complex-value neural network structure [24]. However, they mainly concentrate on the problems of initialization, normalization, and activation functions when extending real-valued operations directly into the complex-value domain. Their designs focus more on complex-value representations than spectral representations, and do not take the properties of spectral data into consideration. Rippel et al. study spectral representations for convolutional neural networks [20]. However, their study focuses on spectral parametrizing

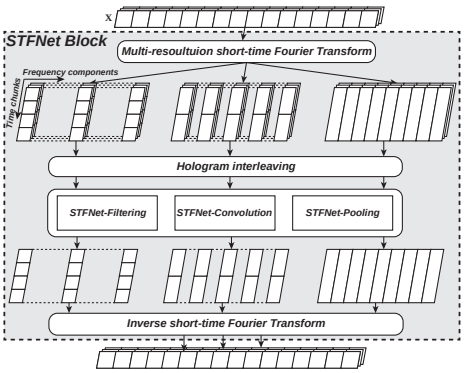

Figure 1: The overview design of STFNet block.

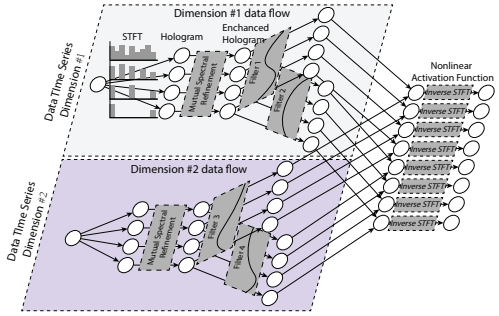

Figure 2: Data Flow within a block of STFNet.

of standard CNNs, instead of designing operations customized for spectral data. In addition, their work treats input data fully from the frequency perspective instead of the time-frequency perspective. Yao et al. propose a neural network that takes short-time Fourier transformed data as inputs [26]. Yet their design uses traditional CNNs and RNNs, combining the real and imagery parts of complex-value inputs as additional features.

To the best of our knowledge, STFNet is the first work that integrates neural networks with traditional time-frequency analysis, and designs fundamental spectral-compatible operations for Fourier-transformed representations. Our study shows that the approach leads to improved accuracy compared to the state of the art. It implies that integrating neural networks with domain-inspired transformation techniques (in our case, the Fourier Transform of physical time-series signals) projects input signals into a space that significantly facilitates the learning process.

3 SHORT-TIME FOURIER NEURAL NETWORKS

We introduce the technical details of STFNets in this section. We separate the technical descriptions into six parts. In the first two subsections, we provide some background followed by a high-level overview of STFNet components, including (i) hologram interleaving, (ii) STFNet-filtering, (iii) STFNet-convolution, and (iv) STFNet-pooling. In the remaining four subsections, we describe the technical details of each of these components, respectively.

3.1 Background and STFNet Overview

IoT devices sample the physical environment generating time-series data. Discrete Fourier Transform (DFT) is a mathematical tool that converts n samples over time (with a sampling rate of f_s) into a n components in frequency (with a frequency step of f_s/n). The more samples are selected, the finer the component resolution is in frequency. We can always transform the whole sequence of data with DFT, achieving a high frequency resolution. However, we then lose information on signal evolution over time, or the time resolution. In order to solve this problem, Short-Time Fourier Transform (STFT) divides a longer time signal into shorter segments of equal length and computes DTF separately on each shorter segment. By losing a certain degree of frequency resolution, STFT helps us regain the time resolution to some extent. In choosing n, there arises a fundamental trade-off between the attainable time and frequency resolution, which is called the *uncertainty principle* [22]. For the purposes of learning to pedict a given output, the optimal trade-off point depends on the time and frequency granularity of the features that best determine the outputs we want to reproduce. The goal of STFNets is thus to learn frequency domain features that predict the output, while at the same time learn the best resolution trade-off point in which the relevant features exist.

The building component of an STFNet is an *STFNet block*, shown in Figure 1. An STFNet block is the layer-equivalent in our neural network. The larger network would normally be composed by stacking such layers. Within each block, STFNet circumvents the uncertainty principle by computing multiple STFT representations with different time-frequency resolutions. Collectively, these representations constitute what we call the *time-frequency hologram*. And we call an individual time-frequency signal representation, a hologram representation. They are then used to mutually enhance each other by filling-in missing frequency components in each.

Candidate frequency-domain features are then extracted from these enhanced representations via general spectral manipulations that come in two flavors; filtering and convolution. They represent global and local feature extraction operations, respectively. The filtering and convolution kernels are learnable, making each STFNet layer a building block for spectral manipulation and learnable frequency domain feature extraction. In addition, we also design a new mechanism, called pooling, for frequency domain dimensionality reduction in STFNets. Combinations of features extracted using the above manipulations then pass through activation functions and an inverse STFT transform to produce (filtered) outputs in the time domain. Stacking STFNet blocks has the effect of producing progressively sharper (i.e., higher order) filters to shape the frequency domain signal representation into more relevant and more fine-tuned features.

Figure 2 gives an example of an SFTNet block that accepts as input a two-dimensional time-series signal (e.g., 2D accelerometers data). Each dimension is then transformed to the frequency domain at four different resolutions using STFT, generating four different internal nodes, each representing the signal in the frequency domain at a different time-frequency resolution. Collectively, the four representations constitute the hologram. In the next step, mutual enhancements are done improving all representations. Each representation then undergoes a variety of alternative spectral manipulations (called “filters" in the figure). Two filters are shown in the figure for each dimension. The parameters of these filters are the weights multiplied by the frequency components of the filter input; a different weight per component. These parameters are what the network learns. Note that, a filter does not change the time-frequency

resolution of the corresponding input. Filter outputs of the same time-frequency resolution are then combined additively across all dimensions and passed through a non-linear activation function (as in a conventional convolutional neural network). An inverse STFT brings each such combined output back to the time domain, where it becomes an input to the next STFNet block. (Alternatively, the inverse STFT can be applied after dimension combination and before the activation function.) Hence, each output time-series is produced by applying spectral manipulation and fusion to one particular time-frequency resolution of all input time-series. Once converted to the time domain, however, the output time-series can be resampled in the next block at different time-frequency resolutions again. The goal of STFNet is to learn the weighting of different frequency components within each filter in each block such that features are produced that best predict final network outputs.

3.2 STFNet Block Fundamentals

In this subsection, we introduce the formulation of our design elements wihin each STFNet block. In the rest of this paper, all vectors are denoted by bold lower-case letters (e.g., $\mathbf{x}$ and $\mathbf{y}$), while matrices and tensors are represented by bold upper-case letters (e.g., $\mathbf{X}$ and $\mathbf{Y}$). For a vector $\mathbf{x}$, the j^{th} element is denoted by $\mathbf{x}_{[j]}$. For a tensor $\mathbf{X}$, the t^{th} matrix along the third axis is denoted by $\mathbf{X}_{[\cdot,\cdot,t]}$, and other slicing denotations are defined similarly. We use calligraphic letters to denote sets (e.g., $\mathcal{X}$ and $\mathcal{Y}$). For set $\mathcal{X}$, $|\mathcal{X}|$ denotes the cardinality.

We denote the input to the STFNet block as $\mathbf{X} \in \mathbb{R}^{T \times D}$, where we divide the input D-dimension time-series into windows of size T samples. We call T the signal length and D the signal dimension. Since we concentrate on sensing signals, we assume that all the raw and internal-manipulated sensing signals are real-valued in time domain.

As shown in Figure 1, the input signal $\mathbf{X}$ first goes through a multi-resolution short-time Fourier transform (Multi_STFT), which is a compound traditional short-time Fourier transform (STFT), to provide a time-frequency hologram of the signal. STFT breaks the original signal up into chunks with a sliding window, where sliding window $\mathbf{W}(t)$ with width τ only has non-zero values for $1 \le t \le \tau$. Then each chunk is Discrete-Fourier transformed,

$$\mathbf{STFT}^{(\tau,s)}(\mathbf{X})_{[m,k,d]} = \sum_{t=1}^{T} \mathbf{X}_{[t,d]} \cdot \mathbf{W}(t - s \cdot m) \cdot e^{-j\frac{2\pi k}{\tau}(t - s \cdot m)}, \quad (1)$$

where $\mathbf{STFT}^{(\tau,s)}(\mathbf{X}) \in \mathbb{C}^{M \times K \times D}$ denotes the short-time Fourier transform with width τ and sliding step s. M denotes the number of time chunks. K denotes the number of frequency components. Since input signal $\mathbf{X}$ is real-valued, its discrete Fourier transform is conjugate symmetric. Therefore, we only need the $\lfloor \tau/2 \rfloor + 1$ frequency components to represent the signal, *i.e.*, $K = \lfloor \tau/2 \rfloor + 1$. In this paper, we focus on sliding chunks with rectangular window and no overlaps to simplify the formulation, *i.e.*, $s = \tau$ and $M = T/\tau$. We therefore denote of short-time Fourier transform as $\mathbf{STFT}^{(\tau)}(\mathbf{X})$.

The Multi_STFT operation is composed of multiple short-time Fourier transform with different window widths $\mathcal{T} = \{\tau_i\}$. The window width, τ_i, determines the time-frequency resolution of STFT. Larger τ_i provides better frequency resolution, while smaller τ_i provides better time resolution. In this paper, we set the window widths to be powers of 2, *i.e.*, $\tau_i = 2^{p_i}\ \forall p_i \in \mathbb{Z}_0^+$, to simplify the design later.

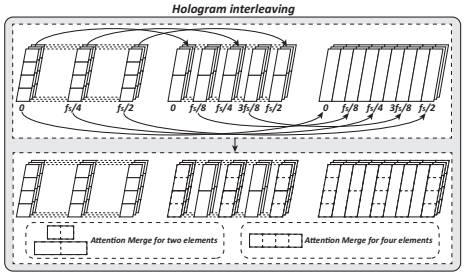

Figure 3: The design of hologram interleaving.

We can thus formulate Multi_STFT as:

$$\mathbf{Multi_STFT}^{(\mathcal{T})}\{\mathbf{X}\} = \left\{\mathbf{STFT}^{(\tau_i)}(\mathbf{X})\right\} \text{ for } 2^{p_i} \in \mathcal{T}. \quad (2)$$

Next, according to Figure 1, the multi-resolution representations go into the hologram interleaving component, which enables the representations to compensate and balance their time-frequency resolutions with each other. The technical details of the hologram interleaving component are introduced in Section 3.3.

The STFNet block then manipulates multiple hologram representations with the same set of spectral-compatible operation(s), including STFNet-filtering, STFNet-convolution, and STFNet-pooling. We will formulate these operations in Section 3.4, 3.5, and 3.6, respectively.

Finally, the STFNet block converts the manipulated frequency representations back into the time domain with the inverse short-time Fourier transform. The resulting representations from different views of the hologram are weighted and merged as the input "signal" for the next block. Since we merge the output representations from different views of the hologram, we reduce the output feature dimension of STFNet-filtering and convolution operations by the factor of $1/|\mathcal{T}|$ to prevent the dimension explosion.

3.3 STFNet Hologram Interleaving

In this subsection, we introduce the formulation of hologram interleaving. Due to the Fourier uncertainty principle, the representations in time-frequency hologram either have high time resolution or high frequency resolution. The hologram interleaving tries to use representations with high time resolution to instruct the representations with low time resolution to highlight the important components over time. This is done by two steps:

(1) Revealing the mathematical relationship of aligned time-frequency components among different representations in the time-frequency hologram.
(2) Updating the original relationship in a data-driven manner through neural-network attention components.

We start from the definition of time-frequency hologram, generated by Multi_STFT defined in (2). Note that, the window width set $\mathcal{T}$ is defined as $\{2^{p_i}\}$, $\forall p_i \in \mathbf{Z}_0^+$. Without loss of generality, an illustration of multi-resolution short-time Fourier transformed representations with input signal having length 16 and signal dimension 3 as well as $\mathcal{T} = \{4, 8, 16\}$ are illustrated in Figure 3.

In order to find out the relationship of aligned time-frequency components, we start with the frequency-component dimension. Since different representations only change the window width τ_i of STFT but not the sampling frequency f_s of input signal, these frequency components represent frequencies from 0 to $f_s/2$ (Nyquist frequency) with step f_s/τ_i. Then we can first obtain the relationship of frequency ranging steps among different representations,

$$\forall p_i > p_j\,,\ \frac{f_s/\tau_j}{f_s/\tau_i} = 2^{p_i-p_j} \in \mathbb{Z}_0^+. \tag{3}$$

Therefore, a low frequency-resolution representation (with window width 2^{p_j}) can find their frequency-equivalent counterparts for every $2^{p_i-p_j}$ frequency components in a high frequency-resolution representation (with window width 2^{p_i}). The upper part of Figure 3 provides a simple illustration of such relationship. In the following analysis, we will use the original index k and corresponding frequency $k \cdot f_s/\tau_i$ interchangeably to recall the frequency component from the time-frequency hologram $\mathbf{STFT}^{(\tau)}(\mathbf{X})_{[m,k,d]}$.

Next, we analyze the relationship over the time-chunk dimension, when two representations have frequency-equivalent components. Note that time chunks in $\mathbf{STFT}^{(\tau)}(\mathbf{X})$ are generated by sliding rectangular window without overlap. Based on (1), for representations having window widths $\tau_i = 2^{p_i}$ and $\tau_j = 2^{p_j}$ $(p_i > p_j)$,

$$\begin{aligned}
\mathbf{STFT}^{(\tau_i)}(\mathbf{X})_{[m,2^{p_i-p_j}k,d]} &= \sum_{t=2^{p_i}m+1}^{2^{p_i}(m+1)} \mathbf{X}_{[t,d]} \cdot e^{-j\frac{2\pi 2^{p_i-p_j}k}{2^{p_i}}(t-m\cdot 2^{p_i})}, \\
&= \sum_{m_j=2^{p_i-p_j}m}^{2^{p_i-p_j}(m+1)-1} \sum_{t=m_j+1}^{2^{p_j}(m_j+1)} \mathbf{X}_{[t,d]} \cdot e^{-j\frac{2\pi k}{2^{p_j}}(t-m\cdot 2^{p_j})}, \\
&= \sum_{m_j=2^{p_i-p_j}m}^{2^{p_i-p_j}(m+1)-1} \mathbf{STFT}^{(\tau_j)}(\mathbf{X})_{[m_j,k,d]}.
\end{aligned} \tag{4}$$

Therefore, given the equivalent frequency component, a time component in low time-resolution representation (with window width 2^{p_i}) is the sum of $2^{p_i-p_j}$ aligned time components of the high time-resolution representation (with window width 2^{p_j}). As a toy example in Figure 3, the first row of the middle tensor is equal to the sum of first two rows of the left tensor for frequencies 0, $f_s/4$, and $f_s/2$. The row of the right tensor is equal to the sum of four rows of the left tensor for frequencies 0, $f_s/4$, and $f_s/2$. The row of the right tensor is equal to the sum of two rows of the middle tensor for frequencies $f_s/8$ and $3f_s/8$, etc.

According to the analysis above, the high frequency-resolution representations lose their fine-grained time resolutions at certain frequencies by summing the corresponding frequency components up over a range of time. However, the high time-resolution representations preserve these information.

The idea of hologram interleaving is to replace the sum operation in high frequency-resolution representation with a weighted merge operation to highlight the important information over time. For a certain frequency component, the weight of merging is learnt through the most fine-grained information preserved in the time-frequency hologram. In this paper, we implement the weighted merge operation as a simple attention module. For a merging input $\mathbf{z} \in \mathbb{C}^{S\times 1}$, where S is the number of elements to be merged, the merge operation is formulated as:

$$\begin{aligned}
\mathbf{a} &= \mathrm{softmax}(|\mathbf{W}_m\mathbf{z}|), \\
y &= S \times \mathbf{a}^\top \mathbf{z},
\end{aligned} \tag{5}$$

where $|\cdot|$ is the piece-wise magnitude operation for complex-number vector; and $\mathbf{W}_m \in \mathbb{C}^{S\times S}$ is the learnable weight matrix. Notice that the final merged result is rescaled by the factor S to imitate the "sum" property of Fourier transform.

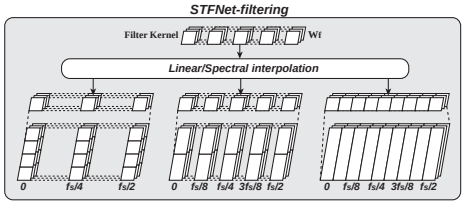

Figure 4: The STFNet-filtering operation.

3.4 STFNet-Filtering Operation

Starting from this subsection, we will introduce our three spectral-compatible operations in STFNet. In each subsection, the introduction includes two main parts: 1) the basic formulation of proposed spectral-compatible operation, and 2) extending a single operation to multi-resolution data.

Spectral filtering is a widely-used operation in time-frequency analysis. The STFNet-filtering operation replaces the traditional manually designed spectral filter with a learnable weight that can update during the training process. Although the spectral filtering is equivalent to the time-domain convolution according to convolution theorem [2], the filtering operation helps to handle the multi-resolution time-frequency analysis, and facilitates the parameterization and modelling. We denote the input tensor as $\mathbf{X} \in \mathbf{C}^{M\times K\times D}$, where M is the number of time chunk, K frequency component number, and D input feature dimension. The STFNet-filtering operation is formulated as:

$$\mathbf{Y}_{[m,k,\cdot]} = \mathbf{X}_{[m,k,\cdot]}\mathbf{W}_{f[k,\cdot,\cdot]}, \tag{6}$$

where $\mathbf{W}_f \in \mathbb{C}^{K\times D\times O}$ is the learnable weight matrix, O the output feature dimension, and $\mathbf{Y} \in \mathbb{C}^{M\times K\times O}$ the output representation.

The function of STFNet-filtering operation is providing a set of learnable global frequency template matchings over the time. However, it is not straightforward to extend the matching operation to the representations with different time-frequency resolutions. Although we can create multiple $\mathbf{W}_f$ with different frequency resolutions K, it can introduce unnecessary complexity and redundancy.

STFNet-filtering solves this problem by interpolating the frequency components in weight matrix. As we mentioned in Section 3.3, data in hologram with different frequency resolutions have the same frequency range (from 0 to $f_s/2$) but different frequency steps (f_s/τ). Therefore, STFNet-filtering operation only has one weight matrix $\mathbf{W}_f$ with $K = \lfloor \tau/2 \rfloor + 1$ frequency components. When the operation input has $K' = \lfloor \tau'/2 \rfloor + 1$ frequency components with $K' < K$, we can subsample the frequency components in $\mathbf{W}_f$. When $K' > K$, we interpolate the frequency components of $\mathbf{W}_f$. STFNet provides two kind of interpolation methods: 1) linear interpolation and 2) spectral interpolation.

The linear interpolation generates the missing frequency components in extended weight matrix $\mathbf{W}'_f \in \mathbb{C}^{K'\times D\times O}$ from the two neighbouring frequency components in $\mathbf{W}_f$:

$$\begin{aligned}
k_l &= \left\lfloor k'\frac{\tau}{\tau'} \right\rfloor \quad k_r = k_l + 1, \\
\mathbf{W}'_{f[k',\cdot,\cdot]} &= \mathbf{W}_{f[k_l,\cdot,\cdot]}\left(k_r - k'\frac{\tau}{\tau'}\right) + \mathbf{W}_{f[k_r,\cdot,\cdot]}\left(k'\frac{\tau}{\tau'} - k_l\right).
\end{aligned} \tag{7}$$

The spectral interpolation utilizes the relationship between discrete-time Fourier transform (DTFT) and discrete Fourier transform (DFT). For a time-limited signal (with length τ), DTFT regards

[2] https://en.wikipedia.org/wiki/Convolution_theorem

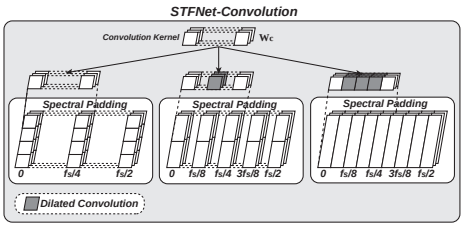

Figure 5: The STFNet-convolution operation with dilated configuration.

it as a infinite-length data with zeros outside the time-limited range, while DFT regards it as a τ-periodic data. As a result, DTFT generates a continuous function over the frequency domain, while DFT generates a discrete function. Therefore, DFT can be regarded as a sampling of DTFT with step f_s/τ. In order to increase the frequency resolution of $\mathbf{W}_f$, we can increase the sampling step from f_s/τ to f_s/τ', which is called spectral interpolation. Spectral interpolation can be done through zero padding in the time domain [22],

$$\mathbf{W}'_{f[\cdot,d,o]} = \mathbf{DFT}\Big(\mathbf{ZeroPad}_{\tau'-\tau}\mathbf{IDFT}\big(\mathbf{W}_{f[\cdot,d,o]}\big)\Big), \tag{8}$$

where $\mathbf{ZeroPad}_t$ denotes padding t zeros at the end of sequence, and $\mathbf{IDFT}(\cdot)$ denotes the inverse discrete Fourier transform. Please note that, if we pad infinite zeros to the IDFT result, then DFT turns into DTFT. An simple illustration of STFNet-filtering operation is shown in Figure 4.

3.5 STFNet-Convolution Operation

In this subsection, we introduce our design of STFNet-convolution operation. Other than filtering operation that handles global pattern matching, we still need the convolution operation to deal with local motifs in the frequency domain. We denote the input tensor as $\mathbf{X} \in \mathbf{C}^{M\times K\times D}$, where M is the number of time chunk, K number of frequency component, and D input feature dimension. The convolution operation involves two steps: 1) padding the input data, and 2) convolving with kernel weight matrix $\mathbf{W}_c \in \mathbb{C}^{1\times S\times D\times O}$, where S is the kernel size along the frequency axis and O is still the output feature dimension.

Without the padding step, the output of convolution operation will shrink the number of frequency components, which may break the underlying structure and information in the frequency domain. Therefore, we need to pad extra "frequency component" to keep the shape of output tensor unchanged compared to that of the input data. In the deep learning research, padding zeros is a common practice. Zero padding is reasonable for inputs such as images and signal in the time domain, meaning no additional information in the padding range. However, padding zero-valued frequency component introduces additional information in the frequency domain.

Therefore, STFNet-convolution operation proposes the spectral padding for time-frequency analysis. According to the definition of DFT, transformed data is periodic within the frequency domain. In addition, if the original signal is real-valued, then the transformed data is conjugate symmetric within each period. Previously, we cut the number of frequency components of a τ-length signal to $K = \lfloor \tau/2 \rfloor + 1$ for reducing the redundancy. In the spectral padding, we add these frequency components back according to the rule

$$\mathbf{X}_{[\cdot,\tau-k,\cdot]} = \mathbf{X}_{[\cdot,-k,\cdot]} = \mathbf{X}^*_{[\cdot,k,\cdot]}, \tag{9}$$

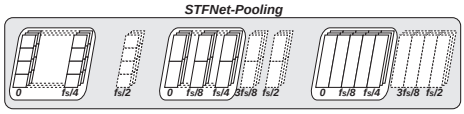

Figure 6: The low-pass STFNet-pooling operation.

where $\mathbf{X}^*$ denotes complex conjugation. In addition, the number of padding before and after the input tensor is same as the previous padding techniques.

Then we can define the basic convolution operation in STFNet

$$\mathbf{Y} = \mathbf{SpectralPad}(\mathbf{X}) \circledast \mathbf{W}_c, \tag{10}$$

where $\mathbf{SpectralPad}(\cdot)$ denotes our spectral padding operation, and $\circledast$ denotes the convolution operation.

Next, we discuss the way to share the kernel weight matrix $\mathbf{W}_c$ with multi-resolution data. Other than interpolating the kernel weight matrix as shown in (7) and (8), we propose another solution for the STFNet-convolution operation. The convolution operation concerns more about the pattern of relative positions on the frequency domain. Therefore, instead of providing additional kernel details on fine-grained frequency resolution, we can just ensure that the convolution kernel is applied with the same frequency spacing on representations with different frequency resolutions. Such idea can be implemented with the dilated convolution [33]. If $\mathbf{W}_c$ is applied to a input tensor with $K = \lfloor \tau/2 \rfloor + 1$ frequency components, for a input tensor with $K' = \lfloor \tau'/2 \rfloor + 1$ frequency components ($\tau' > \tau$), the dilated rate r is set to $\tau'/\tau - 1$. A simple illustration of STFNet-convolution with dilated configuration is shown in Figure 5.

3.6 STFNet-Pooling Operation

In order to provide a dimension reduction method for sensing series within STNet, we introduce the STFNet-pooling operation. STFNet-pooling truncates the spectral information over time with a predefined frequency pattern. As a widely-used processing technique, filtering zeroes unwanted frequency components in the signal. Various filtering techniques have been designed, including low-pass filtering, high-pass filtering, and band-pass filtering, which serve as templates for our STFNet-pooling. Instead of zeroing unwanted frequency components, STFNet-pooling removes unwanted components and then concatenates the left pieces. For applications with domain knowledge about signal-to-noise ratio over the frequency domain, specific pooling strategy can be designed. In this paper, we focus on low-pass STFNet-pooling as an illustrative example.

To extend the STFNet-pooling operation to multiple resolutions and preserving spectral information, we make sure that all representations have the same cut-off frequency according to their own frequency resolutions. A simple example of low-pass STFNet-pooling operation is shown in Figure 6. We can see that our three tensors are truncated according to the same cut-off frequency, $f_s/4$.

4 EVALUATION

In this section, we evaluate the STFNet with diverse sensing modularities. We focus on the device-based and device-free human activity recognitions with motion sensors (accelerometer and gyroscope), WiFi, ultrasound, and visible light. We first introduce the experimental setting, including data collection and baseline algorithms. Next, we show the performance metrics of leave-one-user-out evaluation of human activity recognition with different modularities. Finally, we analyze the effectiveness of STFNet through several ablation studies.

4.1 Experimental Settings

In this subsection, we first introduce detailed information of the dataset we used or collected for each evaluation task. Then we specify the way to test the performance of evaluation task.

Motion Sensor: In this experiment, we recognize human activity with motion sensors on smart devices. We use the dataset collected by Allan et al. [23]. This dataset contains readings from two motion sensors (accelerometer and gyroscope). Readings were recorded when users executed activities scripted in no specific order, while carrying smartwatches and smartphones. The dataset contains 9 volunteers, 6 activities (biking, sitting, standing, walking, climbStair-up, and climbStair-down). We align two sensor readings, linear interpolate two readings by 100Hz, and segment them into non-overlapping data samples with time interval 5.12s. Therefore, each data sample is a 512×6 matrix, where both accelerometer and gyroscope have readings on x, y, and z axis.

WiFi: In this experiment, we make use of Channel State Information (CSI) to analyze human activities. CSI refers to the known channel properties of a communication link, which can be affected by the presence of humans and their activities. We employ 11 volunteers (including both men and women) as the subjects and collect CSI data from 6 different rooms in two different buildings. In particular, we build a WiFi infrastructure, which includes a transmitter (a wireless router) and two receivers. We use the tool to report CSI values of 30 OFDM subcarriers [9]. The experiment contains 6 activities (wiping the whiteboard, walking, moving a suitcase, rotating the chair. sitting, as well as standing up and sitting down). We linearly interpolate the CSI data with a uniform sampling period, and down-sample the measurements into 100Hz. Then we segment the down-sampled CSI data into non-overlapping data samples with time interval 5.12s. Therefore, each data sample is a 512×30 matrix, where each CSI measurement has readings from 30 subcarriers.

Ultrasound: In this experiment, we conduct human activity recognition based on ultrasound. We employ 12 volunteers as the subjects to conduct the 6 different activities. The activity data are collected from 6 different rooms in two different buildings. The transmitter is an iPad on which an ultrasound generator app is installed, and it can emit an ultrasound signal of approximately 19 KHz. The receiver is a smartphone and we use the installed recorder app to collect the sound waves. We demodulate the received signal with carrier frequency 19KHz, and down-sample the measurement into 100Hz. Then we segment the down-sampled ultrasound data into non-overlapping data samples with time interval 5.12s. Therefore, each sample is a 512×1 matrix.

Visible light: In this experiment, we capture the human activity in the visible light system. We build an optical system using photoresistors to capture the in-air body gesture, which can detect the illuminance change (lux) caused by the body interaction. In the experiment, there are three light conditions (natural mode, warm mode, and cool mode) and 4 hand gestures (drawing an anticlockwise circle, drawing a clockwise circle, drawing a cross, and shaking hand side to side). We employ 6 volunteers as the subjects and each of them performs 20 trials of every gesture under a given lighting condition. We linearly interpolate and down-sample the measurements into 25Hz. Then we segment the data into non-overlapping data samples with time interval 5.12s. Therefore, each sample is a 128×6 matrix, where each measurement contains readings from 6 CdS cells.

Table 1: Illustration of models with two sensor inputs.

STFNet-Filter/Conv		DeepSense/ComplexNet	
Sensor Data 1	Sensor Data 2	Chunked Sensor Data 1	Chunked Sensor Data 2
STFNet1-1	STFNet1-2	Conv Layer1-1	Conv Layer1-2
STFNet2-1	STFNet2-2	Conv Layer2-1	Conv Layer2-2
STFNet3-1	STFNet3-2	Conv Layer3-1	Conv Layer3-2

Testing: In the whole evaluation, to illustrate the generalization ability of STFNet and other baseline models, we perform leave-one-user-out cross validation for every task. For each time, we choose the data from one user as testing data with the left as training data. We then compare the performance of models according to their accuracy and F1 score with 95% confidence interval.

4.2 Models in Comparison

In order to evaluate, when compared to conventional deep learning components (*i.e.*, convolutional and recurrent layers), whether our proposed STFNet component is better at decoding information and extracting features from sensing inputs, we substitute components in the state-of-the-art neural network structure for IoT applications with STFNet. In the whole evaluation, we choose DeepSense as the state-of-the-art structure, which has shown signifiant improvements on various sensing tasks [26]. The illustration of structures of five comparing models with two sensor inputs are shown in Table 1. Detailed information of our comparing models are listed as follows,

(1) ***STFNet-Filter:*** This model integrates the proposed STFNet component and the DeepSense structure. Within the STFNet component, we use the STFNet-filtering operation designed in Section 3.4. The intuition of DeepSense structure is to first perform local processing within each sensor and then perform global sensor fusion over multiple sensors. In this model, we replace all convolutional layers used in local/global sensor data processing with our time-frequency analyzing component, STFNet. Since our model has already incorporated time-domain analysis within the STFNet component through multi-resolution processing, we replace the Gated Recurrent Units (GRU) with simple feature averaging time at last.
(2) ***STFNet-Conv:*** This model is almost the same as the STFNet-Filter, except that we use the STFNet-convolution operation designed in Section 3.5.
(3) ***DeepSense-Freq:*** This model is the original DeepSense [26]. It divides the input sensing data into chunks, and processes each chunk with DFT. It treats the real and imagery parts of discrete Fourier transformed time chunks as the additional feature dimensions. This is the state-of-the-art deep learning model for sensing data modelling and IoT applications.
(4) ***DeepSense-Time:*** This model is almost the same as the DeepSense-Freq, except that it directly takes the chunked raw sensing data without DFT as input.
(5) ***ComplexNet:*** This model is a complex-value neural network [24] that can operate on complex-value inputs. Instead of using simple CNN and RNN structure as originally proposed [24], we cheat in their favor by using the DeepSense

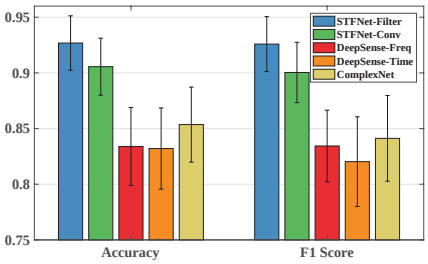

Figure 7: The accuracy and F1 score with 95% confidence interval for motion sensors.

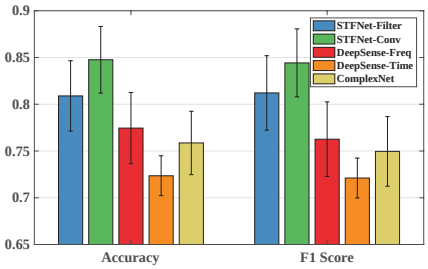

Figure 8: The accuracy and F1 score with 95% confidence interval for WiFi.

structure, which improves the performance in all tasks. The network inputs are chunked sensing data with DFT.

4.3 Effectiveness

In this section, we discuss about the effectiveness of our proposed STFNet based on extensive experiments and diverse sensing modalities, compared with other state-of-the-art deep learning models.

As we mentioned in Section 4.1, all models are evaluated through leave-one-user-out cross validation with accuracy and F1 score accompanied by the 95% confidence interval. STFNet-based models (STFNet-Filter and STFNet-Conv) take a sliding window set for multi-resolution short-time Fourier transform. We choose the set to be $\{16, 32, 64, 128\}$ for activity recognition with motion sensors, WiFi, and ultrasound; and choose set to be $\{8, 16, 32, 64\}$ for activity recognition with visible light. DeepSense-based models (DeepSense-Freq and DeepSense-Time) need a sliding window for chunking input signals. In the evaluation, we cheat in their favor by choosing the best-performing window size from $\{8, 16, 32, 64, 128\}$ according to the accuracy metric. In addition, we consistently configure STFNet-filtering operation with linear interpolation, and STFNet-convolution operation with spectral padding. We will show further evaluations on multi-resolution operations and the effects of diverse operation settings in Section 4.4.

4.3.1 Motion Sensors. For device-based activity recognition with motion sensors, there are 9 users. The accuracy and F1 score with the 95% confidence interval for leave-one-user-out cross validation are illustrated in Figure 7. STFNet based models, *i.e.*, STFNet-Filter and STFNet-Conv, outperform all other baseline models with a large margin. The confidence interval lower bound of STNet-Filter and STFNet-Conv is even better than the confidence interval upper bound of DeepSense-Freq and DeepSense-Time. STFNet-Filter performs better than STFNet-Conv in this experiment, indicating that different activities have distinct global profiling patterns with motion sensor readings in the frequency domain, even among different users.

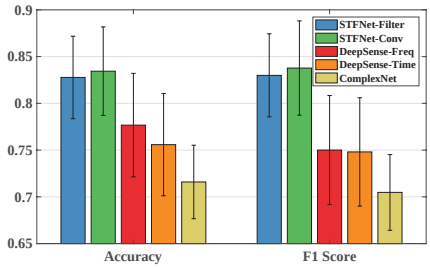

Figure 9: The accuracy and F1 score with 95% confidence interval for Ultrasound.

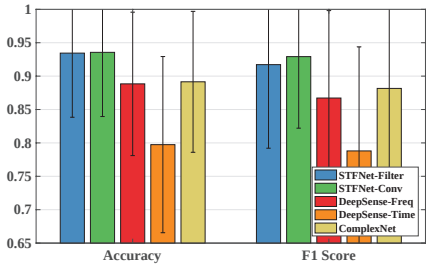

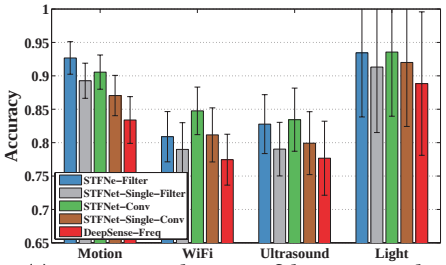

Figure 10: The accuracy and F1 score with 95% confidence interval for Visible light.

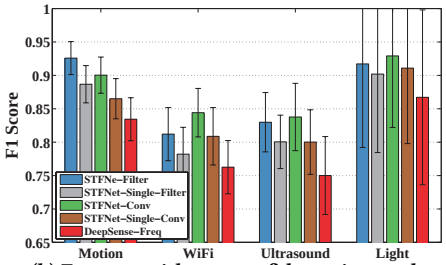
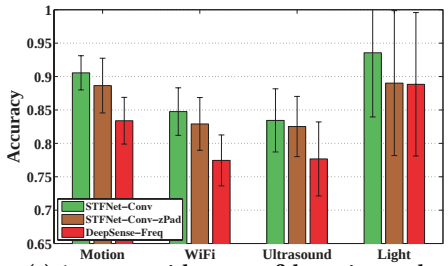
STFNet-Filter is able to learn the accurate global frequency profiling, which makes it the top-performance model in this task. In addition, compared to ComplexNet, STFNet based models show clear improvements. Therefore, using just complex-value neural network for sensing signal is far from enough. The multi-resolution processing and operations that are spectral-compatible are all crucial designs.



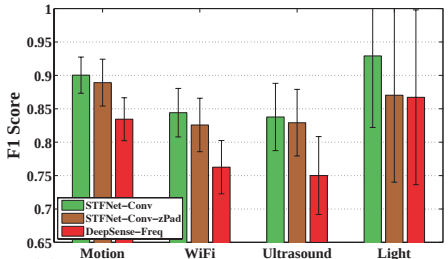
4.3.2 WiFi. For device-free activity recognition with WiFi signal, there are 11 users. The accuracy and F1 score with the 95% confidence interval for leave-one-user-out cross validation are illustrated in Figure 8. STFNet based models still outperform all others with a clear margin, illustrating the effectiveness of principled design of STFNet from time-frequency perspective. DeepSense-Freq outperforms DeepSense-Time in this experiment, which means that even having time-frequency transformation as pre-processing can help. The complex-value network, ComplexNet, performs worse than its real-value counterpart, DeepSense-Freq. This indicates that blindly processing time-frequency representations without preserving their physical meanings can even hurt the final performance. STNet-Conv performs better than STNet-Filter in the WiFi experiment, indicating that local shiftings in the frequency domain are more representative for diverse activities profiled with WiFi CSI.

4.3.3 Ultrasound. There are 12 users in device-free activity recognition with ultrasound experiment. The accuracy and F1 score with the 95% confidence interval for leave-one-user-out cross validation are illustrated in Figure 9. STFNet based models still significantly outperforms all other baselines. An interesting observation is that ComplexNet performs even worse than both DeepSense-Freq and DeepSene-Time, which again validates the importance of designing neural networks for sensing signal with multi-resolution processing as well as preserving the time and frequency information.

4.3.4 Visible Light. There are 6 users in the experiment of device-free activity recognition with visible light. The accuracy and F1 score with the 95% confidence interval are illustrated in Figure 10. Except



(a) Accuracy with 95% confidence interval.



(b) F1 score with 95% confidence interval.

Figure 11: Multi-Resolution v.s. Single-Resolution

(a) Accuracy with 95% confidence interval.

(b) F1 score with 95% confidence interval.

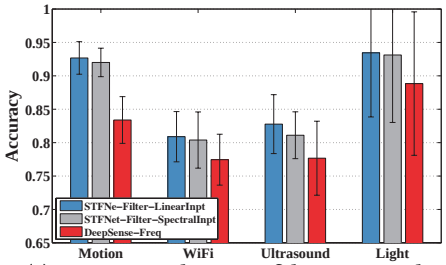
Figure 12: Spectral Padding v.s. Zero Padding

for the DeepSense-Time, all other models can can achieve an accuracy of approximately 90% or higher. STFNet based models still do the best. There is no significant difference between STFNet-Filter and STFNet-Conv, which indicates that measured visible light readings have quite clean representations in the frequency domain.

4.4 Ablation Studies

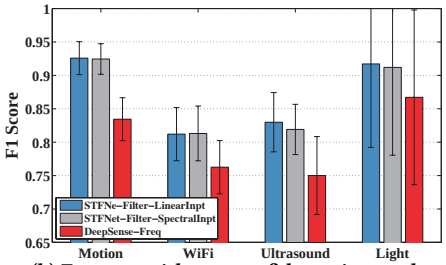
In the previous section, we illustrate the performance of STFNet compared to other state-of-the-art baselines. In this section, we focus mainly on the STFNet design. We conduct several ablation studies by deleting one designing feature from STFNet at a time.

4.4.1 Multi-Resolution v.s. Single-Resolution. First, we validate the effectiveness of our design of multi-resolution processing in STFNet block. As shown in Figure 1, this includes multi-resolution STFT, hologram interleaving, and weights sharing techniques in STFNet-Filtering and STFNet-Convolution operations. In this experiment, we add two more baseline models, STFNet-Single-Filter and STFNet-Single-Conv, generated by deleting the multi-resolution processing in STFNet-Filter and STFNet-Conv respectively. These two models pick the best-performing window size from $\{8, 16, 32, 64, 128\}$ according to the accuracy metric. The results for all four tasks are illustrated in Figure 11, where DeepSense-Freq severs as a decent performance low-bound. The design of multi-resolution processing significantly impacts the performance of STFNet. STFNet-Single-Filter and STFNet-Single-Conv show clear performance degradation compared to their multi-resolution counterparts. In addition, STFNet-Single-Filter and STFNet-Single-Conv still consistently outperform DeepSense-Freq with a clear margin. This is because our other designed operations, including STFNet-Filtering, STFNet-Convolution, STFNet-Pooling still facilitate the learning in time-frequency domain.



4.4.2 Spectral Padding v.s. Zero Padding. Next, we validate our design of spectral padding in the STFNet-Convolution operation as shown in Figure 5. In this experiment, we add a new baseline algorithm, STFNet-Conv-zPad, by replacing spectral padding with traditional zero padding in the STFNet-Conv. The accuracy and F1 score of all four tasks are shown in Figure 12. Here, DeepSense-Freq is still treated as a performance low-bound. By comparing STFNet-Conv-zPad and STFNet-Conv, we can see that spectral padding consistently helps improving the model performance. In most cases, the improvement is limited. However, in the case of visible light, spectral padding significantly improves both accuracy and F1 score. Therefore, designing neural network by preserving the time-frequency semantics of sensing signal is an important rule to follow.

4.4.3 Linear Interpolation v.s. Spectral Interpolation. Then, we compare our two designs of weight interpolation method in the STFNet-Filtering operation, linear interpolation and spectral interpolation, as shown in Figure 4. The STFNet-Filter defined in Section 4.2 uses linear interpolation, so we rename it as STFNet-Filter-LinearInpt in this experiment. We add a new baseline model called STFNet-Filter-SpectralInpt by using spectral interpolation instead of linear interpolation in STFNet-Filter. The results of all four tasks are illustrated in Figure 13. In general, the performance of two design choices are almost the same. At most of time, linear interpolation performs slightly better. In addition, we recommend using linear interpolation, since its implementation is easier,



4.4.4 STFNet Pooling v.s. Mean/Max Pooling. Finally, we validate our design of STFNet-Pooling (low-pass deisgn) as shown in Figure 6. In this experiment, we add two new baseline algorithms, STFNet-Filter-mPad and STFNet-Conv-mPad, by replacing STFNet-Pooling in STFNet-Filter and STFNet-Conv with traditional max/mean pooling in the time domain (through choosing the one has better accuracy). The results are illustrated in Figure 14. In all settings, STFNet-Pooling shows better performance. In some cases, the improvement are significant. We believe that STFNet-Pooling can achieve even better performance if given the detailed signal-to-noise ratio over the frequency domain for each specific sensor. Then we can employ other pooling strategies instead of the low-pass design.

5 DISCUSSION

This paper provides a principled way of designing neural networks for sensing signals inspired by the fundamental nature of the underlying physical processes. STFNet, operates directly in the frequency

domain, in which the measured physical phenomena are best exposed. We propose three types of learnable frequency manipulations that are able to operate on multi-resolution representations, while preserving the underlying time-frequency information. Although extensive experiments have illustrated the superior performance of STFNet, further research is needed to better understand design choices for neural networks from the time-frequency perspective.

One challenge is to explore the possibility of integrating neural networks with other time-frequency transformations. In this paper, STFNet focuses on the short-time Fourier Transform. However, STFT is the most basic one. There are plenty of other transformation basis functions in traditional time-frequency analysis. How to naturally integrate them with neural network while keeping the underlying physical meaning within transformed representations? How to choose or design the most suitable transformation basis functions that meet the corresponding mathematical requirements? Answers to these questions can greatly impact the way researchers design neural networks for sensing signal processing. Another challenge is to empower the frequency manipulations to have heterogeneous behaviours over the time. In STFNet, all designed operations are learnable frequency manipulations, which perform identically over time. In order to fully exploit the potential of time-frequency analysis, further research is needed on designing time-varying time-frequency manipulations, that adapt to current temporal patterns.

Furthermore, a better experimental and theoretical understanding is needed of the basic settings of neural networks to support computation in time-frequency domain. For traditional real-value neural networks, researchers have good intuitions about the basic configurations of initialization, activation functions, dropout and normalization techniques, and optimization methods. However, for neural network in the time-frequency domain, our understanding is limited. Although the reseach community started to study the basic settings of neural networks with complex values [24], the current understanding remains preliminary. Time-frequency analysis can have operations in both the real and complex domains. At the same time, the underlying time-frequency information within the internal representations can make the related studies even more complicated. We believe that this understanding will greatly facilitate future design of deep learning systems for IoT.

In addition, outside the IoT context, there exists a large number of transformations and dimension reduction techniques, such as SVD and PCA, that have made great impact in revealing useful features of complex phenomena. Our study of deep learning with STFT suggests that integrating deep neural networks with other common transformations may facilitate learning in domains where such transformations reveal essential features of the input signal domain. Future work is needed to explore this conjecture.

6 CONCLUSION

In this paper, we introduced STFNet, a principled way of designing neural networks from the time-frequency perspective. STFNet endows time-frequency analysis with additional flexibility and capability. In addition to just parameterizing the frequency manipulations with deep neural networks, we bring two key insights into the design of STFNet. On one hand, STFNet leverages and preserves the frequency domain semantics that encode time and frequency information. On the other hand, STFNet circumvents the uncertainty principle through multi-resolution transform and processing. Evaluations show that STFNet consistently outperforms the state-of-the-art deep learning models with a clear margin under diverse sensing modalities, and our two designing insights significantly contribute to the improvement. The designs and evaluations of STFNet unveil the benefits of incorporating domain-specific modeling and transformation techniques into neural network design.

ABSTRACT

To accelerate software development, much research has been performed to help people understand and reuse the huge amount of available code resources. Two important tasks have been widely studied: *code retrieval*, which aims to retrieve code snippets relevant to a given natural language query from a code base, and *code annotation*, where the goal is to annotate a code snippet with a natural language description. Despite their advancement in recent years, the two tasks are mostly explored separately. In this work, we investigate a novel perspective of *Code annotation for Code retrieval* (hence called "CoaCor"), where a code annotation model is trained to generate a natural language annotation that can represent the semantic meaning of a given code snippet and can be leveraged by a code retrieval model to better distinguish relevant code snippets from others. To this end, we propose an effective framework based on reinforcement learning, which explicitly encourages the code annotation model to generate annotations that can be used for the retrieval task. Through extensive experiments, we show that code annotations generated by our framework are much more detailed and more useful for code retrieval, and they can further improve the performance of existing code retrieval models significantly.[1]

1 INTRODUCTION

Software engineering plays an important role in modern society. Almost every aspect of human life, including health care, education, transportation and web security, depends on reliable software [1]. Unfortunately, developing and maintaining large code bases are very costly. Understanding and reusing billions of lines of code in online open-source repositories can significantly speed up the software development process. Towards that, *code retrieval* (CR) and *code annotation* (CA) are two important tasks that have been widely studied in the past few years [1, 13, 19, 21, 58], where the former aims to retrieve relevant code snippets based on a natural language (NL) query while the latter is to generate natural language descriptions to describe what a given code snippet does.

Most existing work [2, 13, 19, 22, 58, 60] study either code annotation or code retrieval individually. Earlier approaches for code retrieval drew inspiration from the information retrieval field [14, 17, 23, 32] and suffered from surface form mismatches between natural language queries and code snippets [6, 34]. More recently, advanced deep learning approaches have been successfully applied to both code retrieval and code annotation [1, 2, 9, 13, 19–22, 31, 58, 60]. For example, the code retrieval model proposed by Gu et al. [13] utilized two deep neural networks to learn the vector representation of a natural language query and that of a code snippet respectively, and adopted cosine similarity to measure their matching degree. For code annotation, Iyer et al. [21] and Hu et al. [19] utilized encoder-decoder models with an attention mechanism to generate an NL annotation for a code snippet. They aim to generate annotations similar to the human-provided ones, and therefore trained the models using the standard maximum likelihood estimation (MLE) objective. For the same purpose, Wan et al. [58] trained the code annotation model in a reinforcement learning (RL) framework with reward being the BLEU score [41], which measures n-gram matching precision between the currently generated annotation and the human-provided one.

In this work, we explore a novel perspective - code annotation *for* code retrieval (CoaCor), which is to generate an NL annotation for a code snippet so that the generated annotation *can be used for code retrieval* (i.e., *can represent the semantic meaning of a code snippet and distinguish it from others w.r.t. a given NL query in the code retrieval task*). As exemplified by [56], such an annotation can be taken as the representation of the corresponding code snippet, based on which the aforementioned lexical mismatch issue in a naive keyword-based search engine can be alleviated. A similar idea of improving retrieval by adding extra annotations to items is also explored in document retrieval [47] and image search [61]. However, most of them rely on humans to provide the annotations. Intuitively, our perspective can be interpreted as one type of *machine-machine collaboration*: On the one hand, the NL annotation generated by the code annotation model can serve as a second view of a code snippet (in addition to its programming content) and can be utilized to match with an NL query in code retrieval. On the other hand, with

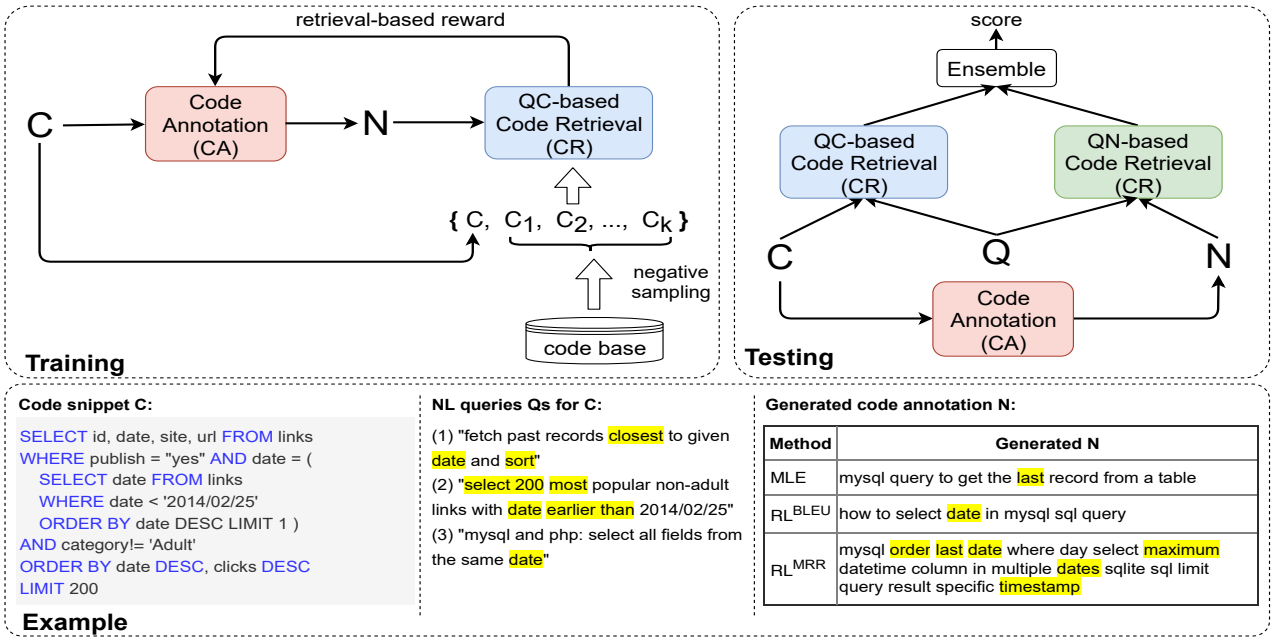

Figure 1: Our CoaCor framework: (1) *Training phase.* A code annotation model is trained via reinforcement learning to maximize retrieval-based rewards given by a QC-based code retrieval model (pre-trained using <NL query, code snippet> pairs). (2) *Testing phase.* Each code snippet is first annotated by the trained CA model. For the code retrieval task, given query Q, a code snippet gets two scores - one matching Q with its code content and the other matching Q with its code annotation N, and is ranked by a simple ensemble strategy[+]. (3) *Example.* We show an example of a code snippet and its associated multiple NL queries in our dataset. The code annotation generated by our framework (denoted as RL^{MRR}) is much more detailed with many keywords *semantically aligned* with Qs, when compared with CA models trained via MLE or RL with BLEU rewards (RL^{BLEU}). [+] We simply use a weighted combination of the two scores, and other ensemble strategies can also apply here.

a goal to facilitate code retrieval, the code annotation model can be stimulated to produce rich and detailed annotations. Unlike existing work [19–21, 58], our goal is *not* to generate an NL annotation as close as possible to a human-provided one; hence, the MLE objective or the BLEU score as rewards for code annotation will not fit our setting. Instead, we design a novel rewarding mechanism in an RL framework, which guides the code annotation model directly based on how effectively the currently generated code annotation distinguishes the code snippet from a candidate set.

Leveraging collaborations and interactions among machine learning models to improve the task performance has been explored in other scenarios. Goodfellow et al. [12] proposed the Generative Adversatial Nets (GANs), where a generative model produces difficult examples to fool a discriminative model and the latter is further trained to conquer the challenge. He et al. [15] proposed another framework called *dual learning*, which jointly learns two dual machine translation tasks (e.g., En -> Fr and Fr -> En). However, none of the existing frameworks are directly applicable to accomplish our goal (i.e., to train a code annotation model for generating annotations that can be utilized for code retrieval).

Figure 1 shows our reinforcement learning-based CoaCor framework. In the training phase, we first train a CR model based on <natural language query, code snippet> (QC) pairs (referred to as QC-based CR model). Then given a code snippet, the CA model generates a sequence of NL tokens as its annotation and receives a reward from the trained CR model, which measures how effectively the generated annotation can distinguish the code snippet from others. We formulate the annotation generation process as a Markov Decision Process [5] and train the CA model to maximize the received reward via an advanced reinforcement learning [53] framework called *Advantage Actor-Critic* or *A2C* [36]. Once the CA model is trained, we use it to generate an NL annotation N for each code snippet C in the code base. Therefore, for each QC pair we originally have, we can derive a QN pair. We utilize the generated annotation as a second view of the code snippet to match with a query and train another CR model based on the derived QN pairs (referred to as QN-based CR model). In the testing phase, given an NL query, we rank code snippets by combining their scores from both the QC-based as well as QN-based CR models, which utilize both the programming content as well as the NL annotation of a code snippet.

On a widely used benchmark dataset [21] and a recently collected large-scale dataset [63], we show that the automatically generated annotation can significantly improve the retrieval performance. More impressively, without looking at the code content, the QN-based CR model trained on our generated code annotations obtains a retrieval performance comparable to one of the state-of-the-art

QC-based CR models. It also surpasses other QN-based CR models trained using code annotations generated by existing CA models.

To summarize, our major contributions are as follows:

- First, we explored a novel perspective of generating useful code annotations *for* code retrieval. Unlike existing work [19, 21, 58], we do not emphasize the n-gram overlap between the generated annotation and the human-provided one. Instead, we examined the real usefulness of the generated annotations and developed a machine-machine collaboration paradigm, where a code annotation model is trained to generate annotations that can be used for code retrieval.
- Second, in order to accomplish our goal, we developed an effective RL-based framework with a novel rewarding mechanism, in which a code retrieval model is directly used to formulate rewards and guide the annotation generation.
- Last, we conducted extensive experiments by comparing our framework with various baselines including state-of-the-art models and variants of our framework. We showed significant improvements of code retrieval performance on both a widely used benchmark dataset and a recently collected large-scale dataset.

The rest of this paper is organized as follows. Section 2 introduces the background on code annotation and code retrieval tasks. Section 3 gives an overview of our proposed framework, with algorithm details followed in Section 4. Experiments are shown in Section 5. Finally, we discuss related work and conclude in Section 6 and 7.

2 BACKGROUND

We adopt the same definitions for code retrieval and code annotation as previous work [9, 21]. Given a natural language query Q and a set of code snippet candidates $\mathbb{C}$, *code retrieval* is to retrieve code snippets $C^* \in \mathbb{C}$ that can match with the query. On the other hand, given a code snippet C, *code annotation* is to generate a natural language (NL) annotation N^* which describes the code snippet appropriately. In this work, we use *code search* and *code retrieval* interchangeably (and same for *code annotation/summary/description*).

Formally, for a training corpus with <natural language query, code snippet> pairs, e.g., those collected from Stack Overflow [51] by [21, 63], we define the two tasks as:

Code Retrieval (CR): Given an NL Query Q, a model F_r will be learnt to retrieve the highest scoring code snippet $C^* \in \mathbb{C}$.

$$C^* = \underset{C \in \mathbb{C}}{\operatorname{argmax}} F_r(Q, C) \tag{1}$$

Code Annotation (CA): For a given code snippet C, the goal is to generate an NL annotation N^* that maximizes a scoring function F_a:

$$N^* = \underset{N}{\operatorname{argmax}} F_a(C, N) \tag{2}$$

Note that one can use the same scoring model for F_r and F_a as in [9, 21], but for most of the prior work [13, 19, 20, 58], which consider either code retrieval or code annotation, researchers usually develop their own models and objective functions for F_r or F_a. In our work, we choose two vanilla models as our base models for CR and CA, but explore a novel perspective of how to train F_a so that it can generate NL annotations that can be used for code retrieval. This perspective is inspired by various machine-machine collaboration mechanisms [15, 28, 55, 59] where one machine learning task can help improve another.

3 FRAMEWORK OVERVIEW

In this section, we first introduce our intuition and give an overview of the entire framework, before diving into more details.

3.1 Intuition behind CoaCor

To the best of our knowledge, previous code annotation work like [19–21, 58] focused on getting a large n-gram overlap between generated and human-provided annotations. However, it is still uncertain (and non-trivial to test) how helpful the generated annotations can be. Driven by this observation, we are the first to examine the real usefulness of the generated code annotations and how they can help a relevant task, of which we choose code retrieval as an example.

Intuitively, CoaCor can be interpreted as a *collaboration mechanism* between code annotation and code retrieval. On the one hand, the annotation produced by the CA model provides a second view of a code snippet (in addition to its programming content) to assist code retrieval. On the other hand, when the CA model is trained to be useful for the retrieval task, we expect it to produce richer and more detailed annotations, which we verify in experiments later.

3.2 Overview

The main challenge to realize the above intuition lies in how to train the CA model effectively. Our key idea to address the challenge is shown in Figure 1.

We first train a base CR model on <natural language query, code snippet> (QC) pairs. Intuitively, a QC-based CR model ranks a code snippet C by measuring how well it matches with the given query Q (in comparison with other code snippets in the code base). From another point of view, a well-trained QC-based CR model can work as a measurement on whether the query Q describes the code snippet C precisely or not. Drawing inspiration from this view, we propose using the trained QC-based CR model to determine whether an annotation describes its code snippet precisely or not and thereby, train the CA model to generate rich annotations to maximize the retrieval-based reward from the CR model. Specifically, given a code snippet C, the CA model generates a sequence of NL words as its annotation N. At the end of the sequence, we let the trained QC-based CR model use N to search for relevant code snippets from the code base. If C can be ranked at top places, the annotation N is treated as well-written and gets a high reward; otherwise, a low reward will be returned. We formulate this generation process as the Markov Decision Process [5] and train the CA model with reinforcement learning [53] (specifically, the *Advantage Actor-Critic* algorithm [36]) to maximize the retrieval-based rewards it can receive from the QC-based CR model. We elaborate the CR and CA model details as well as the RL algorithm for training the CA model in Section 4.1 ∼ 4.3.

Once the CA model is trained, in the testing phase, it generates an NL annotation N for each code snippet C in the code base. Now for each <NL query, code snippet> pair originally in the datasets,

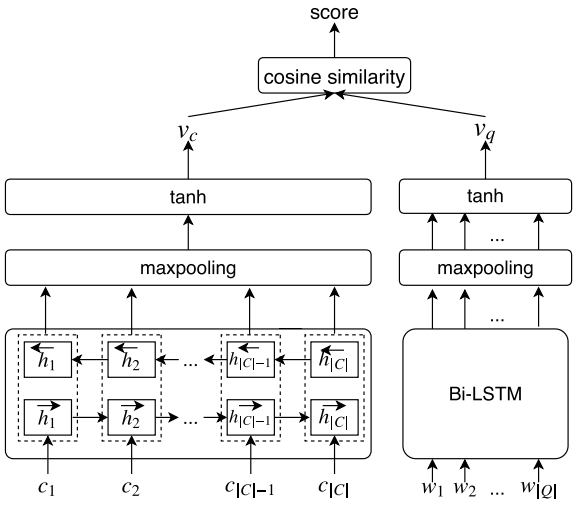

Figure 2: The base code retrieval model encodes the input code snippet C = $(c_1, c_2, ..., c_{|C|})$ and NL query Q = $(w_1, w_2, ..., w_{|Q|})$ into a vector space and outputs a similarity score.

we derive an <NL query, code annotation> (QN) pair and train another CR model based on such QN pairs. This QN-based CR model complements the QC-based CR model, as they respectively use the annotation and programming content of a code snippet to match with the query. We finally combine the matching scores from the two CR models to rank code snippets for a given query.

Note that we aim to outline a general paradigm to explore the perspective of code annotation for code retrieval, where the specific model structures for the two CR models and the CA model can be instantiated in various ways. In this work, we choose one of the simplest and most fundamental deep structures for each of them. Using more complicated model structures will make the training more challenging and we leave it as future work.

4 CoDE ANNOTATION FOR CoDE RETRIEVAL

Now we introduce model and algorithm details in our framework.

4.1 Code Retrieval Model

Both QC-based and QN-based code retrieval models adopt the same deep learning structure as the previous CR work [13]. Here for simplicity, we only illustrate the QC-based CR model in detail, and the QN-based model structure is the same except that we use the generated annotation on the code snippet side.

As shown in Figure 2, given an NL query $Q = w_{1..|Q|}$ and a code snippet $C = c_{1..|C|}$, we first embed the tokens of both code and NL query into vectors through a randomly initialized word embedding matrix, which will be learned during model training. We then use a bidirectional Long Short-Term Memory (LSTM)-based Recurrent Neural Network (RNN) [10, 11, 18, 35, 48, 64] to learn the token representation by summarizing the contextual information from both directions. The LSTM unit is composed of three multiplicative gates. At every time step t, it tracks the state of sequences by controlling how much information is updated into the new hidden state h_t and memory cell g_t from the previous state h_{t-1}, the previous memory cell g_{t-1} and the current input x_t. On the code side, x_t is the embedding vector for c_t, and on the NL query side, it is the embedding vector for w_t. At every time step t, the LSTM hidden state is updated as:

$$
\begin{aligned}
i &= \sigma(\mathbf{W}_i h_{t-1} + \mathbf{U}_i x_t + b_i) \\
f &= \sigma(\mathbf{W}_f h_{t-1} + \mathbf{U}_f x_t + b_f) \\
o &= \sigma(\mathbf{W}_o h_{t-1} + \mathbf{U}_o x_t + b_o) \\
g &= \tanh(\mathbf{W}_g h_{t-1} + \mathbf{U}_g x_t + b_g) \\
g_t &= f \odot g_{t-1} + i \odot g \\
h_t &= o \odot \tanh(g_t)
\end{aligned}
$$

where σ is the element-wise sigmoid function and $\odot$ is the element-wise product. $\mathbf{U}_i, \mathbf{U}_f, \mathbf{U}_g, \mathbf{U}_o$ denote the weight matrices of different gates for input x_t and $\mathbf{W}_i$, $\mathbf{W}_f$, $\mathbf{W}_g$, $\mathbf{W}_o$ are the weight matrices for hidden state h_t, while b_i, b_f, b_g, b_o denote the bias vectors. For simplicity, we denote the above calculation as below (the memory cell vector g_{t-1} is omitted):

$$h_t = \text{LSTM}(x_t, h_{t-1}) \tag{3}$$

The vanilla LSTM's hidden state h_t takes information from the past, knowing nothing about the future. Our CR model instead incorporates a bidirectional LSTM [48] (i.e., Bi-LSTM in Figure 2), which contains a forward LSTM reading a sequence X from start to end and a backward LSTM which reads from end to start. The basic idea of using two directions is to capture past and future information at each step. Then the two hidden states at each time step t are concatenated to form the final hidden state h_t.

$$
\begin{aligned}
\overrightarrow{h_t} &= \text{LSTM}(x_t, \overrightarrow{h_{t-1}}) \\
\overleftarrow{h_t} &= \text{LSTM}(x_t, \overleftarrow{h_{t+1}}) \\
h_t &= [\overrightarrow{h_t}, \overleftarrow{h_t}]
\end{aligned}
$$

Finally, we adopt the commonly used max pooling strategy [24] followed by a *tanh* layer to get the embedding vector for a sequence of length T.

$$v = \tanh(\text{maxpooling}([h_1, h_2, ..., h_T])) \tag{4}$$

By applying the above encoding algorithm, we encode the code snippet C and the NL query Q into v_c and v_q, respectively. Similar to Gu et al. [13], to measure the relevance between the code snippet and the query, we use cosine similarity denoted as $cos(v_q, v_c)$. The higher the similarity, the more related the code is to the query.

Training. The CR model is trained by minimizing a ranking loss similar to [13]. Specifically, for each query Q in the training corpus, we prepare a triple of $<Q, C, C^->$ as a training instance, where C is the correct code snippet that answers Q and C^- is a negative code snippet that does not answer Q (which is randomly sampled from the entire code base). The ranking loss is defined as:

$$\mathcal{L}(\theta) = \sum_{<Q,C,C^->} max(0, \epsilon - cos(v_q, v_c) + cos(v_q, v_{c^-})) \tag{5}$$

where θ denotes the model parameters, ϵ is a constant margin, and v_q, v_c and v_{c^-} are the encoded vectors of Q, C and C^- respectively.

Essentially, the ranking loss is a kind of hinge loss [46] that promotes the cosine similarity between Q and C to be greater than that between Q and C^- by at least a margin ϵ. The training leads the model to project relevant queries and code snippets to be close in the vector space.

4.2 Code Annotation Model

Formally, given a code snippet C, the CA model computes the probability of generating a sequence of NL tokens $n_{1..|N|} = (n_1, n_2, ..., n_{|N|})$ as its annotation N by:

$$P(N|C) = P(n_1|n_0, C) \prod_{t=2}^{|N|} P(n_t|n_{1..t-1}, C) \tag{6}$$

where n_0 is a special token "<START>" indicating the start of the annotation generation, $n_{1..t-1} = (n_1, ..., n_{t-1})$ is the partially generated annotation till time step t-1, and $P(n_t|n_{1..t-1}, C)$ is the probability of producing n_t as the next word given the code snippet C and the generated $n_{1..t-1}$. The generation stops once a special token "<EOS>" is observed.

In this work, we choose the popular sequence-to-sequence model [52] as our CA model structure, which is composed of an encoder and a decoder. We employ the aforementioned bidirectional LSTM-based RNN structure as the encoder for code snippet C, and use another LSTM-based RNN as the decoder to compute Eqn. (6):

$$h_t^{\text{dec}} = \text{LSTM}(n_{t-1}, h_{t-1}^{\text{dec}}), \forall t = 1, ..., |N|$$

where h_t^{dec} is the decoder hidden state at step t, and h_0^{dec} is initialized by concatenating the last hidden states of the code snippet encoder in both directions. In addition, a standard global attention layer [33] is applied in the decoder, in order to attend to important code tokens in C:

$$\tilde{h}_t^{\text{dec}} = \tanh(\mathbf{W}_\alpha[v_{\text{attn}}, h_t^{\text{dec}}])$$

$$v_{\text{attn}} = \sum_{t'=1}^{|C|} \alpha_{t'}\ h_{t'}^{\text{enc}}$$

$$\alpha_{t'} = \text{softmax}((h_{t'}^{\text{enc}})^T h_t^{\text{dec}})$$

where $\alpha_{t'}$ is the attention weight on the t'-th code token when generating the t-th word in the annotation, and $\mathbf{W}_\alpha$ is a learnable weight matrix. Finally, the t-th word is selected based on:

$$P(n_t|n_{0..t-1}, C) = \text{softmax}(\mathbf{W}\tilde{h}_t^{\text{dec}} + b) \tag{7}$$

where $\mathbf{W} \in R^{|V_n| \times d}$, $b \in R^{|V_n|}$ project the d-dim hidden state $\tilde{h}_t^{\text{dec}}$ to the NL vocabulary of size $|V_n|$.

4.3 Training Code Annotation via RL

4.3.1 Code Annotation as Markov Decision Process. Most previous work [9, 19, 21] trained the CA model by maximizing the log-likelihood of generating human annotations, which suffers from two drawbacks: (1) The *exposure bias* issue [4, 44, 45]. That is, during training, the model predicts the next word given the ground-truth annotation prefix, while at testing time, it generates the next word based on previous words generated by itself. This mismatch between training and testing may result in error accumulation in testing phase. (2) More importantly, maximizing the likelihood is not aligned with our goal to produce annotations that can be useful for code retrieval.

To address the above issues, we propose to formulate code annotation within the reinforcement learning (RL) framework [53]. Specifically, the annotation generation process is viewed as a Markov Decision Process (MDP) [5] consisting of four main components:

State. At step t during decoding, a state s_t maintains the source code snippet and the previously generated words $n_{1..t-1}$, i.e., $s_t = \{C, n_{1..t-1}\}$. In particular, the initial decoding state $s_0 = \{C\}$ only contains the given code snippet C. In this work, we take the hidden state vector $\tilde{h}_t^{dec}$ as the vector representation of state s_t, and the MDP is thus processing on a continuous and infinite state space.

Action. The CA model decides the next word (or *action*) $n_t \in V_n$, where V_n is the NL vocabulary. Thus, the action space in our formulation is the NL vocabulary.

Reward. As introduced in Section 3, to encourage it to generate words useful for the code retrieval task, the CA model is rewarded by a well-trained QC-based CR model based on whether the code snippet C can be ranked at the top positions if using the generated *complete* annotation N as a query. Therefore, we define the reward at each step t as:

$$r(s_t, n_t) = \begin{cases} \text{RetrievalReward}(C, n_{1..t}) & \text{if } n_t = \text{<EOS>} \\ 0 & \text{otherwise} \end{cases}$$

where we use the popular ranking metric Mean Reciprocal Rank [57] (defined in Section 5.2) as the RetrievalReward(C, N) value. Note that, in this work, we let the CR model give a valid reward only when the annotation generation stops, and assign a zero reward to intermediate steps. However, other designs such as giving rewards to a partial generation with the reward shaping technique [4] can be reasonable and explored in the future.

Policy. The policy function $P(n_t|s_t)$ takes as input the current state s_t and outputs the probability of generating n_t as the next word. Given our definition about state s_t and Eqn. (7),

$$P(n_t|s_t) = P(n_t|n_{1..t-1}, C) = \text{softmax}(\mathbf{W}\tilde{h}_t^{dec} + b) \tag{8}$$

Here, the policy function is stochastic in that the next word can be sampled according to the probability distribution, which allows action space exploration and can be optimized using policy gradient methods [53].

The objective of the CA model training is to find a policy function $P(N|C)$ that maximizes the expected accumulative future reward:

$$\max_\phi \mathcal{L}(\phi) = \max_\phi \mathbb{E}_{N \sim P(\cdot|C;\phi)}[R(C, N)] \tag{9}$$

where ϕ is the parameter of P and $R(C, N) = \sum_{t=1}^{|N|} r(s_t, n_t)$ is the accumulative future reward (called "return").

The gradient of the above objective is derived as below.

$$\begin{aligned} \nabla_\phi \mathcal{L}(\phi) &= \mathbb{E}_{N \sim P(\cdot|C;\phi)}[R(C, N) \nabla_\phi \log P(N|C;\phi)] \\ &= \mathbb{E}_{n_{1..|N|} \sim P(\cdot|C;\phi)}[\sum_{t=1}^{|N|} R_t(s_t, n_t) \nabla_\phi \log P(n_t|n_{1..t-1}, C;\phi)] \end{aligned} \tag{10}$$

where $R_t(s_t, n_t) = \sum_{t' \geq t} r(s_{t'}, n_{t'})$ is the return for generating word n_t given state s_t.

4.3.2 Advantage Actor-Critic for Code Annotation. Given the gradient in Eqn. (10), the objective in Eqn. (9) can be optimized by policy gradient approaches such as REINFORCE [62] and Q-value Actor-Critic algorithm [4, 54]. However, such methods may yield very high variance when the action space (i.e., the NL vocabulary) is large and suffer from biases when estimating the return of rarely taken actions [39], leading to unstable training. To tackle the challenge, we resort to the more advanced *Advantage Actor-Critic* or *A2C* algorithm [36], which has been adopted in other sequence generation tasks [39, 58]. Specifically, the gradient function in Eqn. (10) is replaced by an *advantage* function:

$$\nabla_\phi \mathcal{L}(\phi) = \mathbb{E}[\sum_{t=1}^{|N|} A_t \nabla_\phi \log P(n_t|n_{1..t-1}, C; \phi)] \tag{11}$$
$$A_t = R_t(s_t, n_t) - V(s_t)$$
$$V(s_t) = \mathbb{E}_{\hat{n}_t \sim P(\cdot|n_{1..t-1}, C)}[R_t(s_t, \hat{n}_t)]$$

where $V(s_t)$ is the state value function that estimates the future reward given the current state s_t. Intuitively, $V(s_t)$ works as a *baseline* function [62] to help the model assess its action n_t more precisely: When advantage A_t is greater than zero, it means that the return for taking action n_t is better than the "average" return over all possible actions, given state s_t; otherwise, action n_t performs worse than the average.

Following previous work [36, 39, 58], we approximate $V(s_t)$ by learning another model $V(s_t; \rho)$ parameterized by ρ, and the RL framework thus contains two components: the policy function $P(N|C; \phi)$ that generates the annotation (called "Actor"), and the state value function $V(s_t; \rho)$ that approximates the return under state s_t (called "Critic"). Similar to the actor model (i.e., the CA model in Section 4.2), we train a separate attention-based sequence-to-sequence model as the critic network. The critic value is finally computed by:

$$V(s_t; \rho) = \mathbf{w}_\rho^T (\tilde{h}_t^{dec})_{crt} + b_\rho \tag{12}$$

where $(\tilde{h}_t^{dec})_{crt} \in R^d$ is the critic decoder hidden state at step t, and $\mathbf{w}_\rho \in R^d$, $b_\rho \in R$ are trainable parameters that project the hidden state to a scalar value (i.e., the estimated state value).

The critic network is trained to minimize the Mean Square Error between its estimation and the true state value:

$$\min_\rho \mathcal{L}(\rho) = \min_\rho \mathbb{E}_{N \sim P(\cdot|C)}[\sum_{t=1}^{|N|} (V(s_t; \rho) - R(C, N))^2] \tag{13}$$

The entire training procedure of CoaCor is shown in Algorithm 1.

4.4 Generated Annotations for Code Retrieval

As previously shown in Figure 1, in the testing phase, we utilize the generated annotations to assist the code retrieval task. Now we detail the procedure in Algorithm 2. Specifically, for each <NL query, code snippet> pair (i.e., QC pair) in the dataset, we first derive an <NL query, code annotation> pair (i.e., QN pair) using the code annotation model. We then build another code retrieval (CR) model based on the QN pairs in our training corpus. In this work, for simplicity, we choose the same structure as the QC-based CR model (Section 4.1) to match QN pairs. However, more advanced methods for modeling the semantic similarity between two NL sentences (e.g., previous work on NL paraphase detection [16, 26]) are applicable and can be explored as future work.

Algorithm 1 : Training Procedure for CoaCor.

Input: <NL query, code snippet> (QC) pairs in training set, number of iterations E.

1: Train a base code retrieval model based on QC pairs, according to Eqn. (5).
2: Initialize a base code annotation model (ϕ) and pretrain it via MLE according to Eqn. (7), using Q as the desired N for C.
3: Pretrain a critic network (ρ) according to Eqn. (13).
4: **for** $iteration = 1$ to E **do**
5: Receive a code snippet C.
6: Sample an annotation $N \sim P(\cdot|C; \phi)$ according to Eqn. (8).
7: Receive the final reward $R(C, N)$.
8: Update the code annotation model (ϕ) using Eqn. (11).
9: Update the critic network (ρ) using Eqn. (13).
10: **end for**

Algorithm 2 : Generated Annotations for Code Retrieval.

Input: NL query Q, code snippet candidate C.
Output: The matching score, score(Q, C).

1: Receive score$_1(Q, C) = cos(v_q, v_c)$ from a QC-based code retrieval model.
2: Generate a code annotation $N \sim P(\cdot|C; \phi)$ via greedy search, according to Eqn. (8).
3: Receive score$_2(Q, C) = cos(v_q, v_n)$ from a QN-based code retrieval model.
4: Calculate score(Q, C) according to Eqn. (14).

The final matching score between query Q and code snippet C combines those from the QN-based and QC-based CR model:

$$\text{score}(Q, C) = \lambda * cos(v_q, v_n) + (1 - \lambda) * cos(v_q, v_c) \tag{14}$$

where v_q, v_c, v_n are the encoded vectors of Q, C, and the code annotation N respectively. $\lambda \in [0, 1]$ is a weighting factor for the two scores to be tuned on the validation set.

5 EXPERIMENTS

In this section, we conduct extensive experiments and compare our framework with various models to show its effectiveness.

5.1 Experimental Setup

Dataset. (1) We experimented with the **StaQC** dataset presented by Yao et al. [63]. The dataset contains 119,519 SQL <question title, code snippet> pairs mined from Stack Overflow [51], making itself the largest-to-date in SQL domain. In our code retrieval task, the question title is considered as the NL query Q, which is paired with the code snippet C to form the QC pair. We randomly selected 75% of the pairs for training, 10% for validation (containing 11,900 pairs), and the left 15% for testing (containing 17,850 pairs). As mentioned in [63], the dataset may contain multiple code snippets for the same NL query. We examine the dataset split to ensure that alternative relevant code snippets for the same query would not be sampled as negative code snippets when training the CR model. For pretraining the CA model, we consider the question title as a

code annotation N and form QN pairs accordingly. **(2)** Iyer et al. [21] collected two small sets of SQL code snippets (called "**DEV**" and "**EVAL**" respectively) from Stack Overflow for validation and testing. In addition to the originally paired question title, each code snippet is manually annotated by two different NL descriptions. Therefore, in total, each set contains around 100 code snippets with three NL descriptions (resulting in around 300 QC pairs). We use them as additional datasets for model comparison.[2] Following [21], QC pairs occuring in DEV and EVAL set or being used as negative code snippets by them are removed from the StaQC training set.

Data Preprocessing. We followed [21] to perform code tokenization, which replaced table/column names with placeholder tokens and numbered them to preserve their dependencies. For text tokenization, we utilized the "word_tokenize" tool in the NLTK toolkit [7]. All code tokens and NL tokens with a frequency of less than 2 were replaced with an <UNK> token, resulting in totally 7726 code tokens and 7775 word tokens in the vocabulary. The average lengths of the NL query and the code snippet are 9 and 60 respectively.

5.2 Evaluation

We evaluate a model's retrieval performance on four datasets: the validation (denoted as "StaQC-val") and test set (denoted as "StaQC-test") from StaQC [63], and the DEV and EVAL set from [21]. For each <NL query Q, code snippet C> pair (or QC pair) in a dataset, we take C as a positive code snippet and randomly sample K negative code snippets from all others except C in the dataset,[3] and calculate the rank of C among the $K+1$ candidates. We follow [9, 21, 63] to set $K = 49$. The retrieval performance of a model is then assessed by the Mean Reciprocal Rank (MRR) metric [57] over the entire set $\mathcal{D} = \{(Q_1, C_1), (Q_2, C_2), ..., (Q_{|\mathcal{D}|}, C_{|\mathcal{D}|})\}$:

$$MRR = \frac{1}{|\mathcal{D}|} \sum_{i=1}^{|\mathcal{D}|} \frac{1}{Rank_i}$$

where $Rank_i$ is the rank of C_i for query Q_i. The higher the MRR value, the better the code retrieval performance.

5.3 Methods to Compare

In order to test the effectiveness of our CoaCor framework, we compare it with both existing baselines and our proposed variants.

Existing Baselines. We choose the following state-of-the-art code retrieval models, which are based on QC pairs, for comparison.

- Deep Code Search (DCS) [13]. The original DCS model [13] adopts a similar structure as Figure 2 for CR in Java domain. To learn the vector representations for code snippets, in addition to code tokens, it also considers features like function names and API sequences, all of which are combined into a fully connected layer. In our dataset, we do not have these features, and thus slightly modify their original model to be the same as our QC-based CR model (Figure 2).
- CODE-NN [21]. CODE-NN is one of the state-of-the-art models for both code retrieval and code annotation. Its core component is an LSTM-based RNN with an attention mechanism, which models the probability of generating an NL sentence conditioned on a given code snippet. For code retrieval, given an NL query, CODE-NN computes the likelihood of generating the query as an annotation for each code snippet and ranks code snippets based on the likelihood.

QN-based CR Variants. As discussed in Section 4.4, a trained CA model is used to annotate each code snippet C in our datasets with an annotation N. The resulting <NL query Q, code annotation N> pairs can be used to train a QN-based CR model. Depending on how we train the CA model, we have the following variants:

- QN-MLE. Similar to most previous work [9, 19, 21], we simply train the CA model in the standard MLE manner, i.e., by maximizing the likelihood of a human-provided annotation.
- QN-RL$^{\text{BLEU}}$. As introduced in Section 1, Wan et al. [58] proposed to train the CA model via reinforcement learning with BLEU scores [41] as rewards. We compare this variant with our rewarding mechanism.
- QN-RL$^{\text{MRR}}$. In our CoaCor framework, we propose to train the CA model using retrieval rewards from a QC-based CR model (see Section 3). Here we use the MRR score as the retrieval reward.

Since CODE-NN [21] can be used for code annotation as well, we also use its generated code annotations to train a QN-based CR model, denoted as "QN-CodeNN".[4]

Ensemble CR Variants. As introduced in Section 4.4, we tried ensembling the QC-based CR model and the QN-based CR model to improve the retrieval performance. We choose the DCS structure as the QC-based CR model as mentioned in Section 4.1. Since different QN-based CR models can be applied, we present the following 4 variants: (1) QN-MLE + DCS, (2) QN-RL$^{\text{BLEU}}$ + DCS, (3) QN-RL$^{\text{MRR}}$ + DCS, and (4) QN-CodeNN + DCS, where QN-MLE, QN-RL$^{\text{BLEU}}$, QN-RL$^{\text{MRR}}$, and QN-CodeNN have been introduced.

5.4 Implementation Details

Our implementation is based on Pytorch [42]. For CR models, we set the embedding size of words and code tokens to 200, and chose batch size in {128, 256, 512}, LSTM unit size in {100, 200, 400} and dropout rate [50] in {0.1, 0.35, 0.5}. A small, fixed ϵ value of 0.05 is used in all the experiments. Hyper-parameters for each model were chosen based on the DEV set. For CODE-NN baseline, we followed Yao et al. [63] to use the same model hyper-parameters as the original paper, except that the dropout rate is tuned in {0.5, 0.7}. The StaQC-val set was used to decay the learning rate and the best model parameters were decided based on the retrieval performance on the DEV set.

For CA models, the embedding size of words and code tokens and the LSTM unit size were selected from {256, 512}. The dropout rate is selected from {0.1, 0.3, 0.5} and the batch size is 64. We updated model parameters using the Adam optimizer [25] with learning rate 0.001 for MLE training and 0.0001 for RL training. The maximum length of the generated annotation is set to 20. For CodeNN, MLE-based and RL$^{\text{BLEU}}$-based CA models, the best model parameters

[2] Previous work [9, 21] used only one of the three descriptions while we utilize all of them to enrich and enlarge the datasets for a more reliable evaluation.
[3] For DEV and EVAL, we use the same negative examples as [21].
[4] There is another recent code annotation method named DeepCom [19]. We did not include it as baseline, since it achieved a similar performance as our MLE-based CA model (see Table 3) when evaluated with the standard BLEU script by [21].

Table 1: The main code retrieval results (MRR). * denotes significantly different from DCS [13] in one-tailed t-test (p < 0.01).

Model	DEV	EVAL	StaQC-val	StaQC-test
Existing (QC-based) CR Baselines				
DCS [13]	0.566	0.555	0.534	0.529
CODE-NN [21]	0.530	0.514	0.526	0.522
QN-based CR Variants				
QN-CodeNN	0.369	0.360	0.336	0.333
QN-MLE	0.429	0.411	0.427	0.424
QN-RL^{BLEU}	0.426	0.402	0.386	0.381
QN-RL^{MRR} (ours)	0.534	0.512	0.516	0.523
Ensemble CR Variants				
QN-CodeNN + DCS	0.566	0.555	0.534	0.529
QN-MLE + DCS	0.571	0.561	0.543	0.537
QN-RL^{BLEU} + DCS	0.570	0.559	0.541	0.534
QN-RL^{MRR} + DCS (ours)	0.582*	**0.572***	0.558*	0.559*
QN-RL^{MRR} + CODE-NN (ours)	**0.586***	0.571*	**0.575***	**0.576***

were picked based on the model's BLEU score on DEV, while for RL^{MRR}-based CA model, we chose the best model according to its MRR reward on StaQC-val. For RL models, after pretraining the actor network via MLE, we first pretrain the critic network for 10 epochs, then jointly train the two networks for 40 epochs. Finally, for ensemble variants, the ensemble weight λ in all variants is selected from $0.0 \sim 1.0$ based on its performance on DEV.

5.5 Results

To understand our CoaCor framework, we first show several concrete examples to understand the differences between annotations generated by our model and by baseline/variant models, and then focus on two research questions (RQs):

- **RQ1 (CR improves CA)**: Is the proposed retrieval reward-driven CA model capable of generating rich code annotations that can be used for code retrieval (i.e., can represent the code snippet and distinguish it from others)?
- **RQ2 (CA improves CR)**: Can the generated annotations further improve existing QC-based code retrieval models?

5.5.1 Qualitative Analysis. Table 2 presents two examples of annotations generated by each CA model. Note that we do not target at human language-like annotations; rather, we focus on annotations that can describe/capture the functionality of a code snippet. In comparison with baseline CA models, our proposed RL^{MRR}-based CA model can produce more concrete and precise descriptions for corresponding code snippets. As shown in Example 1, the annotation generated by RL^{MRR} covers more conceptual keywords semantically aligned with the three NL queries (e.g., "average", "difference", "group"), while the baseline CODE-NN and the variants generate short descriptions covering a very limited amount of conceptual keywords (e.g., without mentioning the concept "subtracting").

We also notice that our CA model can generate different forms of a stem word (e.g., "average", "avg" in Example 1), partly because the retrieval-based reward tends to make the generated annotation semantically aligned with the code snippet and these diverse forms of words can help strengthen such semantic alignment and benefit the code retrieval task when there are various ways to express user search intent.

5.5.2 Code Retrieval Performance Evaluation. Table 1 shows the code retrieval evaluation results, based on which we discuss **RQ1** and **RQ2** as below:

RQ1: To examine whether or not the code annotations generated by a CA model can represent the corresponding code snippet in the code retrieval task, we analyze its corresponding QN-based CR model, which retrieves relevant code snippets by matching the NL query Q with the code annotation N generated by this CA model. Across all of the four datasets, our proposed QN-RL^{MRR} model, which is based on a retrieval reward-driven CA model, achieves the best results and outperforms other QN-based CR models by a wide margin of around $0.1 \sim 0.2$ absolute MRR. More impressively, its performance is already on a par with the CODE-NN model, which is one of the state-of-the-art models for the code retrieval task, even though it understands a code snippet solely based on its annotation and without looking at the code content. This demonstrates that the code annotation generated by our proposed framework can reflect the semantic meaning of each code snippet more precisely.

To further understand whether or not the retrieval-based reward can serve as a better reward metric than BLEU (in terms of stimulating a CA model to generate useful annotations), we present the BLEU score of each CA model in Table 3.[5] When connecting this table with Table 1, we observe an inverse trend: For the RL^{BLEU} model which is *trained for* a higher BLEU score, although it can improve the MLE-based CA model by more than 2% absolute BLEU on three sets, it harms the latter's ability on producing useful code annotations (as revealed by the performance of QN-RL^{BLEU} in Table 1, which is worse than QN-MLE by around 0.04 absolute MRR on StaQC-val and StaQC-test). In contrast, our proposed RL^{MRR} model, despite getting the lowest BLEU score, is capable of generating annotations useful for the retrieval task. This is mainly because that

[5]BLEU is evaluated with the script provided by Iyer et al. [21]: https://github.com/sriniiyer/codenn/blob/master/src/utils/bleu.py.

Table 2: Two examples of code snippets and their annotations generated by different CA models. "Human-provided" refers to (multiple) human-provided NL annotations or queries. Words semantically aligned between the generated and the human-provided annotations are highlighted.

Model	Annotation
Example 1 from EVAL set	
SQL Code	SELECT col3, Format(Avg([col2]-[col1]),"hh:mm:ss") AS TimeDiff FROM Table1 GROUP BY col3;
Human-provided	(1) find the average time in hours , mins and seconds between 2 values and show them in groups of another column (2) group rows of a table and find average difference between them as a formatted date (3) ms access average after subtracting
CODE-NN	how do i get the average of a column in sql?
MLE	how to get average of the average of a column in sql
RL^{BLEU}	how to average in sql query
RL^{MRR}	average avg calculating difference day in access select distinct column value sql group by month mysql format date function?
Example 2 from StaQC-test set	
SQL Code	SELECT Group_concat(DISTINCT(p.products_id)) AS comma_separated, COUNT(DISTINCT p.products_id) AS product_count FROM ...
Human-provided	how to count how many comma separated values in a group_concat
CODE-NN	how do i get the count of distinct rows?
MLE	mysql query to get count of distinct values in a column
RL^{BLEU}	how to count in mysql sql query
RL^{MRR}	group_concat count concatenate distinct comma group mysql concat column in one row rows select multiple columns of same id result

BLEU score calculates surface form overlaps while the retrieval-based reward measures the semantically aligned correspondences.

These observations imply an interesting conclusion: *Compared with BLEU, a (task-oriented) semantic measuring reward, such as our retrieval-based MRR score, can better stimulate the model to produce detailed and useful generations.* This is in line with the recent discussions on whether the automatic BLEU score is an appropriate evaluation metric for generation tasks or not [30, 40]. In our work, we study the potential to use the performance of a relevant model to guide the learning of the target model, which can be generalized to many other scenarios, e.g., conversation generation [27], machine translation [4, 44], etc.

RQ2: We first inspect whether the generated code annotations can assist the base code retrieval model (i.e., DCS) or not by comparing several ensemble CR variants. It is shown that, by simply combining the matching scores from QN-RL^{MRR} and DCS with a weighting factor, our proposed model is able to significantly outperform the DCS model by 0.01 ~ 0.03 and the CODE-NN baseline by 0.03 ~ 0.06 consistently across all datasets, showing the advantage of utilizing code annotations for code retrieval. Particularly, the best performance is achieved when the ensemble weight $\lambda = 0.4$ (i.e., 0.4 weight on the QN-based CR score and 0.6 on the QC-based CR score), meaning that the model relies heavily on the code annotation to achieve better performance.

Table 3: The BLEU score of each code annotation model.

Model	DEV	EVAL	StaQC-val	StaQC-test
CODE-NN [21]	17.43	16.73	8.89	8.96
MLE	18.99	19.87	10.52	10.55
RL^{BLEU}	21.12	18.52	12.72	12.78
RL^{MRR}	8.09	8.52	5.56	5.60

In contrast, QN-CodeNN, QN-MLE and QN-RL^{BLEU} can hardly improve the base DCS model, and their best performances are all achieved when the ensemble weight $\lambda = 0.0 \sim 0.2$, indicating little help from annotations generated by CODE-NN, MLE-based and BLEU-rewarded CA. This is consistent with our conclusions to RQ1.

We also investigate the benefit of our generated annotations to other code retrieval models (besides DCS) by examining a baseline "QN-RL^{MRR} + CODE-NN", which combines QN-RL^{MRR} and CODE-NN (as a QC-based CR model) to score a code snippet candidate. As mentioned in Section 5.3, CODE-NN scores a code snippet by the likelihood of generating the given NL query when taking this code snippet as the input. Since the score is in a different range from the cosine similarity given by QN-RL^{MRR}, we first rescale it by taking its log value and dividing it by the largest absolute log score among all code candidates. The rescaled score is then combined with the cosine similarity score from QN-RL^{MRR} following Eqn. (14). The result is shown in the last row of Table 1. It is very impressive that, with the help of QN-RL^{MRR}, the CODE-NN model can be improved by ≥ 0.05 absolute MRR value across all test sets.

In summary, through extensive experiments, we show that our proposed framework can generate code annotations that are much more useful for building effective code retrieval models, in comparison with existing CA models or those trained by MLE or BLEU-based RL. Additionally, the generated code annotations can further improve the retrieval performance, when combined with existing CR models like DCS and CODE-NN.

6 DISCUSSION

In this work, we propose a novel perspective of using a relevant downstream task (i.e., code retrieval) to guide the learning of a target task (i.e., code annotation), illustrating a novel machine-machine collaboration paradigm. It is shown that the annotations generated by the RL^{MRR} CA model (trained with rewards from the DCS model) can boost the performance of the CODE-NN model, which was not involved in any stage of the training process. It is interesting to explore more about machine-machine collaboration mechanisms, where multiple models for either the same task or relevant tasks can be utilized in tandem to provide different views or effective rewards to improve the final performance.

In terms of training, we also experimented with directly using a QN-based CR model or an ensemble CR model for rewarding the

CA model. However, these approaches do not work well, since we do not have a rich set of QN pairs as training data in the beginning. Collecting paraphrases of queries to form QN pairs is non-trivial, which we leave to the future.

Finally, our CoaCor framework is applicable to other programming languages, such as Python and C#, extension to which is interesting to study as future work.

7 RELATED WORK

Code Retrieval. As introduced in Section 1, code retrieval has been studied widely with information retrieval methods [14, 17, 23, 32, 56] and recent deep learning models [3, 13, 21]. Particularly, Keivanloo et al. [23] extracted abstract programming patterns and their associated NL keywords from code snippets in a code base, with which a given NL query can be projected to a set of associated programming patterns facilitating code content-based search. Similarly, Vinayakarao et al. [56] built an entity discovery system to mine NL phrases and their associated syntactic patterns, based on which they annotated each line of code snippets with NL phrases. Such annotations were utilized to improve NL keyword-based search engines. Different from these work, we construct a neural network-based code annotation model to describe the functionality of an entire code snippet. Our code annotation model is explicitly trained to produce meaningful words that can be used for code search. In our framework, the code retrieval model adopts a similar deep structure as the Deep Code Search model proposed by Gu et al. [13], which projects a NL query and a code snippet into a vector space and measures the cosine similarity between them.

Code Annotation. Code annotation/summarization has drawn a lot of attention in recent years. Earlier works tackled the problem using template-based approaches [37, 49] and topic n-grams models [38] while the recent techniques [2, 19–22, 31] are mostly built upon deep neural networks. Specifically, Sridhara et al. [49] developed a software word usage model to identify action, theme and other arguments from a given code snippet, and generated code comments with templates. Allamanis et al. [2] employed convolution on the input tokens to detect local time-invariant and long-range topical attention features to summarize a code snippet into a short, descriptive function name-like summary. Most related to our work are [19] and [58], which utilized sequence-to-sequence networks with attention over code tokens to generate natural language annotations. They aimed to generate NL annotations as close as possible to human-provided annotations for human readability, and hence adopted the Maximum Likelihood Estimation (MLE) or BLEU score optimization as the objective. However, our goal is to generate code annotations *which can be used for code retrieval*, and therefore we design a retrieval-based reward to drive our training.

Deep Reinforcement Learning for Sequence Generation. Reinforcement learning (RL) [53] has shown great success in various tasks where an agent has to perform multiple actions before obtaining a reward or when the metric to optimize is not differentiable. The sequence generation tasks, such as machine translation [4, 39, 44], image captioning [45], dialogue generation [27] and text summarization [43], have all benefitted from RL to address the *exposure bias* issue [4, 44, 45] and to directly optimize the model towards a certain metric (e.g., BLEU). Particularly, Ranzato et al. [44] were among the first to successfully apply the REINFORCE algorithm [62] to train RNN models for several sequence generation tasks, indicating that directly optimizing the metric used at test time can lead to significantly better models than those trained via MLE. Bahdanau et al. [4] additionally learned a *critic* network to better estimate the return (i.e., future rewards) of taking a certain action under a specific state, and trained the entire generation model via the *Actor-Critic* algorithm [54]. We follow Nguyen et al. [39] and Wan et al. [58] to further introduce an *advantage* function and train the code annotation model via the *Advantage Actor-Critic* algorithm [36], which is helpful for reducing biases from rarely taken actions. However, unlike their work, the reward in our framework is based on the performance on a different yet relevant task (i.e., code retrieval), rather than the BLEU metric.

Machine-Machine Collaboration via Adversarial Training and Dual/Joint Learning. Various kinds of machine-machine collaboration mechanisms have been studied in many scenarios [12, 15, 28, 55, 59]. For example, Goodfellow et al. [12] proposed the Generative Adversarial Nets (GANs) framework, where a generative model generates images to fool a discriminative classifier, and the latter is further improved to distinguish the generated from the real ones. He et al. [15] proposed the dual learning framework and jointly optimized the machine translation from English to French and from French to English. Li et al. [29] trained a paraphrase generator by rewards from a paraphrase evaluator model. In the context of code retrieval and annotation, Chen and Zhou [9] and Iyer et al. [21] showed that their models can be used directly or with slight modification for both tasks, but their training objective only considered one of the two tasks. All these frameworks are not directly applicable to achieve our goal, i.e., training a code annotation model to generate rich NL annotations that can be used for code search.

8 CONCLUSION

This paper explored a novel perspective of generating code annotations *for* code retrieval. To this end, we proposed a reinforcement learning-based framework (named "CoaCor") to maximize a retrieval-based reward. Through comprehensive experiments, we demonstrated that the annotation generated by our framework is more detailed to represent the semantic meaning of a code snippet. Such annotations can also improve the existing code content-based retrieval models significantly. In the future, we will explore other usages of the generated code annotations, as well as generalizing our framework to other tasks such as machine translation.

Snapshot-based Loading Acceleration of Web Apps with Nondeterministic JavaScript Execution

ABSTRACT

JavaScript execution is heavily used during the loading of web apps, taking a substantial portion of the app loading time. To accelerate JavaScript execution, *snapshot-based app loading* has been proposed [5, 17]. We take a *snapshot* of the JavaScript objects in the heap at some point during app loading (which we call *snapshot point*) and save them in a file in advance. Then, we start app loading by copying the objects in the snapshot to the heap directly, skipping JavaScript execution to create those objects. One issue is that the JavaScript execution state at the snapshot point should be the same at every app loading. If JavaScript execution included in the snapshot is involved with some nondeterminism (e.g., use random function or current time/location), snapshot-based app loading might be inapplicable since the loaded state might differ each time.

In this paper, we perform an empirical study for the nondeterministic behavior of web apps during app loading. The result shows that nondeterminism is used frequently, but its impact is small from the user's perspectives. Based on this observation, we propose two techniques that can increase the applicability of snapshot. First, we propose two types of snapshot point, which allows saving as much execution state as possible in the snapshot, just before the nondeterministic execution affects the user's perception. Second, we develop a tool to identify those snapshot points by static and dynamic analysis, so that the developer can easily identify them. Our experimental results show that the techniques can accelerate the app loading by 1.81 times, by applying the snapshot that would otherwise be inapplicable, achieving a performance comparable to that of a snapshot that completely ignores the nondeterminism issues.

1 INTRODUCTION

Web apps are popular because they are extremely portable, running on any device with a web browser. They are standard apps for commercial web platforms such as Tizen [11] or WebOS [8], being employed by embedded devices such as smart TVs, smart watches, or IoT devices.

In the mobile environment, loading time is an important factor affecting the user experience and business revenues [3, 4, 25]. For example, it is found that every 100ms of latency costs 1% reduction of sales for Amazon [10]. Reducing the loading time is also important for web apps, especially in the embedded devices such as smart TVs, since their limited hardware resources might lead to a long loading time, sometimes unacceptable to the users.

One technique to accelerate app loading is *snapshot* [17]. Since app loading usually produces the same execution state, especially the same JavaScript state, we can save the loaded state in a file called the snapshot in advance and perform app loading by copying the state from the file, instead of executing the JavaScript code to produce the same state. Recently, Google's Chrome browser introduced a technique called the *custom snapshot* [5], extending its previous technique *serializer*, which does the same.

Snapshot has a subtle correctness issue. The loading process of a web app may include various *nondeterminisms*. For example, it can executes a JavaScript function *Math.random*, which returns a random value, or a function *Date*, which returns the current time. Also, it can execute Web APIs that retrieve the device status or the browser information. If the results of these nondeterministic executions were also saved in the snapshot, app loading using a snapshot created by a previous run might not produce a correct state for the current run. Existing snapshots include only those JavaScript executions that are deterministic [5, 17]. For this, the app developer must specify a proper snapshot point, up to which only deterministic JavaScript executions are made.

Not all nondeterministic JavaScript executions are unqualified for snapshot, though. Each nondeterminism has a different impact on app loading, and some nondeterminisms do not show any difference from the user's perspectives. For example, the *jQuery* web framework uses *Math.random* to generate a unique identifier and use it as a property name [6]. The property name will change at each loading, but it is used only inside the framework. So, changing the property name does not affect the DOM tree displayed on the screen or the behavior of the event handlers. It is completely safe to include these nondeterministic executions in the snapshot, thus increasing performance without affecting correctness.

Deciding the best snapshot point that excludes unsafe nondeterminism but includes as much JavaScript execution as possible would be a challenge. It is difficult for the app developer to analyze the app to find all variables affected by nondeterministic executions and all affected execution states. If an app uses a JavaScript framework, the developer should fully understand the framework code, which is not easy for most developers. In fact, even the snapshot of the commercial Chrome browser does not give any information on nondeterminism for JavaScript execution [5], so the developers have to analyze by themselves or go through a trial and error method to choose a proper snapshot point.

This paper made three contributions. First, we perform an empirical study of the nondeterministic behavior of web apps at loading time. The result shows that nondeterminism is frequent, but its impact is often little from the user's perspectives, as the unique identifier case of jQuery.

Secondly, we propose two nondeterminism-aware snapshot points that can lead to a higher performance than the snapshot with deterministic executions only. They allow the developers to choose between performance and correctness. The first snapshot point is *deterministic DOM*, which includes the JavaScript executions up to the point where the DOM tree is deterministic. This will include the JavaScript execution that does not affect the user's perception. The second snapshot point is *semi-randomized DOM*, which additionally saves the JavaScript executions that produce a nondeterministic DOM tree with *Math.random*. One example is a game app showing a random initial screen when loaded. If we make a snapshot including *Math.random*, the app will show the same screen at each loading. This does not affect the correctness, but only the user's perception (e.g., a minesweeper app shows the same position of mines at each loading). To handle this issue, we create multiple snapshots and use one of them randomly at loading time to mimic a randomized execution.

Finally, we create a tool to find the snapshot point for web apps using static and dynamic analysis to increase the applicability of the snapshot. We instrument HTML files and JavaScript code, and the browser runs the instrumented app to collect information such as JavaScript variable read/write and DOM tree changes. The tool creates a JavaScript dependency graph based on the information to find all JavaScript statements affected by nondeterminism. If such a JavaScript statement changes the DOM tree, it is regarded as a nondeterministic DOM change. Our tool identifies all script tags or event handlers that make nondeterministic DOM changes so as to help the app developer to decide a proper nondeterminism-aware snapshot point.

Previous studies on nondeterminism classified the source of nondeterminism in the web pages, and made the execution deterministic by saving the execution results of nondeterminism and using them in subsequent executions [2, 14]. Snapshot also saves the results of nondeterministic executions and reuse them for acceleration, but we identify nondeterminisms that affect little the user's perception and save only those executions in the snapshot.

Our experimental results show that the proposed techniques can accelerate the app loading by 1.81 times on average compared to a snapshot with deterministic executions only, by including safe, nondeterministic JavaScript executions in the snapshot that would otherwise be not includable. This achieves a performance comparable to that of a snapshot that completely ignores the nondeterminism issues.

The rest of the paper is as follows. Section 2 reviews snapshot-based app loading. Section 3 analyzes the nondeterminism sources in web apps. Section 4 proposes nondeterminism-aware snapshot points. Section 5 shows the nondeterminism analysis tool. Section 6 depicts the implementation and Section 7 shows the evaluation results. Related work is in Section 8 and conclusion is in Section 9.

2 SNAPSHOT-BASED ACCELERATION OF WEB APPS

The browser loads a web app by executing its HTML code, embedded with the script tags of JavaScript global code. It parses the HTML code to a DOM tree. When a script tag is met, the JavaScript code is executed after creating a *window* object in the heap. After HTML parsing completes, the browser fires *DOMContentLoaded* event and *onload* event, and the JavaScript event handlers registered in the script tags will be executed. This completes the app loading process, and then the app will work in an event-driven manner based on the user events.

Snapshot-based acceleration is based on an observation that app loading often repeats the same initializations. For example, most web apps employ JavaScript frameworks such as jQuery [6], which are initialized during app loading. Similarly, the app itself is initialized as well. These initializations are done by executing the same JavaScript code, which often produces the same objects in the JavaScript heap. So, instead of executing the JavaScript code to create those objects at each loading time, it is better to save the JavaScript objects right after these initializations to a file in advance, and to start an app by copying the JavaScript objects from the file to the heap directly [5, 17]. Even if we need to save or restore the objects one-by-one, starting from the JavaScript *window* object, snapshot-based acceleration is shown to be around four times faster than executing the JavaScript code [17].

Actually, the loading state of a web app includes the DOM state as well as the JavaScript state. Unlike the JavaScript state which can be saved as above, saving the DOM state is not straightforward. For the initial snapshot works [5, 17], the DOM tree is not saved in the snapshot, but completely re-built using the usual HTML parsing. One issue is that if some JavaScript code executed during app loading changes the DOM tree (e.g., add/delete some DOM nodes), such changes will be lost when employing snapshot-based app loading since the snapshot includes only the JavaScript objects. This constrains the snapshot point, such that only the JavaScript executions that do not change the DOM tree are eligible for inclusion in the snapshot [5, 17]. More precisely, since we can have only a single snapshot file, we can save a "consecutive" sequence of JavaScript executions until the first execution that changes the DOM tree is met, which limits the coverage.

More recent snapshots save some of the DOM state as well [16, 29]. One method records the log of all the DOM APIs that JavaScript executions invoke until the snapshot point [16]. Snapshot-based app loading re-builds the DOM tree using HTML parsing as previously, but restores the correct DOM tree state by replaying the DOM logs, while restoring the JavaScript state from the snapshot at the snapshot point. Another method is saving the whole DOM tree as

a serialized HTML string using the *innerHTML* API at the snapshot point [29]. Snapshot-based app loading re-builds the DOM tree, but at the snapshot point, it is overwritten by the de-serialized tree from the HTML string. For the implementation of nondeterminism-aware snapshot points in this paper, we employed the first implementation.

One advantage of saving the DOM state in the snapshot is that we can take a snapshot at a later point of app loading, even after the entire app loading process completes [16], thus increasing the applicability of snapshot. Generally, JavaScript executions during app loading comes from the framework script tags, the app script tags, and the event handlers, in this order. For those snapshots that cannot save the DOM state [5, 17], a snapshot can be taken just before the first DOM-changing JavaScript (actually, the first DOM-changing script tag since they cannot take a snapshot at the event handler). If we save the DOM state, snapshot-based app loading can skip the executions of all script tags and event handlers up to the snapshot point, irrespective of whether they change the DOM tree or not, then restore the JavaScript state from the snapshot, thus performing better.

One issue is that those JavaScript executions included in the snapshot should be deterministic, meaning that they should produce exactly the same execution state every time. If they are nondeterministic, the state stored in the snapshot might be different from the actual app loading state. Previous snapshots did not consider nondeterminism [5, 17], or even if they do, they let the app developer to decide the snapshot point manually [16, 29]. According to our study about nondeterminism in Section 3, however, there occur lots of nondeterminisms during app loading, so we need a better way to apply snapshot considering nondeterminism.

3 NONDETERMINISM IN LOADING OF WEB APPS

In this section, we examine nondeterminisms during app loading and list up the sources of nondeterminism. We also analyze how app loading exploits nondeterminism and examine the impact on the DOM tree.

3.1 Sources of Nondeterminism in App Loading

There are previous researches that analyze the source of nondeterminism that can occur in web apps [2, 14]. Unlike them, we are only interested in nondeterminism that may occur during app loading. For example, many events during app execution are involved with nondeterminism, but only the timer event is source of nondeterminism in the app loading process (see Section 3.1.3).

We have classified the sources of nondeterminism as *nondeterministic functions*, *web APIs*, and *interrupts*. Among the JavaScript functions, those declared in the HTML5 specification are categorized as *web APIs*, and the remaining functions are classified as *nondeterministic functions*. *Interrupts* mean the nondeterminism caused by events such as timer events. Details are discussed below.

3.1.1 Nondeterministic Functions. Among the functions in the JavaScript specification, there are two nondeterministic functions: *Math.random*, which returns a random value, and *Date*, which can be used to return the current time, thus being nondeterministic.

3.1.2 Web APIs. JavaScript supports a variety of APIs for browsers. The most commonly used APIs are related to the DOM tree, allowing the developers to change the display by adding or removing elements from the DOM tree. DOM is standardized and supported by all browsers, but latest APIs are supported by a few browsers. In this paper, we analyze only widely-used APIs, supported by the mainstream browsers. We have classified web APIs into three types.

File system is a set of APIs used to read and write persistent data in the browser, such as cookie, localStorage, or IndexedDB. We use the APIs to read preferences or data, thus being nondeterministic depending on their existence.

Device information is the APIs that fetch the status of the current device. They allow the developers to get device information from the web apps. Among many APIs, we consider geolocation, device orientation, and device motion APIs that are supported by most web browsers. The geolocation API uses GPS or IP address to determine the user's current location, and it is used by apps such as maps and weather to show information based on the location.

Browser Information is an API that retrieves the information of the browser running the app. Developers can get the size/position of the browser using those APIs. The userAgent API is widely used to get the type of the browser and its version. For snapshot implementation, the same browser is used, so we exclude userAgent from our analysis.

3.1.3 Interrupts. Previous researches have analyzed the events in detail [2, 14], but the events that can occur during the app loading process are limited. Generally, events can be triggered by a user interaction, by a JavaScript function call, or by the web browser. In the middle of app loading, the DOM element is not displayed on the screen because the rendering is not completed yet. Since it is difficult for the user to activate an event during loading, the event triggered by the user cannot be the source of nondeterminism.

JavaScript execution can fire an event directly by using the *dispatchEvent* function or by registering a timer event with the *setTimeout*, *setInterval* function. If *dispatchEvent* is used in the JavaScript code, the execution order is fixed because the event occurs immediately after the execution of the code, thus being deterministic. On the other hand, timer events can be nondeterministic. *setTimeout* and *setInterval* are used to register timer events which will be fired after a certain amount of time. Consider two consecutive script tags where the first tag registers a timer event that occurs 2.0 seconds later while the second tag registers a timer event that occurs 1.0 seconds later. If the first tag executes for 0.5 seconds, the first event will fire at 2.0 second while the second one will fire at 1.5 (0.5+1.0) second. If the first tag executes for 1.5 seconds due to some delay (e.g., page miss), however, the first event will still fire at 2.0 second, but the second one will fire at 2.5 (1.5+1.0) second. So, the execution order of the events can be nondeterministic.

Only two events are fired by the browser during app loading: *DOMContentLoaded* event and *onload* event. The *DOMContentLoaded* fires when the HTML parsing is done, and the *onload* event fires when the resources in HTML are completely downloaded. In most apps, the event handlers executed for each of these two events and their execution order are fixed, thus being deterministic.

Table 1: Number of nondeterminism occurrences during app loading

Type	Nondeterministic Functions		File System APIs		Browser Information	Interrupts		Total
	Random	Date	Cookie	localStorage	Size	setTimeout	setInterval	
Framework global code	0/6	0/12	0/0	0/0	0/0	0/0	0/0	0/18
App global code	251/251	1/1	0/0	0/0	9/9	0/1	0/0	261/262
Event handler	582/583	57/64	3/3	3/3	0/0	0/2	0/3	645/658

3.2 Nondeterminism Usage at Web App Loading

We used a dynamic analysis tool *Jalangi* [21] to record all nondeterminisms that occur during app loading. We observe every *function call* and *property access* during app loading, where nondeterministic result might occur (e.g., *Math.random()* or localStorage['setup']). We identify the location and the number of occurrences for nondeterminism defined in Section 3.1. To examine the impact of each nondeterminism on the user's display, we manually analyze the effect on the DOM tree, which is what the user see.

For this study, we selected 9 web apps that make extensive use of JavaScript. We selected these apps from the JavaScript projects on GitHub, and sample apps from the official framework site. Six of them use *jQuery* framework [6] and the rest use *enyo* framework [7]. jQuery is widely used by 73.3% of all websites and enyo is used on the commercial WebOS platform [26].

Each source of nondeterminism has a different impact on app loading. Some nondeterministic value is assigned to a local variable, thus not affecting the global state such as the DOM tree, while others can be used to affect the DOM tree. A previous study has classified nondeterminism based on whether it affects the global state [22]. For example, a nondeterministic JavaScript execution creating a unique identifier affects the global state, but it does not affect the user's display. We also categorized nondeterminism based on if it affects the DOM tree, thus changing the user's display and making the user feel the difference. For *nondeterministic functions* and *web APIs*, we analyzed if the DOM tree changes when the return value changes. For *interrupts*, we checked whether the DOM tree changes when the execution order of event handlers is changed. We also categorized nondeterminism based on where it occurs: *framework global code* in the framework script tag, *app global code* in the app script tag, or *event handlers* of the *DOMContentLoaded* and *onload* events.

Table 1 shows the total number of nondeterminism occurrences during the loading of 9 apps. The left value of each cell is the number of nondeterminisms that affects the DOM tree, while the right value is the total number of occurrences. Some nondeterminisms such as *IndexedDB* and *browser position* are not used, so they are not shown in the table. In the app loading process, nondeterminism occur 938 times in total, and the average number of usages per app is 104. If we categorized nondeterminism based on where it occurs, we can see that the framework global code, app global code, and event handlers use nondeterminism 18 times, 262 times, and 658 times, respectively. Framework global code creates objects and registers event handlers to initialize the framework, and those

(a) Unique identifier generation

```
jQuery.expando =
  "jQuery" + (version+Math.random()).replace(/\D/g, "");
Sizzle.expando = "sizzle" +-(new Date());
```

(b) Timestamp creation

```
jQuery.now = function() {
  return +( new Date() );
};
this.timeStamp = src && src.timeStamp || jQuery.now();
```

Figure 1: jQuery example code with nondeterminism sources

tasks are mostly deterministic. App global code and event handlers heavily use nondeterminism to change the DOM tree by reading the nondeterministic data such as the setting of the app or the current time. Since many jQuery apps uses event handlers to change the DOM tree [13], there are many occurrences of nondeterminism in the event handlers.

Among the sources of nondeterminism, the most frequent calls were *nondeterministic function*, among which *Math.random* is dominant. Since apps often use *Math.random* to determine the location and type of many DOM elements, so it is called frequently.

We examined the effect of nondeterminism on the DOM tree and found that none of the 34 nondeterminisms in the framework global codes affect the DOM tree. The reason is that the framework code uses nondeterminism in a way of not affecting the DOM tree. For example, the jQuery framework global code calls *Math.random* once and *Date* twice, as illustrated in Figure 1. Figure 1 (a) uses *Math.random* and *Date* to create a unique identifier, which is often used for avoiding conflicts between variable names when using multiple versions of jQuery in an app. Figure 1 (b) uses *Date* to record a timestamp, often for an event object to tell when the event is generated. This is useful for profiling the event performance, by measuring the time taken between two events generated as a result of the user interaction.

Since the unit of JavaScript execution included in the snapshot is a script tag or an event handler, we categorized nondeterminisms as a unit of script tags and event handlers. Table 2 shows the number of script tags and event handlers that have nondeterminism during the loading of 9 apps. In the framework script tag, 6 out of 11 are nondeterministic, but none of them affect the DOM tree. In the app script tag, only 4 out of 12 have nondeterminism, but all of them affect the DOM tree. Most of the event handlers (7 out of 9) have

Table 2: Number of script tags and event handlers

Type	Nondeterministic & affecting DOM	Nondeterministic	Total
Framework tag	0	6	11
App tag	4	4	12
Event handlers	6	7	9

nondeterminism, and most (6 out of 7) affect the DOM tree. We also found that nondeterminism is used extensively for some script tags and event handlers, but it is not used at all in others. For example, only two game apps (breakdom and piratepig) call *Math.random* 781 times. Those apps have more than a hundred DOM elements and use *Math.random* to specify the type of DOM elements or position of DOM elements randomly.

In summary, nondeterminism occurs frequently during app loading, but there are many scrip tags and some event handlers that are deterministic, or are nondeterministic yet not affecting the DOM tree. Based on this observation, we propose two nondeterminism-aware snapshot points that minimize the impact on the user's display while achieving a high performance.

4 NONDETERMINISM-AWARE SNAPSHOT POINTS

JavaScript execution order during app loading is fixed, composed of the executions of the framework script tags, app script tags, event handlers for the *DOMContentLoaded* event, and the event handlers for the *onload* event. We will decide a snapshot point at the end of some script in this sequence of scripts, where we create and restore snapshot.

If we consider nondeterminism when we choose a snapshot point, there can be two extremes. One is ignoring the effect of nondeterminism. Since we can save the DOM state in the snapshot [16, 29], this allows us to save all JavaScript executions in the snapshot, thus taking a snapshot point at the end of app loading. We define this snapshot point *nondeterministic JS*, which saves all JavaScript executions without considering nondeterminism.

The other extreme of snapshot is including deterministic JavaScript executions only, which we define *deterministic JS*. This method is consistent with the basic idea of a snapshot that stores and reuses the exactly same result of repeated JavaScript execution. However, as shown in Table 2, 17 out of 32 script tags and event handlers use nondeterminism, and more notably, 54% of the framework script tags have nondeterminism. Since the framework script tags tend to precede other script tags (i.e., the app global code uses the functions defined in the framework global code), if we cannot include some framework script in the snapshot due to nondeterminism, we cannot include any of other subsequent script tags and event handlers, either. This would take a snapshot point early in the app loading process, reducing the coverage of the snapshot. As such, the performance improvement using a snapshot of *deterministic JS* would be seriously limited.

To compromise between performance and correctness that the user perceives, we propose two more snapshot points considering nondeterminism. The first one is *deterministic DOM*, which saves all (even nondeterministic) JavaScript executions as long as they make the DOM tree deterministic. This includes creating unique identifiers using *Math.random* and logging the timestamps in Figure 1. From the user's perspectives, an execution is deemed correct if the result it produces is acceptable to the user [9]. In the web environment, the user observes only the DOM tree and the behavior of the event handlers, so the user will think that snapshot-based app loading is correct if those two states are deterministic. Usually, nondeterminism that affects the event handlers also changes the DOM tree, so we consider only the DOM tree in this paper (we discuss the event handler issue later in Section 5.3). Using a snapshot point of *deterministic DOM*, we can get additional performance by including more JavaScript executions than *deterministic JS* without affecting the user's display.

The second snapshot point is *semi-randomized DOM*, which extends *deterministic DOM* by saving additional JavaScript executions that may change the DOM tree using *Math.random*. Unlike *deterministic DOM*, the DOM tree of snapshot-based app loading can be different from that of regular app loading, but the correctness is not actually compromised. That is, if an app uses *Math.random*, any return value between 0 and 1 is correct, and the snapshot would include one of the possible, correct values (this is not true if a function retrieves the time or the location, since there should be only one correct value). For example, a game app is supposed to show a random, initial screen on each app loading (e.g., a minesweeper game with different mine locations generated by *Math.random*). If such a JavaScript execution is included in the snapshot, the initial screen would be fixed (e.g., the same location of mines), which might look odd, but still correct. *Semi-randomized DOM* exploits this randomness and save the executions that randomly change the DOM tree in the snapshot. Users might feel that the execution is incorrect if the state is fixed in one state, so we created multiple snapshot files generated by multiple app loadings, and use one of them randomly. If we store enough snapshots and use them, users might not feel any difference. This snapshot point is effective for our game apps that change the DOM tree each time of app loading using lots of randomness. For example, breakdom and piratepig app uses *Math.random* 212 and 560 times, respectively. *Semi-randomized DOM* saves those JavaScript executions in the snapshot and archives a substantial performance improvement. This approach leads to space overhead, but users can get a significant performance gain, as will be seen in the experiment.

5 NONDETERMINISM ANALYSIS TOOL

Previous section proposed two nondeterminism-aware snapshot points in the app loading process. Unfortunately, it is difficult for the developers to identify them since they must know every source of the nondeterminism in the app code as well as JavaScript variables and DOM tree elements affected by nondeterminism. In fact, most apps use one or more JavaScript frameworks and it is almost impossible for the developers to understand them completely since the frameworks are substantial with many features. To handle this problem, we propose an analysis tool, which informs the snapshot point automatically by analyzing nondeterminisms that occur during app loading using static and dynamic analysis.

Figure 2: Overview of our nondeterminism analysis tool

5.1 Overview of the Tool

Figure 2 overviews our nondeterminism analysis tool, which uses three steps to identify the snapshot points. First, the tool statically instruments the HTML codes and the JavaScript codes to extract the logs of read/writes for the JavaScript variables and of the DOM mutations in app loading. It also records the sources of nondeterminism. Secondly, we perform app loading with the instrumented app, dynamically collecting the logs, and our instrumented event handler invoked at the end of app loading uses those logs to generate a dependency graph of JavaScript and DOM. We actually run the instrumented app multiple times and get multiple dependency graphs. Since nondeterminism can be used at the conditional statement, the control flow of the app can change, producing a different dependency graph. So we run the app multiple times to deal with diverse control flows. Third, the tool uses the dependency graph to analyze if a DOM change during app loading is affected by a source of nondeterminism. Based on the analysis, it finds which script tags and event handlers can be included for the two proposed snapshot points. Then, the app developer will decide a proper snapshot point considering both their correctness policy and the expected performance benefit.

5.2 Nondeterminism Analysis

Our instrumentor is implemented by extending JS-Slicer [28], which instruments the HTML/JavaScript code to produce a runtime dependency graph for JavaScript and DOM. In the dependency graph, each node represents a statement, and an edge *(i, j)* represents a dependency relationship between node *i* and *j*. JS-Slicer uses static analysis to extract the control dependency and dynamic analysis to identify the JavaScript and DOM dependency.

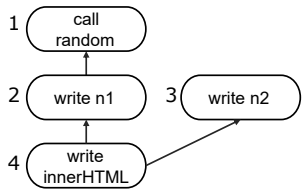
We modified JS-Slicer to record the usages of nondeterminism based on the source of nondeterminism listed in Section 3.1. We check every *function call* and *property read* at app loading time to see if any source of nondeterminism is used. If nondeterminism is used, the *id* of the statement and the *type* of nondeterminism in the statement (e.g., random) is recorded in the *nondeterminism map*. We use the map information to find the snapshot points later.

After running the app, we analyze if a script (script tag or event handler) in the script sequence of app loading includes nondeterminism, and if so, analyze whether the nondeterminism affects the DOM tree or not. So, for each DOM mutation statement, we compute all statements whose execution result is "*reachable*" to it. If a nondeterministic statement is reachable to a DOM mutation statement, the script that includes the nondeterministic statement "*affects*" the DOM tree. It should be noted that a nondeterministic statement can affect a DOM mutation statement in a later, different script in the script sequence.

Figure 3 shows an example of nondeterminism analysis for a script tag. Figure 3 (a) is a JavaScript code that declares two variables and displays the values in the DOM tree. Figure 3 (b) shows the corresponding dependency graph and the nondeterminism map. We create a node of the dependency graph for each statement, and the number next to each node represents its *id*. Since the return value of node 1 is assigned to the variable *n1* in node 2, node 2 has a dependence on node 1. To analyze whether the DOM changes in the script tag are affected by nondeterminism, we find all the reachable nodes to node 4 which has a DOM tree mutation. In this case, node 1, 2, and 3 are reachable to node 4, so we check the nondeterminism map to see if there are nondeterminism among those three nodes. Since node 1 is in the nondeterminism map, and its type is random, we record that this script tag has nondeterminism that affects the DOM tree, and its nondeterminism type is random.

There can be an if-statement in a script whose execution flow depends on the result of a nondeterministic statement such as *nondeterministic functions*, *device info*, or *interrupts*. In this case, we make an edge from the nodes located in the true and false paths of the if-statement to the nondeterministic statement in the dependency graph, based on the control dependence result obtained during static analysis. This is for computing nondeterministic scripts that may affect the DOM tree conservatively.

Even with a conservative dependency graph, there might be a case that might miss a nondeterministic script that affects the DOM tree. For example, consider a DOM tree element defined before an if-statement that is affected by *Math.random*. If it is redefined only in the true path of the if-statement, *Math.random* would appear not affecting the DOM tree if the false path is taken during app loading with the instrumented app, although it is evident that the DOM tree is changed depending on *Math.random*. To handle this case, we run app loading multiple times to cover diverse control flows, hence diverse dependency graphs.



There is a more subtle case. Consider an app whose loading uses a file system API that checks if a file exist, and if so, updates the DOM tree with the file (so the API is nondeterministic). The problem is that the file can be created only by an event handler executed during an user interaction after app loading completes. For a *note* app, for example, if the user writes a new note after current app loading, and the app should show the saved note at the next app loading. Even when we run the instrumented app loading multiple times, if we do not fire the event and execute the event handler after app loading, the API will always return false, thus classified not affecting the DOM tree. So, if an app uses a file system API, we need to collect the information on registered event handlers and fire the user events a few times even after app loading completes.

Based on the above analysis, we identify the scripts to be included in each type of snapshot point. Algorithm 1 shows the algorithm to find a script where we create a snapshot for a given type of snapshot point. *checkCandidate* function analyzes each script

(a) JavaScript code

```
1  var n1 = Math.random();
2  var n2 = 10;
3  document.body.innerHTML = n1 + n2;
```

(b) Dependency graph & Nondeterminism map

Nondeterminism Map

ID	Type
1	random
...	...

Figure 3: Nondeterminism analysis for an example JavaScript code

and tells which candidate snapshot point it can possibly belong to. Since a *deterministic JS* is the strictest candidate, it can also be included in a more relaxed candidate such as *deterministic DOM*, *semi-randomized DOM*, and *nondeterministic JS* snapshot points. Similarly, a *deterministic DOM* candidate can also be included in *semi-randomized DOM* and *nondeterministic JS* snapshot points. Finally, a *semi-randomized DOM* candidate can be included in *nondeterministic JS* as well.

findSnapshotPoint function checks all the scripts to be executed during app loading and returns a script where we need to take a snapshot point for a given type. It checks sequentially for each script in the app loading process if it can be a candidate for a given type of snapshot point based on the result of *checkCandidate*. If so, the script can be a snapshot point but we continue to check if we can extend the snapshot point to the next script (by iterating the loop in Algorithm 1). Otherwise, the script is the first one that cannot be included in the snapshot, so we return the current snapshot point, which is the previous script.

5.3 Limitation

To decide a proper nondeterminism-aware snapshot point, we analyzed if nondeterministic scripts executed during app loading affect the DOM tree. However, they can also affect the behavior of event handlers executed after app loading for some apps. For the nondeterminism analysis tool to cover the behavior of these event handlers, the tool should record a dependency graph for them as well. Unlike the scripts executed during app loading, the execution order of these event handlers would be arbitrary, depending on user interaction. So, we should trigger every sequence of user events and check the event handler is affected by nondeterminism in app loading. It is challenging to test event sequence using dynamic analysis only, so using some static analysis approach for the event handler would be effective [12], which is left as a future work.

For the apps using *file system* APIs, we need to trigger the events for user interaction to explore more paths of app loading scripts, as mentioned in Section 5.2. We currently trigger user events up to a fixed depth of two. App testing time would dramatically increase if we use a higher depth for more precise analysis. In the field of automatic testing, there are researches to minimize the triggered events [1, 23], which we can use for efficient testing in the future.

Algorithm 1 Snapshot Point Detection

```
1:  function checkCandidate(script)
2:      if script has nondeterminism then
3:          if nondeterminism affect DOM tree then
4:              if only random affect DOM tree then
5:                  return "semi-randomized DOM candidate"
6:              else
7:                  return "nondeterministic JS candidate"
8:          else
9:              return "deterministic DOM candidate"
10:     else
11:         return "deterministic JS candidate"
12:
13: function findSnapshotPoint(snapshot_point_type)
14:     snapshot_point ← ∅
15:     for i = 1 to number of scripts do
16:         candidate ← checkCandidate(script_i)
17:         if snapshot_point_type ⊂ candidate then
18:             snapshot_point ← script_i
19:         else
20:             return snapshot_point
21:     return snapshot_point
```

6 IMPLEMENTATION

We extracted dependencies between JavaScript variables on the top of JS-Slicer [28], which performs dynamic slice using JavaScript. For nondeterminism analysis, we update the shadow execution rule of the existing implementation to extract information of nondeterminism. JS-Slicer calculates the dependency for the DOM tree, but only using the *appendChild* and *innerHTML* among the APIs that can modify the DOM tree. The *MutationObserver* API is a Web API that monitors every DOM tree changes [24]. We used the API to track the DOM tree changes after the execution of the *property write* and *function call* statements.

JS-Slicer correctly generated dependency graphs for most JavaScript implementations, but do not for some native functions. JS-Slicer assumes that all arguments have a data dependency on the return value. However, in a native function such as *Array.sort*, we must attach additional edges to the dependency graph. *Array.sort* function compares the elements in an array and sorts them in order. This function compares two values using the function at the first argument. If the function that compares the elements uses nondeterminism, the array is randomly sorted and there must be a dependency between the return value of the function argument and the base array. We analyzed 28 methods of *Array* object. 10 of them update the array after the function call, but JS-Slicer creates no dependency between the argument and the base array. 7 of them need dependency between the return value of the argument and the base array as *Array.sort*. *Array.sort* is included in both case and we add dependencies on those 16 methods.

For automated testing, we use selenium to run and trigger events [20]. We run the app without file system five times and trigger user events up to a fixed depth of two for others. Finally, we create five snapshot files for *semi-randomized DOM* to simulate randomized execution.

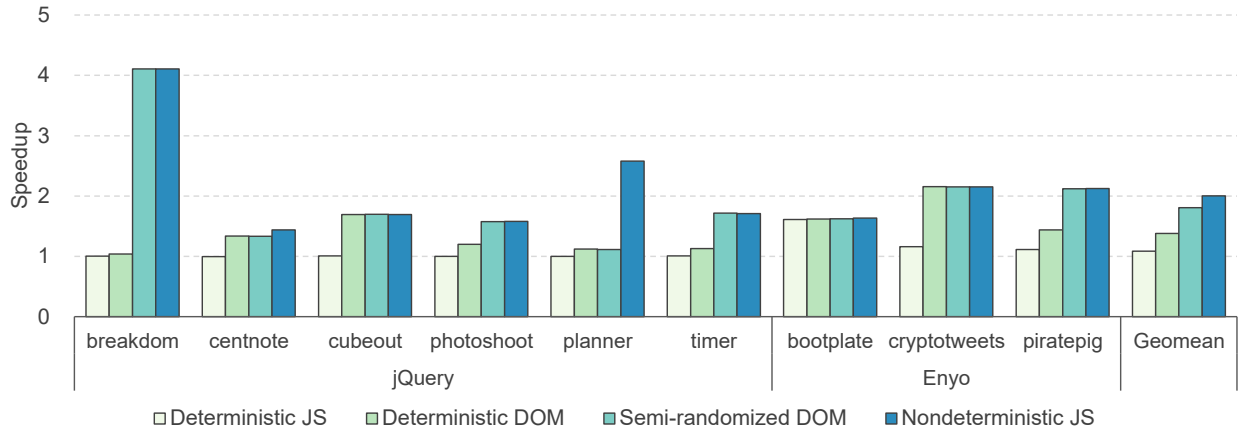


Figure 4: Snapshot-based app loading speedups of four snapshot points compared to original app loading

7 EVALUATION

We measured the performance of app loading based on the four snapshot points obtained from the nondeterminism analysis tool, and examined the effect of nondeterminism in the web app. Our snapshot is implemented based on the WebKit browser (rev-149728) and executed on a Pandaboard ES with 1.2GHz ARM Cortex-A9 CPU and 1GB of RAM. We experimented with 6 jQuery apps and 3 enyo apps used in the analysis in Section 3. We used a nondeterministic analysis tool to find *deterministic JS*, *deterministic DOM*, and *semi-randomized DOM* snapshot points. We also compare with the *nondeterministic JS* snapshot point, which saves the result of the whole JavaScript executions during app loading in the snapshot.

7.1 Snapshot Point Performance

Figure 4 shows the speedup of app loading time for the four snapshot points, compared to the app loading time without the snapshot. *Deterministic JS* accelerate app loading by 1.09 times on average. Web apps in our experiment use the JavaScript framework (jQuery or Enyo). jQuery framework calls the sources of nondeterminism during app loading, so we could not even save the execution state of the first script. On the other hand, Enyo framework does not call sources of nondeterminism source, so execution state of some global codes is included in the snapshot.

Deterministic DOM accelerate app loading by 1.38 times on average. It saves most execution results of framework and app script tags (global code) in the snapshot. Most enyo apps and some jQuery apps show the same performance improvement as *nondeterministic JS*, which ignores nondeterminism and saves the result of all event handlers.

Semi-randomized DOM accelerate app loading by 1.81 times on average. Although it still considers nondeterminism, it shows a performance improvement similar to *nondeterministic JS*, which accelerate app loading by 2.00 times. In most apps, *deterministic DOM* and *semi-randomized DOM* have the snapshot point at the same script, but the breakdom, photoshoot, and piratepig apps, which use lots of randomness, have a difference snapshot point. They use the *Math.random* function to calculate the location or the type of the DOM elements, which take a considerable amount of execution time. *Semi-randomized DOM* could achieve a substantial performance gain by including those executions in the snapshot.

7.2 Size of Nondeterministic Sets

We measured number of statements executed in the app loading. Table 3 shows the result. The first column shows the app names. The second column shows number of executed statements at app loading. The third and fourth columns show number of nondeterminism source statement and statements *reachable* from them. The fifth and sixth column show number of DOM change statement and number of DOM changes *affected* by nondeterminism. We measure LOC of jQuery framework and app code separately. Since the size of the enyo framework varies depending on the module used in the app, we analyzed minimal enyo framework code and both framework and app code together for enyo apps. We collected and averaged all execution results in the test runs.

The results show that many statements are reachable from nondeterminism at app loading. Although the number of nondeterminism sourzce takes less than 1% from executed statements, one source of nondeterminism propagates to average 379 statements. jQuery framework has nondeterminism but does not affect DOM tree with nondeterminism. We checked the statements executed during app loading to ensure that the tool correctly analyzes information on the statement and DOM tree mutations affected by nondeterminism, even in complex apps.

8 RELATED WORK

Wprof [27] classifies dependencies between browser activities and identifies bottleneck activities that contribute to the page load time using critical path analysis. They show that computation is a significant factor that constitute for 35% of the page load time on the critical path and synchronous JavaScript evaluation make a major contribution to page load time since it blocks parsing. Nejati et al. [15] analyzed web page load time for a mobile browser, which has limited hardward and poor network connection. On the mobile

Table 3: Number of executed statements during app loading

Web app	LOC	# exec stmt	# nondeter source	# nondeter affect	# DOM change	# nondeter DOM change
jQuery	10315	4736	4	4	7	0
breakdom	193	274064	217	253195	861	858
centnote	134	5457	5.4	625	7.6	0.6

Average	3037	58962	90.7	34388	122.1	100.1

browser, computation activities is the primary bottleneck which occupy more than 60% of the critical path.

There have been previous studies using snapshots to reduce app loading time. V8 JavaScript engine had a feature called *serialization*, which saves the JavaScript heap's built-in object in a file after the V8 initialization [5]. The V8 engine reads the serialized built-in object into the heap at startup, thus reducing the start-up time. Recently, using the APIs provided by V8, developers can also save the JavaScript execution results in the custom snapshot to accelerate the app loading. However, V8 can store only JavaScript state, and does not save the DOM state in the snapshot. There are earlier researches to accelerate app loading using a snapshot for the WebKit browser [16, 17]. Like V8, they traverse the JavaScript heap to save objects as snapshot files. It can also save the state of the DOM tree to extend the scope of the snapshot. The idea is recording all DOM change logs and restoring the DOM tree state by replaying it [16]. Recently, a different approach has been proposed where the DOM state is saved in serialized HTML [29]. It also provides a method of taking a snapshot point at the event handler, while the previous works take a snapshot at the script tag or at the end of app loading only. All these studies did not consider how to apply the snapshot when there is nondeterminism, so the developer had to analyze the app code and apply the snapshot on his own. This paper proposes a tool that can notify a proper snapshot point with two new nondeterminism-aware snapshot points.

Midas considered nondeterminism in middleware replication environments [22]. It has exploited application-level insight to classify nondeterminism as either affecting the application's persistent state or not. They used dynamic analysis to examine the effect of nondeterminism on the app and suggest ways to make the states the same when nondeterminism occurs in several devices. They classify nondeterminism based on the global state in the COBRA environment, and we categorize nondeterminism from the DOM tree in the web environment. We proposed a method to apply snapshot considering nondeterminism and made it easy to use snapshot through the tool.

Mugshot have developed record-and-replay for debugging for web environment and dealing with nondeterminism [14]. Mugshot classify the nondeterminism that can occur in the browser into five categories. *Tardis* also implemented record-and-replay in a managed runtime environment and considered nondeterminism [2]. They considered various nondeterminism such as network I/O, thread switches, etc. that can occur in the managed runtime, but focused on demonstrating the same execution result as the mugshot. We also classify nondeterminism that can occur in the web environment, but our research has focused on how to consider nondeterminism in environments using snapshots. In an environment where a snapshot is used, nondeterminism must be performed each time differently.

There have been various studies analyzing JavaScript. TypeDevil is research to find out when the type of variables changes dynamically through dynamic analysis [19]. They recorded all the information about how the type changed for each variable and analyzed it. ConflictJS is a study that tells you when a conflict occurs using the same variable between JavaScript libraries [18]. They analyzed the global variables that each JavaScript library writes to find conflicts between the libraries. Our study has analyzed nondeterminism occurring in a JavaScript environment differently from other studies. We also provide information about the scripts that can be included in the snapshot that developers can use based on the analysis.

9 CONCLUSION

In this paper, we analyzed JavaScript executions during app loading and found that nondeterminism occurs frequently but seldom affects the user's display. Based on these observations, we proposed two new snapshot points considering nondeterminism. We also developed a tool to inform the snapshot points automatically. We use the snapshot points obtained by the nondeterminism analysis tool for real apps and acclerate app loading by 1.81 times on average, compatitive to that of a snapshot point that completely ignores the nondeterminism issue.

ABSTRACT

Anonymous network services on the World Wide Web have emerged as a new web architecture, called the *Dark Web*. The Dark Web has been notorious for harboring cybercriminals abusing anonymity. At the same time, the Dark Web has been a last resort for people who seek freedom of the press as well as avoid censorship. This anonymous nature allows website operators to conceal their identity and thereby leads users to have difficulties in determining the authenticity of websites. Phishers abuse this perplexing authenticity to lure victims; however, only a little is known about the prevalence of phishing attacks on the Dark Web.

We conducted an in-depth measurement study to demystify the prevalent phishing websites on the Dark Web. We analyzed the text content of 28,928 HTTP Tor hidden services hosting 21 million dark webpages and confirmed 901 phishing domains. We also discovered a trend on the Dark Web in which service providers perceive dark web domains as their service brands. This trend exacerbates the risk of phishing for their service users who remember only a partial Tor hidden service address.

Our work facilitates a better understanding of the phishing risks on the Dark Web and encourages further research on establishing an authentic and reliable service on the Dark Web.

CCS CONCEPTS

• **Security and privacy** → **Phishing**; • **Information systems** → *Data extraction and integration*; • **Networks** → *Network privacy and anonymity*.

1 INTRODUCTION

The *Web* is the most popular, worldwide, and accessible platform for sharing and disseminating information across the globe. However, there is not only a bright side of the Web, but there is also a dark side. A set of platforms that host websites whose owners and users remain anonymous is now referred to as the **Dark Web**, whereas the *Surface Web* hosts regular websites. The Dark Web hosts websites whose formats and appearances are the same as those of the Surface Web. However, the way to access the Dark Web is different from that of the Surface Web. It demands the use of an anonymity network service for Dark Web service providers and their visitors to hide their identities on the Web.

The definition of the Dark Web has not officially been established [60], but it is often referred by the popular press and security community to emphasize illicit activities that abuse anonymity networks [15]. In this paper, we use the term "Dark Web" to refer to the collection of hidden Web services built on anonymous networks.

The Dark Web has become a major distribution channel for delivering and advertising malicious content. Silkroad [29] and Hansa-Market [13] are well-known Dark Web marketplaces that sell drugs, illegal weapons, and even malware. In addition, researchers have revealed that the Dark Web contained a considerable amount of harmful content [27, 53], and their findings have been confirmed by government investigative agencies [6] as well.

Conversely, the Dark Web offers a last resort for people who want to avoid censorship, to abide freedom of the press, and even to minimize tracking risks for their privacy. For instance, Venezuela experiencing the recent financial turmoil have blocked accessing political and social content on the Web, thus leaving Tor as the only option to access the restricted content [22].

Motivation. Phishing is one of the most effective threats that harvest users' privacy-sensitive information [64]. There thus exist the previous investigative studies that emphasize the severity of phishing attacks and the prevalence of phishing campaigns on the Surface Web [44, 54, 59, 61, 64]. Thomas et al. assessed the severity of Web phishing campaigns. Their study showed that phishing websites on the Surface Web emulating Gmail, Yahoo, and Hotmail logins had managed to steal 1.4 million credentials [61].

Conversely, the phishing threats on the Dark Web are understudied. Relatively little is known about the prevalence of phishing websites across the Dark Web universe. This trend stems from the absence of the oracle telling whether a given dark website is a phishing site or not. There is sufficient information to obtain the identity of owners operating websites on the Surface Web, which include HTTPS certificates, WHOIS, and DNS records. On the other hand, most dark websites' owners seek to hide their identities, which naturally makes it improbable for users to distinguish an authentic dark website from its phishing websites on the Dark Web.

We argue that it is crucial to address these phishing risks. On the Dark Web, users have no practical way to check the authenticity of

Web services except leveraging out-of-band clues, thus exacerbating the severity of phishing threats. To the best of our knowledge, mo previous study has investigated the phishing risks on the Dark Web. Prior work focused on analyzing illegal contents or unexpected activities [26, 42, 43, 46, 51], uncovering illegal activities [24, 25, 29, 34, 58, 63], and analyzing the popularity of the content on the Dark Web [27, 28].

Contributions. We conducted an in-depth analysis to identify phishing websites on the Dark Web. To do this, we collected more than 21 million webpages from 100K Tor hidden services for seven months. Our dataset represents the most up-to-date and comprehensive characteristics of the Dark Web.

We start with identifying phishing candidates whose website contents are almost identical to other websites. In other words, we investigate how many domains with distinct content and their duplicates constituted the Dark Web. We employ a carefully designed content grouping algorithm that classifies onion domains into content-wise distinct website groups based on the text and the title in each Tor onion domain's homepage. We observe that only 5,718 website groups exhibiting distinct content are available on the Tor network. Interestingly, the content of the top two website groups is duplicated in over 200 domains, which calls into question the authenticity of these domains.

For each website group consisting of multiple domains, we analyze all of the identified duplicates and confirm the presence of abundant phishing websites among the duplicates. Specifically, we identify 791 phishing websites that target five major Dark Web services including dark marketplaces and Bitcoin mixing services. We further analyzed how often users would encounter such phishing domains by counting cross references from other domains. In general, an authentic dark website is more frequently referenced by other dark domains than its phishing websites. However, interestingly, the most referenced website of Dream Market, a popular black market, is a phishing domain, which demonstrates that the attacker diligently spreads phishing domains.

To find further phishing websites on the Dark Web, we leverage "gray website." *Gray website* refers to a website that provides their identical services on both of the Surface and Dark Web. By leveraging the same ownership of a gray website and its corresponding surface website, we find 297 phishing websites on the Dark Web that target gray websites including Facebook. Our study is the first large-scale investigative study that confirms prevalent phishing sites on the Dark Web. Biryukov et al. [27] briefly mentioned the presence of one phishing website that mirrored Silkroad.

We also analyze the common trend in onion domain addresses on the Dark Web. Each website on the Tor network is represented by an onion domain name, a cryptographic string computed from the owner's public key. Considering that even picking an arbitrary five character-long prefix of an onion domain is computationally expensive and the visitors should still type the entire domain, we expect no meaningful prefix on onion names. However, we observe that the majority of the Dark Web service providers intentionally generate them to have meaningful prefixes that are at least five characters long. We conclude that the onion domain name itself is perceived as a brand for the service providers on the Dark Web. This trend has led to dark websites being vulnerable to phishing attacks because victims will depend on a partial memorable prefix instead of its entire onion domains to determine the authenticity of a service.

In this paper, we systematically studied unique/duplicate textual contents based on the comprehensive Tor anonymity network dataset, which is larger than any previous research. We observe abundant duplicate websites that target phishing victims and manifest their characteristics. We also confirm close correlations between website content and onion domains, which exacerbate the phishing risks on the Dark Web. Our work facilitates a better understanding of the phishing websites on the Dark Web and invites further research.

2 RELATED WORK

The *Dark Web* is a privacy-centric web environment built on anonymity networks such as Tor [33]. In the name of anonymity, the Dark Web has been aiding and abetting illegal activities. According to Biryukov et al. [27], most dark websites hosted content devoted to adult films (17%), drugs (15%), counterfeit items (8%), and weapons (4%) in 6,579 HTTP(S) Web services. Moreover, another study [53] has shown that the most popular Tor hidden services were botnet command and control (C&C) servers, and a large proportion of the content on the Dark Web is of questionable legality.

The notoriety of the Dark Web has triggered national authorities to seize many websites that are directly involved in illegal activities or that indirectly help users commit crimes [6]. Therefore, there is a growing interest among the authorities as well as researchers to understand the Dark Web, which demands discovering, classifying, and even deanonymizing dark websites.

Unlike the Surface Web, where domain names are well indexed by search engines, the Dark Web domain names are unknown unless they are explicitly announced via public channels. Biryukov et al., however, have demonstrated that it was possible to reveal all the Tor hidden services domain names by exploiting a design flaw of Tor's hidden services protocol [28]. Specifically, they modified the Tor relays (Onion routers) to sniff out the domain names. Today, the Tor administrators are actively detecting and banning such misbehaving onion routers [38, 56]. In addition, a recent study [45] showed that it is also possible to gather some of the onion domain names using conventional search engines that crawl and index hidden services via Tor proxy services [37].

Deanonymization of Tor hidden services has also been studied in previous work. Øverlier and Syverson [51] were the first to demonstrate the deanonymization of Tor hidden services, and there have been other studies [26, 42, 43, 46, 50] until today. More recently, there have been attempts to automate the analysis of the Dark Web; CARONTE [46] is an automatic Tor hidden service deanonymization system, and ATOL [35] is an automated Tor hidden service categorization framework.

Christin [29] and Soska et al. [58] have performed an extensive analysis of anonymous marketplaces on the Dark Web. Several related studies [24, 34] have also assessed the volumes of these marketplaces. On the customer side of dark markets, Van Hout et al. [63] and Barratt et al. [25] have provided notable insights into the participants of drug marketplaces. Biryukov et al. [27, 28] and Owen et al. [53] have analyzed the content and popularity of the Tor hidden services in general. Recently, Sanchez-Rola et al. [57]

measured the structural connection between the Dark Web and the Surface Web, and they also assessed the usage of tracking scripts on the Dark Web.

Phishing has remained a critical security threat [31, 32, 36, 40, 41, 48, 61, 64]. M. Cova et al. [31] investigated the diverse phishing methods of prevalent phishing kits. X. Han et al. [36] proposed a defense sandboxing technique to protect victims from phishing kits. Thomas et al. [61] used a Google dataset to assess the severity of currently on-going phishing campaigns and found that 12.4 million people are potential phishing victims, and 1.9 billion credentials have been leaked due to previous data breaches.

We conducted a content-based analysis to identify phishing websites on the Dark Web. Due the anonymous nature of the Dark Web, identifying phishing websites itself imposes a unique challenge. To the best of our knowledge, our study is the first investigative study that systematically examines the presence of phishing websites on the Dark Web and their distinctive characteristics.

3 DATA COLLECTION

The Dark Web refers to websites accessible via all the anonymity networks, including Tor [33], I2P [39], and Freenet [30]. Our study targets *hidden Web services*, which are the hidden services accessible via HTTP(S) on the most prevalent anonymity network, Tor.

We initially collected 10K Tor hidden service addresses (or onion domain names) from the popular Tor hidden service search engines and directories: Ahmia [23] and FreshOnion [10]. One of the most effective onion domain collection strategies, which Biryukov et al. [28] introduced, would capture all the onion domains available on the Tor network. They introduced a method of deploying modified onion relays that sniff out hidden service descriptors from anonymity network traffic. However, because the Tor policy now bans such misbehaving onion routers [9], we did not employ this method for ethical and respectable research.

We implemented a Web crawler based on Scrapy [18] and Splash [20] to collect not only static content but also dynamically changing content. To bypass anti-crawler/bot mechanisms that dark websites may employ, we used the latest Tor browser user agent for the crawler and distributed HTTP(S) requests towards the same domain via different Tor circuits to avoid being blacklisted due to sending numerous requests.

We deployed 16 web crawler instances and began by exhaustively exploring each of the 10K seed onion domains to collect all of the Tor HTTP(S) hidden services. We configured the crawlers not to follow any hyperlink to the Surface Web, but only to traverse .onion links until there were no more links to follow. We regularly updated our seed onion addresses by visiting the sources above to maximize our data coverage. Because both Ahmia and FreshOnion provide a full list of their indexed hidden services, the collected seeds were not biased to our selections of search keywords. We only collected textual data to avoid downloading any illegal content.

During the data collection period (7 months), we collected 28,928 unique onion domains with 21 million webpages. Table 1 summarizes our dataset coverage. Notably, of the 28,928 onion domains, there were 13,326 distinct second-level domains (2LDs). Our crawlers were initially deployed with 10K seed onion addresses, and by the end of our data collection period, we found 100K distinct Tor hidden services (or 2LDs). Although we were able to collect 100K distinct 2LDs, in the end of our data collection period, our webpage dataset included the webpages collected from 13,326 2LDs. This discrepancy resulted from the fact that not all Tor hidden services were alive during the data collection period (7 months) and a partial fraction of the Tor hidden services provided their Web services.

Table 1: Dark Web data collection

Collection period	January 2017 ~July 2017
Number of domains	28,928
Number of 2LDs	13,326
Number of webpages	21,537,119

Note that previous research [27] covered 100% of the Tor hidden services (or 39,824 2LDs) in 2013, and they reported that *only 3,741 of them provided web (HTTP) services*. We emphasize that the number of domains and webpages of our dataset demonstrates extensive coverage of the Dark Web.

We use *domain* and *2LD* to refer to an onion domain and a second-level onion domain, respectively. The *2LD* of an onion domain is an 80-bit number in base32 encoding and generated from a public key, which represents a unique client who owns the corresponding private key. For a domain not on the Tor network, we explicitly use the term:*surface domain*. The *homepage* of a given domain is the final destination page when visiting the domain with a browser.

4 IDENTIFYING CONTENT DUPLICATES

A phishing adversary lures victims to her website of which content is almost identical to the one of a legitimate website, thus expecting victims to provide sensitive information. Since it is infeasible to vet the authenticity of websites on the Dark Web by its anonymous nature, we exploit this intrinsic characteristic to identify phishing website candidates.

To accurately compute phishing candidates, we cluster a large number of domains into one website group when their homepages showed near-identical text contents. We then analyze how many onion domains share the equivalent contents and how many distinct contents exist on a per-website-group basis. Section 4.1 elaborates on our grouping algorithms, and Section 4.1.3 shows the result.

We further investigate multiple domains that share near-identical content in each website group. We leverage external clues nudging authentic service domains and investigate domains not matching the clues in each website group. Section 4.2 describes our findings and the characteristics of observed phishing websites on the Dark Web.

Several surface websites have been hosting their services on Tor hidden services [16] for privacy-concerned users who refuse to be tracked by the service providers. Such websites that appear on both sides are not truly *dark* because the service providers of these websites are no longer anonymous. We refer to such websites as *gray websites* and analyze their unique characteristics. We then identity gray website groups, each shares an almost identical content. In each group, we excluded the gray website that matches a surface webpage and then investigated the remaining domains to manifest their phishing risks. Section 4.3 describes our algorithm for finding gray websites and discusses our findings.

4.1 Website Classification

Non-text data (e.g., videos or images) published on the Dark Web may contain illegal or abusive content [27, 53]. We refrained ourselves from analyzing visual content on the Dark Web, but focused on storing and analyzing textual data on the Dark Web. For this reason, we only scraped and stored HTTP(S) responses with textual content.

We group the domains whose homepages share near-identical text contents into one group. Our classification algorithm has two phases. Phase I groups domains based on visible texts and titles collected from homepages. For each dynamic homepage, which Phase I has overlooked, Phase II extracts a set of the words that appears on the homepage and finds the website group, of which representative word set best covers the word set from the homepage. Each website group represents a set of homepages that have different domains but share almost identical contents.

4.1.1 Classification Phase I. Phase I groups domains based on *visible texts* and *titles* on their homepages. It starts by grouping the domains that show identical texts on their homepages. In the next step, it merges the previously computed groups when any homepages from two different groups share the same title. We continue to merge groups until there is no overlapping titles. Then, each merged group is called a *website group* that represents a set of onion domains that provide almost identical textual contents on their homepages.

Our approach is a heuristic with limitations. A website group combined based on excessively common title or text does not provide meaningful insights into the group. For example, the Apache Web server default page (e.g., It Works!) could be a homepage of many onion domains. We analyzed all the titles and texts of each group and then identified 46 different common titles and texts. We deliberately ignored such texts and titles because they contain no meaningful content.

We manually analyzed dark website groups and verified whether the homepages in the same group indeed have the same content. We confirmed that the Phase I algorithm produced no error such that no website has text content different to its group's one. However, this analysis was incomplete because there were 4,816 domains left unclassified. Phase I only groups websites sharing an identical title and text content; hence, it cannot correctly group website homepages with dynamic contents (e.g., homepages with a visitor counter or a clock).

4.1.2 Classification Phase II. Phase II completes the grouping of homepages with dynamic contents. From each website group C from Phase I, a group of onion domains, we retrieved a static word set w_C that appear in common. Afterward, for each unclassified homepage, we compute its word set w_h and then find a group C s.t. $w_C \subset w_h$.

The suggested algorithm has a limitation. Phase II becomes ineffective when the representative word set for each group is quantitatively small. Therefore, we selectively compared each ungrouped homepage h with each website group C from Phase I. If the static word set size $|w_C|$ for group C is relatively smaller than the homepage word set size $|w_h|$, we excluded this grouping candidate pair, $\{C, h\}$.

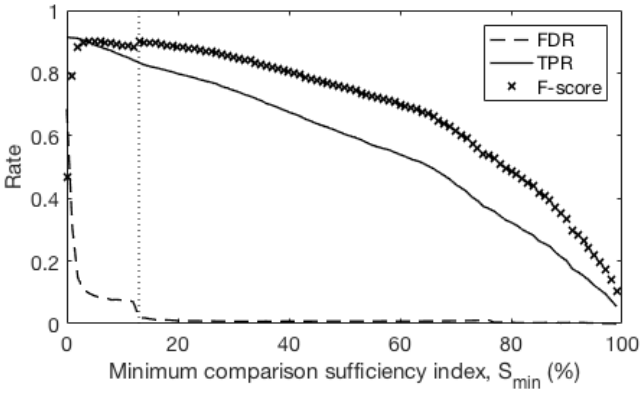

Figure 1: True positive rate (TPR), False discovery rate (FDR) and F-score of the Phase 2 classification by varying the minimum comparison sufficiency index S_{min}.

Quantitatively, for the pair $\{C, h\}$, if the comparison sufficiency index, $S_{C,h} = \frac{|w_C|}{|w_h|}$, is lower than the minimum comparison sufficiency index, S_{min}, we ignored grouping this pair. To determine the optimal S_{min}, we randomly sample 20% of the homepages from each group of onion domains from Phase I and reclassified them using different S_{min}. For each reclassification trial, we measured the true positive rate (TPR) [1] and false discovery rate (FDR) [2] by varying S_{min} as shown in Figure 1.

Our experiment shows that the F-score, the harmonic mean of TPR and 1−FDR, is highest when S_{min} was 13% (dotted line in Figure 1) and the FDR was only 1.9% based on our dataset (the TPR was 83%). We thus disregard any comparison pair whose $S_{C,h}$ is less than 13% in the final grouping phase. Phase II classified 3,397 domains into groups with only one domain member and the remaining 1,419 domains were assigned into the groups with multiple domains. For 200 sampled domains from those 1,419 domains, we manually checked their groups and confirmed that about 84% of websites had their correct grouping.

4.1.3 Classification Result. Table 2 summarizes our final grouping result. From the collected 28,928 onion domains, we found that there were 5,718 text-based distinct website groups. Of the 5,718 website groups, approximately 60% of them were single-domain website groups, and the rest (about 40%) of them were multi domain website groups. This means that 40% of the onion domains had at least one more domain whose homepage text contents were almost identical.

In the rest of this paper, a group of onion domains, which share almost identical texts on their homepages, is referred to as a *website group*. Moreover, we also counted the number of distinct 2LDs for each website group, and the result was not very different from the previous findings (approximately 40% of the website groups were associated with more than one 2LD).

[1] The proportion of websites truly in the group that are correctly classified, a.k.a. recall
[2] The proportion of websites classified to be in the group that are not originally in the group.

Table 2: Distinct website groups (WG) on the Dark Web

# of domains	1	2-50	51-100	101-200	201-300	Total
# of WG (%)	3,397 (59.31)	2,307 (40.35)	7 (.12)	5 (.09)	2 (.03)	5,718 (100)

# of 2LDs	1	2-50	51-100	101-200	201-300	Total
# of WG (%)	3,423 (59.86)	2,286 (39.98)	4 (.07)	4 (.07)	1 (.02)	5,718 (100)

4.2 Phishing Websites

A website group contains all websites that share almost identical texts. However, all websites in such a group are not necessarily the same website managed by one operator. If so, *why do onion domains in such a website group point to different websites although they share the identical content?* In this section, we analyze such domains and manifest 791 phishing onion domains that have targeted six popular dark websites.

There is no known effective method of identifying phishing websites on the Dark Web without an external clue. Dark website owners seek their anonymity and the nature of the Tor hidden network guarantees such anonymity at the protocol level. Therefore, it is improbable to decide whether two websites sharing the identical content belong to the same entity, thus hindering the inference of whether one of them is a phishing website. For the rest of this section, we use different kinds of *external clues* to identify 791 phishing domains. It means that the number of the identified phishing domains is a lower bound in 5,718 website groups, which may contain more phishing dark websites.

We identified the phishing domains that have targeted five (infamously) well-known dark websites (Table 3): Bitcoin Fog, Bitcoin Blender, Helix, AlphaBay Market and Dream Market. We specifically selected these sites, because they provide their authentic domains, which serve as clues for identifying phishing sites. However, there is a technical challenge. The five websites published their authentic domains on forums or their own websites on the Dark Web. It makes difficult for us to verify the authenticity of such information because anyone on the Dark Web can claim that his/her own website is an authentic domain for any of those five websites.

Table 3: Dark websites with known authentic domain names

Service type	Name	Authentic domains (#)	Phishing domains (#)
Bitcoin Mixers	Bitcoin Fog	1	276
	Bitcoin Blender	1	53
	Helix (Grams)	1	187
Dark Marketplaces	AlphaBay Market	16	165
	Dream Market	4	110
Total		24	791

4.2.1 Bitcoin mixers. Although all Bitcoin transactions are pseudonymous, they are public and traceable [49]. Hence, it is possible to link who has been involved in which transactions by analyzing the public blockchain [47, 55]. For this reason, Bitcoin mixing services that anonymize a user's Bitcoin transfers have gained significant popularity. Bitcoin Fog [3], Bitcoin Blender [1] and Helix [12] have been three of the most popular Bitcoin mixing services [62].

One challenge in this study is to identify the authentic onion domains of the three services, which are available exclusively on the Dark Web. Because the operators of these services conceal their identity, it is difficult for them to establish a reliable public channel to announce and promote their services. From our investigation, we learned that Bitcoin-related services are often promoted on a popular online forum called Bitcoin Forum [5], where the operators can anonymously promote their services and build up their reputations. Bitcoin Fog and Bitcoin Blender have first announced and released their authentic domain names on Bitcoin Forum, and both of these services are still currently active [2, 4]. In the case of Helix (or Grams[3]), they have done the same on Reddit [7]. Moreover, the authentic domain names of all three services have also been confirmed in a previous work [62].

By leveraging the authentic domain names of the Bitcoin mixing services and our website classification results, we were able to identify the phishing onion domains. The authentic domain of Bitcoin Fog was found in a website group with 277 different 2LDs, and we were able to conclude that the other 276 domains are phishing domains. To confirm this finding, we manually visited each domain in the Bitcoin Fog website group and investigated their content and behaviors.

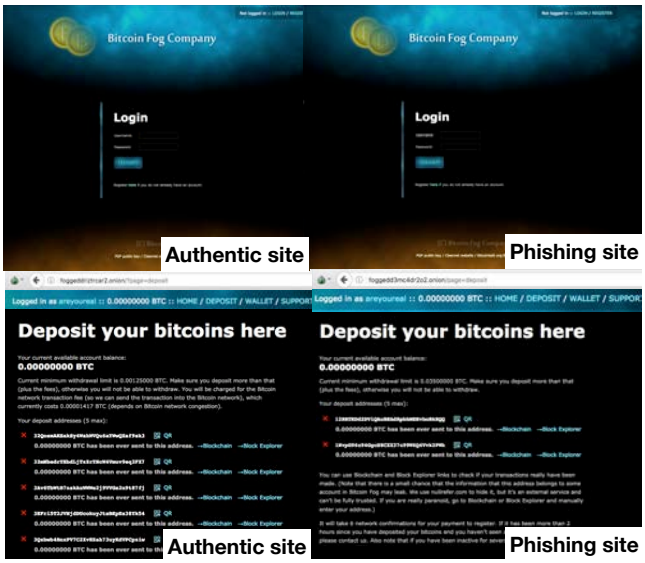

Figure 2: BitcoinFog: Authentic vs. phishing sites

The phishing websites of Bitcoin Fog were surprisingly sophisticated. As shown in Figure 2 (Top), the homepages of both the authentic and phishing sites were a login page and they were visually identical. The behaviors and functionalities of the websites

[3]Grams was a Dark Web marketplace search engine, and they additionally provided Bitcoin mixing services later on. Currently, Grams, including Helix, is discontinued. [12]

were also the same. Figure 2 (Bottom) shows that both the authentic and phishing sites allow users to add or remove Bitcoin deposit accounts. However, the authentic site and the phishing sites did not share the same backend user databases. As demonstrated in Figure 2 (Bottom), we were able to use the same username to create an account for both the authentic and phishing sites, but the Bitcoin deposit addresses linked to the accounts were different.

Bitcoin Blender's authentic domain belonged to a website group with 54 2LDs. Knowing that there is only one authentic 2LD, as shown in Table 3, we could infer that 53 2LDs in the group are phishing domains. We also manually verified each of the 53 phishing domains. Their websites sophisticatedly imitated the authentic website. The authentic website offered more functionalities, such as "Quick Mix" (Bitcoin mixing without an account) and password recovery; however, without knowing that the fact that the authentic website provides such features, it is highly likely that users will not be able to tell which one is the authentic site. Furthermore, the authentic site required users to solve CAPCHA, while the phishing sites did not.

In the case of Helix, its website group contained 188 2LDs, while only one of them was authentic. We also manually analyzed the websites linked to the domains, and we confirmed that the phishing domains led us to non-authentic websites.

4.2.2 Dark Marketplace. Another popular type of dark web services is a dark marketplace, which provides an e-commerce platform to anonymously trade illegal goods or services. Since Silk Road [29] has been terminated, there have appeared other dark marketplaces on the Dark Web. We analyzed two major dark marketplaces that have been active during our data collection period: AlphaBay and Dream Market. Compared to the other cases introduced above, it was even more difficult to identify the authentic domain names of AlphaBay and Dream Market because these sites have been using multiple number of domain names and even frequently changing them over time.

To discover the authentic domain names of AlphaBay, we took advantage of its takedown incident that happened in July 2017 [6]. According to FBI [6], "multiple computer servers used by the AlphaBay website were seized worldwide". Because the incident happened in the last month of our data collection period, we were able to capture the official seizure notice published on the seized websites. In our AlphaBay website group, there were 181 distinct 2LDs. 16 of the 2LDs have been shown the seizure notice since July 2018. Therefore, we inferred such 16 2LDs are authentic AlphaBay domain names, which makes the other 164 domains phishing.

Figure 3: Dream Market: Authentic vs. phishing sites

Dream Market is one of the largest dark marketplace that are currently active, and this market also has multiple mirrors as shown in Figure 3 (Left). Although Dream Market has published a list of the verified domain names to cope with its phishing sites, these phishing sites have also been doing the same by announcing their official domain names (Figure 3-Middle). In addition to actively promoting its authentic domain names, Dream Market provides a domain name verifier (Figure 3-Right), which allows users to check if a given onion domain name is one of the authentic Dream Market domain names or not. By using this verifier, we tested 114 2LDs and found that only four of them are authentic, which suggests that the other 110 domains are phishing domains.

4.2.3 Domain name popularity vs. authenticity. We used different types of clues to identify phishing domains for the five popular dark web services. For these identified phishing domains, we measured the popularity of such domain names on both the Dark and Surface Web. For the popularity, we counted the number of distinct dark webpages that mention each domain name, while excluding any self-references. We used 2LD names that are 16 characters long as keywords to search not only the hyperlinks but also the text that mention them from our dark webpage data collection. To measure the 2LD name popularity on the Surface Web, we counted the number of the search results returned by Google custom search API [11] for each 2LD name.

Figure 4 (a)-(e) shows the popularity of the authentic and phishing 2LD names on the Dark Web for each the service. Each point indicates the number of distinct dark webpages that mention each 2LD name, and two types of markers are used to show the authenticity of the domain names (X markers for phishing domains, O markers for authentic domains). Figure 4 (f)-(j) illustrates the popularity of the 2LD names on the Surface Web, and each point indicates the number of the search results returned from Google when searching for each 2LD name.

In the case of the three Bitcoin mixing services, each of which has the only one authentic domain, the authentic domains have been more popular than the phishing domains on both the Dark and Surface Web except for Bitcoin Blender. One of Bitcoin Blender's phishing domain names has been mentioned more than its authentic domain name on the Dark Web (Figure 4-b). On both of the web environments, the authentic domain names of the dark marketplaces have been referenced more than the phishing domain names; however, on the Dark Web, the most popular domain name of Dream Market was a phishing domain name (Figure 4-e). Furthermore, the phishing domain names have been more frequently mentioned on the Dark Web than on the Surface Web. This difference demonstrates that phishing attackers diligently spread fake information on the Dark Web by abusing their anonymity. In most cases, no result was returned by Google when searching for the phishing domain names of the five major services.

4.3 Gray Websites

A gray website is a dark website that satisfies two conditions: (1) it has the corresponding surface website providing and identical service, and (2) both websites are managed by the same entity. A gray website is usually the mirroring version of a surface website whose customers want to remain anonymous on the Web. We assumed that there are abundant phishing websites on the Dark Web that target such gray website visitors.

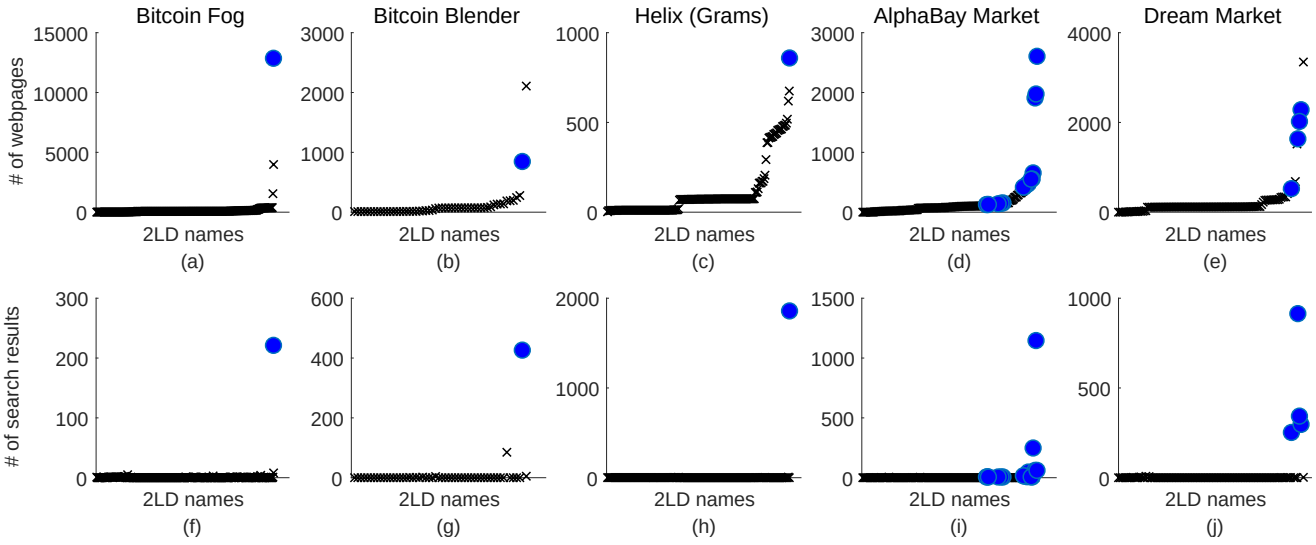

Figure 4: The popularity of five different Dark Web service domain names on the Dark (a-e) and Surface Web (f-j): The authentic domain names (in circular markers) have been mentioned more often than the phishing domain names (in x markers).

To identify such phishing websites, we first find authentic gray websites, each of which has a surface website with identical content. For each authentic gray website, we then compute its website group consisting of content duplicates. Finally, by leveraging information on each surface website paired with an authentic gray website, we confirmed phishing websites using content duplicates.

We started by identifying gray websites by partially applying the algorithm introduced by Matic et al. [46]. Our gray website identification algorithm extracts four types of clues from our dataset and then retrieves the same clues from surface websites. The extracted clues are dark website title, surface domain (e.g., non-onion domain names) in the title, Google Analytics tracking ID, and AdSense publisher ID.

We assumed that the four different clues are effective in deciding whether different websites are managed by the same entity. A homepage title is usually a representative string that shows the characteristics of the website. Because the homepages are already well-indexed by search engines, retrieving a title obtained from a dark homepage is an effective way of checking its existence on the Surface Web. Furthermore, if the title of a dark homepage includes a surface web domain, it is a strong indicator that the surface domain is the entry point of the same website. We also explored the methods of using both Google Analytics tracking and AdSense publisher IDs, which are assigned to each user. Usually, an owner of both dark and surface websites wants to maintain a unified view of his or her services. Therefore, such identifiers are compelling clues to check the same ownership of dark and surface websites.

We used a regular expression that matches surface domain names and matched 5,776 domains from the dark website titles. We then validated the matching surface domains by querying DNS servers, which confirmed 145 valid surface domains. We applied the same technique to extract the other clue types and obtained 276 Google Analytics IDs and 1,171 Google AdSense publisher IDs.

Table 4: Gray websites (GW) by each clue type

Clue type	# of search results	# of potential GW group	# of GW group
Domain in title	N/A	145	82
Homepage title	120,677	1,840	320
Analytics ID	1,241	1,049	80
AdSense ID	17,765	14,720	12

From the three clue types extracted from dark websites, we searched for surface websites using Microsoft's Bing Web Search API [17]. As Table 4 shows, we extracted surface domain candidates for each clue type. Each surface website candidate is then verified whether there exists a dark website whose body texts were similar to the contents of the surface website candidate. We used the same classification technique described in Section 4.1 to decide whether both dark and surface website candidates showed near-identical texts. As a result, we confirmed 383 gray website groups that were also available on the Surface Web.

In addition, we further investigated the contents of what had been identified as gray websites to understand their unique characteristics. We classified the website groups into three major categories: user-privacy-sensitive, provider-privacy-sensitive, and non-privacy-sensitive. A user-privacy-sensitive website is a website whose visitors would want anonymity. Such sites include pornography, file sharing, online gambling, forums, cryptocurrency services, etc. A provider-privacy-sensitive website indicates a website whose owners want to remain completely anonymous because of their illegal activities. Of the 383 gray website groups, about 35% of them were user-privacy-sensitive, about 10% of them were provider-privacy-sensitive, and the rest were non-privacy-sensitive as shown in Table 5.

Among 383 gray website groups, we further identified phishing websites. Note that each gray website group has one authentic

Table 5: Gray website categories

Privacy	Topic type	Percentage (%)	
User	adult	0.86	35.06
	political	2.01	
	forums	3.74	
	file sharing	5.17	
	cryptocurrency	6.9	
	gamble	7.18	
	communications	8.05	
	news	1.15	
Provider	illegal market	9.77	9.77
Irrelevant	academic	3.16	55.17
	software	6.9	
	security company	9.2	
	personal	17.53	
	others	18.39	

gray website with a corresponding surface webpage. We checked whether such a surface webpage explicitly mentions their authentic gray website onion domains. When a gray website group contains other domains that are not promoted by the surface website, we classify other domains as phishing websites. Table 6 summarizes the confirmed gray phishing websites. We confirmed 297 phishing domains from 383 gray website groups consisting of 734 domains. We classified 218 domains in 170 gray website groups as potential phishing websites because their surface websites did not specify their authentic onion domains.

Table 6: Phishing gray websites

Phishing	WG (#)	Authentic gray website domains (#)	Phishing domains (#)
Confirmed	213	219	297
Potential	170	N/A	N/A
Total	383	219	297

One of the phishing gray websites that we have identified targets Facebook. Since Facebook has announced the official onion domain name (facebookcorewwwi.onion) of their dark website [16], the other domains that belong to its website group were obviously phishing domains. As shown in Figure 5, the landing pages of the two domains are visually identical. One notable difference is that the Facebook's official dark website (Figure 5-Top) provides their HTTPS certificate, while the other site (Figure 5-Bottom) does not. We further analyzed the phishing site, and as shown in Figure 5 (Bottom), we confirmed that they were stealing the Facebook login credentials.

4.4 Discussion

By classifying the onion domains into content-wise identical website groups, we confirmed that about 40% of the website groups were associated with more than one onion domain. Then, *why would many website groups have more than one onion domain for their own service?*

Network balancing. One possible explanation is that many websites on the Dark Web could have been using multiple subdomains (lower than second-level) to provide identical content. However,

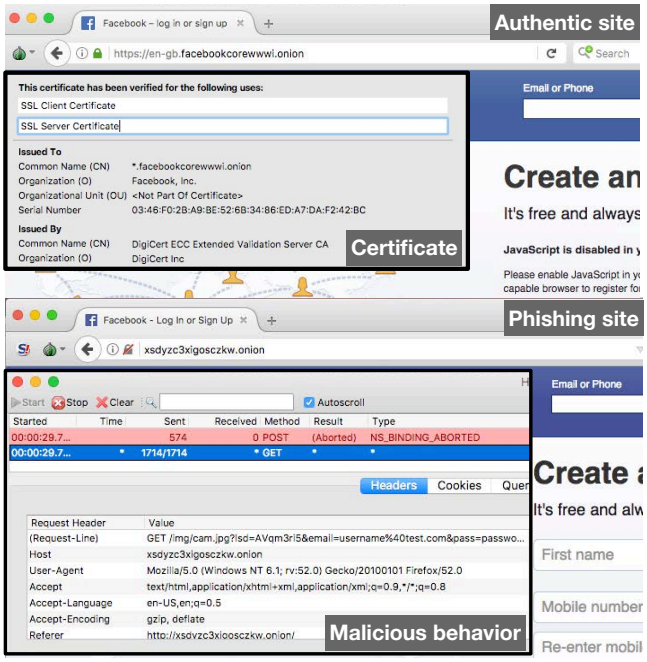

Figure 5: While the official Facebook site (Top) supports HTTPS with a valid certificate, the phishing site (Bottom) does not support HTTPS.

as shown in Table 2, the ratios of single-domain website groups to multi-domain website groups between domains and 2LDs remained almost the same. Hence, we excluded this explanation. Another explanation is that the dark websites could have deployed multiple numbers of Tor clients (or relays) to address the known scalability problems in the Tor hidden service architecture [14, 52].

One scalability problem arises when there are many concurrent requests to a 2LD. A 2LD is bounded only to a unique Tor client because it is computed from the public key assigned to the client. Consequently, one Tor client is solely responsible for the network traffic directed to and originated from its onion address. In such an architecture, the Tor clients that provide hidden services can easily become network bottlenecks as they lack load balancing options [14]. To avoid such a problem, the service providers operating a popular hidden service could have deployed multiple Tor clients, each of which has its own 2LD, to distribute the visitors.

The other scalability problem lies in the *introduction point*, as Tor announced [14], "The current hidden services architecture does not scale well due to introduction points hammered by many clients." An introduction point is a regular Tor relay, chosen by a Tor hidden service for setting up a *rendezvous point*. Thus, accessing such an introduction point is a preceding step to access the hidden service. When the service handles many concurrent requests, their service reliability depends on how many requests their introduction points can handle. This problem was addressed in a previous study [52]; however, Tor has not deployed the proposed solution.

Meanwhile, this problem is easily solvable by deploying multiple 2LDs (or Tor clients). Because multiple 2LDs have more introduction points than one 2LD, each introduction point becomes having less incoming requests of notifying rendezvous points. This simple trick

explains our observation that having multiple 2LDs is common across many dark websites to improve their service availability.

Prevalent phishing websites. We also confirm that phishing is another cause of abundant domains for each website group. We observed numerous phishing websites with content duplicates of authentic dark websites. In particular, we found that at least 791 onion domains have been hosting the phishing websites of the five well-known Dark Web services during our data collection period. After adding 297 gray phishing domains, we confirmed 901 unique phishing domains on the Dark Web.

We observed that many dark websites have been employing different strategies to cope with the phishing threat. One strategy is to leverage a popular social platform on the Surface Web. For instance, Bitcoin Fog and Bitcoin Blender have been building up their reputations on Bitcoin Forum which has more than 2M users. Bitcoin Forum serves as a reliable communication channel among their dark website visitors to establish the authenticity of their onion domains.

The other strategy is to provide an additional service telling whether a given domain is an authentic dark website service. Dream Market, for instance, has been actively announcing their official domain names, and they even provide an address verification service (Figure 3-Right) that tells whether a given domain name is one of their authentic domains or not. Interestingly, Dream Market offers a two-factor authentication (2FA) to protect their users from phishing attacks. Because their users also seek the anonymity as well, instead of requiring the email addresses of their users, they leverage the PGP public/private key pair of a user with 2FA. A user first registers her or his PGP public key. For the following authentications, the website requests the user to decrypt a cipher-text which is encrypted with her or his PGP public key. A phishing attacker is unable to access the Dream Market website even with the stolen credential of a victim unless the attacker has the victim's PGP private key.

We also measured the popularity of the authentic and phishing domain names of the six well-known Dark Web services. We counted the number of surface and dark websites that contain the authentic and phishing domains in their homepages. In most cases, the authentic domain names were relatively more popular than the phishing ones on both the Dark and Surface Web. It shows that the popularity of an onion domain name can be an indicator to determine its dark website authenticity.

Another interesting finding is that the phishing domains are rarely mentioned on the Surface Web while the authentic names are relatively popular in both of the environments. It demonstrates that the anonymous environment of the Dark Web is more susceptible to the fake information on the authentic domains than the Surface Web, which unfortunately has been abused by phishing attackers.

Gray websites. There have been a small number of popular surface websites that are also available as Tor hidden services. Such gray websites are mostly user-privacy-sensitive websites, and each aims to achieve a different goal by allowing users access to the site via the Tor network. For example, The New York Times has been available via nytimes3xbfgragh.onion [21], and as a news company, it aims to allow people around the world to avoid any Internet censorship and read its articles via the Tor network. Facebook has also launched facebookcorewwwi.onion [16] in a similar manner.

We observed that 213 surface websites released their authentic gray website domains. At the same time, we confirmed 297 phishing domains which have lured victims who wish to use gray websites. For instance, DeepDotWeb is a news site covering events and dark website reviews, accessible via www.deepdotweb.com and deepdot35wvmeyd5.onion. Our analysis discovered eight phishing domains cloning the homepage of DeepDotWeb. These phishing websites promoted phishing domains for prevailing dark marketplaces by showing forged user comments and ratings on these websites. Any visitors without knowing the authentic surface website of DeepDotWeb has no practical way of distinguishing its authentic gray website from the phishing websites.

5 DARK WEB DOMAIN NAMES

This section describes our findings regarding how much effort the service providers put into picking their choices of onion domain names. We then explain that this trend leads to many onion domain names containing keywords that reflect the contents of the dark websites. At the same time, this trend exacerbates phishing risks for users who leverage a partial word in a domain name to vet the authenticity of the current dark website.

5.1 Domain Naming Trends

A domain name is a valuable asset especially when it comes to Internet business. For e-commerce or social network services, their domains are often considered as the brands of their businesses. Likewise, a Dark Web service provider may want to obtain a desired domain name; however, onion domain names are fundamentally different from surface domains. An onion domain name must have ".onion" as its top-level domain (TLD), and its 2LD is an 80-bit number in base32 generated from a service provider's public key. Therefore, it is computationally expensive to obtain the exact domain name that a service provider asks for.

A service provider may conduct a brute-force search to find a public key that will generate the desired 2LD. However, finding the desired one (fully matching 16 characters) is computationally infeasible. The author of a brute-force onion address generation tool [19] reported that it would take approximately 2.6 million years to obtain an address that only matches the first 14 characters of the desired domain. Therefore, a service provider might prefer to use a shorter domain prefix, which drastically reduces the domain searching time. Using the same tool, if a service provider looks for a domain whose first five characters matches his/her chosen word, it would only require approximately one minute [19].

We conducted the study to understand how Dark Web service providers perceive their onion addresses. Figure 6 visualizes the domain name similarity heat map. For horizontal and vertical axes, we lexicographically sorted all the second-level onion domain names in our dataset. We then marked a cross point when two corresponding onion domains belonged to the same website group addressed in Section 4.1. We deliberately marked no point when two onion domains on both axes are the same. Finally, we clustered marked points within each 10 by 10 size cell into a color point, which depicts the number of marked cross points. That is, a color point in the figure represents the number of onion domain pairs that share the near-identical content among 100 pairs. Therefore, the existence of

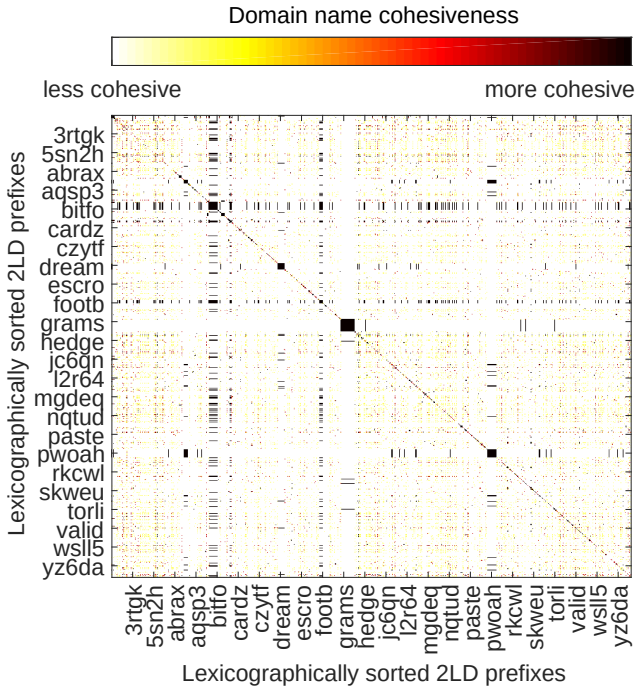

Figure 6: Name similarity heat map of 2LDs.

a clear diagonal line across the heat map of Figure 6 suggests that domain names with text-wise similar content share the same 2LD prefix.

Knowing that many similar 2LDs existed, we further examined whether such domain names were intentionally generated. We reused the website groups that were described in the previous section. We compared the 2LDs to one another for each website group and computed the longest common prefix (LCP) of each domain name combination pair. Therefore, for each website group, there are multiple LCPs out of all the possible domain name pairs. Considering that a 2LD is generated from a random public key, having a long LCP between two domain names is highly unlikely.

We found that at least 67% of the 5,718 website groups had LCPs of at least five characters long. This means that those website groups used brute-force to generate their onion domain names with their preferred prefixes. Interestingly, eight website groups selected domain names whose LCPs were 10 characters long. Generating such onion domains using Shallot [19] on a 1.5GHz processor, could take up to approximately 40 years. Based on this approximation, if a website owners uses 72 cores of Intel Xeon 2.3GHz CPU from Amazon cloud resources [8], it takes approximately 131 days and costs around $9,500.

We further analyzed the LCPs with at least five characters long. There were 184 common words (e.g., crypto, count), and 231 words were from the titles of onion domain homepages (e.g., grams7, alphabayww). Considering that these LCPs are computed from a website group with content duplicates, service providers choose a prefix of their 2LDs based on their content. In summary, a non-negligible portion of Dark Web service providers puts significant computational resources into assigning meaningful prefixes to their onion domain names.

5.2 Discussion

Each onion address is cryptographically bound to the Tor client who owns the private key corresponding to the onion address. Therefore, a correct onion domain that a user wants to visit leads to the webpage owner, who has the private key matching the domain. However, the onion domain itself is not memorable. We have observed that many service providers brute-force generate *partially memorable* onion domain names with human-readable prefixes to make their domains more intuitive.

These trends make phishing easier because people now check the authenticity of a dark website using its partial domain name. Consider two different onion domain names; bitcoinfoganfnad.onion and bitcoinfogansdse.onion. Because both of them share the common prefix "bitcoinfog", the visitors would presume that the addresses will lead them to the BitcoinFog website. However, neither of them is the authentic BitcoinFog website. To introduce one case of this type of abuse, our BitcoinFog website group has 277 domains, while one of them is the official BitcoinFog domain (foggeddriztrcar2.onion). In this website group, there were 109 onion domain names beginning with "bitfog," 40 domains with "fogged," and 19 domains with "btcfog". In the case of our AlphaBay website group (181 domains), where one of the authentic onion addresses is pwoah7foa6au2pul.onion, there were 98 domains with the common prefix "pwoah" and one domain had the longest common prefix "pwoah7foa." One light mitigation for such a phishing attack is to use a completely random onion domain so that its visitors give up on memorizing the domain and use a bookmark instead.

6 CONCLUSION

We conducted a comprehensive investigation of the phishing risks in the Tor anonymity network. We demonstrated that only 5,718 website groups with distinct contents exist among 28,928 onion domains and confirmed 901 phishing domains with content duplicates. We investigated how much effort Dark Web service providers put into selecting their onion domains and addressed that this trend brings an unfortunate side-effect of having many phishing sites with shared onion domain prefixes. We carefully designed the analysis algorithms to identity the phishing risks on the Dark Web and presented the severe phishing risk on the Dark Web, which urges further research to provide users with authentic dark Web services.

ABSTRACT

Recommender systems that can learn from cross-session data to dynamically predict the next item a user will choose are crucial for online platforms. However, existing approaches often use out-of-the-box sequence models which are limited by speed and memory consumption, are often infeasible for production environments, and usually do not incorporate cross-session information, which is crucial for effective recommendations. Here we propose Hierarchical Temporal Convolutional Networks (HierTCN), a hierarchical deep learning architecture that makes dynamic recommendations based on users' sequential multi-session interactions with items. HierTCN is designed for web-scale systems with billions of items and hundreds of millions of users. It consists of two levels of models: The high-level model uses Recurrent Neural Networks (RNN) to aggregate users' evolving long-term interests across different sessions, while the low-level model is implemented with Temporal Convolutional Networks (TCN), utilizing both the long-term interests and the short-term interactions within sessions to predict the next interaction. We conduct extensive experiments on a public XING dataset and a large-scale Pinterest dataset that contains 6 million users with 1.6 billion interactions. We show that HierTCN is 2.5x faster than RNN-based models and uses 90% less data memory compared to TCN-based models. We further develop an effective data caching scheme and a queue-based mini-batch generator, enabling our model to be trained within 24 hours on a single GPU. Our model consistently outperforms state-of-the-art dynamic recommendation methods, with up to 18% improvement in recall and 10% in mean reciprocal rank.

1 INTRODUCTION

For many web applications, making item recommendations that match users' interests is of key importance. Effective recommendations greatly improve users experience and retention, which leads to long-term increase in engagement. In real-world scenarios, user's interests dynamically shift and evolve over time. While interests of a user across different sessions might depend on their long-term interests and are hence somewhat stable, the short-term in-session interests tend to evolve rapidly. Therefore, an ideal recommender system should be able to capture both levels of user's dynamic interests and update those interests in real-time based on user's interactions.

The most direct data sources to build a recommender system are users' past sequences of interactions, which are abundant and well structured. Currently, rule-based models are still widely used to make dynamic recommendations. Many works have shown that rule-based models, e.g., recommending the items with the largest number of interactions, is in fact a very strong baseline [12, 23]. Recent years have witnessed the power of sequence-based deep learning models in computer vision [22], natural language processing [19], and graph structured data [37]. In addition, recent works have applied sequence models for dynamic recommender systems [12, 31, 35] as well. These techniques usually involve using a specific sequence model, such as RNN or Convolutional Neural Networks (CNN), to encode users' past interactions into a latent feature space, which is then used for future predictions.

However, none of these approaches is suitable for recommender systems that scale to modern web-scale production environments with hundreds of millions of user, billions of items and tens of billions of interactions per day. In particular, rule-based models fail to perform well in complex large-scale tasks. Purely RNN-based or CNN-based approaches do not capture the hierarchical nature of in- and cross-session user interests. In addition, RNN-based approaches are slow and difficult to train on massive data due to issues with gradient backpropagation. CNN-based approaches have high memory consumption, and do not involve smooth and interpretable latent representations than can be reused for down-stream tasks.

Here we propose Hierarchical Temporal Convolutional Networks (HierTCN), a novel neural architecture for modeling users'

[1] Work done while at Pinterest.

sequential interactions, which enables real-time large-scale recommender systems. We design our model with modern web-scale recommender system production environment in mind; therefore, HierTCN is memory-efficient and fast to compute. HierTCN consists of two levels of models to capture hierarchical levels of user interests. The high-level model uses RNN to capture users' evolving long-term interests across sessions, while the low-level model is implemented with TCN, utilizing both a user's long-term interests and the short-term interactions within sessions to output a dynamic user embedding and make recommendations. We apply HierTCN to a public dataset as well as a large private dataset with 1.7 billion training examples. We show that HierTCN has the following benefits over existing approaches:

(1) HierTCN has a significant performance improvement over existing deep learning models by about 30% on a public XING dataset and 18% on a private large-scale Pinterest dataset.
(2) Compared with RNN-based approaches, HierTCN is 2.5 times faster in terms of training time and allows for much easier gradient backpropagation.
(3) Compared with CNN-based approaches, HierTCN requires roughly 10% data memory usage and allows for easy latent feature extraction.

Based on HierTCN, we build a dynamic recommender system that scales to millions of users and billions of interactions. In terms of scale, it is at least 100 times larger than existing dynamic deep learning based recommender systems. The HierTCN-based recommender system features in the following components:

(1) A framework for joint modeling the dynamics of millions of users and items, which is not possible by existing approaches.
(2) An efficient offline training pipeline for HierTCN, which consists of efficient data caching and mini-batch generator.
(3) An efficient online inference pipeline that enables real-time recommendations using HierTCN.

2 RELATED WORK

Sequence models. CNNs and RNNs are two important architectures for sequence modeling. The sequential nature of RNN has made it the default choice for sequence modeling, and Long short-term Memory (LSTM) [13] and GRU [4] are the two most popular RNN variants. CNN has a long history of its application to sequence modeling as well [18]. 1D CNN with dilated convolutions have been shown to be powerful for audio data [21]. The idea has been further developed by [2] and is summarized as Temporal Convolutional Network (TCN), demonstrating its capability of modeling sequences in general. Our work here builds on this line of work but extends it by making it feasible for modeling hierarchical user interests and large-scale production environments.

Static recommender systems. Recently, there has been a surge of interest in applying deep learning to recommendation systems. Several approaches treat user interactions as static information by ignoring the temporal dimension, and try to learn a static similarity matrix between users and items [7, 11, 14, 26]. In contrast, our work explicitly considers the dynamics of user-item interactions through sequence modeling.

Dynamic recommender systems. RNN is the most widely used architecture for dynamic recommender systems [6, 12, 16, 23, 34]. Concretely, [34] captures temporal aspects of user-item interactions and uses LSTM cell coupled with stationary factors to identify movie popularity fluctuations. [16] interpolates k-nearest-neighbor method with a session-based RNN [12] and demonstrates performance gains over static recommender systems. Recently, [6, 32] combine point process models with the RNN-style state update functions to capture the co-evolution of user and item embeddings. However, these works only use one RNN network and do not explicitly consider multi-session settings. [23] is the most relevant work with our paper, where a hierarchical Gated Recurrent Units (GRU) framework is proposed. Our work differs in the way we design the hierarchy, the application of the TCN model, and many practical techniques that allow for deployment on real-world large-scale problems. Experimental results also show significant performance improvement of our model in both accuracy and speed. Furthermore, TCN-based sequence models remain largely unexplored for recommender systems, except for a very recent preprint [38]. In comparison, our work significantly alleviates the memory consumption issue of TCN which restricts its large-scale application, and explicitly models different levels of user interests.

3 PROPOSED MODEL

3.1 Problem Setup

We consider the problem of building a dynamic recommender system that adapts to users' preferences in real-time. For each user, we observe a sequence of items $\mathbf{c} = (\mathbf{c}_1, \mathbf{c}_2, ...\mathbf{c}_n)$ that are impressed to a user, where $\mathbf{c}_t \in \mathbb{R}^{d \times m_t}$ are the embeddings of m_t impressions at time t. The user interacts with some subset of the impressed items, which are denoted as $\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, ...\mathbf{x}_n)$, where $\mathbf{x}_t \in \mathbb{R}^d$ is the embedding of the interacted item at time step t, with n being the total number of interactions for the user. In our context, an interaction $\mathbf{x}_t$ refers to *positive* actions such as clicking, saving, sharing, or buying an item, while impressions $\mathbf{c}_t$ refer to just viewing items. In addition, we assume that interactions can be segmented into sessions using a function $q(\cdot)$, such that $i = q(t)$ indicates that the time step t belongs to session i. Our goal is to learn a function that predicts $\mathbf{x}_t$ from $\mathbf{c}_{\leq t}$ and $\mathbf{x}_{<t}$.

3.2 High-level Sketch of Our Approach

Our solution is based on inferring user and item embeddings from the historical data $(\mathbf{x}, \mathbf{c})$. We note that typically users' interests vary significantly within sessions. Hence, it is crucial to update user embeddings in near real-time in order to model their short-term interests accurately. On the other-hand, item embeddings can be fairly stable and only require update after regular time-intervals and in-between these intervals they can be considered static for the sake of efficiency. In practice, we update item embeddings daily, whereas user embeddings are updated in near real-time. This choice is discussed in detail in Section 3.6.1.

The main goal of our recommender system is to predict the next interaction from a set of candidate items. We formulate the problem using a function $f_\theta(\cdot)$ that infers the *user embeddings* $\mathbf{u}_t$, then compute the similarity between $\mathbf{u}_t$ and the candidate item embeddings to produce an unnormalized conditional distribution

$p(\mathbf{x}_t|\mathbf{x}_{<t})$. Specifically,

$$p(\mathbf{x}_t|\mathbf{x}_{<t}) = S(\mathbf{x}_t, \mathbf{u}_t); \quad \mathbf{u}_t = f_\theta(\mathbf{x}_{<t}) \tag{1}$$

where $f_\theta(\cdot)$ is implemented as a deep neural network, and $S(\cdot)$ is a scoring function, e.g., a dot product, that measures the similarity between $\mathbf{x}_t$ and $\mathbf{u}_t$. To finally make a recommendation, we evaluate $p(\mathbf{x}_t|\mathbf{x}_{<t})$ over a pool of candidate items and rank the items in descending order. When the impression data $\mathbf{c}$ is known, the candidate pool consists of m_t impressions at time step t; otherwise, the candidate pool could be all the items, a random subset of all the items, or a selection of items via some simple heuristics. Next, we review the key ingredients that constitute $f_\theta(\cdot)$.

3.3 Single-level Sequence Models

We review the two recent state-of-the-art sequence models, which serve as the building blocks of our model.

3.3.1 Recurrent Neural Networks. RNNs are naturally designed for modeling sequences. RNN maintains a hidden state vector that is updated with new inputs using the following update function:

$$\mathbf{s}_t = \sigma(\mathbf{W}\mathbf{x}_t + \mathbf{U}\mathbf{s}_{t-1}) \tag{2}$$

where $\mathbf{x}_t$ is the input at time step t, $\mathbf{s}_t$ is the hidden state, and $\mathbf{W}, \mathbf{U}$ are trainable parameters. RNNs are known to suffer from vanishing gradient problem, and Gated Recurrent Unit (GRU) is a popular model that mitigates the issue [4]. The update function of a GRU can be written as

$$\begin{aligned}
\mathbf{g}_t &= \sigma(\mathbf{W}^g\mathbf{x}_t + \mathbf{U}^g\mathbf{s}_{t-1}) \\
\mathbf{r}_t &= \sigma(\mathbf{W}^r\mathbf{x}_t + \mathbf{U}^r\mathbf{s}_{t-1}) \\
\mathbf{h}_t &= \tanh(\mathbf{W}^h\mathbf{x}_t + \mathbf{U}^h(\mathbf{s}_{t-1} \odot \mathbf{r_t})) \\
\mathbf{s}_t &= (1 - \mathbf{g}_t) \odot \mathbf{h}_t + \mathbf{g}_t \odot \mathbf{s}_{t-1}
\end{aligned} \tag{3}$$

where $\mathbf{x}_t$ is the input at time step t, $\mathbf{s}_t$ is the hidden state, $\mathbf{g}_t$ is the update gate, $\mathbf{r}_t$ is the reset gate, $\mathbf{h}_t$ is the candidate activation, $\sigma(\cdot)$ is the sigmoid function, and $\mathbf{W}^g, \mathbf{W}^r, \mathbf{W}^h, \mathbf{U}^g, \mathbf{U}^r, \mathbf{U}^h$ are trainable parameters. A Multilayer Perceptron (MLP) with ReLU activation is then used to output prediction $\mathbf{u}_{t+1}$:

$$\mathbf{u}_{t+1} = \mathbf{W}^{(2)}\text{ReLU}(\mathbf{W}^{(1)}\mathbf{s}_t + \mathbf{b}^{(1)}) + \mathbf{b}^{(2)} \tag{4}$$

where $\mathbf{W}^{(1)}, \mathbf{W}^{(2)}, \mathbf{b}^{(1)}, \mathbf{b}^{(2)}$ are trainable parameters. Overall, GRU is a satisfying model for $f_\theta(\cdot)$, as $\mathbf{u}_{t+1}$ depends on all the previous interactions $\mathbf{x}_{\le t}$.

3.3.2 Temporal Convolutional Networks. TCN is a special type of 1D CNN, which is a natural way to encode information from a sequence [2]. A vanilla 1D convolutional layer can be written as

$$\begin{aligned}
F(\mathbf{x}_t) &= (\mathbf{x} * \mathbf{f})(t) = \sum_{j=0}^{k-1} \mathbf{f}_j^T \mathbf{x}_{t-j}, t \ge k \\
\mathbf{u} &= (F(\mathbf{x}_k), F(\mathbf{x}_{k+1}), ..., F(\mathbf{x}_n))
\end{aligned} \tag{5}$$

where $\mathbf{x}$ is the input sequence, $\mathbf{u}$ is the output sequence, and $\mathbf{f} \in \mathbb{R}^{k\times d}$ is a convolution filter with size k. A 1D CNN is then constructed by stacking several vanilla 1D convolutional layers. However, 1D CNN is restricted by its shrinking output size and limited receptive fields when being applied to model sequences, while TCN features with two techniques that solve these problems namely causal convolutions and dilated convolutions.

Causal convolutions. As is shown in Equation 5, a vanilla 1D convolutional layer takes as input a length n sequence and outputs a length $n-k+1$ sequence. The output can shrink further if more such layers are stacked together. This property can be problematic in our domain, as we want our model to make predictions at every time step and make updates in real-time. A causal convolutional layer solves the problem by concatenating a length $k-1$ zero padding at the beginning of the input sequence. Furthermore, it ensures that there is no information leakage from the future into the past, which is crucial when predicting future interactions. Concretely,

$$\begin{aligned}
F(\mathbf{x}_t) &= (\mathbf{x} * \mathbf{f})(t) = \sum_{j=0}^{k-1} \mathbf{f}_j^T \mathbf{x}_{t-j} \quad \mathbf{x}_{\le 0} := \mathbf{0} \\
\mathbf{u} &= (F(\mathbf{x}_1), F(\mathbf{x}_2), ..., F(\mathbf{x}_n))
\end{aligned} \tag{6}$$

This formulation ensures that the output sequence $\mathbf{u}$ is well-defined over each time step, and prediction $\mathbf{u}_t$ only depends on input $\mathbf{x}_{\le t}$.

Dilated convolutions. Another issue with vanilla 1D CNN is that it has a receptive field linear to the number of layers, which in our case is undesirable since we aim to model long-term dependencies. Dilated convolution is a technique that allows for receptive fields exponential to the number of layers. Specifically, when combining with causal convolution, the r^{th} level dilated convolutional layer can be written as

$$\begin{aligned}
F(\mathbf{x}_t) &= (\mathbf{x} *_{l_r} \mathbf{f})(t) = \sum_{j=0}^{k-1} \mathbf{f}_j^T \mathbf{x}_{t-l_r \cdot j} \quad \mathbf{x}_{\le 0} := \mathbf{0} \\
\mathbf{u} &= (F(\mathbf{x}_1), F(\mathbf{x}_2), ..., F(\mathbf{x}_n))
\end{aligned} \tag{7}$$

where l_r is the dilation factor which can be set as $(k-1)^{r-1}$ to achieve exponentially large receptive field. We refer to this formulation in Equation 7 as temporal convolutional layer.

A Temporal Convolutional Network (TCN) is then constructed by stacking multiple temporal convolutional layers. To facilitate training a deep TCN, a common practice is to organize temporal convolutional layers into blocks, and add residual connections [10] between blocks. By setting a proper size of filter and number of layers, $\mathbf{u}_{t+1}$ can depend on the full historical interactions $\mathbf{x}_{\le t}$.

3.4 Design Choices of Hierarchical Sequence Models

It is reasonable to consider using one of the above single-level sequence models to predict users' future interactions based on their past interactions. However, this formulation omits the session information which implies a hierarchy of user interests. Users typically have long-term interests that span across multiple sessions. These interests need to be updated after the end of each session, i.e. in the order of few hours to days. On the other hand, users' short-term interests are reflected via the interactions within each session, which must be updated in the order of a few seconds. In principle, we could include the session information as a feature to the single-level sequence models, enabling them to learn the short- and long-term interests. However, our experiments show that this approach does not work well in practice. The issue is that such an approach does not have the inductive bias over the hierarchy of user interests and thus fails to generalize to unseen cases.

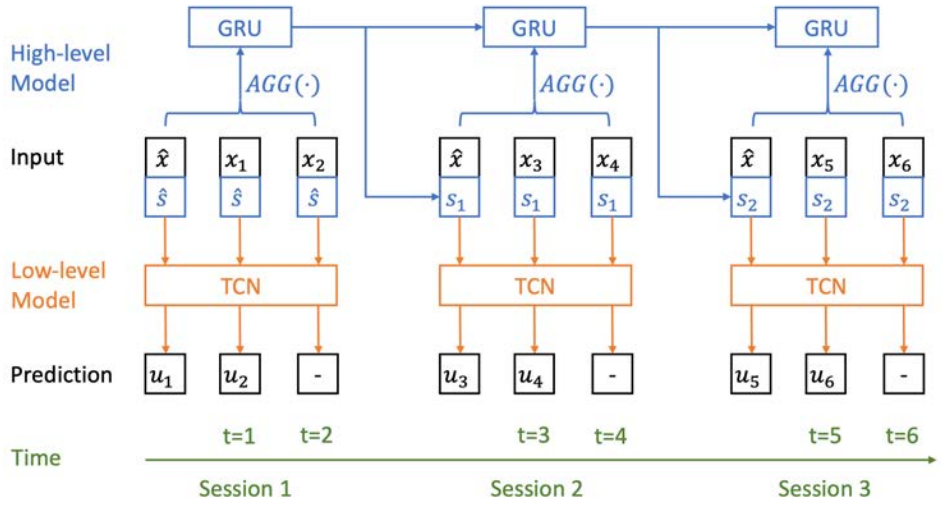

Figure 1: Visualization of HierTCN architecture. HierTCN generates predictions $\mathbf{u}_1, \mathbf{u}_2, ...\mathbf{u}_n$ based on a sequence of interactions $\mathbf{x}_1, \mathbf{x}_2, ...\mathbf{x}_n$. The high-level model (blue) is implemented with GRU which is updated by an aggregation of each session of interactions using function AGG(·). The low-level model (orange) uses TCN to predict user embeddings at each time step, based on a user's past interactions within the session and the hidden state $\mathbf{s}_i$ of the high-level model. $\hat{\mathbf{x}}$, $\hat{\mathbf{s}}$ are the default start tokens, which are used to produce the first output for the low-level model and the high-level model, respectively.

Rather than directly applying single-level sequence models, we impose the inductive biases over users' hierarchical interests via incorporating the hierarchical structure in the design of the neural network architecture. Specifically, our hierarchical model has a low-level component that learns from interactions within a session, and a high-level component that carries over information across sessions. The low-level component outputs a user embedding $\mathbf{u}_t$ using a neural network $f_\omega(\cdot)$, which can be written as:

$$\mathbf{u}_t = f_\omega((\mathbf{x}_i | \forall q(i) = q(t), i < t), \mathbf{s}_{q(t)}) \tag{8}$$

where $(\mathbf{x}_i | \forall q(i) = q(t), i < t)$ is the sequence of within-session item embeddings before time step t, and $s_{q(t)}$ represents a user's long-term interest which is modeled by a high-level component:

$$\mathbf{s}_{q(t)} = f_\phi((\mathbf{x}_i | \forall q(i) < q(t))) \tag{9}$$

where $f_\phi(\cdot)$ is the high-level model that summarizes the sequence of interactions before the session $q(t)$. In the remainder of this section, we will discuss different ways of designing hierarchical sequence models over multi-session data.

3.4.1 Choices of sequence models. The low-level model focuses on predicting the next interaction, based on both within-session interactions and the high-level information. The task is similar to making sequential prediction without considering the session structure, but over a much shorter sequence compared with taking all historical interactions of a user as input. Although RNN is generally much slower than TCN since the computation cannot be paralleled, both RNN and TCN can be chosen to represent $f_\omega(\cdot)$.

For the high-level model, the goal is to model a user's long-term interests. For this task, RNN has a natural advantage, because it maintains a hidden representation over different time steps, which can be naturally interpreted as a representation of the user's long-term interests. In contrast, TCN calculates the output directly through layers of convolution. Since there is no hidden state being maintained, the output is less smooth and interpretable, which is undesirable, especially when we would like to model a relatively stable long-term interests for all users. Moreover, TCN requires taking the raw input sequences as input. For the high-level model, this requirement corresponds to keeping track of users' entire history of interactions whenever inference is needed, resulting in high data memory usage, which is undesirable for large-scale implementation. Thus, we conclude that RNN is more suitable for representing $f_\phi(\cdot)$.

3.4.2 Choices of combining different levels of models. There are two problems to consider when trying to combine the low-level and the high-level model. The first problem is how to condition the low-level prediction on the high-level information, to which there are two approaches. The first approach is to use the high-level representation to initialize the low-level model; the second approach is to enforce the high-level representation propagated into the low-level model at each time step. These two approaches are first explored in [23], and we refer to them as *Init connection* and *Full connection*, respectively.

The second problem is to update the high-level model with low-level information. Suppose a user has n total interactions over m sessions, and function AGG(·) aggregates the embeddings within a session whose output is then used to update the high-level model. [23] explores using the low-level model as the aggregation function, where the final hidden state of a RNN is used to update the high-level model. However, this approach complicates the path of gradient backpropagation, as the longest backpropagation path has a length of n. In addition, the method couples the training of the low-level model and the high-level model; consequently, the biased low-level model at the start of training can negatively affect the training of the high-level model, resulting in a slow convergence. In contrast, we propose to use a simpler AGG(·) function, e.g., the MEAN(·) pooling function, by assuming that the ordering

of within-session interactions carries little information. Using a MEAN$(\cdot)$ pooling function only results in a length-m backpropagation path and decouples the training of the low-level model and the high-level model. We empirically find that this approach converges much faster and provides much better prediction performance.

3.5 HierTCN

Based on the discussions in Section 3.4, we design HierTCN, an efficient and scalable hierarchical sequence model.

3.5.1 Model design. HierTCN consists of a high-level model implemented with GRU and a low-level model implemented with TCN. The long-term user interests are represented via GRU's hidden state. The hidden state is updated by an aggregation over item embeddings within each session, using the MEAN$(\cdot)$ pooling function. Specifically, after all the interactions in a session $q(t)$ have been observed, user's long-term interests, represented as the GRU hidden state $\mathbf{s}_{q(t)}$, are updated using the following equation:

$$\mathbf{s}_{q(t)} = \text{GRU}(\mathbf{s}_{q(t)-1}, \text{MEAN}((\mathbf{x}_i | \forall q(i) = q(t)))) \tag{10}$$

where $q(t)$ refers to the session that contains time step t, $(\mathbf{x}_i | \forall q(i) = q(t))$ is the sequence of item embeddings in the session $q(t)$, and GRU$(\cdot)$ is a GRU described in Section 3.3.1.

The low-level TCN model represents short-term interests of the users and predicts their next interactions within the session. We use the *Full connection* (Section 3.4.2), i.e., include $\mathbf{s}_{q(t)}$ as the input to the TCN at each time step. TCN outputs a prediction $\mathbf{u}_t$, which can be interpreted as a dynamic user embedding. Concretely,

$$\mathbf{u}_t = \text{TCN}((\text{CONCAT}(\mathbf{x}_i, \mathbf{s}_{q(t)-1}) | \forall q(i) = q(t), i < t)) \tag{11}$$

where CONCAT$(\cdot)$ concatenates an input item embedding with the corresponding high-level hidden state, $(\mathbf{x}_i | \forall q(i) = q(t), i < t)$ is the sequence of within-session item embeddings before time step t, $\mathbf{s}_{q(t)}$ is passed from the high-level model and propagates its gradients into the high-level model when being trained, and TCN$(\cdot)$ is a TCN described in Section 3.3.2.

To output a final recommendation, HierTCN uses dot product between user and item embeddings as the scoring function to compute the unnormalized distribution $p(\mathbf{x}_t | \mathbf{x}_{<t})$

$$p(\mathbf{x}_t | \mathbf{x}_{<t}) = \mathbf{x}_t^T \mathbf{u}_t \tag{12}$$

We then compute $p(\mathbf{x}_t | \mathbf{x}_{<t})$ over the items in a candidate pool and rank the items in descending order, and output the top k items as the final recommendations. The overall architecture of HierTCN is visualized in Figure 1.

3.5.2 Objective function. In this section, we discuss the possible objective functions than can be used to train HierTCN when being applied to recommender systems. The performances of differ objective functions are compared in Section 4.4.1 When items can be represented as real-value vectors, the following objective functions are commonly used.

- **L2 loss** The simplest objective function would be minimizing the L2 distance between the user embedding and the interacted item embedding:

$$\min ||\mathbf{x}_t - \mathbf{u}_t||_2 \tag{13}$$

- **Noise Contrastive Estimation (NCE)** This objective is first proposed by [8], and is popularized by the Word2Vec paper [20]. This objective function makes use of the negative samples. Specifically, the objective function encourages the user embedding to be similar to the positive item embedding, while enforcing the user embedding to be different from the negative items' embeddings. NCE employs the following formulation:

$$\min -\log(\sigma(\mathbf{x}_t^T \mathbf{u}_t)) - \sum_i -\log(\sigma(-\mathbf{c}_{ti}^T \mathbf{u}_t)) \tag{14}$$

- **Bayesian personalized ranking (BPR)** [24] proposes using the following BPR objective function, which can be interpreted as maximizing the posterior estimator derived from a Bayesian analysis of the item recommendation problem:

$$\min -\sum_i \log(\sigma(\mathbf{c}_{ti}^T \mathbf{u}_t - \mathbf{x}_t^T \mathbf{u}_t)) \tag{15}$$

- **Hinge loss** Hinge loss is based on the idea of max margin learning [30], which has the following form:

$$\min \sum_i \max \left\{0, \delta + \mathbf{c}_{ti}^T \mathbf{u}_t - \mathbf{x}_t^T \mathbf{u}_t\right\} \tag{16}$$

When items do not come with features and thus are represented as one-hot vectors, the following cross entropy loss can be used:

- **Cross entropy loss** When $\mathbf{x}_t$ are one-hot vectors, cross entropy loss can be written as

$$\min -\mathbf{x}_t^T \log(\mathbf{u}_t) \tag{17}$$

3.5.3 Regularization and Normalization. There are many techniques to facilitate model convergence and prevent overfitting, and we adopt the dropout [29] and batch normalization [15] in the HierTCN model for both TCN and GRU modules. These techniques are not widely adopted for sequence models, and we provide a thorough discussion in this section.

Dropout. Dropout can be easily implemented for TCN by randomly dropping activations for the subsequent layers. For RNN, normally dropout is applied at the input, the output and the state transition function [1]. However, the benefits of applying dropout for state transition function are in fact doubtful because early state information can be wiped out by an exponential factor over the sequence length n. For recommender systems where users usually generate long interaction sequences, this approach is especially undesirable.

We use the following approach [27] to applying dropout for GRU transition. Specifically, dropout is only applied to the candidate activation $\mathbf{h}_t$, and only the last equation in Equation 3 is modified into $\mathbf{s}_t = (1 - \mathbf{g}_t) \odot D(\mathbf{h}_t) + \mathbf{g}_t \odot \mathbf{s}_{t-1}$, where $D(\cdot)$ is the dropout function. This technique does not wipe out information from the last time step, while still adding randomness to the state transition to prevent overfitting.

Batch normalization. When carrying out batch normalization, we find it necessary to keep track of the average statistics over each time step independently [5]. For dynamic recommender systems, since different users can have diverse sequence lengths, a common technique is to zero pad all the sequences to the same length. When updating the average statistics, it is important to mask out zero padded values in the batch normalization layer, in order to prevent it from using these meaningless values to update the statistics.

3.6 HierTCN for Real-world Recommender Systems

In this section, we discuss how to apply HierTCN to build a real-world dynamic recommender system. Specifically, we propose a general framework that allows for a joint update of user and item embeddings, and discuss some key techniques to ensure efficient model training and inference.

3.6.1 Joint modeling of user and item embeddings. When applying HierTCN for recommender systems, we propose two separate update mechanism: (1) User interests change rapidly and thus their embeddings get updated in real-time. (2) Item information changes more slowly and thus we update item embeddings on a daily schedule. This choice turns out to be very important in practice. Existing approaches that learn latent variables over all the interactions in a global chronological order between all the users and items [6] cannot scale to billions of interactions that are observed in a real-world recommender system. Such models become computationally prohibitive and infeasible for large datasets.

We side-step this problem by designing a two-phase update scheme. In the first phase, item embeddings are generated. The second phase considers the item embeddings fixed and only generates user embeddings.

Update of item embeddings. In the first phase, we first build an item graph based on user-item interactions, where each node represents an item and an edge is built if two items are interacted by the same user within a short period of time. Then, we compute the node embedding for each item, which integrates both visual and textual features as well as the structural features of the item graph using graph convolutional neural networks (GCN) based on localized graph convolutional layers [36], whose computation can be paralleled on a distributed system. Specifically, each node is initialized with the concatenated visual and textual embeddings of the item. We then apply 2 layers of localized graph convolutional layers to compute the node embedding for a node u, where the l^{th} layer can be written as

$$\begin{aligned} \mathbf{n}_u^{(l)} &= \text{AGG}(\text{ReLU}(\mathbf{Q}^{(l)}\mathbf{z}_v^{(l)} + \mathbf{q}^{(l)} | v \in N(u))) \\ \mathbf{z}_u^{(l+1)} &= \text{ReLU}(\mathbf{W}^{(l)}\text{CONCAT}(\mathbf{z}_u^{(l)}, \mathbf{n}_u^{(l)})) \end{aligned} \tag{18}$$

where $\mathbf{z}_u^{(l)}$ is the l^{th} level node embedding for node u, $N(u)$ is the local neighborhood of u, $\text{AGG}(\cdot)$ is an order invariant aggregation function such as $\text{MEAN}(\cdot)$ pooling, and $\mathbf{Q}^{(l)}, \mathbf{q}^{(l)}, \mathbf{W}^{(l)}$ are trainable parameters. After gathering new user-item interactions, we update the item graph and recompute the node embeddings for each item.

Update of user embeddings. In the second phase, we keep the item embeddings fixed and train the HierTCN model using the past interactions of users. Once the model is trained, any new within-session or across-session activity leads to a relatively fast update of the HierTCN model. Model can then be used in parallel to compute user embeddings in real time.

Training user and item models. The GCN model is trained by minimizing the following NCE-based objective function

$$-\log(\sigma(\mathbf{z}_u^T\mathbf{z}_v)) - C\mathbb{E}_{v_n \sim P_n(u)}[\log(\sigma(-\mathbf{z}_u^T\mathbf{z}_{v_n}))], \forall v \in N(u) \tag{19}$$

where $P_n(u)$ is a negative sampling distribution for node u and C is the number of negative samples, while HierTCN is trained with the hinge loss described in Section 3.5.2. GCN model is trained with about 7.5 billion samples and the HierTCN model is trained with about 1.7 billion samples, more details of training the GCN model are described in [36] and HierTCN training techniques are discussed in 3.6.2.

Overall, this two-phase approach enables the dynamic modeling of both user and item embeddings, which can be computationally cost-prohibitive otherwise. We conduct extensive offline evaluation on a subset of 6 million Pinterest users and present our results in Section 4.

Table 1: Statistics of the datasets (mean|std. deviation). Note that XING dataset does not have the impression data.

Dataset	XING	Pinterest
Users	65,347	5,923,659
Items	20,778	74,202,787
Interactions	1,450,300	56,050,857
Impressions	-	1,685,877,684
Sessions	535,747	23,354,523
Impressions per event	-	9.8|8.6
Impressions per session	-	25.8|51.1
Events per session	2.5|3.8	2.4|3.0
Sessions per user	8.2|7.0	3.9|4.7
Events per user	22.2|20.8	9.7|13.4
Impression per user	-	284.6 | 252.0

3.6.2 Efficient offline training of HierTCN. HierTCN is trained offline with about 6 million users and 1.7 billion training examples (Table 1). To conduct the training, we design an efficient offline training pipeline for HierTCN, which includes the following key components.

Item embedding cache. The item embeddings are represented as 512 dimensional float vectors, thus directly storing 1.7 billion interactions requires tens of terabytes of storage and even loading all the data to memory takes a day. To speed up the data pipeline, we first assign a universal ID to each of the 74 million items, and only keep item IDs when saving the user interaction data. Then we employ Linux huge page table [17] to cache all the item embeddings in a fixed chunk of memory. Finally, a sequence of item embeddings can be fetched by a direct look-up in the page table with a negligible query time. This approach enables us to load the item embeddings once; then, any subsequent models can share the embedding cache without the need to reload/rebuild the cache. In practice, this approach can reduce the data loading time from a day to a minute when launching a sequence model. Note that in the online deployment setting, the item embedding cache is rebuilt daily.

Queue-based mini-batch generator. To train a HierTCN, a mini-batch of training data should consist of the same number of sessions. In practice, the number of sessions that a user has can range from 1 to several hundreds; thus, the common approach of doing zero padding will cause huge amount of unnecessary data memory consumption. To address the problem, we design a queue-based mini-batch generator to significantly reduce memory consumption and speed up training, based on the data loading scheme proposed in [23]. The mini-batch generator first initializes B data queues where

B equals the batch size. Then an enqueue process loads a new user's sequence data and parses them by sessions, and enqueues the sessions of data along with the user ID to the queue with the least number of sessions. At the same time, a dequeue process takes a number of sessions from each queue, with each session zero-padded to the same length, then concatenates the sessions into batches and feeds a batch of data into HierTCN. During computation, HierTCN model constantly checks whether the user ID changes after a session; if so, the model will reset the hidden state of the high-level GRU to ensure each new user's state is properly initialized. The proposed mini-batch generator also naturally conducts the truncated backpropagation technique [33], a key technique that ensures stable training of RNN over long sequences.

3.6.3 Real-time inference. For real-time inference, the recommender system consists of a mini-batch generator that produces mini-batches and a trained HierTCN model that consumes the mini-batches. The mini-batch generator can be paralleled by creating multiple enqueue and dequeue processes, while the computation of HierTCN model can be paralleled by deploying multiple copies of the trained model, in order to achieve fast real-time computation. Two of the key techniques are discussed below.

User hidden state cache. A real-time dynamic recommender system requires efficient update of users' hidden states. Similar to item embedding cache, we cache all the users' hidden states into the memory, and maintain a dictionary that maps a user to the corresponding hidden state. Whenever a user starts a session, the system will read the hidden state of the user. After a session is closed, the hidden state of a user is updated with the high-level GRU, and is written to the original memory address.

Online queue-based mini-batch generator. We extend the offline mini-batch generator into the online settings. Specifically, after a user has interacted with an item, an enqueue process will fetch a session of data that contains the user's past interactions within the session. In addition, the enqueue process reads the cached hidden state of the user and concatenates the hidden state vector to all the interactions within the session. Finally, the process enqueues the session of data. At the same time, a dequeue process dequeues a batch of sessions with each session zero-padded to the same length and feeds them to HierTCN model. The process also retrieves the recommendation results and sends the results to the web API, while writing the updated hidden states to the cache.

4 EXPERIMENTS

4.1 Datasets

We use a public XING dataset and a large-scale private Pinterest dataset. The statistics of the datasets are summarized in Table 1. The aim of experimenting on a small-scale public dataset is to demonstrate that HierTCN can achieve transferable and robust performance, while rigorous and extensive evaluations are done over the large-scale Pinterest dataset.

The public XING dataset is extracted from XING Recsys Challenge 2016 dataset [3], with about 11 thousand users and 500 thousand interactions. The items do not come with features thus we represent each item as a one-hot vector. The dataset also does not have session information, thus we manually partition the interactions using a 30-minute idle threshold. Following the prior work [23], we remove interactions with type "delete" and do not consider the interaction types in the data. We remove items with less than 50 interactions and users with less than 10 or more than 1000 interactions.

The private Pinterest dataset is an internal dataset from Pinterest, with 6 million users, 56 million interactions and 1.7 billion impressions over 3 months. We clean the dataset by removing users with less than 10 or more than 1000 interactions. We represent items using a Pinterest internal item graph based on user-item interactions, with 3 billion nodes and 18 billion edges. Specifically, each item is represented as a node, and we connect two items if an user has interacted with both of them within a very short period of time. Each item is initialized with 4096 dimensional visual features, extracted from the 6-th fully connected layer of an image classification network using VGG-16 architecture [28], and 256 dimensional textual annotation features trained with Word2Vec [20]. A 2-layer GraphSage model [9] is then trained over the item graph using hinge loss function to differentiate positive and negative item samples. Finally, each item is represented by a 512 dimensional node embedding vector. More details about learning the item embeddings are discussed in [36].

4.2 Experimental Setup

4.2.1 Experimental setting. We consider two types of experiments. The first is *cold-start recommendations*. We split all the data by user, and select 80% of the users to train the model, 10% to tune the hyper-parameters of the model and test on the remaining 10% users. The second is *warm-start recommendations*. We select a fixed set of users, then train the model on the first two months of data and test on data in the following month. All the hyper-parameters remain the same with the cold-start recommendation settings.

All the deep learning based models are trained with Adam optimizer, with learning rate 0.001 and batch size 32. We stop training the model when the validation error plateaus. We find that weight normalization [25] does not help with the tasks we are experimenting, while batch normalization [15] and dropout [29] is helpful for the smaller XING dataset. For the large-scale Pinterest dataset, the vanilla models without regularization perform well.

4.2.2 Evaluation metrics. Our primary goal is to predict the user interaction in the next time step, which is evaluated by ranking the ground truth interaction against a pool of candidates at the given time step. For the XING dataset, the candidate pool is the set of all the items, while for the Pinterest dataset, the candidate pool is the impression data at the evaluated time step, which is given by a separate production system and cannot be altered by the model.

For models that can directly produce the ranking of an item (e.g., Maximum item similarity (MaxItem)), we directly use the predicted ranking for evaluation. For models that can output specific user embeddings, we compute the probability $p(\mathbf{x}_t|\mathbf{x}_{<t})$ over the candidate pool and rank the probability in descending order. We repeat the same process over all the interactions for all the users in the test data, and report various ranking statistics that are listed below.

Table 2: Performance of cold-start recommendation on the XING dataset and the large-scale Pinterest dataset.

Dataset	Metric	**HierTCN**	HierGRU	HRNN [23]	TCN	GRU	MV	MaxItem
XING	Recall@10 (Higher is better)	**0.139**	0.105	0.113	0.108	0.124	0.107	-
	MRR (Higher is better)	**0.071**	0.037	0.040	0.038	0.043	-	-
	MRP (Lower is better)	**0.121**	0.161	0.149	0.198	0.141	-	-
Pinterest	Recall@1	**0.206**	0.184	0.174	0.194	0.195	0.1658	0.1487
	Recall@5	**0.663**	0.639	0.619	0.653	0.655	0.6120	0.5843
	Recall@10	**0.855**	0.839	0.828	0.850	0.852	0.8173	0.7921
	MRR	**0.402**	0.380	0.366	0.391	0.392	0.3593	0.3400
	MRP	**0.304**	0.326	0.338	0.313	0.311	0.3484	0.3724

Table 3: Performance of warm-start recommendation on the large-scale Pinterest dataset.

Dataset	Metric	**HierTCN**	HRNN [23]	TCN	MV	MaxItem
Pinterest	Recall@1	**0.202**	0.188	0.183	0.174	0.155
	Recall@5	**0.667**	0.650	0.641	0.631	0.600
	Recall@10	**0.855**	0.848	0.838	0.830	0.801
	MRR	**0.399**	0.386	0.379	0.370	0.348
	MRP	**0.313**	0.324	0.336	0.346	0.374

- **Recall@K**. Recall@K reports the proportion of times that the ground truth interacted item is ranked within the top K list of recommendations. Higher Recall@K is better.
- **Mean Reciprocal Rank (MRR)**. This is a standard metric for evaluating recommender systems, which is the average reciprocal rank for the items that a user actually interacts with. Higher MRR is better.
- **Mean Rank Percentile (MRP)**. We divide the rank of the ground truth interaction by the size of the candidate pool, and average over all test cases. This is useful for Pinterest dataset where the size of candidate pool vary over different interactions. Lower MRP is better.

4.2.3 Baseline methods. We compare HierTCN with a variety of baseline methods, which are summarized below. To ensure a fair comparison, for all deep learning based model, we adjust the layer number and hidden units number such that all the models have very similar number of trainable parameters.

Rule-based models. Rule-based models maintain a pool $\mathbf{P}_t$ that consists of the past k interacted item embeddings t for each user.

- **Moving average (MV)**. The moving average model outputs the average of all the item embeddings in $\mathbf{P}_t$.
- **Maximum item similarity (MaxItem)** Rather than output a prediction, the MaxItem model can only evaluate a given candidate item embedding. An evaluation score is calculated as the highest dot product value between a candidate item embedding and embeddings in $\mathbf{P}_t$, which is then used for ranking the candidates.

Single-level sequence models. Single-level sequence models take sequences of user interactions without being partitioned into sessions. To make a fair comparison, we include a session indicator, marking the start of a session, as a input feature. Specifically, we consider the following two sequence models:

- **TCN** We implement a TCN model with 6 blocks of convolutional layers, where each block consists of 2 temporal convolutional layers that have 128 filters with size 5. The dilation factor of each block is set to grow exponentially with the number of the block, which is 1,2,4,8,16,32 in our scenario. We also add residual connections [10] between each block to facilitate training the model.
- **GRU** We construct a GRU model by stacking 4 layers of GRU cells described in Equation 3, each with 200 dimensional hidden state.

Hierarchical sequence models. We also compare HierTCN with the state-of-the-art hierarchical deep learning model, as well as a variant which we refer to as HierGRU.

- **HRNN** We implement a hierarchical GRU model following the paper [23]. Both high-level and low-level model are implemented with 4 layers of GRU cells, each with 128 dimensional hidden state. The high-level GRU's hidden state is used to initialized the low-level GRU, while the final hidden state of the low-level GRU is used to update the high-level GRU.
- **HierGRU** We implement a baseline version of HierTCN, where the only difference is that we change the low-level model from TCN to GRU. Both the high-level GRU and the low-level GRU has 4 layers of GRU cells, each with 128 dimensional hidden state.
- **HierTCN** This is our proposed model. The high-level model is a 4-layer GRU, each layer has 128 dimensional hidden state. The low-level model is a TCN with 4 blocks of convolutional layers, and the other settings are the same as a single-level TCN.

4.3 Experimental results

4.3.1 Results on Public XING dataset. Table 2 summarize the performance of all the models in XING dataset. Since items are represented as one-hot vectors, MV model cannot rank properly for unseen items thus only Recall@10 is reported. For the same reason, MaxItem is not implemented as the dot product between one-hot vectors is not meaningful. Our model significantly outperforms all the baseline methods by a large margin, and achieves 30.4% average performance improvement over the best baseline method (GRU). We observe that hierarchical GRU models converge very slowly,

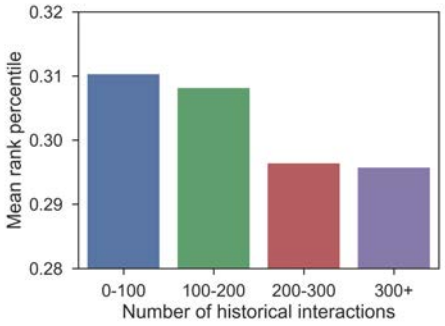

Figure 2: Summary of HierTCN's performance over users with different number of historical interactions. Lower is better.

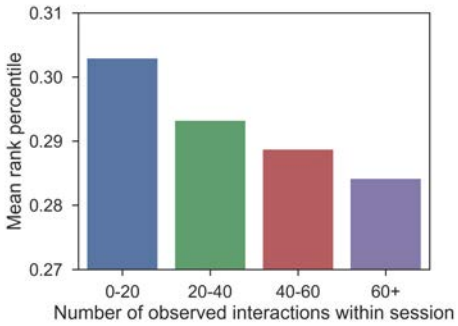

Figure 3: Summary of HierTCN's performance when observing different number of interactions within a session.

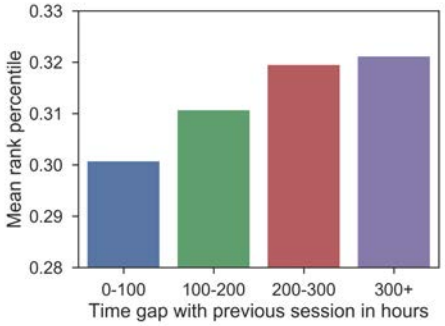

Figure 4: Summary of HierTCN's performance over sessions that have different time gap with previous sessions.

which may result from the complex gradient propagation path. In this task, all the models directly predict the probability of each item over all possible items, resulting an output dimension of over 10 thousand. We train the models with the simplest cross entropy loss, and people can use a more complex loss function including [23] to achieve better performance. The aim here is not to achieve the state-of-the-art performance on the XING dataset; rather, the results are used to show that the proposed HierTCN model can achieve more robust performance compared with baseline methods even in this simplified setting.

Table 4: The total time to finish one epoch training for the Pinterest dataset (in seconds).

Dataset	Model	Training
Pinterest	**HierTCN**	**295.3s**
	HierGRU	747.8s
	HRNN [23]	693.1s
	TCN	**254.0s**
	GRU	776.8s

Table 5: Cold-start performance of HierTCN with different objective functions. 10% of the training data are used for the experiment.

Dataset	Metric	L2	NCE	BPR	Hinge
Pinterest	Recall@1	0.167	0.192	0.183	**0.201**
	Recall@5	0.611	0.642	0.632	**0.657**
	Recall@10	0.817	0.838	0.832	**0.851**
	MRR	0.360	0.386	0.377	**0.396**
	MRP	0.349	0.322	0.331	**0.309**

4.3.2 Results on Large-scale Pinterest dataset. Table 2 and Table 3 summarize the performance of all the models in the large-scale Pinterest dataset. For cold-start evaluation, HierTCN outperforms the best hierarchical baseline by 18% in Recall@1, 10% in MRR. The gain over the best single-level sequence model is 6% in Recall@1, 3% in MRR. The gain over the best rule-based model is 24% in Recall@1, 13% in MRR. From the results, we can see that deep learning approaches perform much better than rule-based models, since users are possible to interact with hundreds of millions of items in Pinterest, and thus rule-based models are incapable of capturing this complex dynamics. Among deep learning approaches, it is interesting to see that hierarchical GRU models perform worse than single-level sequence models; empirically, we find that hierarchical GRU models converge slowly when we use the same learning rate as other models (0.001), while experiencing performance oscillation when we try to increase the learning rate. On the contrary, HierTCN consistently outperforms the single-level sequence models, and we do not observe issues for optimizing the model. This indicates that the hierarchical structure does capture more aspects of user interests. For warm-start evaluation, HierTCN also significantly outperforms the baseline models, with on average 12% improvement in Recall@1 and 5% improvement in MRR, and we can find similar observations from the results.

4.3.3 Running time. Table 4 summarizes the running time of different methods. We report the running time to finish one epoch training for all the deep learning models. We observe that models that make use of TCN are roughly 2.5 times faster than GRU-based models, which supports the argument that TCN is generally much faster than GRU. Moreover, adding the hierarchical structure in HierTCN only slightly affects the computation speed, owing to the fact that we only update the high-level model of HierTCN after each session and we use an efficient mini-batch generator. The efficient mini-batch generator makes the training of hierarchical GRU models even slightly faster than the single-level GRU model.

Table 6: Effects of adding different regularizations to HierTCN. BN and Drop stands for batch normalization and dropout.

Dataset	Regularization	None	Drop	BN	Drop + BN
XING	Recall@10	0.139	0.129	0.145	**0.147**
	MRR	0.071	0.066	0.073	**0.075**
	MRP	0.121	0.120	0.109	**0.107**

4.3.4 GPU memory consumption. GPU memory consumption consists of the memory to store model parameters, which is the same for all models in our experiments, and the memory to store the input data. TCN model takes a huge amount of memory to store the input data, because it has to keep the entire historical sequence to make a prediction. In contrast, HierTCN only needs to store the input sequence at each session. The specific reduction of memory consumption varies with the number of sessions that a user has, and we observe up to 90% reduction in the experiments.

4.4 Performance analysis

4.4.1 Choice of objective functions. Table 5 summarizes the results of using different loss functions for HierTCN on the Pinterest dataset. We conduct experiments in the cold-start setting and use only 10% of all the training data for this objective function comparison, thus the performance scores are worse than Table 2. We observe that using hinge loss provides about 5% improvement of Recall@1 and 3% improvement of MRR over the best competing loss function (NCE). In addition, using negative samples significantly improves the performance, and we observe 20% improvement of Recall@1 and 10% improvement of MRR over L2 loss.

4.4.2 Effects of dropout and batch normalization. To make fair comparison with baseline methods, we do not add dropout or batch normalization in the experiments. We conduct further experiments to examine the effects of adding dropout and batch normalization. From Table 6, we can see that adding dropout out alone does not improve the model performance, while adding batch normalization do help. When combining both techniques, there is further performance improvement. In addition, when adding batch normalization, we observe significant faster convergence; however, the model eventually overfits, and thus doing early stopping is necessary.

4.4.3 Model behavior analysis. We conduct further analyses to understand the performance of HierTCN under different scenarios. We select MRP as the metric and lower is better. To examine the overall performance of HierTCN, we summarize the performance of HierTCN over users with different historical interactions in Figure 2. It is clearly shown that HierTCN's performance increases as more interactions are observed. We analyze the performance of the low-level model by summarizing HierTCN's performance over different number of observed interactions within a session. Figure 3 shows that as more interactions are observed within a session, the performance of HierTCN gets better. Finally, we examine the performance of the high-level model by summarizing the performance of sessions that have different time gaps with previous sessions. Figure 3 shows that as the session's time gap increases,

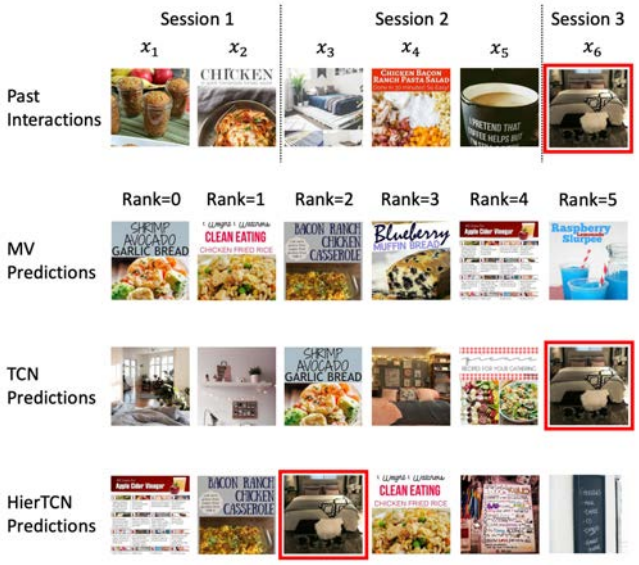

Figure 5: Recommendations given by different models. The first row shows the past interactions of a user, and the following 3 rows show the top-6 recommendations at time step 6 made by different models. The image marked with a red box is the ground-truth interaction.

a user's behavior becomes less predictable and the performance of HierTCN decreases. In summary, these analyses show that all the components of HierTCN perform reasonably under different scenarios.

4.4.4 Visualization of recommendations. Finally, we select a typical example to illustrate the superior performance of HierTCN. The first row in Figure 5 shows the past interactions of a user, which includes items related to food and bed. The following three rows illustrate the performance given by a rule-based model, a single-level sequence model and HierTCN. From the results we can see that rule-based model recommends all food-related items because they are prevalent in the past interactions, TCN exaggerates the existence of bed-related item and recommends too many items related to furniture, and HierTCN reaches a balance between recommending both types of items and achieves better performance.

5 CONCLUSION

In this paper, we have proposed Hierarchical Temporal Convolutional Networks for real-time large-scale recommender systems. By designing a novel hierarchical model using RNN and TCN, our model efficiently captures different levels of user interests and combines RNN's benefits of maintaining long-term hidden states and TCN's ability of conducting efficient and effective computation. We proposed a framework for large-scale dynamic recommender systems and applied HierTCN to a real-world dataset that contains millions of users and billions of activities. Compared with the state-of-the-art methods, HierTCN achieves superior performance and is much more scalable.

ABSTRACT

To enhance the performance of the recommender system, side information is extensively explored with various features (e.g., visual features and textual features). However, there are some demerits of side information: (1) the extra data is not always available in all recommendation tasks; (2) it is only for items, there is seldom high-level feature describing users. To address these gaps, we introduce the *spectral features* extracted from two hypergraph structures of the purchase records. Spectral features describe the *similarity* of users/items in the graph space, which is critical for recommendation. We leverage spectral features to model the users' preference and items' properties by incorporating them into a Matrix Factorization (MF) model.

In addition to modeling, we also use spectral features to optimize. Bayesian Personalized Ranking (BPR) is extensively leveraged to optimize models in *implicit feedback* data. However, in BPR, all missing values are regarded as negative samples equally while many of them are indeed unseen positive ones. We enrich the positive samples by calculating the similarity among users/items by the spectral features. The key ideas are: (1) similar users shall have similar preference on the same item; (2) a user shall have similar perception on similar items. Extensive experiments on two real-world datasets demonstrate the usefulness of the spectral features and the effectiveness of our spectrum-enhanced pairwise optimization. Our models outperform several state-of-the-art models significantly.

1 INTRODUCTION

Recommender systems have been widely used in online services such as E-commerce and social media sites to predict users' preference based on their interaction histories. Modern recommender systems uncover the underlying latent factors that encode the preference of users and properties of items. In recent years, to strengthen the presentation ability of the models, various features are incorporated for additional information, such as visual features from product images [14, 44, 48], textual features from review data [8, 9], and auditory features from music [5]. However, these features are not generally applicable, for example, visual features can only be used in product recommendation, while not in music recommendation. Also, these features are unavailable in some recommendation tasks, such as point-of-interest recommendation [43, 45]. Even they are available, we need extra efforts to collect and process them. Moreover, we can only get features for items while there is seldom high-level feature for users. To address these gaps, we introduce spectral features extracted from the purchase records for both items and users in this paper. We then use the spectral features to (1) model users' preference and items' properties and to (2) optimize the proposed model.

Recommender systems predict the missing value by uncovering the similarity of users/items, thus the information of similarity is vital in recommendation tasks. For example, in user-/item-based collaborative filtering, we recommend by calculating the similarity among users/items [12, 39]; in model-based collaborative filtering, the low-rank form ensures the linear dependence of latent factors, i.e., the similarity among users/items [1, 22, 35]. Inspired by this, we propose a new feature that contains the similarity information. We define the front K eigenvectors of a Laplacian matrix as the spectral feature. Devised for spectral clustering [29], the spectral feature describes the distance among vertices in a graph space thus contains abundant information of similarity. The spectral feature extracts information from the purchase history rather than additional data, thus it is generally applicable and works in almost all situations. Also, we can extract spectral features for both users and items.

We define the set of users near in the graph space as a *latent community*, which means they have similar purchase behaviors. For an item preferred by a specific user, it may get a high score for her latent community members. Also, the set of items near in the graph space is defined as a *latent category*, items in the same latent category have similar properties. Users who like certain item may have interests in the latent category the item belongs to. Of special notice is that a latent category is not like a real category, items in it may be relevant items, similar items, etc., in a word, items strongly connected in the graph. In this paper, we incorporate the spectral features into a Matrix Factorization (MF) model [22, 37] to propose our **S**pectrum-enhanced **C**ollaborative **F**iltering (**SCF**) model. By

learning spectral dimensions, SCF uncovers users' preference for latent categories and items' fitness for latent communities.

Compared with other side information features, our spectral feature is more suitable for the *implicit feedback* data. Implicit feedback data is like "purchase" or "browse" in E-commerce sites, "like" in social media sites, "click" in advertisements, etc. In real-world applications, the data of user behaviours in "one-class" (implicit feedback) is easier to collect and more generally applicable than "multi-class" scores (*explicit feedback*). The spectral features, which are independent of extra data, are more suitable for the implicit feedback data, since they maintain the advantages of easy to collect and generality.

Besides providing information of similarity, we also use the spectral features to enhance the pairwise learning. When optimizing model on implicit feedback data, Bayesian Personalized Ranking (BPR) is widely used due to the outstanding performance [14, 37, 44]. It aims to maximize the likelihood of pairwise preference over positive samples and negative samples. However, there is a critical issue: All missing values are simply treated as negative samples in BPR. In fact, some of the missing values are indeed unlabelled positive samples, users may like them but just have not seen them yet. To deal with this issue, we cluster all items and users by spectral features to construct the latent categories and latent communities, respectively. We assume that a user shows stronger preference for items that are in the same latent category with what she purchased, or items that purchased by her neighbors in the same latent community, than other missing entries. Considering the enriched preference relationship, we propose an optimization method called **S**pectrum-enhanced **P**airwise **L**earning to **R**ank (**SPLR**), and optimize SCF with it. Finally, we validate the effectiveness of our proposed model by comparing it with several baselines on the *Amazon.Clothes* and *Amazon.Jewelry* datasets. Extensive experiments show that we improve the performance significantly by exploring spectral features.

Specifically, our main contributions are listed as follows:

- We leverage novel spectral features in recommendation tasks to capture the similarity information of users/items, and propose an SCF model by injecting these features to the MF model.
- We propose a spectral clustering-enhanced pairwise ranking method, SPLR, to optimize our model. We construct latent categories and latent communities to enrich the positive samples.
- We extend our model and propose a framework to use side information features for modeling and for optimization. We can explore any kinds of features in our framework, including spectral features and other conventional features. Multiple features can be utilized at a time.
- We devise comprehensive experiments on two real-world datasets to demonstrate the effectiveness of our proposed methods.

2 RELATED WORK

After Matrix Factorization (MF) is utilized to deal with recommendation tasks [1, 22, 37], modern recommender systems develop rapidly. MF models learn the latent factors of users and items by reconstructing the purchase records in a low-rank form. Latent factors represent the preference of users and properties of items. Many variants are proposed to promote the ability to model the complex preference that users exhibit toward items based on their past interactions. [15, 18] used deep structure to learn embedding. [7, 17] took time into account when making predictions. [19, 46] focused on fast algorithms for online recommendation.

2.1 Side Information Features

One important way to enhance the presentation ability is to leverage the side information. Theoretically, latent dimensions can capture all relevant factors, but they usually cannot in applications due to the sparsity of the datasets, thus extra information is desired. The visual features are widely used since users' decisions depend largely on products' appearance [14, 27, 44, 48]. [14, 27] predicted consumers' behavior with the CNN feature. Yu et al. [44] utilized the aesthetic feature to model users' aesthetic preference on clothes. Zhao et al. [48] leveraged several visual features to recommend movies. There are also many efforts exploring the textural feature to recommend [9, 26], McAuley and Leskovec [26] proposed models with the textural feature from the review data and Chen et al. [9] extracted the textural feature from time-synchronized comments for key-frame recommendation. In music recommendation, the auditory feature is generally used, Cao et al. [5] extracted the auditory feature by a pre-trained deep structure to recommend music.

Various features are used for different kinds of information. However, one feature, the spectral feature, has never been explored. In this paper, we extract the spectral features from the hypergraphs of users and items, which represent the similarity of vertices in the hypergraphs. Compared with features mentioned above, the spectral features are independent of additional information so they are suitable for more situations. Moreover, conventional features are all for items, while we extract spectral features for both users and items.

2.2 Graph-enhanced Recommendation

In recent years, hypergraph gains increasing attention in the recommendation domain [4, 23, 34]. Lierde and Chow [23] proposed a user-based collaborative filtering enhanced with the hypergraph: The similarity of the users is calculated with the hypergraph embedding. [4, 34] filtered the latent factors with hypergraph regularized term to smooth them. There are also some efforts promoting the recommendation performance with social networks [21, 42]. Walter et al. [42] calculated similarities with the social networks embedding for memory-based collaborative filtering. Jamali and Ester [21] calculated the latent factors of a user with its neighbors to give the prediction. Graph convolution networks are also widely used in recommendation tasks [2, 50]. Berg et al. [2] proposed a graph convolutional auto-encoder that learns the structural information of a graph for latent factors of users and items. Zheng et al. [50] constructed random walk laplacian matrix of the user-item bipartite graph and then introduced a deep spectral convolutional network to capture the user-item connectivity information.

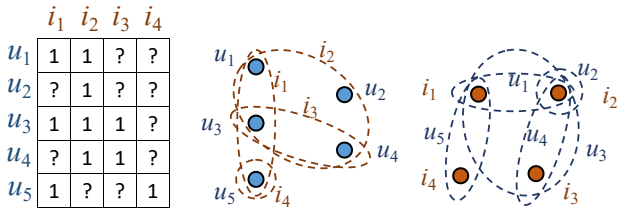
In this paper, we introduce a new way to explore graph structures in recommendation tasks. We extract features from the Laplacian matrix of the hypergraphs of users and items, and make prediction

with the MF term jointly. We also utilize these features to optimize our proposed method.

2.3 Learning to Rank

As implicit feedback data is easier to collect, it is extensively used in real-world application. However, prediction on implicit feedback dataset is a challenging task because there are only positive samples and unobserved samples. We cannot discriminate negative samples and unlabeled positive samples from the unobserved ones. Rendle et al. [37] treated all unobserved samples as negative ones when sampling while some of them are indeed unlabelled positive samples. Users may like them but just have not seen them yet. To address this gap, many works improved the pairwise learning to rank method. It is assumed that all users are independent in BPR, Pan and Chen [30] tried to relax this constraint and proposed a method called group preference-based Bayesian personalized ranking (GBPR), which modeled the preference of user groups. Qiu et al. [33] constructed the preference chain of item groups for each user. Liu et al. [24] utilized collaborative information mined from the interactions between users and items. [36, 47] proposed dynamic negative sampling strategies to maximize the utility of a gradient step by choosing "difficult" negative samples. [10, 31] used view information to enrich positive samples. [6, 25] proposed listwise ranking methods instead of pairwise ones. Hwang et al. [20] utilized both implicit and explicit feedback data to improve the quality of negative sampling.

In existing efforts, only low-order connections are considered when measuring the similarity among vertices [24, 30, 33]. In this paper, we use the spectral features, which contains the information of high-order connections, to enhance the pairwise learning. We cluster all items/users by spectral features to construct latent categories/communities. For vertices (users/items) in the same cluster, they are strongly connected[1] in the hypergraph thus are very similar to each other. For each user, we regard items in the same latent category with her positive samples and items purchased by her latent community members as the potential samples, and assume that the user prefers them than other negative samples.



3 SPECTRUM-ENHANCED COLLABORATIVE FILTERING

In this section, we propose a novel recommendation model called Spectrum-enhanced Collaborative Filtering (SCF). We first introduce the spectral features and then inject them into an MF model. In this paper, bold uppercase letters refer to matrices. For example, $\mathbf{A}$ is a matrix, $\mathbf{A}_i$ is the i-th row of $\mathbf{A}$, $\mathbf{A}_{*,j}$ is the j-th column of $\mathbf{A}$, and $\mathbf{A}_{ij}$ is the value at the i-th row and the j-th column of $\mathbf{A}$. $\mathbf{A}^U$ is the matrix for user and $\mathbf{A}^I$ is the matrix for item, $\mathbf{A}^{(k)}$ is the k-th matrix.

3.1 Spectral Feature

In a recommendation task, we use matrix $\mathbf{R} \in \mathbb{R}^{N\times M}$ to denote the interactions between users and items (there are N users and M items in total). $\mathbf{R}_{ui} = 1$ if user u purchased items i and $\mathbf{R}_{ui} = 0$ otherwise. Our task is to predict the missing values (0 in $\mathbf{R}$) to recommend top-n items for each user.

The hypergraph is a generalization of the simple graph, where an hyperedge (edge in hypergraph) connects any number of vertices rather than just two. A hypergraph is usually represented with the incidence matrix $\mathbf{H} \in \mathbb{R}^{N\times M}$ (there are N vertices and M hyperedges). Each row in $\mathbf{H}$ is for a vertex and each column is for a hyperedge. $\mathbf{H}_{ij} = 1$ if vertex i is connected by hyperedge j and $\mathbf{H}_{ij} = 0$ otherwise. We can see that a hypergraph can represent the purchase records by nature. We define two hypergraph structures, a user hypergraph and an item hypergraph. In the user hypergraph, users are vertices and items are hyperedges while in the item hypergraph, items are vertices and users are hyperedges.

(a) Interaction Matrix (b) User Hypergraph (c) Item Hypergraph

Figure 1: An example for user hypergraph and item hypergraph. For the user hypergraph, the incidence matrix $\mathbf{H}^U = \mathbf{R}$ and for the item hypergraph, $\mathbf{H}^I = \mathbf{R}^\top$.

For a hypergraph represented with the incidence matrix $\mathbf{H}$, the Laplacian matrix $\mathbf{L}$ is defined as [51]:

$$\mathbf{L} = \mathbf{D}^{-\frac{1}{2}}(\mathbf{D} - \mathbf{H}\mathbf{W}\mathbf{\Delta}^{-1}\mathbf{H}^\top)\mathbf{D}^{-\frac{1}{2}}, \tag{1}$$

where the diagonal matrix $\mathbf{D} \in \mathbb{R}^{N\times N}$ denotes the degrees of vertices, the diagonal matrix $\mathbf{W} \in \mathbb{R}^{M\times M}$ denotes the weights of hyperedges, and the diagonal matrix $\mathbf{\Delta} \in \mathbb{R}^{M\times M}$ denotes the degrees of hyperedges. Laplacian matrix is a difference operator of a hypergraph [28], for any signal $\mathbf{S} \in \mathbb{R}^{N\times L}$, it satisfies:

$$(\mathbf{LS})_i = \sum_{j\in\mathcal{N}_i}\sum_{k=1}^{M}\mathbf{H}_{ik}\frac{\mathbf{W}_{kk}}{\mathbf{\Delta}_{kk}}\mathbf{H}_{jk}\left(\frac{\mathbf{S}_i}{\sqrt{\mathbf{D}_{ii}}} - \frac{\mathbf{S}_j}{\sqrt{\mathbf{D}_{jj}}}\right),$$

where $\mathcal{N}_i$ is the set of vertices connected to vertex i. We can see the effect of the Laplacian matrix is to take the first-order difference in the neighborhood of vertex i. In many machine learning tasks, the parameter $\mathbf{S}$ is smoothed by minimizing the Laplacian regularization term $trace(\mathbf{S}^\top\mathbf{L}\mathbf{S})$ [11, 34].

To extract the spectral feature, we factorize the Laplacian matrix with eigen-decomposition: $\mathbf{L} = \mathbf{\Phi}\mathbf{\Lambda}\mathbf{\Phi}^\top$, where $\mathbf{\Lambda} = diag(\lambda_1, \lambda_2, \cdots, \lambda_N)$ is the eigenvalue matrix, all eigenvalues are in ascending order, i.e., $\lambda_1 \le \lambda_2 \le \cdots \le \lambda_N$. We define the matrix formed by the first K eigenvectors as the spectral feature matrix: $\mathbf{F} = \mathbf{\Phi}_{*,1:K}$, and $\mathbf{F}_i$ is the spectral feature of vertex i. The spectral feature can be used for spectral clustering [23, 29] and graph Fourier transform [28]. It contains the information of the similarity among vertices thus we can measure the similarity of two vertices i and j with $\mathbf{F}_i\mathbf{F}_j^\top$. Though eigen-decomposition is computationally expensive (taking the user hypergraph as an example, with $O(N^3)$ time complexity, where N

[1] We use "strongly connected" to indicate that vertices are connected by many paths in the graph (including direct connections or high-order connections), which is different from the conception in directed graphs [40].

is the user number), however, $\mathbf{L}$ is highly sparse in recommendation tasks. Considering there are $O(N)$ non-zero elements in $\mathbf{L}$, the time complexity could be $O(K^2N)$ with Lanczos method [13, 32], which is much smaller than $O(N^3)$.

3.2 Hybrid Model

For the hybrid model (SCF), we incorporate the spectral features into a basic MF model, which is the state-of-the-art for rating prediction as well as modeling implicit feedback, to reconstruct the interaction matrix with the low-rank form:

$$\hat{\mathbf{R}} = \mathbf{U}\mathbf{V}^\mathsf{T} + \mathbf{P}\mathbf{F}^\mathsf{T} + \mathbf{E}\mathbf{Q}^\mathsf{T}, \tag{2}$$

where $\hat{\mathbf{R}} \in \mathbb{R}^{N\times M}$ is the reconstruction, $\mathbf{U} \in \mathbb{R}^{N\times K_0}$ and $\mathbf{V} \in \mathbb{R}^{M\times K_0}$ are the latent factors of users and items respectively. $\mathbf{U}_i$ is the preference of user i and $\mathbf{V}_j$ is the properties of item j. $\mathbf{E} \in \mathbb{R}^{N\times K_1}$ and $\mathbf{F} \in \mathbb{R}^{M\times K_2}$ are the spectral features of users and items respectively. $\mathbf{P} \in \mathbb{R}^{N\times K_2}$ is the preference matrix of users, $\mathbf{Q} \in \mathbb{R}^{M\times K_1}$ is the fitness matrix of items.

Considering that strongly connected users/items shall have similar preference/properties, $\mathbf{E}/\mathbf{F}$ contains the information of similarity among users/items. We use the similarity information to enhance the MF predictor. We call the three terms in Equation (2) as model-based, item-based, and user-based collaborative terms respectively. In a conventional item-based collaborative filtering model, we calculate the similarity between each pair of items. For a positive sample i and a missing sample j, if j is similar with i, we recommend j to current user. Similarly, in the second term of our predictor, for current user u and her purchased item i, $\mathbf{P}_u\mathbf{F}_i^\mathsf{T}$ is high. For a similar item j, $\mathbf{F}_i\mathbf{F}_j^\mathsf{T}$ is high, thus $\mathbf{P}_u\mathbf{F}_j^\mathsf{T}$ is high as well, and j can be recommended to u. We can see that this procedure is just the same as item-based collaborative filtering, so we call the second term of Equation (2) item-based collaborative term. And the third term, for the same reason, is called user-based collaborative term.

Now we briefly discuss the advantage of our item-based collaborative term over conventional item-based collaborative filtering. In item-based collaborative filtering, when calculating the similarity between a pair of items, only first-order connections are taken into account, while in our item-based collaborative term, high-order connections are also considered. Take Figure 1(c) as an example, i_3 and i_4 are not connected by certain hyperedge directly, hence the similarity is 0 in conventional item-based collaborative filtering. While in our model, connections i_4-i_1-i_3 and i_4-i_1-i_2-i_3 are also considered, therefore $sim(i_3, i_4) > 0$ (we will discuss the reason detailedly in the next section). In fact, in Equation (2), three models give the final prediction jointly: An MF model, and two hypergraph spectrum-enhanced memory-based collaborative filtering models.

4 SPECTRUM-ENHANCED PAIRWISE LEARNING

Besides providing information to model users' preference and items' property, spectral features are also used to optimize the model. Optimization on implicit feedback data usually takes the form of pairwise learning, which maximizes the likelihood of relative preference over a pair of positive and negative feedbacks:

$$\text{BPR_OPT} = \sum_{u\in\mathcal{U}}\sum_{i\in\mathcal{I}_u^+}\sum_{j\in\mathcal{I}\setminus\mathcal{I}_u^+} \ln\sigma\left(\hat{\mathbf{R}}_{uij}\right) - \frac{\lambda_r}{2}\|\mathbf{\Theta}\|_\mathrm{F}^2 .$$

where $\mathcal{U}$ and $\mathcal{I}$ are the sets of users and items. $\mathcal{I}_u^+$ is the set of positive items of u. $\sigma(\ )$ is the sigmoid function. $\hat{\mathbf{R}}$ is defined in the Equation (2) and $\hat{\mathbf{R}}_{uij} = \hat{\mathbf{R}}_{ui} - \hat{\mathbf{R}}_{uj}$. The last term is the regularization term to prevent overfitting, where λ_r is the regularization coefficient, $\|\ \|_\mathrm{F}$ is the Frobenius norm of the matrix, and $\mathbf{\Theta}$ represents the parameters of the model.

There is a critical issue: A user did not purchase an item may not because she has no interest in it, but just because she has never seen it yet. Our task is to uncover users' preference and recommend them unseen items they are interested in. However, in BPR, all missing entries are treated as negative samples nevertheless some of them are indeed unlabeled positive samples. To address this gap, we enrich the positive samples by the spectral clustering.

4.1 Objective Function

We cluster all vertices (items/users) by the normalized spectral features. Vertices in the same cluster are strongly connected in the hypergraph, though may not be connected directly.

Latent category: We define a cluster of items as a latent category, items in it are of the similar kind, or highly relevant, since they are purchased by the same user or users with similar preference. For certain item i, the latent category it belongs to is denoted as C_i. We argue that if a user likes i, she may like the items in C_i with a high probability.

Latent community: Similarly, we define a cluster of users as a latent community, users in it purchase the same items, similar items, or relevant items, thus they have similar preference. For certain user u, the latent community she belongs to is denoted as C_u. If a user likes i, her latent community members may like i as well.

To give the relative preference, we construct three sets for each user u:

$$\begin{cases} \mathcal{I}_u^+ = \{i|\mathbf{R}_{ui} = 1\}, & \text{Positive set} \\ \mathcal{P}_u = \mathcal{P}_u^U \bigcup \mathcal{P}_u^I, & \text{Potential set} \\ \mathcal{I}_u^- = \mathcal{I} - \mathcal{I}_u^+ - \mathcal{P}_u, & \text{Negative set} \end{cases}, \tag{3}$$

where $\mathcal{P}_u^U = \{i|i \in \mathcal{I}_v^+, v \in C_u \& i \notin \mathcal{I}_u^+\}$ is the user-based collaborative potential set, $\mathcal{P}_u^I = \{j|j \in C_i, i \in \mathcal{I}_u^+ \& j \notin \mathcal{I}_u^+\}$ is the item-based collaborative potential set. We have the preference relationship:

$$(u, \mathcal{I}_u^+) \succ (u, \mathcal{I}_u^-),\ (u, \mathcal{I}_u^+) \succ (u, \mathcal{P}_u),\ (u, \mathcal{P}_u) \succ (u, \mathcal{I}_u^-).$$

We can see that, $\mathcal{P}_u$ is the set of items that u may have interests in returned by the memory-based collaborative filtering.

BPR tries to optimize the standard AUC that is designed for binary classification [3], while we try to optimize a generalized AUC (GAUC) [24, 41],

$$\text{GAUC} = \frac{1}{|\mathcal{U}|}\sum_{u\in\mathcal{U}}\Big[\text{AUC}(u, \mathcal{I}_u^+, \mathcal{I}_u^-) + \eta_1\text{AUC}(u, \mathcal{I}_u^+, \mathcal{P}_u) + \eta_2\text{AUC}(u, \mathcal{P}_u, \mathcal{I}_u^-)\Big],$$

where $\text{AUC}(u, \mathcal{A}, \mathcal{B}) = \frac{1}{|\mathcal{A}||\mathcal{B}|}\sum_{i\in\mathcal{A}}\sum_{j\in\mathcal{B}}\delta\left(\hat{\mathbf{R}}_{uij} > 0\right)$ is the standard AUC, η_1 and η_2 are confidence coefficients. We use differentiable loss $\delta(x > 0)$ which is identical to $\ln\sigma(x)$. We can see

that GAUC is the weighted combination of three standard AUC terms. To maximize it, we propose our **S**pectrum-enhanced **P**airwise **L**earning to **R**ank (**SPLR**) optimization:

$$\begin{aligned}\text{SPLR_OPT} = \sum_{u\in\mathcal{U}}\Bigg[&\sum_{i\in\mathcal{I}_u^+}\sum_{j\in\mathcal{I}_u^-}\ln\sigma\left(\hat{\mathbf{R}}_{uij}\right)\\ &+\eta_1\sum_{i\in\mathcal{I}_u^+}\sum_{j\in\mathcal{P}_u}\ln\sigma\left(\hat{\mathbf{R}}_{uij}\right)\\ &+\eta_2\sum_{i\in\mathcal{P}_u}\sum_{j\in\mathcal{I}_u^-}\ln\sigma\left(\hat{\mathbf{R}}_{uij}\right)\Bigg]-\frac{\lambda_r}{2}\|\mathbf{\Theta}\|_{\mathrm{F}}^2.\end{aligned}\tag{4}$$

4.2 Model Learning

To maximize the SPLR objective function, we take the first-order derivatives of Equation (4) with respect to each model parameter:

$$\begin{aligned}\nabla_{\mathbf{\Theta}}\text{SPLR_OPT} = \sum_{u\in\mathcal{U}}\Bigg[&\sum_{i\in\mathcal{I}_u^+}\sum_{j\in\mathcal{I}_u^-}\sigma\left(-\hat{\mathbf{R}}_{uij}\right)\frac{\partial\hat{\mathbf{R}}_{uij}}{\partial\mathbf{\Theta}}\\ &+\eta_1\sum_{i\in\mathcal{I}_u^+}\sum_{j\in\mathcal{P}_u}\sigma\left(-\hat{\mathbf{R}}_{uij}\right)\frac{\partial\hat{\mathbf{R}}_{uij}}{\partial\mathbf{\Theta}}\\ &+\eta_2\sum_{i\in\mathcal{P}_u}\sum_{j\in\mathcal{I}_u^-}\sigma\left(-\hat{\mathbf{R}}_{uij}\right)\frac{\partial\hat{\mathbf{R}}_{uij}}{\partial\mathbf{\Theta}}\Bigg]-\lambda_r\,\mathbf{\Theta}.\end{aligned}\tag{5}$$

We use $\boldsymbol{\theta}$ to denote certain row of $\mathbf{\Theta}$, the derivatives in Equation (5) are:

$$\frac{\partial\hat{\mathbf{R}}_{uij}}{\partial\boldsymbol{\theta}}=\begin{cases}\mathbf{V}_i-\mathbf{V}_j & \text{if}\quad \boldsymbol{\theta}=\mathbf{U}_u\\ \mathbf{U}_u/-\mathbf{U}_u & \text{if}\quad \boldsymbol{\theta}=\mathbf{V}_i/\mathbf{V}_j\\ \mathbf{F}_i-\mathbf{F}_j & \text{if}\quad \boldsymbol{\theta}=\mathbf{P}_u\\ \mathbf{E}_u/-\mathbf{E}_u & \text{if}\quad \boldsymbol{\theta}=\mathbf{Q}_i/\mathbf{Q}_j\end{cases}.\tag{6}$$

$\frac{\partial\hat{\mathbf{R}}_{uij}}{\partial\boldsymbol{\theta}}$ in Equation (6) is certain row of $\frac{\partial\hat{\mathbf{R}}_{uij}}{\partial\mathbf{\Theta}}$ in Equation (5), for example, the u-th row when $\boldsymbol{\theta}=\mathbf{U}_u$.

The detailed procedure is shown in Algorithm 1. We calculate the Laplacian matrices with the Equation (2) (line 1) and decompose them, the first K_1/K_2 eigenvectors of $\mathbf{L}^U/\mathbf{L}^I$ form $\mathbf{E}/\mathbf{F}$ (line 2). We then construct the three sets in Equation (3) for each user (line 3). Lines 5-14 show the process of model learning. For each record $\{u,i\}$, we choose m potential samples $\{j_1,\cdots,j_m\}$ from $\mathcal{P}_u$ (line 9) and m negative samples $\{k_1,\cdots,k_m\}$ from $\mathcal{I}_u^-$ (line 10), m is the sampling rate. The model is optimized with the pairs $\{u,i,j_1\},\cdots,\{u,i,j_m\},\{u,i,k_1\},\cdots,\{u,i,k_m\},\{u,j_1,k_1\},\cdots,\{u,j_m,k_m\}$. We finally calculate the derivatives given by Equation (5) with a batch of pairs (line 12) and update the parameters (line 13).

Like many existing works [30, 33, 49], we also use the connections of users and items to enhance the pairwise learning. However, in previous works, only one-order connections are utilized while in our SPLR model, we leverage connections with all orders. In a hypergraph, we have $\mathbf{L}^n=(\mathbf{I}-\mathbf{A})^n=\sum_{r=1}^{n}C_n^r(-\mathbf{A})^r$, where $\mathbf{A}=\mathbf{D}^{-\frac{1}{2}}\mathbf{H}\mathbf{W}\mathbf{\Delta}^{-1}\mathbf{H}^{\mathsf{T}}\mathbf{D}^{-\frac{1}{2}}$ is the normalized adjacency matrix. $\mathbf{A}^r$ indicates the r-order connections, therefore $\mathbf{L}^n$ contains the information of all connections less than n-order in the hypergraph. For the i-th eigenvector $\mathbf{u}_i$ of $\mathbf{L}$, λ_i is the corresponding eigenvalue, we have $\mathbf{L}\mathbf{u}_i=\lambda_i\mathbf{u}_i$. Since $\mathbf{L}^n\mathbf{u}_i=\lambda_i^n\mathbf{u}_i$, $\mathbf{u}_i$ is also the eigenvector of $\mathbf{L}^n$, therefore $\mathbf{F}$ contains information of all-order connections in the hypergraph. Constructed with the spectral features, latent communities/categories also take the high-order information into consideration, that is the superiority of our model over existing learning to rank methods.

Algorithm 1: Mini-batch gradient descent algorithm

Input: Implicit feedback matrix $\mathbf{R}$, regularization coefficient λ_r, batch size b, learning rate η, weighting parameters η_1 and η_2, sampling rate m, maximum number of iterations $iter_max$.
Output: top-n predictions given by the completed matrix $\hat{\mathbf{R}}$

1 calculate the Laplacian matrices of user hypergraph $\mathbf{L}^U$ and item hypergraph $\mathbf{L}^I$ from $\mathbf{R}$;
2 decompose the Laplacian matrices to get the spectral features $\mathbf{E}$ and $\mathbf{F}$;
3 cluster vertices and calculate the potential set for each user;
4 initialize $\mathbf{\Theta}$ randomly;
5 **for** $iter = 1$ *to* $iter_max$ **do**
6 split all purchase records into b-size batches;
7 **for** *each batch* **do**
8 **for** *each record in current batch* **do**
9 select m potential items randomly from $\mathcal{P}_u$;
10 select m negative items randomly from $\mathcal{I}_u^-$;
11 add these items to the current batch;
12 calculate $\nabla_{\mathbf{\Theta}}$SPLR_OPT with current batch;
13 $\mathbf{\Theta}=\mathbf{\Theta}+\eta\nabla_{\mathbf{\Theta}}$SPLR_OPT;
14 calculate $\hat{\mathbf{R}}$ to predict the top-n items;
15 **return** *the top-n items*;

5 EXPERIMENTS

In this section, we design experiments on real-world datasets to validate the effectiveness of our models. We evaluate our proposed methods focusing on the following three key research questions:

RQ1: How is the performance of our entire spectrum-enhanced recommendation model (effectiveness of SCF_SPLR)?
RQ2: How is the performance of the spectral features to model users' preference and items' properties (effectiveness of SCF_BPR)?
RQ3: How is the performance of the SPLR optimization criterion (effectiveness of MF_SPLR)?

Table 1: Statistics of datasets

Dataset	Purchase	User	Item	Sparsity
Clothes	115841	32728	8777	99.9597%
Jewelry	37314	15924	3607	99.9350%

5.1 Datasets

In this paper, we perform experiments on the *Amazon* dataset [14], which is the consumption records from *Amazon.com*. We consider two large categories *Amazon.clothes* and *Amazon.jewelry*, which are filtered from the *Amazon* dataset. We take users' review histories as implicit feedback. Some details of the datasets are shown in Table 1.

5.2 Baselines

We adopt the following methods as baselines for performance comparison:

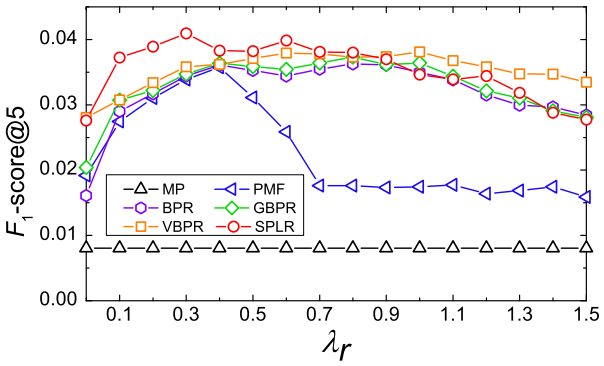
- **MP:** This **M**ost **P**opular method ranks items according to their popularity. It is a non-personalized method to benchmark the recommendation performances.
- **PMF:** This **P**robabilistic **M**atrix **F**actorization method, which was proposed by [38], is a frequently used state-of-the-art approach for rating-based optimization and prediction. We set the score of positive samples as 1 and missing values as 0.
- **BPR (MF_BPR):** This **B**ayesian **P**ersonalized **R**anking method is the most widely used ranking-based method for implicit feedback [37]. It regards all unobserved samples as negative samples and maximizes the likelihood of users' preference over a pair of positive sample and negative sample.
- **GBPR (MF_GBPR):** This **G**roup Preference-based **B**ayesian **P**ersonalized **R**anking method [30] is an extension of BPR, which tries to relax BPR's assumptions to a group pairwise preference assumption. We fix the number of grouped users to 3.
- **VBPR:** This **V**isual **B**ayesian **P**ersonalized **R**anking method is a stat-of-the-art visual-based recommendation method [14]. The visual features are extracted from the product images with a pre-trained deep convolutional neural network (CNN).

5.3 Experiment Settings

The eigen-decomposition of Laplacian matrices is implemented with `sparse.linalg()` function of `scipy` library in `python`. The *Amazon* dataset is filtered with 5-core (remove users and items with less than 5 purchase records) and records before 2010 is removed. We then filter *Jewelry* and *Clothes* datasets from *Amazon*. Each dataset is split into training set (80%), validation set(10%), and test set (10%) randomly. Cold items and users (items and users with no record in training set) in validation and test sets are removed. We adapt F_1-score and normalized discounted cumulative gain (*NDCG*) to evaluate the performance of the baselines and our proposed model. Mini-batch stochastic gradient descent (MSGD) is leveraged to optimize our model. The learning rate is determined by grid searching in the range of {0.005, 0.01, 0.02, 0.05, 0.1, 0.2} and the batch size is determined in the range of {1000, 2000, 3000, 4000, 5000}. We evaluate different number of latent factors K_0 in the range of {10, 20, 50, 100, 200}, the regularization coefficient λ_r in the range of $\{0, 0.1, 0.2, \cdots, 1.5\}$, and the weighted parameters η_1 and η_2 in the range of $\{0, 0.01, 0.1\}$. We conduct our experiments by predicting top-{2, 5, 10, 20} items to each user. The sampling rate m is set as 5 (select 5 negative/potential samples for each positive sample to construct pairs) in all pairwise learning to balance the accuracy and efficiency.

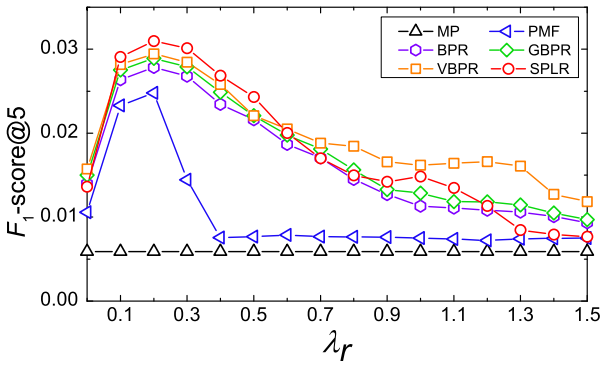
5.4 Performance of Our Entire Model (RQ1)

In this subsection, we report the performance of our entire model (SCF model optimized with SPLR, SCF_SPLR, abbreviated as SPLR) and baselines to give some analysis. We tune all models in the validation set and test the performance in the test set. The impact of some important hyperparameters, such as the number of latent factors, regularization coefficient, and weighted parameters, are shown. When training, we iterate the whole dataset 200 times to learn models and select 1000 samples randomly from the test/validation set to test all models in each iteration (except MP, we just test 200 times without training). We record the best performance of each model during this procedure as the evaluation of it. We execute all models 5 times and then report the mean and standard deviation. The learning rate is set as 0.05 and the batch size is set as 5000 for all models.



The performance of all models is represented in Table 2, we can see that all personalized models outperform MP significantly in all situations — about 3-6 times improvement. Comparison between BPR and PMF shows the superiority of pairwise learning over point-wise one. Considering the group behaviour, GBPR gets a further enhancement and outperforms BPR in all situations. As an enhanced learning to rank method, we compare our model with BPR and GBPR, and the improvement is shown in the last two columns in Table 2. We can see that our model dramatically outperforms these two models. In GBPR, only one-order user connections are utilized while in SPLR, the spectral features capture high-order connections for both users and items, thus provides high-level and comprehensive description of the similarity among vertices.

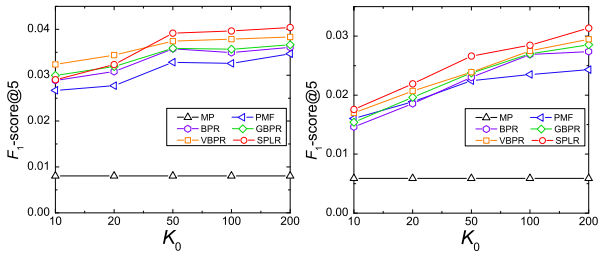
We also report the performance of VBPR, the state-of-the-art side information-based model. With the extra visual feature, it performs the best among all baselines. As we can see, our model can even outperform VBPR in most situations. Though both utilizing "side" information to enhance the accuracy, VBPR uses "outside" information, i.e., extra visual data, while SPLR uses "inside" information extracted from the purchase records. From the last two columns of Table 2, we can see that in *Jewelry* dataset, the relative improvement of our model decreases with the increasing of n (the number to recommend), while in *Clothes* dataset, the relative improvement is stable. That is not because the our model performs badly with a large n, it is the property of the dataset. We can see that in *Jewelry* set, the gap (relative improvement) between any two pairwise learning models decreases with the increasing of n.



To analyze the sensitivity of our model, we report the performance (F_1-score@5) with different hyperparameters. The impact of regularization coefficient λ_r is represented in Figure 2. Though both filtered from *Amazon* dataset, these two datasets have pretty different properties. From Figure 2(a), we can see that all models perform quiet differently to each other in *Jewelry* dataset, PMF, BPR, GBPR, VBPR, and SPLR get the best performance when λ_r is set to 0.4, 0.8, 0.8, 1.0, and 0.3 respectively. While in Figure 2(b), all models get the best performance when λ_r is set to 0.2. With the increasing of λ_r, accuracy of the point-wise learning method decreases rapidly compared with pairwise learning methods.

We also report F_1-score@5 with different length of latent factors to get the best K_0. In both two datasets, performance of all models (except MP) increase with the increasing of dimensions. We can see that due to the smaller size, the purchase record matrix of *Jewelry* has a smaller rank than that of *Clothes*: The performance in *Jewelry* tends to be stable after K_0 is larger than 50 while the performance in *Clothes* keeps increasing obviously with K_0 changing from 10 to 200. To get the best performance, we set K_0 as 200 for all models.

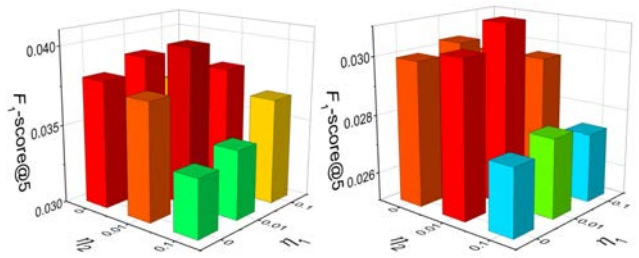
The impact of weighting parameters is illustrated in Figure 4. Our model performs the best when $\eta_1 = 0.01$ and $\eta_2 = 0.01$ in these two datasets. When $\eta_1 = 0$ and $\eta_2 = 0$, SPLR (SCF_SPLR) degenerates into SCF_BPR. From the figures we can see that SPLR outperforms SCF_BPR 4.70% in *Jewelry* validation dataset and 4.03% in *Jewelry* validation dataset on F_1-score@5. We can see that the enhancement of SLPR is not so significant, this is because we have explored the similarity information by incorporating the spectral features into SCF_BPR model, which outperforms MF_BPR significantly (Table 3). We leverage SPLR optimization to explore the similarity information thoroughly for further accuracy improvement.



(a) *Jewelry*

(b) *Clothes*

Figure 2: Impact of regularization coefficient λ_r (validation set)



(a) *Jewelry* (b) *Clothes*

Figure 3: Impact of latent factor dimensions K_0 (validation set)

We demonstrated the effectiveness of our entire model in this subsection, and in next subsections, we illustrate the effectiveness of each part of our model — spectral feature-enhanced model (SCF_BPR) and spectral clustering-enhanced pairwise learning optimization strategy (MF_SPLR).

5.5 Effectiveness of SCF_BPR (RQ2)

In this subsection, we denote all models with the model names and optimization methods. We rename BPR as MF_BPR, which means

(a) *Jewelry* (b) *Clothes*

Figure 4: Impact of weighting parameters η_1 and η_2 (validation set)

MF model optimized with BPR algorithm. Similarly, SCF_BPR is SCF model optimized with BPR. We demonstrate the effectiveness of spectral features by comparing SCF_BPR with other baselines. We first report the sensitivity with the number of eigenvectors by grid searching in the range of {0,10,100,1000}. All experiments in this and next subsection are conducted in *Jewelry* dataset.

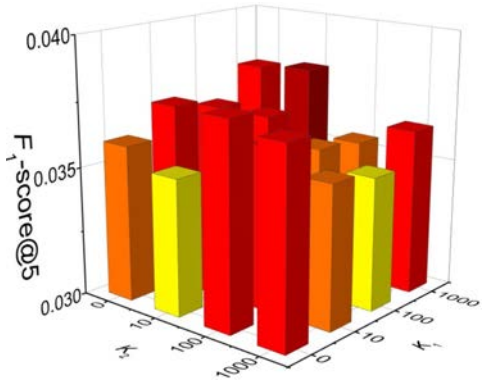


Figure 5: Performance of SCF_BPR with different length of spectral features (*Jewelry*, validation set)

The sensitivity of SCF_BPR with the length of spectral features is shown in Figure 5. When $K_1 = 1000$ and $K_2 = 10$, SCF_BPR performs the best. When $K_1 = 0$ and $K_2 = 0$, SCF_BPR degenerates into MF_BPR. SCF_BPR outperforms MF_BPR 7.2% on F_1-score@5 in *Jewelry* validation set. From Figure 5 we can see that user feature and item feature do not jointly work well since SCF_BPR does not perform well when K_1 and K_2 are both large. In real-world application, we can set $K_1 = 0$ and $K_2 = 100$ to balance the accuracy and the efficiency.

The performance of SCF_BPR and baselines in test set is shown in Table 3. To save space, only the performance of MF_BPR is reported, since it is the most important baseline. We can check Table 2 for the performance of other baselines. With the spectral features providing similarity information, SCF_BPR outperforms MF_BPR 7.27% and 6.38% on F_1-score and *NDCG* respectively in the best situation.

Table 3: Performance comparison for SCF_BPR (*Jewelry*, test set)

Metrics (%)		MF_BPR	SCF_BPR	Improvement
F-1@	2	3.684±0.194	**3.952**±0.221	7.27%
	5	3.576±0.137	**3.768**±0.098	5.37%
	10	3.159±0.099	**3.301**±0.087	4.50%
	20	2.489±0.042	**2.596**±0.029	4.30%
NDCG@	2	3.722±0.184	**3.953**±0.151	6.21%
	5	2.775±0.106	**2.952**±0.074	6.38%
	10	2.227±0.039	**2.366**±0.037	6.24%
	20	1.738±0.017	**1.835**±0.023	5.58%

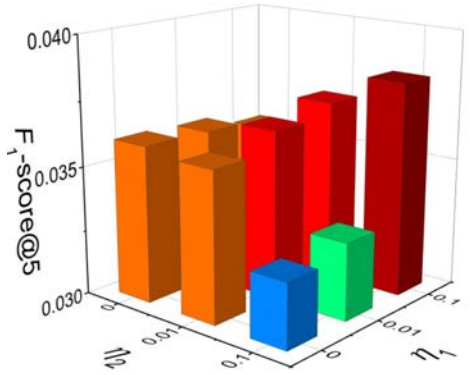

Figure 6: Performance of MF_SPLR with different weighting parameters (*Jewelry*, validation set)

5.6 Effectiveness of MF_SPLR (RQ3)

The sensitivity of MF_SPLR with the weighting parameters η_1 and η_2 are shown in Figure 6. We can see that MF_SPLR performs the best when $\eta_1 = 0.1$ and $\eta_2 = 0.1$. When $\eta_1 = 0$ and $\eta_2 = 0$, MF_SPLR degenerates to MF_BPR. MF_SPLR outperforms MF_BPR 6.13% F_1-score@5 in *Jewelry* validation set. Comparing Figure 4(a) and Figure 6 we can see that though both enhanced with SPLR optimization, MF_SPLR gains more improvement than SCF_SPLR, and the SPLR terms are weighted more in MF_SPLR ($\eta_1 = 0.1$, $\eta_2 = 0.1$ in MF_SPLR while $\eta_1 = 0.01$, $\eta_2 = 0.01$ in SCF_SPLR). It is because that the similarity information has been leveraged in SCF_SPLR by modeling with the spectral features. While in SCF_SPLR, SPLR is the only way to utilize the similarity information.

The performance of MF_SPLR and baselines in *Jewelry* test set is shown in Table 4. From the table we can see that SCF_BPR outperforms MF_BPR 8.20% and 5.42% on F_1-score and *NDCG* respectively in the best situation. Comparing Tables 2, 3, and 4, we can see that the improvement of the entire model is less than the sum of the improvement of each part. That may be because our model utilizes the similarity information by modeling (SCF) and optimizing (SPLR), thus these two parts provide the same information in different ways.

In Figure 7, we show some latent categories of the *Jewelry* set, which contains all watches and jewelries. There are six latent categories in Figure 7. Not like a real category, items in a latent category

Figure 7: Latent categories (*Jewelry* set)

Table 4: Performance comparison for MF_SPLR (*Jewelry*, test set)

Metrics (%)		MF_BPR	MF_SPLR	Improvement
F-1@	2	3.684±0.194	**3.986**±0.074	8.20%
	5	3.576±0.137	**3.789**±0.123	5.96%
	10	3.159±0.099	**3.314**±0.056	4.91%
	20	2.489±0.042	**2.578**±0.054	3.58%
NDCG@	2	3.722±0.184	**3.924**±0.151	5.43%
	5	2.775±0.106	**2.923**±0.074	5.33%
	10	2.227±0.039	**2.339**±0.037	5.03%
	20	1.738±0.017	**1.797**±0.023	3.39%

are relevant items or similar items (items strongly connected in the hypergraph). For example, in Figure 7(a), items are watches and some relevant commodities, such as watch bands and watch boxes[2]. Users who want to by watches may have interests in this category. Though items in the same latent categories may be different kinds of commodities, they are in the same style. For example, items in Figure 7(a) are designed for business men, they are luxurious, with metallic luster, look mature and steady. On the contrary, different categories may contain items of the same kind, but they are in different styles. For example, the category in Figure 7(b) is also for watches, however is in a totally different style from that in Figure 7(a). Most items in this category are plastic and cheap digital watches for sports and boys may have interests in them. Items in Figure 7(c) are watches and jewelries for young girls, they look simple and elegant. Jewelries in Figure 7(d) and Figure 7(e) are luxurious and exaggerative, which are full of diamonds and gemstones. Items in Figure 7(f) are in punk style and rebellious teenagers may prefer them.

Table 5: Performance with different features (*Jewelry*, test set)

Metrics (%) \ Features		None	Spectral features	CNN feature	Spectral features & CNN feature
F-1@	2	3.684±0.194	4.104±0.185	4.218±0.213	**4.414**±0.177
	5	3.576±0.137	3.905±0.136	3.974±0.106	**4.108**±0.165
	10	3.159±0.099	3.339±0.068	3.398±0.103	**3.567**±0.120
	20	2.489±0.042	2.638±0.064	2.631±0.067	**2.800**±0.103
NDCG@	2	3.722±0.184	4.057±0.179	4.184±0.165	**4.392**±0.278
	5	2.775±0.106	3.099±0.121	3.173±0.090	**3.315**±0.183
	10	2.227±0.039	2.450±0.048	2.542±0.078	**2.623**±0.137
	20	1.738±0.017	1.861±0.046	1.934±0.073	**2.011**±0.092

Figure 7 shows how the item spectral feature helps to recommend. The item spectral feature indicates the style of the item, circle of interest the item belongs to, the price level, target users, etc. Modeling with the item spectral feature (SCF) makes the items in the same latent category tend to have similar score. And optimizing with the item spectral feature (SPLR) makes the items in the positive category (latent category containing positive samples) tend to have a high score. For the user spectral feature, we can draw the same conclusion.

Both spectral features and latent factors are extracted from graph structures which are constructed from the purchase records (one bipartite graph and two hypergraphs). In fact, they both mine the similarity information while with different emphasis — user/item spectral features describe the similarity of users/items, while latent factors describe the similarity between a user and an item. Spectral features and latent factors complete each other in describing the similarity information and enhance the effectiveness of the recommendation model.

6 EXTENSION

In this paper, we proposed new spectral features and incorporated them into an MF model to predict users' preference. We then introduced new spectral clustering-based pairwise learning method to optimize our model. In this section, we extend our model and propose a framework of learning to rank models enhanced with side information features. Not only the spectral features, all features can be leveraged in our framework. Assuming there are n features for users $\mathbf{E}^{(1)}, \cdots, \mathbf{E}^{(n)}$ and m features for items $\mathbf{F}^{(1)}, \cdots, \mathbf{F}^{(m)}$, the prediction is given by:

$$\hat{\mathbf{R}} = \mathbf{U}\mathbf{V}^\top + \sum_{j=1}^{m} \mathbf{P}^{(j)}\mathbf{F}^{(j)\top} + \sum_{k=1}^{n} \mathbf{E}^{(k)}\mathbf{Q}^{(k)\top},$$

where $\mathbf{P}_u^{(j)}$ is the preference of user u based on the j-th item feature. These item features can be high-level features like the spectral feature, CNN feature, auditory feature, or low-level features like the color histogram or tags. $\mathbf{Q}_i^{(k)}$ is the fitness of item i based on the k-th user feature. These user features can be high-level features like the spectral feature, or the low-level information vector containing such as age, genders, addresses, etc.

For pairwise learning, we use the latent community $C_u = \bigcup_{j=1}^{n} C_u^{(j)}$ and latent category $C_i = \bigcup_{k=1}^{m} C_i^{(k)}$ to construct the potential set in Equation (3), where $C_u^{(j)}$ is the latent community of user u clustered by the j-th feature and $C_i^{(k)}$ is the latent category of item i clustered by the k-th feature.

Experimental results of our extended model are shown in Table 5. These four columns are performances of our extended models with no feature (i.e., MF_BPR), with the spectral features (i.e., SCF_SPLR), with the CNN feature (i.e., VBPR optimized with visual clustering-enhanced pairwise learning to rank), and with the spectral features plus the CNN feature. Enhanced with the spectral features, SCF_SPLR outperforms MF_BPR 9.20% on F_1-score@5. Leveraging appearance information, our extended model with the CNN feature outperforms MF_BPR 11.13% on F_1-score@5. Comparing Table 2 and Tale 5 we can see that it also outperforms VBPR 4.03% on F_1-score@5 due to the enhanced pairwise learning optimization. Our extended model with the CNN feature and spectral features outperforms MF_BPR 14.88% on F_1-score@5.

7 CONCLUSION AND FUTURE WORK

In this paper, we investigated the usefulness of the spectral features in recommendation tasks. We first introduced novel spectral features, which contain similarity information, and injected them into an MF structure to model users' preference and items' properties. We then clustered the spectral features to construct the latent communities and categories for users and items respectively, and used them to enhance the pairwise learning. We finally extended our model and proposed a framework for side information-enhanced pairwise learning. Experiments on challenging real-world datasets show that our proposed methods significantly outperform state-of-the-art models.

For future work, we will investigate the effectiveness of our proposed spectral features in the setting of explicit feedback. Also, we are interested in explaining the recommendation result to users with the information of latent communities and categories. Lastly, we will use neural networks [16, 18] to learn how to combine features, such as the item spectral feature and user spectral feature, or spectral features and other kinds of features.

ABSTRACT

In taxi ride-sharing, multiple customers are allotted to the same taxi as long as they are *compatible*, i.e., if none of them suffers a detour beyond a permissible threshold. To attract customers to ride-sharing, taxi operators promise a reduced fare upfront. As a result, if the taxi fails to pair the initial customer with additional compatible passengers, the taxi operator incurs a financial loss. Hence, it is important to ensure that the taxi finds compatible customers once it has picked up the initial customer. In the current scenario, the appearance of subsequent compatible customers is left to luck: a taxi moves along the shortest (or quickest) path for the existing customer and hopes to find additional compatible customers on its way. In this paper, we ask: *Is the shortest path the optimal path for ride-sharing?* To investigate this question, we develop a route recommendation algorithm called SHARE, which predicts the route with the highest probability of finding compatible customers, while staying within the detour limits. Through extensive evaluations on real datasets, we show that SHARE reduces failure rate in ride-sharing by up to 40%, while also improving waiting time for customers by 20%. Technically, the route recommendation problem is NP-hard. We overcome this bottleneck, by reducing the search space of the entire road network into a smaller directed acyclic graph, on which we perform *dynamic programming* to identify the optimal route. This strategy allows us to answer queries within 0.2 seconds, and thereby making SHARE deployable on real road conditions.

1 INTRODUCTION

With well known brands such as Uber and Didi Chuxing promoting *ride-sharing*, the taxi-service industry has become a prominent part of the internet-based "Sharing economy" [11]. In contrast to traditional ride-hailing services where a taxi is assigned at most one *ride-order* (request for a taxi), in ride-sharing, multiple *compatible* ride-orders are allocated to the same taxi. Two ride-orders are compatible if both of them can be serviced by a single taxi without taking a significant detour in either of their travel routes.

Ridesharing offers several benefits. From the riders' perspectives, their travel costs are reduced since they share a vehicle. For the ride-hailing service providers, ride-sharing allows them to better utilize their limited vehicles by servicing more customers, which results in more profits [42]. This is particularly useful during peak hours. In addition, ride-sharing is more environment-friendly as it helps reduce fuel consumption, carbon footprint and vehicular traffic congestion in cities. Owing to the numerous benefits of ride-sharing, the problem has received significant interest both from academia [10, 15, 25, 41] and industry [24, 37, 42]. In this work, we study the problem of *route recommendation* in ride-sharing environments.

The context is this: In the current technology scenario, when a taxi is allocated to a ride-order opted for ride-sharing, it picks the ride-order from the source location and travels to its destination in the shortest (or quickest) route. While travelling along this shortest route, the taxi may get lucky and be allocated to another compatible ride-order from a nearby location by the taxi service provider, and the taxi is re-routed to pick up the new request. To entice customers into opting for ride-sharing, taxi service providers such as Uber and Didi show the exact ride-sharing fare upfront even before the trip is started. Typically, this fare is much lower than what the customer would pay if an exclusive access to the taxi is requested. Since the

fare would not hike even if the taxi is not allocated to another compatible ride-order, from the service providers' perspective, they risk incurring a loss with the ride-sharing model. This risk depends on the probability of being allocated to a compatible ride-order while travelling on the shortest route of the first ride-order. Therefore, an important question arises: *Can we move beyond shortest paths by recommending a route that is close in length to the shortest path and offers much higher chance of finding a compatible ride-order?* In this paper, we investigate this question and present substantial evidence that moving beyond shortest paths is indeed a promising approach.

Existing works on ride-sharing optimization are in two primary aspects: taxi assignment [10, 15, 24, 25, 32, 41] and route planning [37, 42]. Given the current status of all taxis and the ride-orders, the taxi assignment problem looks into the aspect of mapping each ride-order to a taxi such that a particular objective function is maximized. This objective function can be maximizing profit, minimizing detour, etc. The route planning problem identifies the sequence of customer pick-ups and customer drop-offs that maximizes an objective function. In both aspects of works, it is assumed that the taxi travels on the shortest path between two consecutive pick-up/drop-off points. Furthermore, there is no predictive element: all computations are deterministic in nature and based solely on the known ride-orders and taxi locations.

In our problem, we attack the *route recommendation* problem. Specifically we ask: Can we *predict* a slightly longer path that significantly enhances the chances of finding compatible customers? Our recommendation achieves three goals. First, by enhancing the likelihood of finding compatible customers, it reduces the risk associated with ride-sharing for taxi service providers. Second, by ensuring the length of recommended path is close to the shortest path, the customer experience is not compromised. Third, by anticipating where future ride-orders are likely to come from, the recommended route reduces the waiting time for customers and thereby improves their experience. The key contributions of our work are as follows:

- We formulate a novel problem of route recommendation for taxi in the ride-sharing environment.
- We show that the proposed problem is NP-hard. We overcome the computational bottleneck by developing an algorithm called SHARE:*Ride-Sharing with History-Aware Route Recommendations*. SHARE reduces the exponential search space of all possible paths in the entire road network to a directed acyclic graph, on which we perform dynamic programming to identify the optimal path.
- We perform extensive experiments on real taxi datasets from New York and Singapore across a range of metrics. We show that the routes recommended by the proposed model receives up to 40% reduction in orders without ride-sharing than the shortest path. In addition, the recommended routes reduce waiting time for customers by 20% while improving number of passengers per kilometer for the taxi operator.

2 PROBLEM STATEMENT

DEFINITION 1 (ROAD NETWORK). *A road network is a directed graph $G = (V, E, \delta, \lambda)$, where V is the set of nodes representing geographical sites, $E \subseteq V \times V$ is the set of edges representing road segments between sites, a distance function $\delta : E \to \mathbb{R}$ representing the length (weight) of each road segment, and a spatial mapping λ representing the geographic locations of sites in the form (latitude, longitude) tuples.*

We use the notation $e = (u, v)$ to denote a road segment (edge) from node u to v. The length $\delta(e)$ of an edge e is the Haversine distance from u to v. A *route* corresponds to a *simple path* in the network, i.e., path without cycles. In the rest of this paper, we use the word "path" to refer to a simple path. The length of a path $P = \{e_1, \cdots, e_k\}$ over k edges is $\delta(P) = \sum_{\forall e_i \in P} \delta(e_i)$. A path may also be represented as a sequence of connected nodes. We use the notation $e_i \in P$ and $v_i \in P$ to denote the fact that path P goes through edge e_i and node v_i respectively. Finally, we use the notation $SP(u, v)$ to denote the length of the *shortest path* from node u to v.

DEFINITION 2 (RIDE ORDER). *A ride-order o is represented as $\langle o^s, o^d, o^t \rangle$ where $o^s \in V$ denotes the pick-up point, $o^d \in V$ denotes the drop-off point, and o^t denotes the time at which the order request is made.*

A path P *covers* order o if there exists a *sub-path* $P' \subseteq P$, such that P' originates at o^s and ends at o^d. We use the notation $\delta_o(P) = \delta(P')$ to denote the distance travelled to fulfill order o through path P. The *detour ratio* $dr(o, P)$ of P with respect to order o is the proportion of extra distance travelled compared to the shortest path, i.e.,

$$dr(o, P) = \frac{\delta_o(P)}{SP(o^s, o^d)}. \tag{1}$$

When two ride-orders are allocated to the same taxi, they may incur a detour. To ensure that these detours are not too long, taxi service providers allocate two orders to the same taxi only if both their detours are at most α [37, 42], where $\alpha \geq 1$ is a *detour threshold*. We call such ride-orders *compatible*.

DEFINITION 3 (COMPATIBLE RIDE ORDERS). *Let $o_1 = \langle o_1^s, o_1^d, o_1^t \rangle$ be a ride-order being serviced by taxi C and $o = \langle o^s, o^d, o^t \rangle$ is a new ride-order request. Furthermore, let $P_1 = \left\{o_1^s, \cdots, n\right\}$ be the path taken by C so far where n is its current location at time o^t. We call o compatible with o_1 if there exists a path P_2 originating at n such that P_2 covers o, $P_C = P_1 + P_2$ is a path that covers o_1 and both $dr(o_1, P) \leq \alpha$, $dr(o, P_2) = dr(o, P_C) \leq \alpha$.*

To generalize the above definition for arbitrary number of passengers, we assume each taxi is associated with a capacity of X passengers. Furthermore, for some m s.t. $0 \leq m \leq X$, $\mathbb{O} = \{o_1, \cdots, o_m\}$ is the set of orders currently being serviced by the taxi and P_1 is the path it has taken till now. A new request o can be allotted to this taxi if $Compatible(\mathbb{O}, o) = 1$.

$$Compatible(\mathbb{O}, o) = \begin{cases} 0 & \text{if } m = X \\ 1 & \text{if } \exists \text{ path } P_2 \text{ from current node } n, \\ & \text{such that } P_2 \text{ covers } o, \\ & \forall o_i \in \mathbb{O},\ P_C = P_1 + P_2 \text{ covers } o_i, \\ & \forall o_i \in \{\mathbb{O} \cup o\},\ dr(o_i, P_C) \leq \alpha \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

EXAMPLE 1. *Consider the scenario shown in Fig. 1. A taxi is at v_1 servicing $\mathbb{O} = \{o\}$, where $o = \langle v_1, v_{10}, o^t \rangle$. There are two other*

orders, $o_1 = \langle v_5, v_8, o^t \rangle$ and $o_2 = \langle v_9, v_3, o^t \rangle$, that are yet to be allotted to a taxi. Now, we will calculate $Compatible(\mathbb{O}, o_1)$ and $Compatible(\mathbb{O}, o_2)$.

For o_1, there exists a path $P_C = \{v_1, v_3, v_5, v_6, v_8, v_{10}\}$ of distance 23. This path P_C covers both o and o_1. Assume $\alpha = 1.5$. A sub-path $P'_C = \{v_5, v_6, v_8\} \subseteq P_C$ is the shortest path for o_1 so the detour ratio is 1. Furthermore, $SP(v_1, v_{10}) = 20$, so the detour ratio for o is $23/20 = 1.15 \leq 1.5$. Hence, $Compatible(\mathbb{O}, o_1) = 1$.

For o_2, there does not exist a path that satisfies Eq. 2 without violating the detour constraint. Hence, $Compatible(\mathbb{O}, o_2) = 0$.

Let C be a taxi of capacity X servicing a set of ride-orders $\mathbb{O}$, $|\mathbb{O}| < X$. Taxi C has just picked up the order request $o_m = \langle o_m^s, o_m^d, o_m^t \rangle \in \mathbb{O}$. Without loss of generality (*WLOG*), we assume the taxi has taken path P_1 till now. We now need to recommend the *best feasible* route to the taxi. Formally, this problem is defined as follows.

Problem 1 (Route Recommendation in Ride-sharing). *A path P in the network is feasible if (i) P originates at o_m^s, and (ii) $P_1 + P$ does not exceed the detour ratio for any of the orders in $\mathbb{O}$. The best feasible path is the one that has the highest number of expected compatible orders with respect to $\mathbb{O}$ at time o^t. More specifically, find the path P^* where*

$$P^* = \arg\max_P \left\{ E\left(P|\mathbb{O}, o^t\right) \mid P \text{ is a feasible path} \right\} \tag{3}$$

$E\left(P|\mathbb{O}, o^t\right)$ denotes the expected number of compatible passengers in P at time o^t.

The next task therefore is to mathematically quantify $E\left(P|\mathbb{O}, o^t\right)$ for any given feasible path P.

2.1 Computing Expected Number of Passengers

To compute the expected number of compatible passengers, we use the historical data $\mathbb{H}$ containing past ride-orders. We use the notation $\mathbb{H}_D \subseteq \mathbb{H}$ to denote the set of ride-orders made on a particular date D. Given a node v and current time o^t, we extract the set of compatible orders originating at v from $\mathbb{H}_D$ for each date D covered in the history.

$$\mathbb{H}_{D,v,\mathbb{O},o^t} = \{o' | o' \in \mathbb{H}_D,\ o'^s = v, \\ \|o^t - o'^t\| \leq \Delta, Compatible(\mathbb{O}, o') = 1\} \tag{4}$$

Here, Δ is a smoothing parameter on the time dimension. It is reasonable to set Δ to any value between 5 to 15 minutes. Therefore, the *expected* number of ride-orders arising from node v at time o^t is the average count across all dates in $\mathbb{H}$. Specifically,

$$E(v|\mathbb{O}, o^t) = \frac{1}{Y} \sum_{\forall \mathbb{H}_{D_i} \in \mathbb{H}} \left| \mathbb{H}_{D_i,v,\mathbb{O},o^t} \right| \tag{5}$$

where Y is the total number of days spanning $\mathbb{H}$.

Let $P = \langle v_1, \cdots, v_n \rangle$ be a feasible path. The expected number of compatible passengers in P is therefore

$$E(P|\mathbb{O}, o^t) = \sum_{\forall v_i \in P} E(v_i|\mathbb{O}, o^t) \tag{6}$$

Eq. 6 completes the problem formulation.

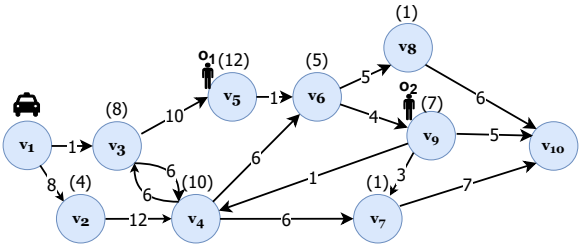

Figure 1: An illustration of a road network G. In this graph, the length of each edge is shown as edge weights. The numbers in brackets above each node denotes the expected number of compatible passengers, $E(v|\mathbb{O}, o^t)$, which we define in Sec. 2.1.

3 BASELINE: SHORTEST PATH

The baseline algorithm is to select the shortest path [37, 42]. There is no predictive element in this approach. Formally, let taxi C be servicing order set $\mathbb{O}$. We now introduce the concept of a *route plan.*

Definition 4 (Route Plan). *A* route plan, *RP, is a sequence of drop-off locations corresponding to each order in $\mathbb{O}$.*

A path P *satisfies* route plan RP if it visits the drop-off locations in the same sequence as in RP. Let $SP(RP)$ denote the shortest path satisfying route plan RP. The *shortest route plan* for $\mathbb{O}$, RP^*, is the route plan with the smallest shortest path. Mathematically,

$$RP^* = \arg\min_{RP} \{SP(RP) \mid RP \in \mathbb{RP}\} \tag{7}$$

where $\mathbb{RP}$ is the set of all possible route plans for $\mathbb{O}$. In the shortest path approach, the taxi therefore simply follows $SP(RP^*)$.

4 SHARE:RIDE-SHARING WITH HISTORY-AWARE ROUTE ReCOMMENDATIONS

The shortest path approach is blind to the need of finding compatible passengers on its way. Our formulation addresses this weakness.

4.1 Complexity Analysis

Definition 5 (Longest Path Problem). *Given a weighted graph $G = (V, E)$ with non-negative edge weights w_e, the Longest Path problem is to find the longest simple path from a source node (s) to a destination node (d).*

Definition 6 (Max-Weight Path Problem). *Given a graph $G = (V, E)$ with non-negative node weights w_v, the Max-Weight path problem is to find the maximum weight simple path from a source node (s) to a destination node (d).*

The route recommendation problem for ride-sharing is essentially the *Max-Weight Path* problem, where the weight of each node v is the expected number of compatible passengers at v (Eq. 5). The route with the highest number of expected compatible customers is therefore the Max-Weight path.
We also know that the Longest Path problem is NP-hard [6].

Theorem 1. *Finding the Max-Weight path is NP-Hard*

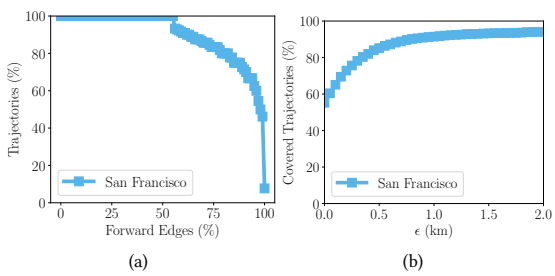

Figure 2: (a) Frequency distribution of trajectories against the percentage of forward edges. (b) Distribution of covered trajectories against the extra distance threshold ϵ.

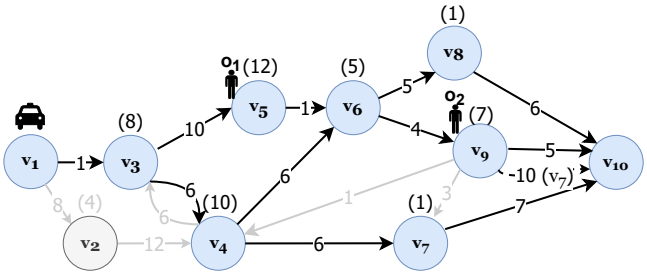

Figure 3: The subgraph D of the graph G in Fig. 1. The solid edges represent those that are part of E_D. The greyed-out edges and nodes represent those that are part of the original graph G but omitted from the D (See Ex. 2 for further details). The only dashed edge (v_9, v_{10}) represents an edge that is part of the extended DAG X (See Sec. 4.4) but not D.

Proof : Given an arbitrary instance of the Longest Path Problem, we reduce it to an instance of the Max-Weight Path problem through the following procedure. Consider the given graph $G = (V, E)$ in the Longest Path Problem, we design a graph $G' = (V', E')$ such that $\forall v \in V$, we have a node N_v in V' and $\forall e = (u, v) \in E$ we have a node N_e in V'. Furthermore, $\forall e = (u, v) \in E$ we have the edges $e_1 = (u, N_e)$ and the edge $e_2 = (N_e, v) \in E'$. We assign the weight w_e to all $N_e \in V'$, the weight 0 to all N_v and all the edges $e \in E'$ are un-weighted.

In G' the Max-Weight problem is to identify the path from a source s to a destination d with maximum weight. Since each node N_e selected in the path in G' corresponds to selecting the edge $e \in E$, if Max-Weight problem is solved, the resultant path is the longest path from s to d in graph G and hence, we would have solved the Longest Path Problem. □

Owing to the NP-hardness, an optimal algorithm is not feasible. This result motivates us to study real-world taxi trajectories and identify properties that may help reduce the search space.

4.2 An inspection of real-life trajectories

When a passenger is in a taxi, the taxi is expected to progressively get closer to the destination o^d through *forward* edges.

Definition 7 (Forward and Backward Edge). *Given a destination node o^d, we call an edge (u, v) to be a* forward edge *if $SP(u, o^d) > SP(v, o^d)$; otherwise, it is a* backward *edge.*

Taking a backward edge is a sub-optimal decision as it detours away from the destination, so we expect most real-life taxis move predominantly through forward edges. To verify this hypothesis, we analyze taxi trajectories in San Francisco [31] and compute the distribution of trajectories containing at least x% of forward edges. The details of the San Francisco dataset are provided in Sec. 5.1.1.

Fig. 2(a) presents the result. As can be seen, more than 55% of the trajectories have only forward edges. Even when a taxi travels on backward edges, the proportion of backward edges is generally small. For example, more than 80% of the trajectories have at least 80% forward edges. This result gives credence to our hypothesis that taxis progressively move closer to its destination in general.

4.3 Inducing a Directed Acyclic Graph on the Road Network

Motivated by the above result, we reduce the search space from all feasible paths to only those feasible paths that are comprised entirely of forward edges. To formalize this idea, let C be a taxi servicing order set $\mathbb{O}$ and have just picked up order $o \in \mathbb{O}$ from node o^s. Furthermore, let node o^{d*} be the next drop-off point according to the shortest route plan RP^* for $\mathbb{O}$. Then we extract the subgraph $D(V_D, E_D)$ from the entire road network $G(V, E)$, where

$$V_D = \left\{ v \in V \mid SP(v, o^{d*}) \leq SP(o^s, o^{d*}) \right\} \quad (8)$$

$$E_D = \{(u, v) \in E \mid u, v \in V_D, (u, v) \text{ is a forward edge}\} \quad (9)$$

Example 2. *Let us revisit graph G from Fig. 1. Fig. 3 presents the subgraph $D = (V_D, E_D)$ constructed from G corresponding to the order set $\mathbb{O} = \{o = \langle v_1, v_{10}, o^t \rangle\}$. Furthermore, only the solid edges in Fig. 3 are part of E_D. We illustrate the importance of the dashed edge (v_9, v_{10}) later in Sec. 4.4.*

In D, according to Eq. 8, $v_2 \notin V_D$ since $SP(v_2, v_{10}) > SP(v_1, v_{10})$. Moreover, according to Eq. 9, the edge (v_9, v_7) is omitted since $SP(v_7, v_{10}) = 7 > SP(v_9, v_{10}) = 5$.

Theorem 2. *$D(V_D, E_D)$ is a directed acyclic graph (DAG).*

Proof by contradiction. D is directed since G is directed. Let us assume that the set of edges $E_c = \{(v_1, v_2), (v_2, v_3) \cdots, (v_m, v_1)\}$ form a cycle in D. In D, an edge (u, v) from G is retained if and only if $SP(u, o^d) > SP(v, o^d)$. This leads to both $SP(v_1, o^d) > SP(v_m, o^d)$ and $SP(v_m, o^d) > SP(v_1, o^d)$, which is a contradiction. □

Thm. 2 has deep implication on our problem. Specifically, although the Max-Weight Path problem is NP-hard on a graph, on a DAG, it can be solved in polynomial time [33]. Specifically, let (d_1, o^{d*}) and (d_2, o^{d*}) be the two incoming edges to destination node o^{d*}. The longest path, $LP(o^s, o^{d*})$, from o^s to o^{d*} in a node-weighted graph is $LP(o^s, o^{d*}) = \max\{LP(o^s, d_1), LP(o^s, d_2)\} + weight(o^{d*})$. Since the Max-Weight Path problem in a DAG can be broken down into smaller problems, this can be solved in polynomial time using *dynamic programming (DP)*.

Unfortunately, this DP formulation cannot directly be applied to our problem. Specifically, we have two kinds of weights: the edge

weights denoting the road distance, and the node weights denoting the expected number of compatible customers. We need to find the Max-Weight path from o^s to o^{d*} in the domain of expected customers, such that the path, in terms of distance, does not violate the detour ratio (Eq. 1) of any of the orders in $\mathbb{O}$. We satisfy these dual needs through the following DP policy.

For each order $o_i \in \mathbb{O}$, let l_i be the length of the path they have travelled so far. The maximum amount of distance o_i can further travel in its path towards o^{d*} without violating the detour constraint is therefore $\overrightarrow{l_i} = \alpha \times SP(o_i^s, o_i^d) - l_i - SP(RP^*(o^{d*}, o_i^d))$, where $RP^*(o^{d*}, o_i^d)$ is the subsequence of the shortest route plan from o^{d*} to o_i^d. Therefore, any path P from o^s to o^{d*} is feasible if $\delta(P) \leq \overrightarrow{l_{min}}$, where $\overrightarrow{l_{min}} = \min\left\{\overrightarrow{l_i} \mid o_i \in \mathbb{O}\right\}$.

Next, we introduce the notation $c_{v,j}$ to denote the maximum expected number of compatible passengers among all paths of length j from o^s to some node v. Mathematically,

$$c_{v,j} = \arg\max_{\forall P \in \mathbb{P}_{v,j}} \left\{E(P|\mathbb{O}, o^t)\right\} \tag{10}$$

where $\mathbb{P}_{v,j} = \{P|\delta(P) = j, P \text{ is a path from } o^s \text{ to } v \text{ in } D\}$. We are now ready to define the DP. The initialization condition in the DP is

$$c_{v,j} = \begin{cases} 0 & \text{if } v = o^s, j = 0 \\ -\infty & \text{otherwise} \end{cases} \tag{11}$$

Now, the recurrence is defined as:

$$c_{v,j} = \max_{\forall (u,j') \in N_j(v)} \left\{c_{u,j'}\right\} + E\left(v \mid \mathbb{O}, o^t\right) \tag{12}$$

where $N_j(v) = \left\{(u, j') \mid (u, v) \in E_D,\ j = j' + \delta(u, v) \leq \overrightarrow{l_{min}}\right\}$ is the set of all incoming edge-length pairs that result in a path of length j without violating the detour ratio. The recurrence is computed using *memoization* for all nodes. The recommended path to o^{d*} corresponds to the path leading to $c^* = \max_{\forall j}\left\{c_{o^{d*},j}\right\}$.In addition, we also store the incoming neighbor from $N_j(v)$ that maximizes $c_{v,j}$. This is used to backtrack and identify the path providing the highest expected number of compatible passengers.

Example 3. *Table 1 presents the $c_{v,j}$ values for each node in the DAG D in Fig. 3. We assume source $o^s = v_1$ and destination $o^{d*} = v_{10}$. The shortest path from o^s to o^{d*} is of length 20. Assuming $\alpha = 1.5$, $l_{min} = 30$. Thus, $c_{v,j}$ matters only if $j \leq 30$.*

Consider calculating $c_{v_6,12}$, the possible (u, j') pairs are $N_{12}(v_6) = \{(v_5, 11), (v_4, 6)\}$. The maximum $c_{u,j'}$ is $c_{v_5,11} = 20$. Thus $c_{v_6,12} = c_{v_5,11} + E\left(v_6 \mid \mathbb{O}, o^t\right) = 20 + 5 = 25$.

At o^{d*}, the maximum $c_{v_{10},j}$ out of the feasible js is 32, which is highlighted in bold. The row corresponding to $\rightarrow$ in Table 1 indicates the incoming neighbor that maximizes the $c_{v,j}$ value. By backtracking using the incoming neighbors, we conclude that the optimal path P^* is $\{v_1, v_3, v_5, v_6, v_9, v_{10}\}$.

The computational complexity of the proposed DP remains exponential since, for each node v, the number of possible js can be as large as the number of possible ways to reach v from o^s, which is exponential. This implies an exponential number of columns in the table. The exponential cost can be avoided by moving from the continuous space to a discrete space. Particularly, each value

Table 1: The DP table corresponding to the DAG in Fig. 2(a) ($c_{v,j} = -\infty$ is omitted). Refer to *Ex.* 3 for further details.

v	v_1	v_3	v_4	v_5	v_6	v_6	v_7	v_8	v_8	v_9	v_9	v_{10}	v_{10}	v_{10}	v_{10}	v_{10}

Algorithm 1 Path finding using Dynamic Programming in DAG

Input: Starting location o^s, destination o^{d*}, detour threshold α, number of bins Ω, Graph G
Output: Optimal path p^* in DAG
1: $D \leftarrow$ Construct DAG from G
2: $\forall v \in V_D$, compute $top-order(v)$
3: $c_{o^s,0} \leftarrow 0$
4: **for** $i \leftarrow 1$ **to** $top-order(o^{d*})$ **do**
5: $\quad V_i \leftarrow \{v \in V_D \mid top-order(v) = i\}$
6: $\quad$ **for each** $v \in V_i$ **do**
7: $\quad\quad \forall b,\ 1 \leq b \leq \Omega$, Compute $c_{v,b}$ (Eq. 12)
8: $c^* \leftarrow \max_{\forall b}\{c_{o^{d*},b}\}$
9: $P^* \leftarrow$ backtrack with c^* to get optimal path
10: **return** P^*

of j is assigned to bin $b = \left\lceil \frac{j}{\omega} \right\rceil$, where ω is the width of each bin. All aspects of the DP remains identical except (1) instead of computing $c_{v,j}$, we compute $c_{v,b}$; (2) instead of $N_j(v)$, we use $N_b(v) = \left\{(u, b') \mid (u, v) \in E_D,\ b = \left\lceil \frac{b' \times \omega + \delta(u,v)}{\omega} \right\rceil \leq \Omega\right\}$, where Ω is the total number of bins and the bin width ω is set to $\frac{\overrightarrow{l_{min}}}{\Omega}$. As we will see in our empirical evaluation (Sec. 5.4), $\Omega = 100$ provides a good balance between efficiency and quality.

Alg. 1 presents the pseudocode of the DP. After constructing the DAG D (line 1), we compute the *topological order* of each node in D (line 2). From the construction of D, it is guaranteed that the source o^s will have a topological order of 1 and o^{d*} will have the largest order. The nodes in D are processed according to their topological order (line 4) and $c_{v,b}$ for each node is computed (lines 5-7). By processing nodes in *topological order*, we ensure that all incoming neighbors of a node has already been processed. Finally, the path corresponding to the highest expected number of compatible passengers is returned (lines 8-10).

4.3.1 Properties: We next outline the key properties of Share.

Theorem 3. *The shortest path is one of the possible solutions.*

Proof. Consider the shortest path $P = \{v_1, \cdots, v_n\}$, where $v_1 = o^s$ and $v_n = o^{d*}$. Since it is the shortest path, $SP(v_i, o^{d*}) > SP(v_{i+1}, o^{d*})$ for $i < n$. Therefore, this path exists in D. □

Time Complexity: Topological sorting of all nodes in the DAG consumes $O(|V| + |E|)$ time. The number of states in the dynamic programming is $|V|\Omega$. To compute the value of each state, we consider all incoming edges. Hence, each edge is considered at most once per discrete distance leading to a complexity of $O((|V| + |E|) \cdot \Omega)$.

Space Complexity: Since we have $|V|\Omega$ states in the worst case, the space complexity is $O(|V|\Omega)$.

4.4 Improving the Search Space through Extended DAG

Our search space in the DAG is restricted to only paths formed by forward edges. Fig. 2(a) reveals that $\approx 55\%$ of the taxis conform to this assumption. Therefore, we ask: *Is it possible to incorporate more paths in the DAG by slightly relaxing the forward edge assumption?*

Whenever a taxi takes a backward edge from some node u, it moves further away from the destination, and therefore, incurs some *extra distance* over what would have been the shortest path from u. We hypothesize that the extra distance incurred by a taxi owing to a backward edge is small since no taxi would want to burn unnecessary fuel. *Extra distance* is formally defined as follows.

Definition 8 (Extra Distance). *Let (u, v) be a backward edge. Furthermore, let $P = \{u, v, \cdots, x\}$ be the sequence of nodes following the backward edge till the taxi reaches some node x such that $SP(x, o^{d*}) \leq SP(u, o^{d*})$. The extra distance, denoted as $eDist(u, v, o^{d*}) = \delta(P)$, is the distance travelled by the taxi to reach a node that is at least as close to the destination as u.*

To verify our hypothesis that backward edges are taken by a taxi only when the resulting extra distance is small, we revisit the San Francisco dataset and call a taxi trajectory T *covered* if $\forall (u, v) \in T$, either (1) (u, v) is a forward edge, or (2) $eDist\left(u, v, o^{d*}\right) \leq \epsilon$, where ϵ is a threshold and o^{d*} is the next drop-off point of T. ϵ controls when we call the extra distance owing to a backward edge *small*; when $\epsilon = 0$, only forward edges are allowed. Fig. 2(b) presents the results as ϵ is varied. As can be seen, at $\epsilon = 0.5km$, more than 85% trajectories are covered. We take inspiration from this result and propose the idea of an *extended* DAG $X = (V_X, E_X)$.

The nodes in the extended DAG is same as in the original DAG, i.e., $V_X = V_D$. The edge set $E_X = \{E_D \cup E_\epsilon\}$, where E_D is the set of forward edges (Eq. 9), and E_ϵ is the set of *extended* edges that capture paths through backward edges incurring an extra distance of at most ϵ. Formally, an extended edge is defined as follows.

Definition 9 (Extended Edge). *We add an* extended *edge between two nodes u, $x \in V_X$ if the following conditions hold:*

1. *$SP(x, o^{d*}) \leq SP(u, o^{d*})$, where o^{d*} is the next drop-off point according to RP^* for $\mathbb{O}$.*
2. *There exists a path $P = \{u, v, \cdots, x\}$ in the road network G such that (i) (u, v) is a backward edge, and (ii) $\delta(P) \leq \epsilon$. It is possible that multiple paths from u to x satisfy both conditions (i) and (ii). Consequently, multiple edges may exist between u and x.*

Since multiple edges may exist between two nodes in the extended DAG, we denote each edge with the tuple (u, x, P). For extended edges, P corresponds to the path satisfying condition (2) in Def. 9. On the other hand, in a forward edge (u, x, P), $P = \{u, x\}$. The *length* of any edge (u, x, P) is therefore $\delta(P)$. Condition (1) in Def. 9 ensures that the extended DAG remains acyclic. This enables us to extend Share from the forward edge assumption.

Example 4. *The extended DAG X of the network in Fig. 1 at $\epsilon = 10$ is shown in Fig. 3. The solid edges correspond to the forward edge, and the dashed edge from v_9 to v_{10} corresponds to an extended edge. This extended edge exists due to the path $P = \{v_9, v_7, v_{10}\}$. Now we can obtain a path $\{v_1, v_3, v_5, v_6, v_9, v_7, v_{10}\}$ with an optimal $c^* = 33$, which is higher than 32 obtained in plain DAG D.*

The size of the extended DAG is exponential in ϵ: All extended edges originating from node u can be identified by initiating a depth-first exploration from u, traversing a backward edge to v first, then exploring further edges until the total length exceeds ϵ or a node x is reached that is closer to the destination than u. Since the number of paths between any two nodes is potentially exponential, the worst case number of edges in E_ϵ is exponential in ϵ. Hence, constructing the extended DAG and solving the DP are both exponential in ϵ. However, by limiting ϵ to a small value such as $0.5km$, we can obtain a good balance between running time and quality. We further explore this aspect in Sec. 5.

Searching Algorithm: The dynamic programming (DP) applied on the DAG can also be applied on the extended DAG to identify the path having the largest number of expected compatible customers. However, there are two issues that need to be treated differently. First, each extended edge (u, x, P) corresponds to path P from the network. Thus, each extended edge (u, x, P) is replaced with P in the optimal path identified by the DP. Second, although any path in the extended DAG is simple, once extended edges are replaced with their corresponding paths, they may introduce repeated vertices. To give an example, consider two connected extended edges (u, x, P_1) and (x, z, P_2). It is possible that $\exists v \in V_X,\ v \in P_1$ and $v \in P_2$. To reject such paths, the recurrence is allowed to proceed only through incoming edges that do not introduce a cycle. To accommodate this additional constraint, we modify the definition of feasible incoming neighbors $N_j(x)$ of node x in Eq. 12 as follows.

$$N_j(x) = \{(u, j') \mid (u, x, P) \in E_X,\ j = j' + \delta(P) \leq \overrightarrow{l_{min}},\ P \cap path(c_{u,j}) = \emptyset\} \quad (13)$$

$path(c_{u,j})$ denotes the path that leads to $c_{u,j}$. Recall that this path can be identified through backtracking. Computing the intersection between two paths can be done in $O(|V|)$ time through hashing.

To summarize, the extended DAG includes paths with backward edges under the constraint that the backward edge does not cause an additional detour beyond ϵ than a path consisting of only forward edges. As shown in Fig. 2(b), more than 85% of real-life taxis do not take any backward edge that results in an extra distance of more than $0.5km$. The online recommendation pipeline is therefore as follows: every time a new order o is picked up by a taxi, we first compute the nearest drop-off location o^{d*} according to the shortest route plan RP^* (Recall Eq. 7). The extended DAG X is constructed with o^s and o^{d*} as the source and destination nodes and the feasible path with the highest number of expected customers is computed.

Time Complexity: As discussed earlier, the construction time of the extended DAG is exponential in ϵ and the time for executing the DP on this DAG is also similarly exponential in ϵ. Consequently, by limiting ϵ to a small value, we obtain a good balance between efficiency and quality.

Space Complexity: Since each backward edge corresponds to a path from the road network, and there could potentially be exponential number of paths, the number of extended edges is also exponential. However, in a practical scenario, under a small ϵ in the range $[0.1km, 0.7km]$, the space consumption is less than 0.4 GB on large metropolitan cities like New York and Singapore.

4.5 Infusing Additional Intelligence

The proposed prediction model is generic enough to accommodate further optimizations. We discuss some possibilities below. These optimizations are not part of SHARE, but may be added if preferred. We empirically evaluate their impact in Sec. 5.6

4.5.1 Non-linear weighting of nodes: The expected number of compatible customers in a path is simply the summation of the expected customers in each of the constituent nodes. This formulation does not incorporate the factor that finding a customer early in a path is much more profitable than in one of the later nodes. This aspect can be modeled by applying a non-linear weighting factor to each node. Specifically, we may modify Eq. 6 as:

$$E\left(P|\mathbb{O}, o^t\right) = \sum_{\forall v_i \in P} E\left(v_i|o^t\right) \cdot w_i \tag{14}$$

where w_i is the weight importance of node v_i. Under an exponential decay function, $w_i = e^{-\lambda \frac{dist_i}{\delta(P)}}$, where $dist_i$ is the distance travelled till node v_i in path P and λ is the decay parameter.

4.5.2 Regional Expectations: The expected number of compatible customers in a node v is derived from the historical pick-up data of v . In reality, a taxi can always deviate slightly from the path, pick up a customer, and then continue on its journey. To model the expected number of compatible customer from the region around a node instead of the node itself, we may modify Eq. 5 as:

$$E(v|\mathbb{O}, o^t) = \frac{1}{Y} \sum_{\forall \mathbb{H}_{D_i} \in \mathbb{H}} \sum_{\forall u \in R(v,\theta)} \left|\mathbb{H}_{D_i,u,\mathbb{O},o^t}\right| \tag{15}$$

where $R(v, \theta) = \{u \in V \mid SP(v, u) \leq \theta\}$ is the set of all nodes reachable within a distance of θ from v.

4.5.3 Incorporating Expected Time: If an order o is picked up by a taxi at time o^t, the expected number of customers at all nodes in a path $P = \{v_1, \cdots, v_n\}$ is computed conditioned on o^t. In reality, the taxi reaches any node $v_i \in P$ some time after o^t. To reflect the time component more accurately, we can compute the average commute time t_e for each edge e in the network. Next, one may modify Eq. 6 as follows to obtain better estimates.

$$E\left(P|\mathbb{O}, o^t\right) = \sum_{\forall v_i \in P} E\left(v_i \mid (o^t + time(P, v_i))\right) \tag{16}$$

where $time(P, v_i) = \sum_{j=1}^{i-1} t_{(v_j, v_{j+1})}$

5 EXPERIMENTS

In this section, we benchmark SHARE and establish that

- **Quality:** The path recommended by SHARE is better than the shortest path across a range of practical metrics.
- **Route Planning:** Using SHARE as the base approach, instead of shortest paths, reduces ride-sharing failure rates by up to 40% in the route planning problem for ride-sharing [42].
- **Efficiency:** SHARE consumes only ≈ 0.2 seconds to answer recommendation queries, and is therefore fast-enough for real-time recommendations on large metropolitan cities.

The code and datasets used can be downloaded from https://github.com/Ride-SHARE/SHARE.

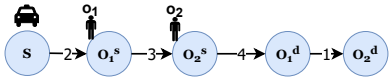

Figure 4: Illustrates the Passengers per km metric.

5.1 Experimental Setup

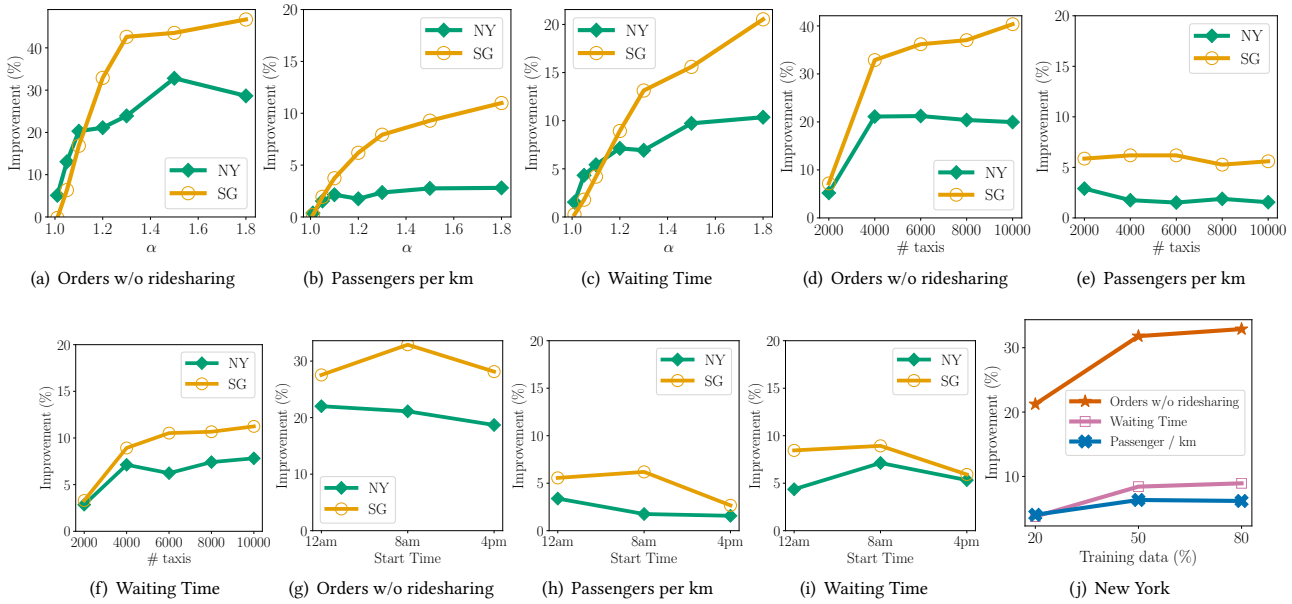
All experiments are implemented in Java and performed on a machine with Intel(R) Xeon(R) CPU 2.50GHz E5-2680 with 32GB RAM on Red Hat Enterprise Linux Server release 6.9.

5.1.1 Datasets. Table 2 summarizes the real taxi datasets used for our empirical evaluation. The road networks of all three cities have been obtained from OpenStreetMap [29].

•**New York [8]:** This dataset contains records of yellow and green taxis in the city of New York. Each record includes fields capturing pick-up and drop-off dates/times, locations and trip distances. From this dataset, we extract all pick-ups for yellow taxis in January, 2013 and construct our dataset.

•**Singapore [38]:** This dataset contains records of taxis from Singapore. Each record includes a series of tuples of the form $\langle Latitude, Longitude, TaxiID, DriverID, TaxiStatus\rangle$, which are recorded at 1-minute intervals. The $TaxiStatus$ field indicates whether the taxi is occupied or idling. We extract all pick-ups in January, 2012.

•**San Francisco [31]:** The dataset has been collected over a duration of one month and contains the trajectories and taxi pick-up and drop-off information from taxis in San Francisco.



In all these datasets, the capacity of a taxi is not mentioned. We assume it to be 3 passengers.

5.1.2 Evaluation Framework: To evaluate the performance of SHARE, we partition each taxi pick-up dataset into two portions: the training set and the testing set. The recommendation model is learned from the training set and evaluated on the testing set. The training set contains a random 80% of all orders and remaining portion is assigned to test set. All taxis in the test set are initially randomly positioned in the road network. Next, each order $o = \langle o^s, o^d, o^t\rangle$ from the test set is picked sequentially according to o^t and added to a queue of pending orders. A pending order o is removed from the queue when a compatible taxi, i.e., a taxi servicing order set $\mathbb{O}$ such that $compatible(\mathbb{O}, o) = 1$ (Recall Eq. 2), $|\mathbb{O}| \geq 1$ passes through o^s. If it is detected that no compatible taxi can reach o^s within 5 minutes, then the closest empty taxi to o is assigned. To compute the expected time to reach a particular location, we use the mechanism described in Sec. 4.5.3.

For fast computation of shortest path distances, the road networks are indexed using the *two-hop* index structure[16].

Table 2: Summary of the datasets used

City	# nodes	# edges	# ride-orders
New York	61,298	141,373	14.77 million
Singapore	52,653	86,410	12.57 million
San Francisco	3,527	7,964	0.372 million

(a) Orders w/o ridesharing (b) Passengers per km (c) Waiting Time (d) Orders w/o ridesharing (e) Passengers per km

(f) Waiting Time (g) Orders w/o ridesharing (h) Passengers per km (i) Waiting Time (j) New York

Figure 5: Improvement of SHARE over Shortest Path (SP) against (a-c) α, (d-f) number of taxis and (g-i) time slot of the day (j) training dataset size.

5.1.3 Baselines: As discussed in Sec. 1, existing techniques for taxi ride-sharing primarily look into either route planning or taxi assignment. In both these problems, there is no element of prediction. Thus, a direct comparison is not possible. Therefore, We consider the following baselines.

•**Shortest Path:** Most major app-based taxi services such as Uber and Didi Chuxing move according to the shortest route plan [37, 42]. We therefore compare the performance of SHARE with shortest path.

•**Route Planning [42]:** Our goal in this comparison is to show that route planning algorithms can be improved by assuming the taxi moves along the path recommended by SHARE instead of the shortest path. Towards that end, we compute route based on SHARE and compare the performance with the state-of-the-art *Greedy* approach by Zheng et al. [42].

•**Optimal path:** Since the route recommendation problem is NP-hard, the extended DAG is used to approximate the optimal solution. To understand the approximation quality, we compare the path output by SHARE with the optimal path. We perform this evaluation only on the smaller San Francisco dataset since finding the optimal path has exponential computation cost.

5.1.4 Metrics: We use the following well-established metrics to quantify the performance of SHARE and other baselines.

Percentage of orders without ride-sharing [1]: Whenever a taxi is unable to find a compatible co-passenger for a ride-order, the taxi operator incurs a financial loss. Thus, we measure the percentage of ride-orders without any co-passenger. The lower the value, the better is the performance.

Passengers per kilometer (km) [9]: This metric measures the mean occupancy level per km. More specifically, let D_k be the total distance covered by all taxis with k passengers. Then the average passengers per km is $\frac{\Sigma_{\forall k} k D_k}{\Sigma_k D_k}$. A simple example is illustrated in Fig. 4. An empty taxi starts at S. Then, it picks up passengers at o_1^s and o_2^s after travelling 2km and 5km respectively, and finally, drops them off at o_1^d and o_2^d. In this scenario, the average number of passengers per km is $\frac{0\times2+1\times3+2\times4+1\times1}{2+3+4+1} = 1.2$. Clearly, the higher the value, the better is the performance.

Average waiting time [1]: Average waiting time measures the average number of minutes between an order being placed and a taxi reaching the pick-up location.

Rejection rate [42]: Rejection rate measures the number of ride-orders who remain in the queue of pending orders for more than a certain time threshold. Under a 15 minute time threshold, which is often used [42], we observe a rejection rate of less than 5% for both SHARE as well as the other baseline algorithms. Hence, we do not present results with respect to rejection rate.

5.1.5 Parameters: Share requires two key parameters, the extension threshold ϵ to construct the extended DAG, the number of bins Ω for discretization in the dynamic programming. Unless specifically mentioned, their default values are set to $\epsilon = 0.5km$ and $\Omega = 100$. Nonetheless, we also include experiments where we vary them explicitly and study their impact on the performance of SHARE.

5.2 Route Recommendations

First, we analyze the quality of the recommended routes. The performance of SHARE is compared with the shortest path in terms of the *Improvement (%)* over each metric in Sec. 5.1.4. Intuitively, *Improvement* measures the percentage by which SHARE improves upon shortest path. A higher *Improvement* signifies a better performance of SHARE. Mathematically, let $SHARE_M$ and SP_M be the

values obtained by Share and shortest path respectively in metric M. The *Improvement* in M is

$$Improvement\ (\%) = \frac{SP_M - SHARE_M}{SHARE_M} \times 100^1 \quad (17)$$

Figs. 5(a)-5(c) present the results as the detour parameter α is varied. Across all three metrics, Share improves upon shortest path. The improvement is most stark in the reduction of orders without ride-sharing (Fig. 5(a)); in New York (NY) Share is up to 30% better, while in Singapore (SG) the reduction is as high as 42%. This result highlights that Share is indeed able to learn from the historical data and recommend paths that lead to more ride-sharing. In contrast, in shortest paths, taxis solely depend on their luck since the route selection is done purely based on distance.

In its effort to maximize the number of expected customers, Share may recommend slightly longer routes. It is therefore important to ensure that this extra distance adds value to the taxi operators. The second metric, which compares the distance travelled per customer, evaluates this aspect. Fig. 5(b) reveals that Share leads to more customer density per km.

The third dimension that we measure is the amount time customers spend waiting for the taxis to arrive at their pick-up locations. We expect the waiting time to reduce in Share since we predict the locations where more requests are likely to originate from, and accordingly select routes that provides strategic advantage to taxis. This behavior is prominently visible in Fig. 5(c), where the reduction is as high as 20% in SG.

Two key patterns emerge from the results in Figs. 5(a)-5(c). First, the improvements are consistently higher in SG than in NY. A deeper look into the data reveals that the number of ride-orders is higher in NY and more importantly, highly concentrated in the smaller geographical area of Manhattan. In contrast, the orders are much more spread out in SG. When the density of ride-orders is very high in a particular region, like in Manhattan, any route has almost equal chance of finding compatible passengers. Thus, the improvement of Share in NY over shortest paths is not as prominent as in SG.

The second pattern that emerges from Figs. 5(a)-5(c) is that the improvement in general increases with α. Naturally, with higher α, the search space increases and Share has more scope to improve upon shortest paths.

Next, we benchmark the performance of Share as the number of taxis is explicitly varied. In this experiment, we randomly position C taxis in the city and initiate the simulation on the test set. Next, C is varied on the x-axis and *Improvement* is measured. We set $\alpha = 1.2$ in this experiment. As visible in Figs. 5(d)-5(f), the results follow a similar trend as earlier: Share is consistently better than shortest path and the improvement is higher in SG. As number of taxis increases, the improvement in orders without ridesharing and waiting time increases. When the number of taxis is small, the ratio of orders to taxis is high and hence there is a higher chance that a taxi would find a customer. But when the number of taxis increases, the taxis compete among each other for the same passenger. Hence route recommendation becomes important for a taxi to travel on a route which has a higher probability of picking up passengers. Thus, the improvement of Share over shortest paths increases.

In the next experiment, we analyze the performance at three different time slots of the day: 12AM-1:30AM (least busy), 8AM-9:30AM (office going traffic), and 4PM-5:30PM (home-bound). As expected, Share consistently outperforms shortest path. While the improvement of Share is relatively stable across different time slots of the day, a slight dip is observed in the last time slot of 4PM-5:30PM. This slot has the highest customer density and as we observed earlier, the competitive advantage of Share decreases when the ratio of orders to number of taxis is higher.

Finally, we analyze the performance of Share against the size of the training dataset in Fig. 5(j). As expected, the performance improvement begins to saturate as the training dataset size increases.

5.3 Taxi Assignment and Route Planning

The entire ride-sharing pipeline can be divided into three key stages: assigning taxis to orders, constructing the route plan that decides the sequence of order pick-ups and drop-offs, and finally, selecting the routes between each of the order pick-up and drop-off locations as decided in the route plan. While Share directly targets the third stage of the ride-sharing pipeline, we show that Share also makes the task of the other two stages easier.

In route planning, given the current positions of all taxis, and the pending order requests, the task is to dispatch the order into an optimal route plan of a taxi. The algorithm must ensure all constraints are met such as respecting the taxi capacity and detour ratio. While we allot the closest empty compatible taxi to a pending ride-order, in which only simple taxi assignment and no route planning is involved, more sophisticated algorithms have been proposed [42]. In this experiment, we compare the performance of Share with the state-of-the-art algorithm by Zheng et al. [42], where the assumption is that taxis always move along the shortest path.

Fig. 6(a) presents the results. As can be seen, Share has better performance across all three metrics. Note that the improvement is more prominently visible at lower values of α, which is the detour limit. When the detour limit is low, a taxi does not have much flexibility to re-route and pick up a passenger that is not already close to its current position. With Share, a taxi is more likely to be close to a new order since Share strategically chooses the routes based on prior historical patterns rather than travels through the shortest path. Consequently, the percentage of ride-sharing improves, waiting time decreases and passengers per km goes up, when compared to the shortest path route in conjunction with the route planning algorithm of Zheng et al. [42].

We also note that while the improvement of Share increases with α in Figs. 5(a)-5(c), in Fig. 6(a) the improvement decreases. This follows from the fact that in the route planning experiment, a taxi is allowed to re-route and pick up a pending order that is not directly on its path, but can be serviced without violating the detour limit of α. In the previous experiments, an order is serviced only by taxis that goes directly through the pick-up location. All in all, the results reveal that regardless of the model used, Share leads to substantially improved performance over shortest paths.

[1]For the Passengers per km metric, a higher value is better. Thus, the numerator is changed to $SHARE_M - SP_M$

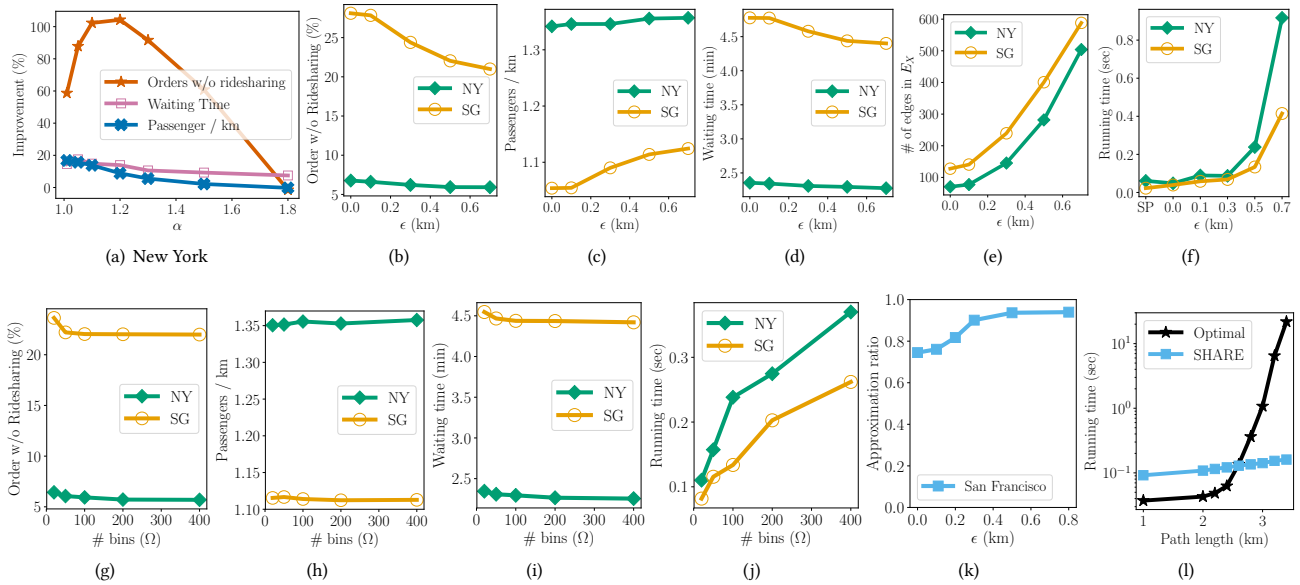


Figure 6: (a) Performance comparison of SHARE with the algorithm proposed by Zheng et al. [42]. Impact of extension threshold on (b-d) quality, (e) size of extended DAG, and (f) running time. Impact of number of bins on (g-i) quality and (j) running time. Comparison of SHARE with the optimal algorithm in term of (k) quality and (l) running time.

5.4 Impact of Input Parameters

Figs. 6(b)-6(d) present the impact of ϵ on the quality of SHARE as measured by the three metrics. We observe an improvement across all three metrics with higher values of ϵ. This is natural since the search space increases with increase in ϵ and this property is evident from Fig. 6(e), where we measure the number of edges in the extended DAG against ϵ. This improvement in quality, however, comes at the cost of higher running time since more paths need to be processed. Specifically, the number of edges increases exponentially with ϵ, which leads to an exponential increase in running time as well (Fig. 6(f)). Given all these factors, $\epsilon = 0.5km$ is suggested as the optimal choice since the quality saturates beyond this point, while the running time increases exponentially. Fig. 6(f) also shows that at $\epsilon = 0.5$, recommendations can be made within ≈ 0.2 seconds. This result substantiates our claim that SHARE is effective and fast enough to handle the load of any metropolitan city.

Next, we analyze the impact of number of bins, Ω, on the quality and running time. Figs. 6(g)-6(i) show that the quality remains stable against Ω. The running time, however, increases with number of bins, and thereby, justifying the choice of $\Omega = 100$.

5.5 Approximation Quality

SHARE approximates the longest path problem by searching only within the extended DAG. To diagnose the approximation quality, we plot the approximation ratio against the extension threshold ϵ. The approximation ratio is quantified as $\frac{w_{SHARE}}{w^*}$, where w^* and w_{SHARE} are the expected number of compatible passengers on the optimal path and the path recommended by SHARE respectively. Since computing w^* is NP-hard, we perform this analysis on the smaller San Francisco dataset. Fig. 6(k) shows that at $\epsilon = 0.5$, the approximation quality is near-optimal with a ratio larger than 0.95.

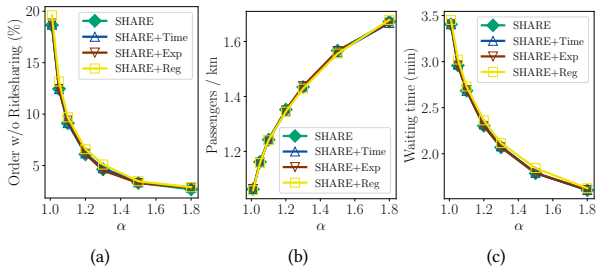

Figure 7: Impact of additional intelligence in New York (Time = Incorporate expected time, Exp = Exponential decay, Reg = Regional expectations).

The utility of the extended DAG is further highlighted by the running time analysis in Fig. 6(l). In this plot, we study the running times of the optimal algorithm and SHARE as a function of the distance between the source and destination nodes. As visible, SHARE is more than two orders of magnitude faster at $\epsilon = 0.5$, while providing near-optimal quality.

5.6 Impact of Additional Intelligence

In Sec. 4.5, we discussed some strategies to further improve the prediction model. Figs. 7(a)-7(c) present the impact of these various strategies. In these figures, SHARE+Time, SHARE+Exp, and

Share+Reg correspond to Sec 4.5.3, Sec. 4.5.1, and Sec. 4.5.2 respectively. In our experiments, we do not observe a noticeable improvement with any of these strategies except Share+Reg marginally improves in the metric of Passengers per km.

6 RELATED WORK

Historical trajectory data has been used for an array of smart-city applications such as anomaly detection[2], infrastructure improvement [20, 26–28] and community detection [34, 35]. In this work, we use historical data to recommend routes to partially occupied taxis such that their chances of finding ride-sharing passengers improve. Existing work on ride-sharing has focused on primarily two aspects: *taxi assignment* and *route planning*.

The taxi assignment approach works to optimize metrics such as profit, detour, etc. by assigning the right taxi with spare capacity to compatible orders [10, 15, 24, 25, 41]. Most recently, Ta et. al. work with a typical solution paradigm for this approach: they solve the assignment problem using an algorithm based on bipartite matching [36]. The focus on assignment makes the ride-sharing problem basically a generalization of the classical *dial-a-ride problem (DARP)* [5]One key difference of DARP with taxi ride-sharing is that in the ride-sharing partially occupied taxis can also be assigned to fulfill orders. The route planning approach assumes that a number of orders and taxis are available and it seeks to dispatch taxis to orders in a sequence computed such that the taxis can fulfill the orders while optimizing the appropriate metrics [37, 42]. This approach is a contemporary version of the classical vehicle routing problem [21] and typically involves solving a variant of the travelling salesman problem. Zheng et. al. apply a greedy method to overcoming this difficulty in [42], whereas Tong et. al. take a dynamic programming approach [37]. In the same line is the work by Cheng et. al. [4], which adds the dimension of rider utility and social connections. Some works take a hybrid approach of choosing an assignment and then repositioning empty taxis after order drop offs [1]. All these works, however, share one feature: An order once picked up is dropped off by following the shortest path between pick-up point and destination. And this is where our approach diverges.

Our method seeks to recommend good routes based on historical data. Historical data has been used to address various other problems related to taxis in the literature [13, 40, 41]. We refer the reader to den Hoedt's Masters thesis for a fuller discussion [7].

Our problem is a variant of the NP-hard longest path problem which cannot be approximated to with a factor of $\exp(\theta(\log^{1-\epsilon} n))$ for any $\epsilon > 0$ and a graph with n nodes [17]. So, we turn to heuristics without good approximation guarantees. Our basic optimization problem most resembles the orienteering problem which is a variant of the longest path that seeks to collect the maximum benefit on a graph using a path of given length [14]. Given the approximability constraints of the problem research on this problem has focused on meta-heuristics that work for small instances [3, 19, 25]. A recent work in this line also uses a dynamic programming approach like we do, but the formulation and approach is very different [25].

In the domain of route recommendations, it has been studied for both the cab service industry [12, 38] as well as itinerary recommendations [18, 22, 23, 30, 39]. These techniques, however, do not apply to our problem due to the recommendation setting being different.

7 CONCLUSION

In this paper, we established that it is indeed possible to learn from historical data and recommend routes for ride-sharing in taxis that significantly enhances the likelihood of finding more customers.The key weakness of the current taxi-sharing paradigm is that discounted fares are offered to promote sharing, which in turn, leads to a risk of revenue loss if sufficient number of orders are not allocated for ride-sharing. Till now, no effort has been made on the routing front to mitigate this risk, a shortcoming that we have endeavoured to address. Our route recommendation algorithm, Share, reduces failure rates in finding ride-sharing partners by as much as 40% when compared to the shortest paths used as default currently. In addition, it improves mean occupancy level and waiting times for customers by up to 20%. These excellent results are obtained by reducing the route recommendation problem to the classical problem of finding the *longest path* in a network. Share overcomes the scalability challenges posed by this NP-hard problem through an approximation algorithm based on *dynamic programming*. Extensive evaluation on real datasets demonstrate that Share provides near-optimal accuracy, while limiting the running time to within 0.2 seconds and thereby making it deployable on any major metropolitan city.

ABSTRACT

Online behavior leaves a digital footprint that can be analyzed to reveal our cognitive and psychological state through time. Recognizing these subtle cues can help identify different aspects of mental health, such as low self-esteem, depression, and anxiety. Google's web search engine, used daily by millions of people, logs every search query made by a user, which is accessible through a platform called Google Takeout. Previous researchers have made efforts to detect and predict behaviors associated with depression and anxiety from web data, but only at a population level. This paper fills in the gap of looking into signs of low self-esteem, a condition that work in a vicious cycle with depression and anxiety, at an individual level by looking into Google search history data. We target college students, a population prone to depression, anxiety, and low self-esteem, and ask to take mental health assessment survey along with their individual search history. Textual analysis show that search logs contain strong signals that can identify individuals with current low self-esteem. For example, participants with low self-esteem have fewer searches pertaining to family, friend, and money attributes; and we also observed differences in the search category distribution, over time, when compared with individuals with moderate to high self-esteem. Using these markers we were able to build a probabilistic classifier that can identify low self-esteem conditions, based on search history, with an average F1 score of 0.86.

1 INTRODUCTION

Mental health can be viewed as a complex interaction between biological, genetic, social, and environmental factors. Due to the multifaceted nature and stigma of mental health, people are likely to rely on online services to investigate their problems in the World Wide Web [24, 50]. Google search is one such platform that is used by millions of people everyday and approximately 3.5 billion searches are made every day with 40,000 queries per second[1]. Hence, online searches may leave digital footprints that can be analyzed to reveal our cognitive and emotional state through time. Detecting these subtle cues can help therapists and others better recognize different components of mental health such as anxiety, stress, depression, and low self-esteem. Due to the complex nature of mental health and various factors associated to it, identifying individuals who are at risk or need help has been a challenge in the mental health research community [4, 8, 45]. For example, among college students, low self-esteem and stress are conditions that are more likely to correlate with suicidal ideation [51].

Our work brings significant new approaches and insights to the table: (i) Self-esteem has been rarely addressed in the AI literature before as part of the discussion of depression, and our approach provides a more expansive parsing of the conceptual frameworks in which constructs such as "depression," "self-esteem," and "suicidal ideation" are embedded [48]. (ii) We provide a scalable, lightweight solution that can be deployed at the point-of-care to use immediately available search history data to provide instantly actionable therapeutic targets for clinicians. (iii) Our work opens a way for clinicians to obtain access to patients' internal mental health states and traits, with high fidelity and accuracy far beyond the limits of traditional self-reported data: we are, in fact, now incorporating the approach into planned clinical trials.

Researchers have been using social media data to identify and predict different mental health conditions and associated factors [1, 6, 15, 15, 40]. Twitter, Facebook, Reddit, Instagram, and Weibo are some of the common data sources exploited by researchers to explore signs of depression, anxiety, suicidal ideation, and other related conditions.

With only a few exceptions [11, 12], these prior studies have not had access to ground-truth data about the subjects' mental health as assessed by a validated clinical instrument. While they make

[1] http://www.internetlivestats.com/google-search-statistics/

claims about depression at a population or individual level, they cannot justify those claims in a manner that would be actionable by a healthcare professional.

Another limitation of most prior work is that data is only gathered from users of particular social media sites. Because users self-select for particular sites, there may well be confounding factors that influence both the users' mental health and their online behavior. For example, people who routinely broadcast their thoughts on Twitter may have different ways of talking about depression than more private individuals. A further confounding factor is that users may choose to self-censor when posting to social media [22].

In this paper we investigate observable textual signatures related to current low self-esteem condition using both Google search histories and answers to a validated mental health assessment survey. For search, as opposed to use of social media, users do not self-select or face the same temptations to self-censor. Another advantage of search data is that the nature and volume of search queries give temporal behavioral information about a user. While some prior researchers have analyzed search logs for large aggregate populations using Google Trends [2, 55], applying their results to individuals may result in ecological errors. In addition, Google Trends data cannot be used to understand or predict *individual* behavior.

In summary, our dataset and analyses are unique in that they (i) include gold-standard individual psychological assessment data; (ii) use data from a form of online behavior (search) that engages all internet users — that is, 89% of the US adult population [46]; and (iii) employ a data-collection methodology (described below) that is scalable to hundreds or thousands of subjects while preserving users' privacy. Psycholinguistics analysis identified variables capable of differentiating people with low self-esteem. When compared with someone with moderate to high self-esteem, we observed noticeable differences in the type of searches made by individuals with low self-esteem condition. We demonstrated that these identifiers can be used to build statistical models that do better than chance for classifying users with low self-esteem condition using historical search data.

2 RELATED WORK

Researchers have used data from social media, public forums, blogs, and search engine logs to explore interaction of various aspects of mental health, including depression, anxiety, suicidal ideation, mood, and stress. De Choudhury provides an excellent overview of the role of social media in mental health research [11]. Her own previous work showed that lexicons in Tweets contain strong signals for predicting risk of major depressive disorder [14], and she recently identified linguistic markers to identify Twitter users likely to develop future suicidal ideation [15]. In 2018, Liu et al. examined statuses of Weibo users and demonstrated that users exposed to domestic violence showed increase in depressive symptoms, higher suicide risk, and decrease life satisfaction when compared against control group [30]. Other researchers have shown that Tweets contains meaningful clues for various mental health concerns including Adderall use [23], insomnia [26], and depression [10–14, 16].

Perhaps the dataset closest to ours which has been explored by researchers in the past is search logs from Google Trends [19]. Researchers have utilized Google Trends data to demonstrate deeper insight about population behavior and health related phenomena to build predictive models around mental and physical health assessment. For example, surveillance of influenza outbreaks [9, 18]; monitoring toxicological outbreaks [54]; identifying seasonality in seeking mental health [2]; monitoring suicide related terms to help predict rates of self-injury and death within the population [31]; and effects of geographic location on depression related searches [52] are some of the areas that researchers have explored. Nuti et al. provides a through review of the usage of Google Trends in the health care domain [33]. Sueki et al. investigated variations in the volume of Google searches about suicide and depression in Japan and found that the monthly search volumes for "suicide" and "suicide method" were not significantly correlated with the monthly suicide rate, but searches for "depression" were [49]. Yang et al. replicated this associations between the volume of Google search terms and the monthly suicide rate in Taipei City [53]. Gunn and Lester found that suicide rate for Americans was positively correlated with the search volume for search terms such as "commit suicide", "how to commit suicide", and "suicide prevention" [20]. They showed that monitoring internet searches for suicide related terms may provide a faster way to capture, in the moment, possible trends in mental health conditions such as depression, anxiety, and suicide. Song et al. showed that suicide and stress related searches are positively associated with suicide rates in Korea [47]. Hagihara et al. demonstrated that Google search volume for terms associated with hydrogen sulfide in Japan was correlated with the monthly suicide rate for people in their 20's and 30's [21]. Ayers et al. showed that there was a significant increase in suicide related terms in Google for the 19 days following the release of a popular Netflix show *13 Reasons Why*, which narrates the suicide of a fictional teen [3]. However, Page et al. found that internet search trends related to suicide terms are not necessarily straightforward indicators of the degree of suicide behavior in Australia [36]. It is debatable whether any query preceded an actual suicide attempt; but it is quite evident that search logs monitoring can be used to access understanding of different mental health conditions and capture any potential signals of low self-esteem, depression, anxiety, self harm risk, etc.

All of the work above was performed on search logs aggregated over a large population. By contrast, our work is the first to investigate search history data at an *individual level* for signs of low self-esteem.

3 DATA

Data for this study were collected through a 2-month on-campus recruitment to investigate how online services such as Google search can be used to detect early symptoms of suicidal ideation, depression, anxiety, low self-esteem, and lack of social supports. As described below, we developed a Human Subjects Review Board approved cloud-based application to acquire consent from subjects, download and anonymize their search histories, and link anonymized histories to corresponding mental health survey answers.

3.1 Participants

In total 108 individuals, 40 male and 68 female, volunteered to participate. Subjects were recruited through advertisements. To limit

any participation bias, the information on the advertisement was generic and had no mention of mental health related phenomena because some participants with certain personality traits can avoid recruitment.

A step in the data collection involves subjects completing an online written questionnaire about mental health, anxiety, suicidal ideation, and self-esteem. We call this the *Promote Health* survey. In addition to academic and demographic information, the survey incorporates questions from several standard instruments such as the depression module of the Patient Health Questionnaire (PHQ-9) [29] and the Rosenberg self-esteem scale [41, 43]. PHQ-9 is a common psychological instruments that has been used by previous researchers for depression related screening while mining social media data [27, 56]. Rosenberg self-esteem scale has been used to study usage of social media and its' association with low self-esteem among undergraduate students [39].

3.2 Recruitment Procedure

Interested participants were required to be at least 18 years old, able to read and write in English, and have an active Google services account. Qualified subjects were informed about the purpose, procedure, and goal of the study; then they reviewed and signed a statement of informed consent explaining the Human Subjects Committee approval. The study had 100% participation rate, meaning none of the 108 individuals decided to opt out of the study after the study was explained to them.

There are two parts to the data collection process. First, study recruiter asks participants to type their Google login credentials into a web-based app running on a tablet. Second, study participants were asked to take the *Promote Health* survey, a brief self assessment online questionnaire. There are 38 freshmen, 18 sophomore, 17 juniors, and 19 seniors in our dataset. In addition, there were 12 graduate students and 4 fifth year undergraduates. Participants' mean GPA was 3.51. Note that we did not make use of these additional data in the analyses presented in this paper, but that it may help explain the surprising level of low-self esteem described below.

3.3 Google Search History

Anyone with a Google account can freely access his or her entire personal data, at any time, through a platform called Google Takeout[2]. Using Google Oauth authentication protocol, participants authorize our search download application to access users Google related data. Although data about many forms of Google services can be accessed through this portal, this study uses only data from Google search. None of the other potential sources of data are accessed or stored at any time. Individuals who did not have Google search history tracking enabled were excluded from our analysis.

Once a user authorizes the application to obtain a copy of the search history, a one-time log in authorization is used to automatically transfer the search data from user's google drive to a secured server in the cloud. The oauth token that our application uses to access a user's data is valid only for 24 hours.

Before any data is transferred from "the cloud" and given to the research team to store as part of this study, the data is de-identified via Google's Cloud Data Loss Prevention (DLP) API. The API scans for personal identifiers such as names, addresses, phone numbers, etc., that can potentially identify individual study participants, and this information is automatically removed from the search history data prior to being saved as research data.

Once the search history data is successfully de-identified and transferred to the research team, the one-time log in authorization is permanently deleted. The research team is no longer able to use this authorization to access any participant's online data again. Fig. 1 presents the entire data collection process.

3.4 Promote Health

Promote Health is a computer assisted survey instrument (CASI), designed at a fifth grade reading level and includes questions about age, academic concentration, gpa, race, gender, mental health (PHQ-9), Interpersonal violence (IPV), sexual health, self-esteem, etc. Users did not write their names on the survey at anytime, but instead entered a random ID number that was used to link their responses to their search history data. No records connecting subject names to ID numbers was maintained.

3.5 Data Description

A section in the survey asks series of questions for evaluating individual self-esteem. The answer to the self-esteem questions were used to compute the Rosenberg Self-Esteem Scale(RSES). 53 individuals had RSES score less than 12 (on a scale of 0-30, people with average to high self-esteem have score ≥ 15), indicating low self-esteem(LS). On the contrary, 55 individuals had score greater than or equal to 12 indicating no sign of low self-esteem(NLS). However, there were 13 individuals who participated but did not have any search data and were excluded from any analysis.

Before any analysis and modeling, we separate the dataset into two parts, namely **analysis set** and **test set**. This is illustrated in Table 1. For the self-esteem analysis, 27 participants had LS and 28 had NLS condition. The test set had 19 subjects with NLS and 21 with LS condition.

Through the *Promote Health*, we measured the current RSES score. Low self-esteem is one of the vulnerable factors that works in a vicious cycle with depression, anxiety, and suicide ideation [5]. However, low self-esteem state and any specific mental health condition may not necessarily occur at the same time but can have indirect effect on the quality of life.

In our survey responses, we observed that low self-esteem condition stood out strongly than depression in the responses. The average gpa of the participants is 3.51, which is quite high. A potential explanation can be "imposter syndrome" – where high performing students do not feel they are as smart as their colleagues. Young college undergraduates are more prone to self-criticism, social anxiety, achievement pressures, and depressive tendencies [28].

4 OBSERVATION ON GOOGLE SEARCH LOGS

Google search phrases tend to be short, recorded in the present and are good indicators of what may be going through an individual's mind at the moment. The context of a search phrase can be anything. We are interested in identifying the categories of the searches and uncover any linguistic signals in the search phrases that can help distinguish subjects with LS and NLS conditions. In the following sections, all the search logs analysis is carried out on the **analysis set**, see Fig 1.

4.1 Variance of Search Categories

Using the content classification feature of the Google Cloud NLP API[3] we were able to classify the search queries of every participating subjects. The API returns a hierarchical category label for every search query. We treat the broad category as the 'category' label for the query. For instance, for a query q, if the label from the API is '/Arts & Entertainment/Humor/Funny Pictures & Videos', we consider 'Arts & Entertainment' as the category for q.

In total, there are 27 such categories. We observed that, at any time of the day, individuals with LS condition consistently searched more on topics related to 'Sports', 'Health', 'Finance', 'News', 'Books & Literature', 'Reference', and 'Law & Government'. This is illustrated in Fig. 2. The 'Reference' category constitutes mostly of topics associated to humanities, language resources, geographic references, and general references such as concepts from Encyclopedias, Wikipedias, etc. One explanation for such high prevalence

[3]https://cloud.google.com/natural-language/docs/classifying-textt

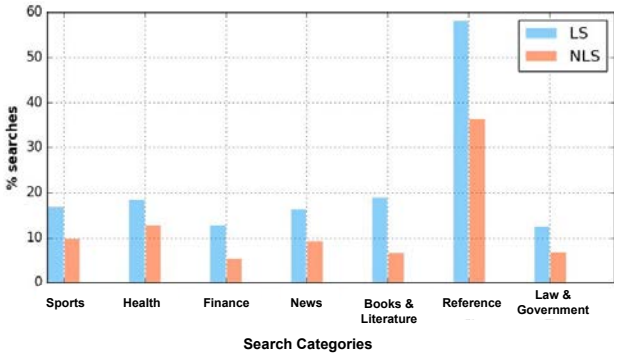

Figure 2: Search categories that were more frequent in LS population

of searches from this category can be that students with low self-esteem condition are more reliant on search engines to do their daily school works compared to the population that does not exhibit low self-esteem.

We also observed that individuals with current LS, on average, search more about certain topics than students with NLS condition during late hours (1AM - 5AM). For instance, students with LS condition made more searches pertaining to categories such as 'Reference', 'Jobs & Education', 'Books & Literature', and 'Health' than students with NLS condition. This increased late night activity disrupts normal sleep cycle which is reported to be one of the core symptoms of depression and can eventually lead to poor quality of mental health and life in general [34].

Context(i.e.category of a search) and frequency of searches on Google vary from person to person. Over the entire search history, we noticed observable differences in distribution of search categories between the LS and NLS population. For example, searches pertaining to the '/Arts & Entertainment' category were more frequent for both the groups. However, there are categories such as 'Health', 'Food & Drink', 'Sensitive Subjects', 'References', etc. for which the distribution demonstrate apparent differences.

4.2 Psycho linguistic attribute detection in search logs

At first, it may not be self-evident that query logs can be good indicators of what may be going through an individual's mind at the moment. Traditionally, researchers have done psycho linguistic analysis on social media data to uncover signals of mental health related phenomena. In 2017, Oexle et al. have shown that there is a strong stigma associated to expressing oneself related to mental illness and other related issues [35]. As a defensive mechanism, users may stop generating content on social media platforms [25]. However, when someone searches, there is no fear of any judgment; and what he/she is searching can potentially reveal his/her psychological state at that moment.

LIWC is a text analysis toolkit that outputs the proportion of words in a given text that fall into one or more of over 80 linguistic (such as prepositions, adverbs, first-person singular pronouns, conjunctions), psychological (happy, anger, achievement, etc.), and topical (leisure, money, etc.) categories [37]. Researchers have been

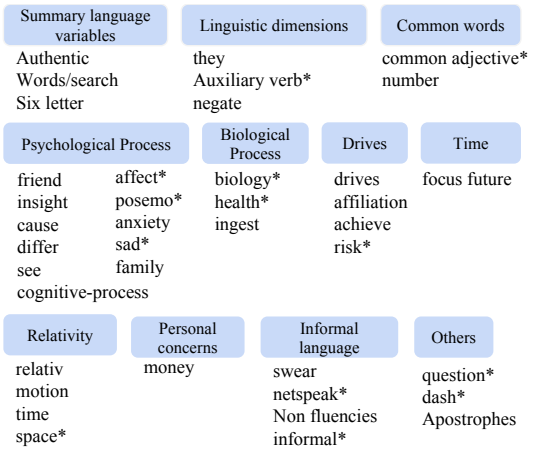

Figure 3: LIWC attributes that were statistically significantly different between the subjects with LS and NLS condition. Concepts with * were more prevalent among subjects with LS condition.

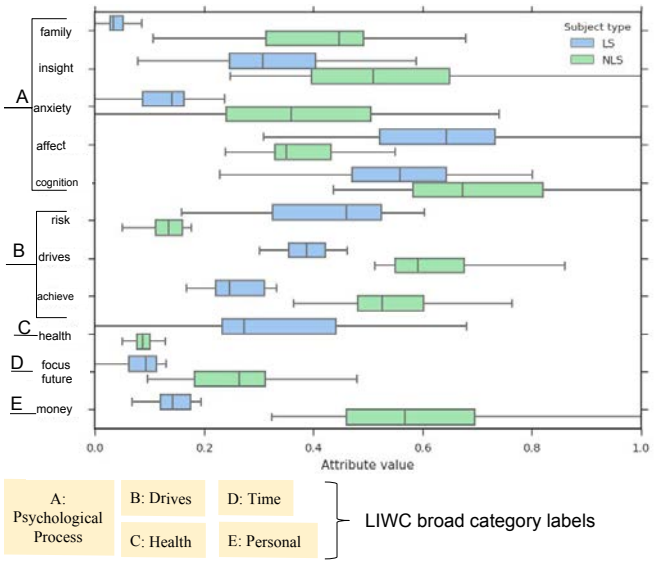

Figure 4: Distribution of some LIWC attributes score between participants with LS and NLS condition. These are some of the attributes from Fig. 3

using this tool to study the distribution of analytical thinking, authenticity, emotional tone, social and cognitive process present in a piece of text. Clinicians and social computer scientists do psychometric analysis using LIWC lexicons. Some popular text data analyzed using this lexicon includes social media, online forums, written notes, and self-introductions [42]. We are the first to demonstrate the presence of these linguistic attributes in individual level search data.

For the low self-esteem analysis, our data consists of 27 subjects with LS and 28 subjects with NLS condition from the **analysis set**(see Fig 1). For every subject with LS condition, all the Google search phrases are analyzed using LIWC and the output is a 92 dimension vector. The result can be treated as a table with 27 rows and 92 columns. A similar procedure is repeated for every participants with NLS condition, resulting in a table with 28 rows and 92 columns.

Next, we explore whether there are any statistically significant LIWC categories between the two populations (LS vs NLS). Our sample size is small, assuming normal distribution, we consider the LIWC variables from the LS and NLS groups and do student's t-tests. We found 40 LIWC attributes that were statistically significantly different(with p-value < 0.05) between participants with LS and NLS, as shown in Fig. 3.

In the low self-esteem analysis, the family variable was significantly lower for almost every participant with LS condition than participants with NLS condition. This supports previously established findings where researchers have shown that family support influences self-esteem, which impacts adolescent suicide risk behaviors [32, 44]. Fig. 4 presents a visual representation of the distribution of some of the LIWC attributes (from Fig 3) that are statistically significantly different between LS and NLS.

Search phrases are short and lack syntactic structure compared to other forms of data that are popularly analyzed using LIWC. Yet, we found strong signals in LIWC categories that can differentiate and identify individuals with low self-esteem. Our analysis of search data strengthens prior findings regarding the association of self esteem with other mental health phenomena [32] .

This indicates that there are some shared lexicons, even in Google search phrases, among individuals with LS condition. For instance Affect, Insight, Cogproc, Space, and Affiliation are some of the linguistic variables that are significantly to differentiate a population between LS and NLS.

5 MODELING LOW SELF-ESTEEM (LS) CONDITION

For the classification task, we ask the question: *Based on the search history, can we identify subjects with low self-esteem?*

We use the **analysis set** from Fig. 1 for selecting features and training our classifiers. Our training set consists of 27 individuals with LS and 28 with NLS condition.

The performance of the trained model is evaluated using a test set. We separated this set from the data prior to the feature selection and the training process. The held out test set consists of 19 subjects with NLS and 21 with LS.

5.1 Feature Selection from Analysis Set

Based on our observation from section 4.1 & 4.2, we consider two types of features for the classification task.

5.1.1 Features based on LIWC:. There were 40 linguistic attributes that were statistically significantly different between the LS and NLS population (see Fig. 3). We treat these LIWC attributes as features for training our models.

5.1.2 Features based on search category distribution: Searching behavior varies from person to person. Knowing the categories of

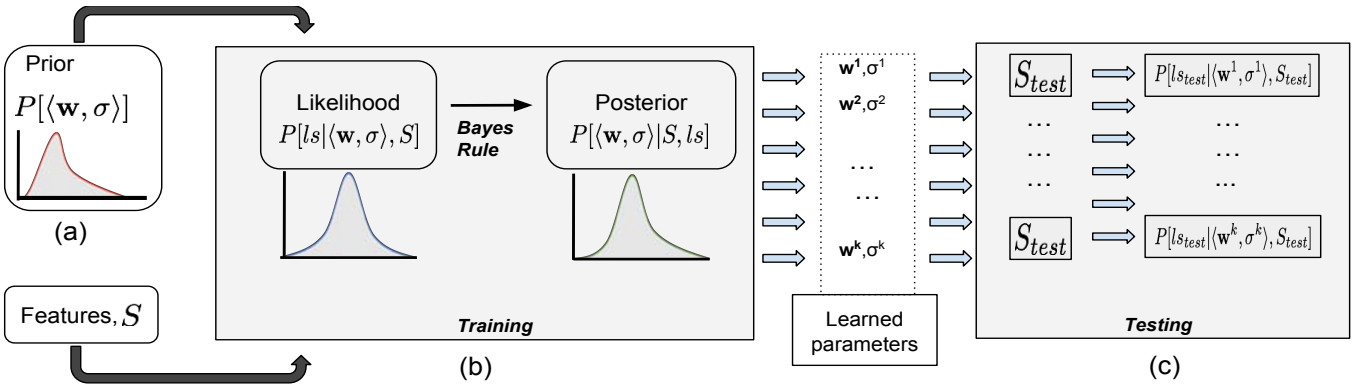

Figure 5: Process depicting learning and testing procedure of the HyBaR model. (a) Prior distribution of the parameters w and σ. Prior of σ is uniform distribution. In case of LIWC based features the prior of w is Laplace distribution defined in (4) and is Gaussian distribution with category similarity matrix as the covariance matrix for the search category based features. (b) Posterior is obtained from the corresponding prior and the likelihood using Bayes Rule. Using Metropolis-Hastings Algorithm several model parameters are sampled from the approximate posterior. (c) S_{test} represents the test data which has been held out prior to any analysis and training. Each of the learned parameters are used individually to classify S_{test}. This helps in model generalization.

searches can reveal insightful patterns in internet activities. Different individuals exhibit different searching behavior. For example, following Fig 3, we found that students with LS condition consistently searched more about certain topics than students with NLS condition. This motivated us to treat the search category distribution, over one's entire search history, as features for our models. Using the Google Cloud NLP API, we labelled search queries into 27 categories. We treat the distribution of these 27 search categories as features and train our classifiers.

5.2 Models

We propose a discriminative model whose parameters are learned using Bayesian approach. We call our model Hybrid Bayesian Regression (HyBaR) because it is a cross-breed between the Bayesian Linear Regression and the Bayesian Logistic Regression [7]. For details about the model, see section 5.2.1.

In addition, we trained a **Logistic Regression(LR)**, a **Support Vector Machine(SVM)** and compare their performance with HyBaR.

5.2.1 ***Hybrid Bayesian Regression (HyBaR):.*** HyBaR has advantage over Maximum Likelihood Estimation (MLE) due to the additional prior information. Compared to the maximum a posteriori (MAP) estimation, which outputs a parameter that maximizes the posterior probability for the given data, HyBaR estimates the entire posterior distribution which can avoid over-fitting and lead to a more generalized model.

Unlike LR and SVM, HyBaR incorporates domain knowledge in the form of prior. For the LIWC based features, we have used a sparse prior, and for the category distribution based features we employed the semantic distance between the categories as prior.

The Model: For $i \in [1, \ldots, n]$ we denote $\boldsymbol{s}^i = (s^i_1, \ldots, s^i_m)$ to be the vector that represents the features extracted from the search history of the person p_i, where n is the number of people and m is the number of search categories. For instance, when we consider the search category based features, s^i_j represents the percentage of searches of category j for i^{th} person. Also, let $ls_i \in \{0, 1\}$ be a binary variable denoting whether a person p_i exhibits low self-esteem or not. In particular, $ls_i = 1$ when the person p_i exhibits low self-esteem and 0 otherwise. Now we propose HyBaR, a probabilistic discriminative model with parameters $\boldsymbol{w}(\in \mathbb{R}^m)$ and $\sigma(\in \mathbb{R})$. For each $i \in [1, \ldots, n]$ we assume

$$ls_i \sim \text{Bern}\left(f(\mathbf{w}^T \mathbf{s}^i + \epsilon)\right) \tag{1}$$

where $\epsilon \sim \mathcal{N}(0, \sigma^2)$ is a latent variable and f is a function whose range is $[0, 1]$ (i.e.which outputs a valid probability). One choice for f can be **Sigmoid**. Also, Bern(p) denotes the bernouli distribution, i.e., $X \sim \text{Bern}(p)$ iff,

$$X = \begin{cases} 1 & \textit{with probability } p \\ 0 & \textit{with probability } (1-p) \end{cases}$$

Next, we describe the prior distribution of the parameters.

Remark: Let $\mathbf{x}$ be the data and y be its label. In case of linear regression, class label, $y(\in \mathbb{R})$ is modeled as,

$$y \sim \mathbf{w}^T \mathbf{x} + \epsilon \tag{2}$$

where $\epsilon \sim \mathcal{N}(0, \sigma^2)$ and $\mathbf{w}$ is the model parameter. However, for logistic regression, class label $y \in \{0, 1\}$ and is modeled as,

$$y \sim \text{Bern}\left(Sigmoid(\mathbf{w}^T \mathbf{x})\right) \tag{3}$$

Hence from (2) and (3) it follows that our model (1) is a simple hybrid of the two models.

Prior Selection: Domain knowledge is incorporated in the model through our priors. Hence, an important component during the model construction is prior selection. The prior of σ is chosen to be uniform in both types of features. However, we set the prior of $\boldsymbol{w}$ depending on the features we are selecting.

For the LIWC based features, the prior is set to be the Laplace distribution, i.e.,

$$P(w_i|\mu, b) = \frac{1}{2b} \exp\left(-\frac{|w_i - \mu|}{b}\right) \tag{4}$$

where μ and b are hyper-parameters. It is to note that Laplace prior is equivalent to sparsity constraint. In the context of LIWC based features, for any individual, these linguistic categories do not co-occur in the search history frequently. This motivated us to select a sparse prior.

For the search category distribution based features, we first construct a similarity matrix that represents the semantic distance between the search categories using GloVe [38]. We set the prior of $\boldsymbol{w}$ to be multivariate Gaussian with mean 0 and the category-similarity matrix as the covariance matrix, i.e.,

$$\boldsymbol{w} \sim \mathcal{N}(\vec{0}, \boldsymbol{Cov}) \tag{5}$$

where $\boldsymbol{Cov}_{ij}$ is the semantic similarity between category i and category j. We set this prior to enforce the similarities between the search categories.

Posterior Inference: Let $S = \left\{\boldsymbol{s}^i | i \in \{1, \ldots, n\}\right\}$ be the set of features for all the participants and $L = \left\{ls^i | i \in \{1, \ldots, n\}\right\}$ be the corresponding self esteem label for them. Now, we formalize the posterior for our model as follows:

$$\begin{aligned} P[\boldsymbol{w}, \sigma^2, \epsilon | L, S] &\propto P[L|\boldsymbol{w}, \sigma^2, \epsilon, S] \cdot P[\boldsymbol{w}, \sigma^2, \epsilon | S] \\ &= \underbrace{P[L|\boldsymbol{w}, \sigma^2, \epsilon, S] \cdot P[\epsilon|\sigma^2]}_{\text{Likelihood}} \cdot \underbrace{P[\boldsymbol{w}] \cdot P[\sigma^2]}_{\text{Prior}} \qquad (6) \\ &= \left(\prod_{i=1}^{n} P[ls_i|\boldsymbol{w}, \sigma^2, \epsilon, \boldsymbol{s}^i]\right) \cdot \left(P[\epsilon|\sigma^2] \cdot P[\boldsymbol{w}] \cdot P[\sigma^2]\right) \qquad (7) \end{aligned}$$

Here (6) follows from conditional independence of S & $\boldsymbol{w}$ and (7) follows from the i.i.d. properties of the data. From (1) we can see that,

$$P[ls_i|\boldsymbol{w}, \sigma^2, \boldsymbol{s}^i] = prob_i^{ls_i} \cdot (1 - prob_i)^{(1-ls_i)}, \tag{8}$$

where, $prob_i = Sigmoid(\mathbf{w}^T \mathbf{s}^i + \epsilon)$. Now, for LIWC based features $P[\boldsymbol{w}]$ in (7) is given by the distribution as in (4) and for the search category based features $P[\boldsymbol{w}]$ in (7) is the distribution as in (5).

In summary, we get the posterior of the parameters from the corresponding prior distribution and the training data likelihood by using Bayes Rule. Then our goal is to estimate the entire posterior distribution and sample model parameters from the posterior distribution. The complete process is depicted in Fig. 5 (b). However, it important to note that exact inference of the posterior given in (7) is intractable. Hence, we use Metropolis-Hastings Algorithm to get approximate sample from the posterior distribution.

Parameter Estimation: Our next step is to choose a parameter for the classification task. We sample several parameters from the posterior distribution as shown in Fig. 5. Let $\{\langle \boldsymbol{w}^1, \sigma^1 \rangle, \cdots, \langle \boldsymbol{w}^k, \sigma^k \rangle\}$ be the sampled parameters. Using each of these learned parameters, we classify the test data as follows,

$$ls^i_{test} \sim \text{Bern}\left(Sigmoid(\mathbf{w}^{\mathbf{i}^T} \mathbf{s}_{test} + \epsilon)\right),$$

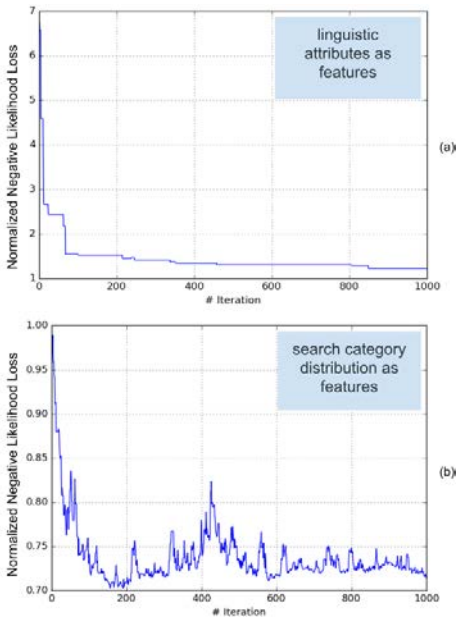

Figure 6: An instance of the convergence of negative log likelihood during training for HyBaR when trained using the two types of features separately.

where $\epsilon \sim \mathcal{N}(0, \sigma^{i^2})$. Hence we get k labels ($\{ls^1_{test}, \cdots, ls^k_{test}\}$) for each of the data point $\mathbf{s}_{test}$. We record the performance of the model for each $\langle \mathbf{w}^i, \sigma^i \rangle$ and report the average performance of the model on test set in Fig 8 (b) & (d).

Generalization Ability: Following the PAC-Bayesian framework in [17] we can set the normalized negative log likelihood as the loss function for the posterior inference problem. Fig 6 presents an instance of the convergence of negative log likelihood loss during training. Next, we ask the question, how well this model generalizes on a completely new data set? We test the generalization ability of HyBaR by running simulation on large synthetic data. Fig 7 shows the convergence of the expected empirical loss towards the expected true loss. A potential explanation for such behavior can be due to the Bayesian approach used in designing HyBaR.

Driving Search Categories: After training HyBaR on the 27 search categories (from 5.1.2), the top ten categories (ranked according to learned weights) that drive the classification tasks are: Internet & Telecom (2.17), Law & Government (1.91), People & Society (1.85), News (1.73), Real Estate (1.69), Jobs & Education (1.55), Online Communities (1.45), Finance (1.16),Science (1.15), and Health (1.00). High prevalence of these categories in a college student's search history may help identify conditions such as a low self-esteem. For example, searchers pertaining to People & Society categories: how to 'fit in' with communities in college settings, looking for ways to make friends etc. are practical situations that teenagers encounter when they move to college.

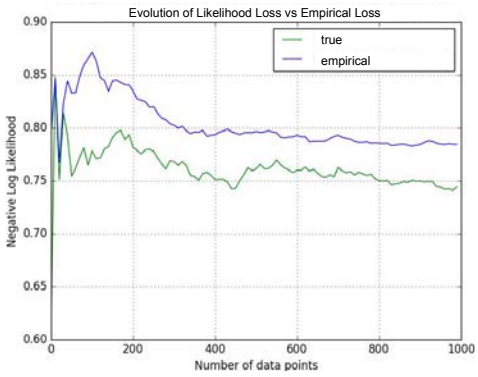

Figure 7: Convergence of the expected empirical loss towards expected true loss on the synthetic data.

6 RESULTS

The performance of our trained models is evaluated using the held out test set which consists of 19 individuals with NLS and 21 with LS condition. Fig. 8 presents the performance of our models. To evaluate the accuracy of the classification, we use F1 score to capture the balance between precision and recall and compare our models.

HyBaR samples multiple parameters from the posterior. We use each of these learned parameters individually to classify our test data and report the average/best performance on the test data (in terms of F1 score).

When LIWC's linguistic attributes are considered as features, on average, HyBaR performed better than both the SVM and the baseline model i.e., LR in classifying participants with low self-esteem. This is evident from Fig. 8 (a) & (b), where HyBaR has an average F1 score of 0.72 compared to SVM's 0.61 and LR's 0.46. We also report the best performance of HyBaR in Fig. 8(b) (numbers with * as superscript) and found that the best model has F1 score of 0.77.

When search category distributions were used as features, HyBaR performed significantly better than SVM and LR, compare Fig. 8 (c) & (d). On average, HyBaR has F1 score of 0.86 compared to SVM's 0.62 and LR's 0.47. Using the category distribution, HyBaR had the best performance with F1 score of 0.89.

Since our test set is small, we compared the performance of the models on the test set by analyzing the confusion matrix. Through Fig. 9, we compare the performance of our models (on the test set) when they are trained using the LIWC based features. The green and the yellow cell in the table represent number of misclassification and HyBaR made the fewest misclassifications compared to LR, our baseline, and SVM. We repeated our analysis on various test set with different ratios of the two categories and obtained similar results.

On average, HyBaR performed significantly better than LR and SVM when we trained it using features based on the search category distribution. The performance of HyBaR on the test set can be evaluated through the confusion matrix presented in Fig. 10. Out of 21 participants with LS condition, HyBaR only misclassified 2 subject (see yellow cell in Fig. 10) and misclassified 4 out of the 19 individuals with NLS condition.

7 DISCUSSION AND FUTURE WORK

Individual level Google search history data can be treated as a rich longitudinal data source that can capture quotidian online activities of individuals. This data has recently become readily accessible through the Google Takeout interface. We built a scalable human-subject review board-approved system for consenting, collecting, and anonymizing subjects' search history data, and created the first data set that links search history data to that from a clinically-used mental health survey instrument.

We showed that search history data provides identifiable signals for detecting low self-esteem. In addition to considering search category distribution, we were able to identify linguistic variables whose frequency of use was significantly different among subjects suffering from low self-esteem and those not exhibiting low self-esteem condition. Using these features, we have managed to build mental-health related predictors, for instance consider our low self-esteem model, that is superior to predicting by random chance. This motivates us to consider that search history data can be used to build models for capturing various mental health phenomena such as self-harm, suicide ideation, etc.

It will be interesting to explore whether both psycho linguistic attributes and search categories can be used simultaneously to build models. Due to small sample size, we could not use both sets of features at the same time. However, this limitation can be easily overcome as we collect more data through our future studies.

The mental health survey we employed red-flagged low self-esteem as the biggest mental health issue for the subject population of college students. Our next study will recruit a more general population and compare the findings. Recruitment sites will include mental-health inpatient and outpatient clinics, emergency rooms, and family court. Individuals from these sites are more likely to have relatively high incidence and prevalence of conditions such as major depression, anxiety, and stress, along with low self-esteem.

We will also consider features beyond linguistic and search categories. Other factors one can consider are time at which these searches are made, seasonality of certain types of searches. The time of a search is likely to be of particular value because searching in the middle of the night can be used as a proxy for sleeplessness, a symptom of many mental health problems. We will test the hypothesis that an increase in a user's volume of searches is a proxy for an increased use of technology due to withdrawal from social interactions.

The fact that search logs are time and date tagged means that they can be used for longitudinal studies on disease progression, as well as part of longitudinal treatment plans for individuals. We are currently beginning a study where subjects who are undergoing outpatient treatment for attempted suicide may consent to allow their history of PHQ-9 survey answers to be analyzed in conjunction with their search histories. The goal of the study will be to model the dynamics of health and online behavior in order to provide new tools for therapists to assess the efficacy of treatment strategies.

Finally, the accessibility of individual level search log data opens the door to studying signals for other mental health phenomena, such as anxiety and panic disorders, bipolar disorder, eating disorders, suicide ideation, and substance abuse and addiction. A feasible use case of our system can be in the university counselling services

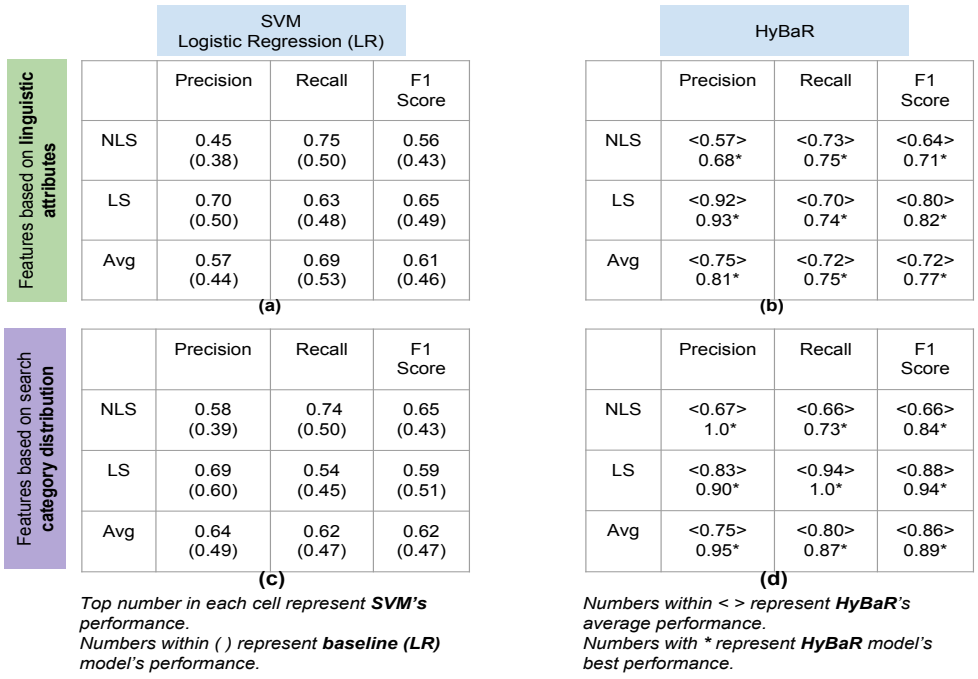

Figure 8: Classifiers performance on the Test Set. LR, SVM, and HyBaR are trained for the classification task. (a) & (b): Tables present the performance on the test set when LIWC based features are used. (c) & (d): Tables present the performance on the test set when search category based features are used. In case of HyBaR, the model learns multiple parameters (see From Fig 5), the test set is evaluated using each of the parameters. Numbers in ⟨⟩ represents the average performance over the learned parameters. Numbers with * represent the score of the best performing HyBaR parameter on the test set.

to access the morale of the student population which can eventually lead to better understanding of student life.

We are working with other researchers and clinicians at our university's medical center to include this work as a core component of a suicide prevention center that is currently being developed. For example, this is now a central feature of the proposed ALACRITY Research Center focused on suicide prevention among patients with Serious Mental Illness at our institution's medical center[4]. It will form a core data component for use in all NIH-funded sub-projects within the Center. This offers to expand the overall social impact by influencing clinical care in the future for those individuals who are among the absolute highest risk for suicide mortality.

ABSTRACT

We study the computation contests where players compete for searching a solution to a given problem with a winner-take-all reward. The search processes are independent across the players and the search speeds of players are proportional to their computational powers. One concrete application of this abstract model is the mining process of proof-of-work type blockchain systems, such as Bitcoin. Although one's winning probability is believed to be proportional to his computational power in previous studies on Bitcoin, we show that it is not the case in the strict sense.

Because of the gaps between the winning probabilities and the proportions of computational powers, the Matthew effect will emerge in the system, where the rich get richer and the poor get poorer. In addition, we show that allowing the players to pool with each other or reducing the number of solutions to the problem may aggravate the Matthew effect and vice versa.

1 INTRODUCTION

In a computation contest, a group of players compete with each other on solving a given computational problem and only the player who first finds a solution to this problem will receive a fixed reward. To solve the problem, the most efficient way is to execute a random brute force search across the candidate set, so the computational power is a critical resource for each player to increase the probability of winning this contest. Practical examples abound, ranging from tuning the parameters for a deep neural network, selecting random seeds for reinforcement learning to recovering the spatial structure of proteins and discovering new drugs for cancers [4, 9, 13, 16, 17].

The mining process of *Bitcoin* [14] is a concrete example that perfectly matches the computation contest in terms of mathematics. The Bitcoin system is maintained as a chain of blocks and it awards the builder of each block by a certain amount of BTC, which is about 12.5 BTC (≈ 79,400 USD) at the time this paper is written. To build (or mine) a block, one must find a block header (a fixed-length bit string) whose hash value meets a certain criteria and announce it before other competitors. Because it is hard to invert the secure hash function, the most efficient way is to enumerate (in an arbitrary order) and verify the candidate block headers. This is exactly the case as we described in the computation contest and the mining process is now an extremely fierce competition — the total computational power of the community is roughly 48E (4.8×10^{19}) hash per second.[1]

To participate such a vast contest, understanding the winning probability or the expected reward is undoubtedly important to the players. So far, the winning probability of each player is believed to be proportional to his computational power (or his speed of verifying one candidate) [7]. Their argument is briefly as follows: For each player, the wins follow a Poisson process with a strength proportional to his computational power and hence the expected reward is also proportional to his computational power.

However, in the strict sense, this conclusion is incorrect due to the nature of draws without replacement in the computation contests: Conditioned on no solution has been found yet, the more candidates one has already checked, the higher probability the next candidate will be a solution. To see this concretely, take the following extreme case as an example. There are only two players with computational powers being 2 and 1. When there is only one solution to the given problem, the winning probabilities of them are in fact 3/4 and 1/4, instead of 2/3 and 1/3. In Section 3, we will demonstrate the analysis in details. In general, our analysis shows that the gap between one's winning probability and the proportion of his computational power increases as the number of solutions of the problem decreases.

Such gaps, if not negligible, will lead to the Matthew effect in the system where the players repeatedly participate the computation contest. In practice, the reward received now often results in increments of computational powers in the future, for example, research groups can attract more researcher and funds by their results and Bitcoin miners can purchase more machines using BTCs. The gaps, as we will show in this paper, offer higher increments for those

with relatively high computational powers and makes *the rich (relatively) richer and the poor (relatively) poorer*. Eventually, the entire system could be dominated by a single player, which is undesirable in most applications. The converging speed could be accelerated if the players are allowed to form groups or *pools* where they can jointly search for the solution and split the rewards.

Our analysis of the computation contest then suggests that keeping the number of solutions large is critical to suppress the Matthew effect in the system.

1.1 Our contribution

In this paper, we make the following contributions, where all the results apply to general multiple-solution cases:

- We give the winning probabilities of the players in closed-form, both for the single-solution case (Theorem 1) and the multiple-solution case (Theorem 9).
- In general, the probabilities are *not* proportional to the computational powers of the players. In extreme cases, this may lead to *the Matthew effect* in terms of computational powers: "the rich get richer and the poor get poorer".
- We introduce a pool choosing game between the players, where each of them can either specify one pool to join or keep himself independent. We analyse the incentives of the players under this game (Section 4) and identify a non-trivial Nash equilibrium (Theorem 4).
  In particular, in the Nash equilibrium, there is always a pool (or a single player) who has more than half of the total computational power. It implies that the Matthew effect could become even stronger when pooling is allowed. For the application of Bitcoin, it also means the 51% attack[2] could emerge in this case.
- Last but not least, we show that increasing the number of solutions will mitigate the Matthew effect. This is because as the number of solutions grows, the winning probabilities will gradually get close to being proportional to computational powers, where the gap between the probabilities and the proportions can be roughly bounded by the order of n^{-1} (Theorem 11).

1.2 Related work

The blockchain and Bitcoin are first presented in 2008 under the pseudonym Nakamoto [14] and widely concerned in the past decade. Thousands of papers follow the work by Nakamoto [14] with research areas including cryptography, game theory, and distributed systems. The book "Mastering Bitcoin" [1] introduces the basic knowledge about Bitcoin for beginners and Tschorsch and Scheuermann [19] summarize some early studies and progresses of the Bitcoin techniques.

The game-theoretical analysis of the mining systems, where each miner performs as a self-interested player to maximize his reward, is one of the central topics of blockchain researches and most relevant to this work. Rosenfeld [15] introduces the attack called "pool-hopping", where the miner can work in one pool at the beginning of one round and hop to another pool when the current round is longer than a threshold, and analyzes the advantages and disadvantages under several reward mechanisms of mining pools. Eyal and Sirer [6] introduce the attack called "selfish mining". In such an attack, when a miner successfully mines a block, he can choose to not publish it and continue mining based on that block, called the private chain. Results show that a rational miner will follow the selfish mining strategy as long as the selfish miner controls at least 1/3 of the total computational power. Kiayias et al. [10] consider a mining game with similar attacks, where the model structure is a tree of blocks and a block becomes valid when its height is larger than a given threshold. Eyal [5] proposes an attack that a mining pool can send some "spies" to other pools and share the utilities of the spies obtained from these pools. Liu et al. [12] consider how a miner should choose a mining pool of which the required computational power is fixed. Fisch et al. [7] show that the geometric pay pool achieves the optimal social welfare based on the power utility function.

In the famous economic model, R&D race [3, 8], a similar setting is analyzed, where each agent can choose his effort rate to the winner-takes-all competition. However, the expected profits are still assumed to be linear to the agents' effort rates with additional costs. To the best of our knowledge, no literature drops the assumption about the proportional winning probability and this paper is the first to mathematically consider the winning probabilities in first principles.

2 PRELIMINARIES

Consider the following model of an abstract computation contest where the problem is solved via random trials:

- m players compete with each other in solving a problem;
- The problem is to find a solution of $h(v) = 0$ from a candidate set V, where $|V| = N$ is finite;
- There are $n \geq 1$ solutions to the problem, but only the player who first finds one solution receives a reward 1.

In particular, there is no trick for solving the problem in the sense that enumerating and verifying all candidates from V in an arbitrary order is the best algorithm. Formally, let h be randomly drawn from a ground set $\mathcal{H}$ according to some distribution, such that for any $v \in V$, the event $h(v) = 0$ is independent of the function values of any subset of $V \setminus \{v\}$. In addition, the probability of $h(v) = 0$ is the same for any $v \in V$ and the computational resource needed to determine whether $h(v) = 0$ or not is the also the same for any $v \in V$, both independent of the knowledge about the function values on $V \setminus \{v\}$.[3]

Throughout the paper, we refer each $v \in V$ as a *candidate* and the ones such that $h(v) = 0$ as *solutions*. In the contest, each player i has a type $x_i > 0$ called the *computational power*, i.e., the number of candidates he can verify in a unit of time. The player with higher computational power will be able to test more candidates and of course has higher chance to win. Here, we assume that each

[2]The 51% attack is a concept in PoW blockchain systems [19]. It states that if one player (or a pool) has computational power more than half of the total computational power in the system, then he/she is able to manipulate the blockchain.

[3]Although the assumption here can hardly be exactly met in real applications, our analysis still applies at some extend. For example, in the case of blockchain under PoW schemes, the hash function h is fixed and so are its solutions. However, as long as the hash function is still secure, the algorithmic advantage of solving the problem is negligible and every one is searching in a random order. As a result, the probability of the t-th candidate v_t being a solution is still a constant.

player is enumerating through the candidate set in a random order independent of others.

Blockchain. One concrete real-world example of this computation contest is the application of blockchains under Proof of Work (PoW) schemes. As its name would suggest, a *blockchain* is a chain of many blocks that are accepted by the peers, where each accepted block must have a valid *block header* pointing to the previous block.

Taking Bitcoin as the example: Each block header has a fixed length of 80 bytes (640 bits) which in general could be divided into two parts: (i) the fixed part (e.g., the hash value of the previous block header) and (ii) the adjustable part (e.g., the *nonce* and the *merkle root*). In other words, there is a fixed and finite set V containing all block header candidates.

A block header is valid if its hash value (a 256-bit integer) is less than a target threshold, i.e., $2^{208}(2^{16}-1)/D \approx 2^{224}/D$, where D is a positive number called *difficulty*. In this case, the probability of a randomly selected block header being valid is $2^{224}/D \cdot 2^{-256} = 2^{-32}D$. In the language of our computation contest model, the function value $h(v)$ of a candidate block header v is 0, if and only if v is a valid block header.

Since the hash function is deterministic, for any specific block, the number of valid block headers (solutions), n, is fixed (but unknown). Note that the fixed part of block header is randomly determined by the previous block and the system, therefore it can be seen as the random index of the function h, given that the hash function is ideal.

The main computational challenge of building the next block is to find one of the n valid block headers from the N possible candidates, or equivalently, solving $h(v) = 0$. In particular, if the hash function resists preimage attacks, the most efficient algorithm one can hope for is the brute force search (in arbitrary orders). In the context of blockchain, the procedure of searching a valid block header is referred as *mining* and the speed of computing the hash function is often referred as the *hash rate* or the computational power.

In the classic PoW scheme, such as Bitcoin, every miner has the equal right to mine and the one who first announces the next block with a valid block header will win the reward on that block. The reward is a constant with respect to the mining procedure. Therefore, the mining process of each block could be well-modeled by our computation contest, where each miner corresponds to a player, block headers correspond to candidates, and valid block headers correspond to solutions.

Pooling. In practice, the probability of winning the contest could be extremely low for a single player and hence the variance of the random reward is very high. To avoid the high variance, it is a common practice that individuals form a *pool* and jointly search for the solution. Once the pool wins, the reward will be distributed to the players in the pool according to a pre-specified policy. The most common policy, in the case of Bitcoin, is essentially a proportional allocation rule, i.e., the reward a player receives is proportional to the computational power he contributes to the pool.[4] In the same spirit, work by Bloch [2] analyzes sequential coalition game, splitting the whole party into subsets, and studies subgame perfect equilibrium.

[4]As recorded on https://investoon.com/mining_pools/btc, the most common reward schemes in the pools are PROP, PPS, PPLNS, all with expected reward approximately proportional to their hashrates.

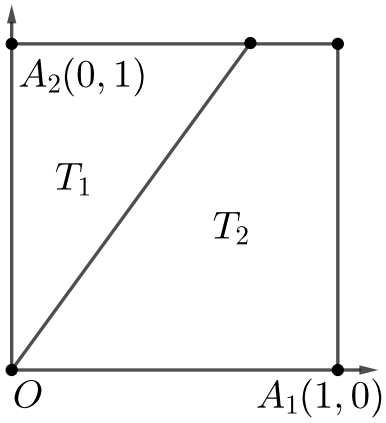

Figure 1: In the two-player case, player 1 wins if and only if the random coordinate t falls into T_1.

In this paper, we focus on two types of questions under this computation contest model:

- Given the environment and the computational powers, what are the winning probabilities of the players? Are the probabilities proportional to their computational powers?
- If not proportional to their computational powers, what is the optimal pooling strategy for the players?

3 THE SINGLE-SOLUTION CASE

In this section, we start with the basic case with only one solution, i.e., $n = 1$. Later in Section 5, we will generalize all results for single-solution cases to multiple-solution cases.

3.1 Warmup: two players and a single solution

As defined in the previous section, the player who find its first solution earliest wins. To compute the winning probabilities of the players, we use real numbers in $[0,1]$ to index the candidates in the order that they are verified by player i.[5] Since each candidate in general will have different indices in the enumerating sequences of different players, putting the indices together, a *coordinate* of each candidate is defined. In particular, let t_i be the index of the first solution in player i's sequence and then t_i/x_i is the time that player i first finds a solution. In this case, the player with minimum t_i/x_i wins. Note that the t_i's are random variables and also the source of the randomness of the outcome.

Let p_i be the winning probability of player i, we have

$$p_i = \Pr[i \text{ wins}] = \Pr\left[t_i/x_i \le \min_{j\neq i} t_j/x_j\right].$$

[5]Here we simplify the analysis by using real numbers to index the candidates. One can of course use the fractions k/N with integers $k < N$ to index the candidates for an even more rigorous analysis. In this case, our analysis still applies by replacing the integrations with summations. The only difference here is the break-ties at $t_i/x_i = t_j/x_j$. Their probabilities are zero under real number indexing but at order $1/N$ for fraction number indexing, which is also negligible for large N.

For the two-player single-solution case, since there is only one solution, t_1 and t_2 are independently and uniformly distributed over $[0,1]$. Denote $\boldsymbol{t} = (t_1, t_2)$ and let T_1 be the set of $\boldsymbol{t}$ where player 1 wins:

$$T_1 = \{\boldsymbol{t} \in [0,1]^2 : t_1/x_1 \le t_2/x_2\}.$$

Similarly, we can define T_2:

$$T_2 = \{\boldsymbol{t} \in [0,1]^2 : t_2/x_2 \le t_1/x_1\}.$$

Because $\boldsymbol{t}$ is uniformly distributed over $[0,1]^2$, $p_1 = \int_{T_1} \mathrm{d}\boldsymbol{t} = \mathrm{area}(T_1)$ equals to the area of set T_1 (see Figure 1). Suppose that $x_1 \le x_2$, then with some primary calculation, we know that the slope of the line separating T_1 and T_2 is x_2/x_1 and hence

$$p_1 = \mathrm{area}(T_1) = x_1/2x_2,\ p_2 = \mathrm{area}(T_2) = 1 - x_1/2x_2,$$

which are not proportional to the computational power x_1 and x_2 (unless $x_1 = x_2$).

3.2 m players and a single solution

For the general m-player case, the winning probability of each player is summarized by the following theorem, where $\pi(z)$ and $\pi_{-i}(z)$ are defined to simplify the notations:

$$\pi(z) = \prod_{i=1}^{m} \left(1 - \frac{x_i}{x_m} \cdot z\right), \quad \pi_{-i}(z) = \frac{\pi(z)}{1 - \frac{x_i}{x_m} \cdot z}.$$

Theorem 1. *Suppose that $x_1 \le x_2 \le \cdots \le x_m$, then the winning probability of player i is:*

$$p_i = \frac{x_i}{x_m} \int_0^1 \pi_{-i}(z)\mathrm{d}z.$$

Proof. Recall that

$$p_i = \Pr\left[t_i/x_i \le \min_{j \ne i} t_j/x_j\right] = \Pr\left[\bigwedge_{j \ne i} t_i/x_i \le t_j/x_j\right].$$

Let $f_i(\cdot)$ be the probability density function of the random variable t_i, then

$$p_i = \int_0^1 \Pr\left[\bigwedge_{j \ne i} t_j \ge \frac{t_i x_j}{x_i} \middle| t_i = t\right] f_i(t)\mathrm{d}t.$$

Since the orders of the players enumerating through the candidates are independent, we have that

$$\Pr\left[\bigwedge_{j \ne i} t_j \ge \frac{t_i x_j}{x_i} \middle| t_i = t\right] = \prod_{j \ne i} \Pr\left[t_j \ge \frac{t x_j}{x_i}\right].$$

In the meanwhile, note that $t_1, \ldots, t_m$ are uniformly distributed, hence $f_i(t) = 1$ and

$$\Pr\left[t_j \ge \frac{t x_j}{x_i}\right] = \max\left\{1 - \frac{t x_j}{x_i}, 0\right\}.$$

Thus the production is zero for $t \ge x_i/x_m$, which implies

$$p_i = \int_0^{x_i/x_m} \prod_{j \ne i} \left(1 - \frac{t x_j}{x_i}\right) \mathrm{d}t.$$

By substituting $t = x_i z/x_m$, we complete the proof

$$p_i = \frac{x_i}{x_m} \int_0^1 \prod_{j \ne i} \left(1 - \frac{x_j}{x_m} \cdot z\right) \mathrm{d}z = \frac{x_i}{x_m} \int_0^1 \pi_{-i}(z)\mathrm{d}z.$$

□

According to Theorem 1, the winning probabilities p_i are proportional to the computational powers x_i if and only if the integration $\int_0^1 \pi_{-i}(z)\mathrm{d}z$ is a constant for all $1 \le i \le m$, which in general is not true.

In particular, as we will show in Section 5, the observation above holds even when there are multiple solutions, i.e., $n > 1$. Nevertheless, as n goes to infinity, the winning probabilities will gradually get close to being proportional with respect to the computational powers.

However, the larger the player's computational power is, the higher efficiency (winning probability divided by computational power) it achieves.

3.2.1 The Matthew Effect. The next theorem in fact indicates the Matthew effect in such systems: the player with higher computational power gets higher return (or higher probability to win) for each unit of their computational power, i.e., $p_i/x_i \le p_j/x_j$.

Theorem 2 (The Matthew Effect). *If $x_i \le x_j$, then $p_i/x_i \le p_j/x_j$, where the equality is reached if and only if $x_i = x_j$.*

If both of them invest all the rewards (such as bitcoins) they get to increase their future computational power, the ratio of x_j/x_i will become larger and larger over time:

Δx_i and Δx_j are proportional to p_i and p_j, respectively, hence

$$\Delta x_i/x_i \le \Delta x_j/x_j, \quad \Longrightarrow \quad (x_i + \Delta x_i)/(x_j + \Delta x_j) \le x_i/x_j.$$

In other words, the player with the highest computational power in the system will gradually take a more and more fraction of the total computational power and eventually dominate the entire system.

Proof of Theorem 2. To simplify the notations, write

$$\pi_{-ij}(z) = \frac{\pi(z)}{\left(1 - \frac{x_i}{x_m} \cdot z\right)\left(1 - \frac{x_j}{x_m} \cdot z\right)}.$$

Therefore, by $x_i \le x_j \le x_m$ and $\pi_{ij}(z) \ge 0$, we have that $\forall z \in [0,1]$,

$$\left(1 - \frac{x_j}{x_m} \cdot z\right) \cdot \pi_{-ij}(z) \le \left(1 - \frac{x_i}{x_m} \cdot z\right) \cdot \pi_{-ij}(z).$$

Finally, using Theorem 1, we conclude that

$$\begin{aligned} \frac{p_i}{x_i} &= \frac{1}{x_m} \int_0^1 \left(1 - \frac{x_j}{x_m} \cdot z\right) \cdot \pi_{-ij}(z)\mathrm{d}z \\ &\le \frac{1}{x_m} \int_0^1 \left(1 - \frac{x_i}{x_m} \cdot z\right) \cdot \pi_{-ij}(z)\mathrm{d}z = \frac{p_j}{x_j}. \end{aligned}$$

In particular, the equality is reached if and only if $x_i = x_j$. □

4 POOLING INCENTIVES

In this section, we investigate the incentives of players to pool together assuming that the reward is split proportional to their computational powers. In particular, we identify a non-trivial Nash equilibrium of the following *pool choosing game*.

Definition 3 (Pool choosing game). *Let $\mathcal{P}_1, \ldots, \mathcal{P}_m$ be m pools. The actions of each player is either to choose one from these m pools (say $\mathcal{P}_i$) or to be independent (denoted as $\perp$). The utility of each*

player is the expected winning reward and if a pool wins, the reward is split proportional to its members' computational powers.

In the practice of Bitcoin, there are many such pools. The pools have their own websites, cooperatively mining tools, and reward splitting policies. Usually, the pools always welcome miners to join so that they can attract more computational resources. In contrast, each individual miner can of course work by himself.

As a quick example, the action profile $(\mathcal{P}_1, \ldots, \mathcal{P}_1)$ results in a giant pool including everyone ($\{1, \ldots, m\}$) and the action profile $(\perp, \ldots, \perp)$ results in everyone being independent. Although trivial, the latter is a Nash equilibrium of the game. Because, for example, if player i deviates, then the result is that only player i in a pool and all others being independent. No difference.

The following theorem then identifies a non-trivial Nash equilibrium for two cases.

Theorem 4 (Nash Equilibrium). *Suppose that $x_m \geq x_{m-1} \geq \cdots \geq x_1$. If $x_m \leq x_1 + \cdots + x_{m-1}$, then the action profile $(\mathcal{P}_1, \ldots, \mathcal{P}_1)$ is a Nash equilibrium, yielding a giant pool.*

Otherwise, we have $x_m \geq x_1 + \cdots + x_{m-1}$, and the action profile $(\mathcal{P}_1, \ldots, \mathcal{P}_1, \perp)$ is a Nash equilibrium, with player m being independent and the others in one pool.

To prove this theorem, we first need to understand the conditions that a player has incentive to join a pool (or another player). With the theorems and lemmas in place, we prove Theorem 4 at the end of this section.

We also emphasize that the results in this section will later be generalized to the multiple-solution case in Section 5.

4.1 Incentive Analysis

First of all, an important and immediate observation for pooling is that pooling is always beneficial when taking the pool as a whole. Formally,

Observation 5. *A pool's winning probability is no less than the sum of the winning probabilities of its members when they participate the computation contest separately.*

This is easy to get by considering a "pseudo-pool" of the members, where they enumerate through the candidates in the same order as they do when participate the contest separately. Clearly, the winning probability of the "pseudo-pool" equals to the sum of the winning probabilities of the members working separately. Since the players in the "pseudo-pool" may repeatedly verify some of the candidates, the winning probability could be even higher if they simply skip those already verified by other members in the pool. In particular, this "higher" winning probability equals to the winning probability of the real pool by symmetry.

Theorem 6. *For any player i, pooling with another player with higher computational power than him is always beneficial.*

Proof. Consider a player i pooling with another player j with $x_j \geq x_i$. We use p_{ij} to denote the winning probability of the pool. Then by Observation 5, we have $p_{ij} \geq p_i + p_j$ and hence the reward of player i from the pool is

$$p_i' = \frac{x_i}{x_i + x_j} \cdot p_{ij} = \frac{p_{ij}}{1 + x_j/x_i} \geq \frac{p_i + p_i}{1 + x_j/x_i}.$$

Note that by Theorem 2, we have

$$p_i/x_i \leq p_j/x_j \quad \Longleftrightarrow \quad x_j/x_i \leq p_j/p_i.$$

Therefore

$$p_i' \geq \frac{p_i + p_i}{1 + x_j/x_i} \geq \frac{p_i + p_j}{1 + p_j/p_i} = p_i.$$

In other words, player i gets more reward by pooling with player j. □

A direct consequence of this theorem is that a pool is stable against single deviation as long as the largest player's computational power is no more than half of the computational power of the pool.

Corollary 7. *Any individual member of a pool has no incentive to leave if its computational power is no more than half of the pool's computational power.*

Proof. Otherwise, once the player left the pool, he would have incentive to rejoin the pool by Theorem 6, a contradiction. □

In fact, the corollary asserts that any player (or pool) always has incentive to pool with a player (or pool) that has higher computational power than himself. In contrast, there would be a tradeoff for the player (or pool) being proposed:

- **Pros**: By pooling together, they form a larger pool, which by Theorem 2, has a higher efficiency in terms of computational power (i.e., higher ratio of reward divided by computational power).
- **Cons**: However, the player (or pool) with low computational power may actually takes more than he contributes. In this case, the total tradeoff for the player with high computational power could be negative and he would have incentive to be independent.

The following lemma then provides a sufficient condition where the tradeoff is positive.

Lemma 8. *If $x_i + x_j \leq x_m$, then both i and j will be better off in terms of the expected reward by pooling.*

Proof. Throughout the proof, we use the notations $\pi_{-ij}(z)$ (defined in the proof of Theorem 2) and p_{ij} (the winning probability of the pool $\{i, j\}$).

Without loss of generality, suppose that $x_i \leq x_j \leq x_m$. Then by Theorem 6, player i gets better off by pooling. In the rest of the proof, we show that player j gets better off as well.

On one hand, according to the proportional allocation rule, the reward of player j by pooling is $p_j' = \frac{x_j}{x_i + x_j} \cdot p_{ij}$. Thinking the pool $\{i, j\}$ as a player with computational power $x_i + x_j$, then by Theorem 1,

$$p_{ij} = \frac{x_i + x_j}{x_m} \int_0^1 \pi_{-ij}(z) \mathrm{d}z.$$

Hence

$$p_j' = \frac{x_j}{x_i + x_j} \cdot p_{ij} = \frac{x_j}{x_m} \int_0^1 \pi_{-ij}(z) \mathrm{d}z.$$

On the other hand, the reward of player j without pooling is p_i, which by Theorem 1 is,

$$p_j = \frac{x_j}{x_m} \int_0^1 \pi_{-j}(z)\mathrm{d}z.$$

Note that for any $z \in [0, 1)$, since $x_i < x_m$ and $\pi_{-ij}(z) > 0$,

$$\pi_{-ij}(z) > \left(1 - \frac{x_i}{x_m} \cdot z\right) \pi_{-ij}(z) = \pi_{-j}(z).$$

Therefore,

$$p'_j > p_j.$$

In other words, player j gets strictly higher expected reward by pooling with player i. □

4.2 Equilibrium Analysis

Now we are ready to prove Theorem 4.

Theorem (Theorem 4 restate). Suppose that $x_m \geq x_{m-1} \geq \cdots \geq x_1$. If $x_m \leq x_1 + \cdots + x_{m-1}$, then the action profile $(\mathcal{P}_1, \ldots, \mathcal{P}_1)$ is a Nash equilibrium, yielding a giant pool.

Otherwise, we have $x_m \geq x_1 + \cdots + x_{m-1}$, and the action profile $(\mathcal{P}_1, \ldots, \mathcal{P}_1, \perp)$ is a Nash equilibrium, with player m being independent and the others in one pool. □

Proof of Theorem 4. The first case is a direct consequence of Corollary 7. Because none of them has computational power more than half of the pool, no player has incentive to deviate (leave the pool).

For the second case, we first show that player m has no incentive to deviate (or equivalently, join pool $\mathcal{P}_1$).

We use x_{-m} and p_{-m} to denote the computational power and the winning probability of the pool $\{1, \ldots, m-1\}$, respectively. Since $x_m \geq x_{-m}$, by Theorem 2, $p_m/x_m \geq p_{-m}/x_{-m}$. Note that $p_m + p_{-m} = 1$, hence $p_{-m} = 1 - p_m$. Then we have

$$\frac{p_m}{x_m} \geq \frac{1 - p_m}{x_{-m}} \iff p_m \geq \frac{x_m}{x_{-m} + x_m},$$

where the right-hand-side is the reward of player m if he joins the pool. In other words, if player m deviates by joining pool $\mathcal{P}_1$, his winning probability will decreases.

Then we prove that any player $i \in \{1, \ldots, m-1\}$ has no incentive to deviate (or equivalently, leave pool $\mathcal{P}_1$).

To show this, we prove that player i has incentive to join pool $\mathcal{P}'_1$, when $\mathcal{P}'_1 = \{1, \ldots, i-1, i+1, \ldots, m-1\}$ and player m chooses $\perp$. Thinking the pool $\mathcal{P}'_1$ as a player with computational power $x' = x_1 + \cdots + x_{i-1} + x_{i+1} + \cdots + x_{m-1}$. Since $x_i + x' \leq x_m$, then by Lemma 8, player i has incentive to join pool $\mathcal{P}'_1$. In other words, player i gets (weakly) higher reward in pool $\mathcal{P}_1$ than being independent.

In summary, for the second case, no player has incentive to deviate, hence a Nash equilibrium. □

5 THE MULTIPLE-SOLUTION CASE

In this section, we first extend our results of single-solution cases to multiple-solution cases. Then we show that as the number of solutions goes to infinity, the winning probabilities become asymptotically proportional to the player computational powers. In particular, it means that the Matthew effect gets weaker as the number of solutions increases.

5.1 Generalization

We start with generalizing Theorem 1.

Theorem 9. *Suppose that $x_1 \leq \cdots \leq x_m$, then the winning probability for player i in the multiple-solution case is*

$$p_i = \frac{x_i}{x_m} \int_0^1 \pi_{-i}(z) \cdot \pi(z)^{n-1}\mathrm{d}z.$$

We omit the proof of this theorem but highlight the only two differences with the proof of Theorem 1. Both are because of the definition of t_i, the index of *the first solution* in player i's sequence. Therefore, the probability density function of t_i and the probability that $t_j \geq t x_j/x_i$ are different with those in the single-solution case:

$$f_i(t) = n(1-t)^{n-1}, \Pr\left[t_j \geq \frac{t x_j}{x_i}\right] = \max\left\{1 - \frac{t x_j}{x_i}, 0\right\}^n.$$

Then by substituting these two terms in the proof of Theorem 1, we get Theorem 9.

Based on Theorem 9, we claim that all previous results (except Theorem 1) also apply to multiple-solution cases:

Claim 10 (Generalization). *Theorem 2 and Lemma 8 can be easily reproved for multiple-solution cases with Theorem 9. Based on this, Theorem 4, Observation 5, Theorem 6, and Corollary 7 are automatically generalized because their proofs do not rely on the number of solutions.*

5.2 Asymptotically Proportional Winning Probabilities

Consider the probability that the first solution comes after $t_1, \ldots, t_m$ for each of the players. Since the distribution of each t_i is independent, we have:

$$\Pr[\boldsymbol{\tau} \geq \boldsymbol{t}] = \prod_{i=1}^m \Pr[\tau_i \geq t_i] = \prod_{i=1}^m (1 - t_i)^n,$$

hence its density function:

$$f(\boldsymbol{t}) = \prod_{i=1}^n f_i(t_i) = \prod_{i=1}^n \frac{\partial (1 - t_i)^n}{\partial t_i} = n^m \prod_{i=1}^m (1 - t_i)^{n-1}.$$

Let T_i be the set of $\boldsymbol{t}$ that player i wins and $T = T_1 \cup \cdots \cup T_m = [0, 1]^m$. Then the winning probability of player i is

$$p_i = \int_{\boldsymbol{t} \in T_i} f(\boldsymbol{t})\mathrm{d}\boldsymbol{t}.$$

Theorem 11 (Asymptotically Proportional). *For any fixed number of players, m, as the number of solutions, n, approaches to infinity,*

$$p_i \longrightarrow \frac{x_i}{x_1 + \cdots + x_m}.$$

In particular, the difference is vanishing in the order of $\widetilde{O}(n^{-1})$,[6] *i.e.,*

$$\left| p_i - \frac{x_i}{x_1 + \cdots + x_m} \right| = \widetilde{O}(n^{-1}).$$

The theorem could be directly derived based on the following Lemma 12 and Lemma 13.

We use $\rho_i(z)$ to denote the $(m-1)$-dimensional volume of set $\{\boldsymbol{t} \in T_i : t_1 + \cdots + t_m = z\}$ and $\rho(z) = \rho_1(z) + \cdots + \rho_m(z)$.

Then Lemma 12 essentially means that $\boldsymbol{p}_i$ is asymptotically proportional to $\rho_i(1)$.

Lemma 12. *For any constant* $m \ll n$,

$$p_i = \frac{\rho_i(1)}{\rho(1)} \cdot n^m \int_0^{n^{-1+\epsilon}} (1-z)^{n-1} \rho(z) \mathrm{d}z + \widetilde{O}(n^{-1}).$$

Furthermore, Lemma 13 indicates that $\rho_i(1)$ is proportional to the computational power of player i.

Lemma 13.

$$\frac{\rho_i(1)}{\rho(1)} = \frac{x_i}{x_1 + \cdots + x_m}.$$

Proof of Theorem 11. By Lemma 12 and Lemma 13. □

We dedicate the rest of this section to prove Lemma 12 and Lemma 13.

Proof idea of Lemma 12. The proof is done by a careful estimation of p_i using a technique called the *core-tail decomposition* [11]. To estimate the probability, consider the core-tail decomposition of the set T_i, i.e., let

$$\mathsf{core} = \{\boldsymbol{t} : \bar{t} \le \alpha\} \quad \text{and} \quad \mathsf{core}(T_i) = \mathsf{core} \cap T_i,$$

where $\bar{t} = t_1 + \cdots + t_m$ and $\alpha > 0$ is a parameter to be determined later. Similarly, define $\mathsf{tail} = [0,1]^m \setminus \mathsf{core}$ and $\mathsf{tail}(T_i) = \mathsf{tail} \cap T_i$. Thus,

$$p_i = \int_{\mathsf{core}(T_i)} f(\boldsymbol{t}) \mathrm{d}\boldsymbol{t} + \int_{\mathsf{tail}(T_i)} f(\boldsymbol{t}) \mathrm{d}\boldsymbol{t}. \tag{1}$$

The following two lemmas would be helpful on simplifying the analysis.

Lemma 14. *Let* $g(\boldsymbol{t}) = n^m (1-\bar{t})^{n-1}$. *If* $\alpha < n^{-2/3}$, *then*

$$\int_{\mathsf{core}(T_i)} f(\boldsymbol{t}) \mathrm{d}\boldsymbol{t} = \int_{\mathsf{core}(T_i)} g(\boldsymbol{t}) \mathrm{d}\boldsymbol{t} + O(n^{m+1} \alpha^{m+2}).$$

Lemma 15.

$$\int_{\mathsf{tail}(T_i)} f(\boldsymbol{t}) \mathrm{d}\boldsymbol{t} \le e^{-\alpha(n-1) + m \ln n}.$$

We postpone the proofs of these lemmas to Section 6, which are mainly elaborate treatments of the Taylor series.

Proof of Lemma 12. Plugging Lemma 14 and Lemma 15 into (1), and letting $\alpha = \frac{(m+1)\ln n}{n-1}$, we have that,

$$p_i - \int_{\mathsf{core}(T_i)} g(\boldsymbol{t}) \mathrm{d}\boldsymbol{t} = O\left(n^{-1} (\ln n)^{m+2}\right) = \widetilde{O}(n^{-1}).$$

[6] The $\widetilde{O}$ notation here hides a poly-log factor, meaning that the residue term is bounded by $O\left(n^{-1}(\ln n)^c\right)$, for some positive constant $c > 0$ when n is sufficiently large.

Hence we remain to show the following equation:

$$\int_{\mathsf{core}(T_i)} g(\boldsymbol{t}) \mathrm{d}\boldsymbol{t} = \frac{\rho_i(1)}{\rho(1)} \cdot n^m \int_0^{\alpha} (1-z)^{n-1} \rho(z) \mathrm{d}z,$$

or equivalently,

$$\int_{\mathsf{core}(T_i)} (1-\bar{t})^{n-1} \mathrm{d}\boldsymbol{t} = \frac{\rho_i(1)}{\rho(1)} \int_0^{\alpha} (1-z)^{n-1} \rho(z) \mathrm{d}z. \tag{$*$}$$

First of all, note that the left-hand-side of $(*)$ could be rewritten as a double integration over $\mathsf{core}_z(T_i) = \{\boldsymbol{t} \in \mathsf{core}(T_i) : \bar{t} = z\}$ and then for z from 0 to α:

$$\begin{aligned}\int_{\mathsf{core}(T_i)} (1-\bar{t})^{n-1} \mathrm{d}\boldsymbol{t} &= \int_0^{\alpha} \mathrm{d}z \int_L (1-z)^{n-1} \mathrm{dcore}_z(T_i) \\ &= \int_0^{\alpha} (1-z)^{n-1} \mathrm{d}z \int_L \mathrm{dcore}_z(T_i),\end{aligned}$$

where $\int_L \mathrm{d}S$ is the Lebesgue integration over a set S. In particular, $\int_L \mathrm{dcore}_z(T_i)$ is the $(m-1)$-dimensional volume of the set $\mathsf{core}_z(T_i)$, denoted as $\rho_i(z)$.

Then consider the ratio between $\rho_i(z)$ and the volume of set $\mathsf{core}_z(T)$, $\rho(z)$. Since both $\mathsf{core}(T_i)$ and $\mathsf{core}(T)$ are the intersections of the core and positive cones in $\mathbb{R}^m$, hence $\rho_i(z)$ and $\rho(z)$ must be proportional to z^{m-1} accordingly:

$$\rho_i(z) = z^{m-1} \rho_i(1), \quad \rho(z) = z^{m-1} \rho(1).$$

Finally, we conclude that

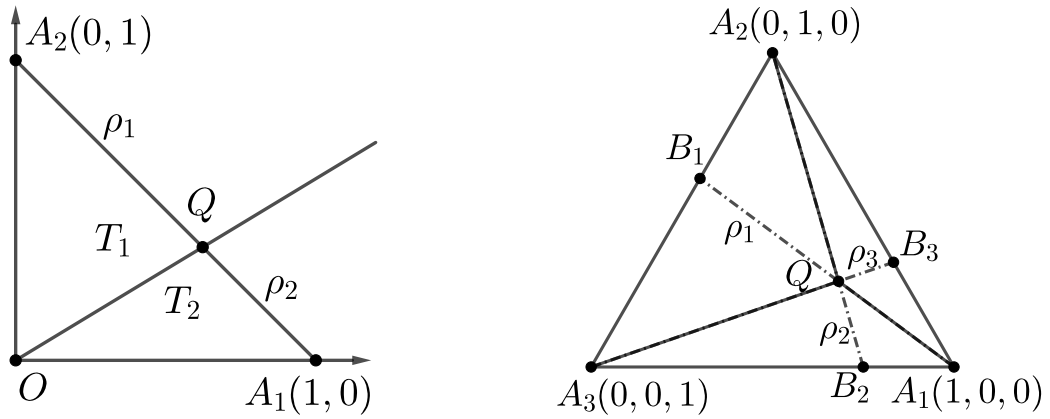
$$\int_L \mathrm{dcore}_z(T_i) = \rho_i(z) = \frac{\rho_i(1)}{\rho(1)} \cdot \rho(z),$$

which then directly implies $(*)$. □

Proof idea of Lemma 13. To smoothly proceed the analysis, we will start with the cases of $m = 2$ and $m = 3$.

For the two-player case (see Figure 2a), by definition,

$$T_1 = \{\boldsymbol{t} \in [0,1]^2 : t_1/x_1 \le t_2/x_2\},$$
$$T_2 = \{\boldsymbol{t} \in [0,1]^2 : t_2/x_2 \le t_1/x_1\}.$$



Therefore, the formula of the hyperplane (in fact a line in the 2-dimensional case) separating T_1 and T_2 is $t_1/x_1 = t_2/x_2$ and Q is the intersection of this line and the simplex A_1A_2. In particular, the 1-dimensional volume of the set $\{\boldsymbol{t} \in T_1 : \bar{t} = 1\}$ is exactly the length of the line segment QA_2, which equals to $\rho_1(1) = \sqrt{2}x_1/(x_1 + x_2)$. Similarly, we get $\rho_2(1) = \sqrt{2}x_2/(x_1 + x_2)$.

For the three-player case (see Figure 2b), by definition,

$$T_1 = \{\boldsymbol{t} \in [0,1]^3 : t_1/x_1 \le t_2/x_2, t_1/x_1 \le t_3/x_3\},$$
$$T_2 = \{\boldsymbol{t} \in [0,1]^3 : t_2/x_2 \le t_1/x_1, t_2/x_2 \le t_3/x_3\},$$
$$T_3 = \{\boldsymbol{t} \in [0,1]^3 : t_3/x_3 \le t_1/x_1, t_3/x_3 \le t_2/x_2\}.$$

In this case, there are three hyperplanes separating T_1, T_2, and T_3: $t_1/x_1 = t_2/x_2$, $t_2/x_2 = t_3/x_3$, and $t_3/x_3 = t_1/x_1$. Note that the intersection of the three hyperplanes is a line, $t_1/x_1 = t_2/x_2 = t_3/x_3$, which then intersects with the simplex $A_1A_2A_3 = \{\boldsymbol{t} : t_1 + t_2 + t_3 = 1\}$ at a point Q.

Therefore, the 2-dimensional volumes (or areas) $\rho_1(1)$, $\rho_2(1)$, and $\rho_3(1)$ are exactly the areas of triangles $\triangle QA_2A_3$, $\triangle A_1QA_3$, and $\triangle A_1A_2Q$, respectively. Note that $A_1A_2A_3$ is a regular 2-simplex,

(a) The two-player case. **(b) The three-player case.**

Figure 2: Simplexes for two-player and three-player cases.

hence $A_2A_3 = A_3A_1 = A_1A_2$. Thus the ratios between the areas of the triangles equal to the ratios between the heights of the triangles, because their bases (A_2A_3, A_3A_1, A_1A_2) are of the same length.

We conclude that

$$\frac{\rho_1(1)}{\rho_2(1)} = \frac{d(Q, A_2A_3)}{d(Q, A_3A_1)}, \frac{\rho_1(1)}{\rho_3(1)} = \frac{d(Q, A_2A_3)}{d(Q, A_1A_2)},$$

where d denotes the distance between a point and a line.

In the meanwhile, recall that the coordinate of point Q is:

$$\left(\frac{x_1}{x_1+x_2+x_3}, \frac{x_2}{x_1+x_2+x_3}, \frac{x_3}{x_1+x_2+x_3}\right),$$

and with some primary calculation, we know that

$$\frac{d(Q, A_2A_3)}{d(Q, A_3A_1)} = \frac{x_1}{x_2} \quad \text{and} \quad \frac{d(Q, A_2A_3)}{d(Q, A_1A_2)} = \frac{x_1}{x_3}.$$

In other words, $\rho_i(1)/\rho(1) = x_i/(x_1+x_2+x_3)$.

Finally, we generalize the observations above to get the proof.

Proof of Lemma 13. By the definition, $T_1, \ldots, T_m$ are separated by $\binom{m}{2}$ hyperplanes:

$$\forall i \neq j, t_i/x_i = t_j/x_j.$$

In particular, the intersection of them is a line and the line intersects the $(m-1)$-simplex $A_1 \cdots A_m$ at a unique point Q, whose coordinate is:

$$Q : \left(\frac{x_1}{x_1+\cdots+x_m}, \ldots, \frac{x_m}{x_1+\cdots+x_m}\right).$$

In the meanwhile, note that for each $i \in [m]$, point $A_j \in T_i$ for all $j \neq i$. Therefore, the set $\{\boldsymbol{t} \in T_i : \bar{t} = 1\}$ is a $(m-1)$-simplex, $A_1 \cdots A_{i-1} Q A_{i+1} \cdots A_m$ and its volume is proportional to the $(m-2)$-dimensional volume of its base $A_1 \cdots A_{i-1} A_{i+1} \cdots A_m$ times its height (the distance between point Q and the base).

Because $A_1 \cdots A_m$ is a regular $(m-1)$-simplex, the volumes of the bases for each i are the same. Therefore, $\rho_i(1)/\rho_j(1)$ equals to the ratios between the distances from Q to the corresponding bases. Based on the coordinate of Q, we conclude that the ratio equals to x_i/x_j. In other words,

$$\frac{\rho_i(1)}{\rho(1)} = \frac{\rho_i(1)}{\rho_1(1)+\cdots+\rho_m(1)} = \frac{x_i}{x_1+\cdots+x_m}.$$

□

6 MISSING PROOFS

The following technical lemma is repeatedly used in the proofs.

Lemma 16. *For all $x \in \mathbb{R}$, $e^x \geq 1+x$.*

Proof of Lemma 14. For the core part, because $\bar{t} < \alpha < n^{-2/3}$,

$$\prod_{i=1}^{m}(1-t_i) = 1 - \sum_i t_i + \sum_{i\neq j} t_i t_j + \cdots = 1 - \bar{t} + O(\bar{t}^2),$$

$$\prod_{i=1}^{m}(1-t_i)^{n-1} = (1-\bar{t})^{n-1}\left(1 + \frac{O(\bar{t}^2)}{1-\bar{t}}\right)^{n-1}.$$

Since $n\bar{t}^2 \leq n\alpha^2 < n^{-1/3}$, then by Lemma 16 and Taylor's expansion of e^x at 0,

$$\begin{aligned}\prod_{i=1}^{m}(1-t_i)^{n-1} &\leq (1-\bar{t})^{n-1} e^{\frac{O(\bar{t}^2)}{1-\bar{t}}\cdot(n-1)} \\ &= (1-\bar{t})^{n-1}\cdot\left(1 + \frac{O(\bar{t}^2)(n-1)}{1-\bar{t}} + O(n^2\bar{t}^4)\right) \\ &= (1-\bar{t})^{n-1} + O(n\bar{t}^2).\end{aligned}$$

Thus

$$\int_{\mathsf{core}(T_i)} f(\boldsymbol{t})\mathrm{d}\boldsymbol{t} \leq \int_{\mathsf{core}(T_i)} n^m\left((1-\bar{t})^{n-1} + O(n\bar{t}^2)\right)\mathrm{d}\boldsymbol{t},$$

where

$$\int_{\mathsf{core}(T_i)} n^m \cdot O(n\bar{t}^2)\mathrm{d}\boldsymbol{t} \leq n^{m+1}\int_{\mathsf{core}} O(\bar{t}^2)\mathrm{d}t.$$

Consider rewrite the right-hand-side as a double integration over $\mathsf{core}_z = \{\boldsymbol{t} \in \mathsf{core} : \bar{t} = z\}$ and then for z from 0 to α:

$$\int_{\mathsf{core}} O(\bar{t}^2)\mathrm{d}t = \int_0^\alpha O(z^2)\mathrm{d}z \int_L \mathrm{dcore}_z$$

Note that $\int_L \mathrm{dcore}_z$ is the Lebesgue integration over the set core_z and hence equals to its $(m-1)$-dimensional volume, which is $\rho(z) = \frac{\sqrt{m}}{(m-1)!} \cdot z^{m-1}$ [18]. Therefore,

$$\int_{\mathrm{core}} O(\bar{t}^2)\mathrm{d}t = \int_0^{\alpha} O(z^2) \cdot z^{m-1}\mathrm{d}z = O(\alpha^{m+2}).$$

That is

$$\int_{\mathrm{core}(T_i)} n^m \cdot O(n\bar{t}^2)\mathrm{d}\boldsymbol{t} \le O(n^{m+1}\alpha^{m+2}).$$

In summary,

$$\int_{\mathrm{core}(T_i)} f(\boldsymbol{t})\mathrm{d}\boldsymbol{t} = \int_{\mathrm{core}(T_i)} g(\boldsymbol{t})\mathrm{d}\boldsymbol{t} + O(n^{m+1}\alpha^{m+2}).$$

□

Proof of Lemma 15. For the tail part, according to the inequality of arithmetic and geometric means,

$$\prod_{i=1}^{m}(1-t_i) \le (1-\bar{t}/m)^m,$$

then by Lemma 16 and $\bar{t} \ge \alpha$,

$$\prod_{i=1}^{m}(1-t_i)^{n-1} \le (1-\bar{t}/m)^{m(n-1)} \le e^{-\bar{t}(n-1)} \le e^{-\alpha(n-1)}.$$

Therefore, $f(\boldsymbol{t}) \le n^m e^{-\alpha(n-1)} = e^{-\alpha(n-1)+m\ln n}$. Also note that $\int_{\mathrm{tail}} \mathrm{d}\boldsymbol{t}$ is the volume of tail, which is less than 1, hence

$$\int_{\mathrm{tail}(T_i)} f(\boldsymbol{t})\mathrm{d}\boldsymbol{t} \le e^{-\alpha(n-1)+m\ln n} \int_{\mathrm{tail}} \mathrm{d}\boldsymbol{t} \le e^{-\alpha(n-1)+m\ln n}.$$

ABSTRACT

Facial appearance matters in social networks. Individuals frequently make trait judgments from facial clues. Although these face-based impressions lack the evidence to determine validity, they are of vital importance, because they may relate to human network-based social behavior, such as seeking certain individuals for help, advice, dating, and cooperation, and thus they may relate to centrality in social networks. However, little to no work has investigated the apparent facial traits that influence network centrality, despite the large amount of research on attributions of the central position including personality and behavior. In this paper, we examine whether perceived traits based on facial appearance affect network centrality by exploring the initial stage of social network formation in a first-year college residential area. We took face photos of participants who are freshmen living in the same residential area, and we asked them to nominate community members linking to different networks. We then collected facial perception data by requiring other participants to rate facial images for three main attributions: dominance, trustworthiness, and attractiveness. Meanwhile, we proposed a framework to discover how facial appearance affects social networks. Our results revealed that perceived facial traits were correlated with the network centrality and that they were indicative to predict the centrality of people in different networks. Our findings provide psychological evidence regarding the interaction between faces and network centrality. Our findings also offer insights in to a combination of psychological and social network techniques, and they highlight the function of facial bias in cuing and signaling social traits. To the best of our knowledge, we are the first to explore the influence of facial perception on centrality in social networks.

1 INTRODUCTION

Many cultures share beliefs about the human face being a window to a personâĂŹs characters. Humans frequently make trait judgments from facial clues [29, 31, 33]. Studies have indicated that 100 milliseconds of exposure to unfamiliar faces is sufficient for

participants to form impressions about competence or trustworthiness [31]. Indeed, some have reported that people can make social judgments with exposures of less than 100 milliseconds, with any longer time being used to confirm judgments [2, 20, 29]. Moreover, there is a consensus concerning trait judgments based on faces among adults and even among 3- to 4-year-old children [9], despite the limited evidence of the validity of these judgments [23].

Although these facial impressions of traits may not be accurate, they are very important within social network environments, because they may influence social behaviors such as seeking certain individuals for help, advice, dating, and cooperation [24, 30]. For example, people invest more money with those who they perceive as more trustworthy in economic games [10, 22]. Evaluations of faces have impacted decisions in electoral politics [28], mate preferences [13], hypothetical crime verdicts [21], as well as approach or avoidance behaviors [12, 32] as well as approach or avoidance behaviours [27]. In particular, regarding network centrality, individualsâĂŹ roles and relationships with others are more likely to be influenced by facial appearance at the early stage of central networks construction without or with little interaction or information on others.

However, little to no research has explored the effect of facial perceptions on social networks. Although previous work has investigated the relationships between trait perceptions and social networks, those perceptions are based on assessments of personality, behavior, emotion, ability, etc. (e.g. [4, 8, 11, 14]) rather than appearances or facial perception. Moreover, recent work suggests that psychological traits (based on psychological scales) correlate with the centrality of social networks [16]. However, whether face-based perceived psychological traits relate to centrality of networks is scarcely known. We therefore aim to explore the relationship between facial appearance and social networks by exploring newly formed social networks in a first-year college residential area. We took face photos of participants and asked them to nominate community members associated with different networks. We then collected image evaluation data by asking other participants to rate face photos for three main attributions: dominance, trustworthiness, and attractiveness on a seven-point Likert-type scale. Our results revealed different social networks in different freshman residential areas. Moreover, we found that perceived facial dominance, trustworthiness, and attractiveness are effective at predicting the centrality of people on different networks. Our contributions are as follows.

- We explore the use of perceived facial features in a social network environment, and particularly for network centrality, to discover whether facial appearance affects social networks, which has scarcely been done before.
- We investigate the predictability of network centrality by rating face stimuli. The experimental results indicate that face-based traits predict membership of freshman community networks at the initial stage of formation.
- We propose a novel framework to conduct social network analysis in a psychological setting, and particularly for corroboration of facial bias. The results contribute to psychological knowledge of facial perception, because they are consistent with previous research that facial appearance affects network-based social behaviors.

This paper is organized as follows. In next section, we discuss the related work. In section 3, we introduce the details of data collection. In section 4, we describe methods used in this study. In section 5, we show the experiment results. In final section, we present conclusion of this paper.

2 RELATED WORK

2.1 Dimensions of Face Evaluation

Oosterhof and Todorov [19] provided empirical evidence contributing to our knowledge of face evaluation. To identify the dimensions on which individuals evaluate faces, they conducted a principal component analysis on various trait adjectives inferred from neutral faces, and they reduced them to two main axes; dominance and trustworthiness. They constructed computer models of three-dimensional face shapes that correlated with ratings of trustworthiness and dominance [19].They found that by moving from the negative to positive extremes (low and high ratings) of the trustworthiness dimension, the faces changed from expressing slight anger to slight happiness. Likewise, in the dominance dimension, the faces varied from expressing feminine and baby-faced traits to masculine and mature-faced traits. The trustworthiness dimension arguably signaled an individualâĂŹs harmful intent, whereas the dominance dimension signaled the capability to carry out the harmful intention [19]. Hence, they suggested that perhaps these evaluations of emotional valence and dominance are rooted in evolutionary mechanisms of threat detection [19].

Additionally, Sutherland et al [25]. described a third dimension of youthful attractiveness. In their study, they created average faces from photographs of people perceived as high or low in intelligence, trustworthiness, dominance, and confidence, and participants rated them on various traits. The stimuli of faces did not control for variables like hairstyle and piercings [25]. The stimuli of faces did not control for variables like hairstyle and piercings [25]. Their results supported the two dimensions proposed by Oosterhof and Todorov [19], and they indicated a third dimension of facial youthful attractiveness, which Sutherland et al. argued was important in making facial evaluations [25]. This additional dimension may be due to the wider age range of faces used in the study [25]. The aforementioned studies suggest that the main attributions made to faces are dominance, trustworthiness, and attractiveness; thus, we conducted studies based on these three dimensions.

Some studies have been done on how attractiveness, trustworthiness, and dominance impact network-related social behaviors. Alison et al. have studied how facial appearance can impact entrepreneurs to finance projects [5]. When entrepreneurs start a business, investors prefer pitches from attractive people, because they are much more persuasive. In strategic economic games, it is almost impossible for a player with an untrustworthy-looking face to be trusted by other players, even when he/she has a good

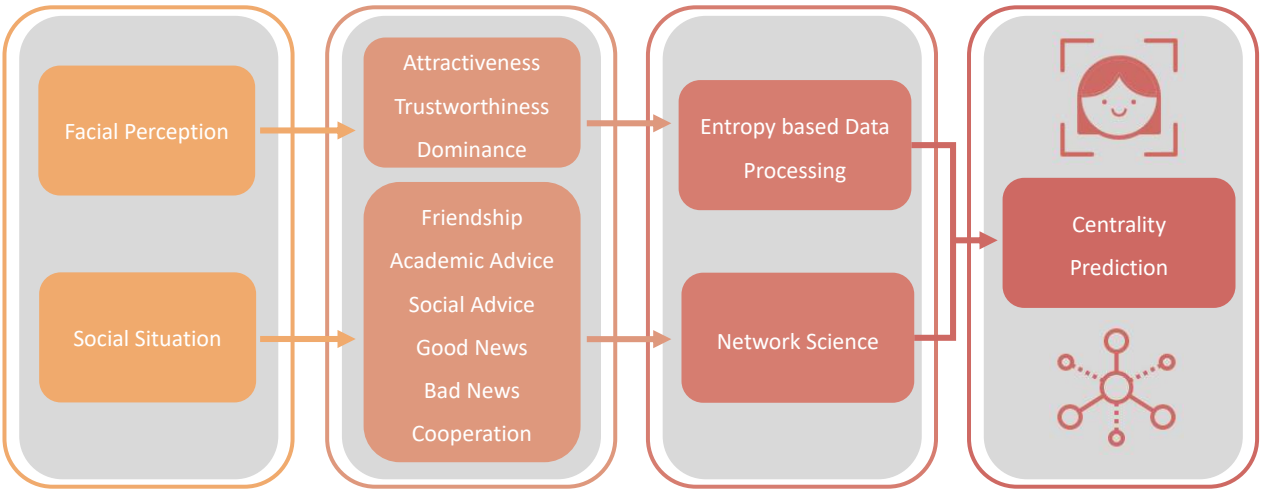

Figure 1: Methodology (PSP framework) used to analyze correlations between facial perception and social situation, and then to predict the centrality of different social networks. First, data of facial perception and social situation are collected from participants. Second, entropy-based data processing method and network science are used to process data. Finally, classification algorithm is used to predict the centrality in social networks according to facial perception features.

credit record [22, 26]. Moreover, Olivola et al. suggested that perceived dominance is correlated with professional success within the military and politics, because people believe that the leaders of these fields tend to look masculine, mature, and âĂIJcoldâĂİ [18]. Therefore, since perceived trustworthiness, attractiveness, and dominance relate to social behavior in social network settings, they may influence network centrality.

2.2 Positions in Social Networks

PeopleâĂŹs positions in social networks are affected by many factors, such as behavior, personality, and emotion. Previous research indicates that behavioral tactics are associated with certain structural positions, such as indegree centrality [4]. A person who is considered assertive and rational, and who has upward appeal, can also use behavioral tactics. These people are always considered dependable and reliable. Therefore, people tend to ask these persons to help them when they are in trouble, or they share good news with them. Thus, people like to follow those who have social power, and to give them central positions in social networks. A personâĂŹs behavior is the reflection of his/her personality. Psychological research suggests that peopleâĂŹs personalities have impacts on their positions in social networks. Feiler et al. [11] found that extraverted people have more friends than introverted people, and that two extraverts are more likely to become friends because of the homophily effect. Therefore, extraverted people are much more likely to be involved in social networks, which places them in central positions. Not only do different personalities have impacts on peopleâĂŹs positions in social networks, but also emotions can change peopleâĂŹs centrality in networks. PeopleâĂŹs emotions also relate to their personalities. Research indicates that people who have positive attitudes to life are attractive in social networks [8]. This is because people with high life satisfaction find it easy to attract their peersâĂŹ attention and alliances [15]. Those who have positive emotions like to experience positive emotions. Therefore, such persons tend to become extraverted. As we all know, outgoing people are much more active in social networks. They are likely to communicate with others and to make their positions more central.

3 DATA COLLECTION

3.1 Privacy Protection

Prior to participation, all participants provided a consent form and consented to take part in the study. They were debriefed after taking part in the experiments. Participants were informed that data gathered during this research would be coded and kept confidentially by the researcher, with only the researcher and supervisor having access; all information is stored with a code, and there is no immediately identifiable information. Part of the research involved taking photographic images. These images are kept secure and stored with no identifying factors, i.e., consent forms and questionnaires.

3.2 Facial Image and Social Network Data Collection

We used both online and offline campus advertisements to recruit college freshman participants who might be interested in this research in the universityâĂŹs freshman residential area. Student participants were required to be more than 18-year-old freshmen, who lived in several specific freshman residential buildings (next to each other) in the same area. A total of 185 participants (aged 18-20, mean = 19.07, SD = 0.18, males=102, female=84) were recruited (89% of the freshman in this area). They were called to the lab, they completed a social network questionnaire, and their photos were taken. This took place at the beginning of third month of freshman

registration of university entrance, and it lasted for one month. Monetary compensation was given for participation in the study.

When participants arrived at the lab, prior to participation, they provided a consent form and consented to take part in the study. Participants first reported their age, gender, country of birth, country of residence, and ethnicity via a questionnaire. They then listed up to eight people on six questions in random order with reference to additional name lists, which gave the names of all freshmen living in this area. Eight people should be listed with the priority from high to low: âĂIJ1âĂİ stands for the highest priority, and priority decreases in turn; âĂIJ8âĂİ stands for the lowest priority. The six questions are as follows: âĂIJPlease list your good friends.âĂİ âĂIJTo whom will you turn for help, when you have difficulties in study?âĂİ âĂIJTo whom will you turn for help, when you encounter some troubles in life?âĂİ âĂIJWhen you get a piece of good news, with whom will you share it?âĂİ âĂIJWhen you get a piece of bad news, with whom will you share it?âĂİ âĂIJWhom do you want to invite to join your team when you have a task that requires a team to accomplish it?âĂİ We also took face photographs of students after they completed the network questionnaire. Participants were instructed to look at the center of the camera lens with neutral expressions, hair pulled back, and no adornment. They were photographed under standardized lighting conditions with a fixed camera distance. They were debriefed after taking part in the experiments. A set of 185 images of 185 identities in six groups (30 or 31 images of each group) were thus available for the study.

3.3 Facial Perception Data Collection

A total of 180 participants (no freshmen) were recruited in the university with payment(aged 18-27, mean = 23.09, SD = 3.06, males=112, female=68). We used different participants from those freshmen to rate images because we focus on the effect of facial bias which frequently made by strangers. They were called to the lab for face rating by appointment. The set of stimuli for rating included 30 identity images (30 of 185 images in each block with no face identities repeated) with randomized allocation for different participants. Each image was rated by 30 participants. Each participant saw 30 images in a random order. Participants completed three ratings: trustworthiness, attractiveness, and dominance. Participants saw one image at a time. For trustworthiness (attractiveness or dominance) ratings, participants were instructed âĂIJYou will make judgements regarding trustworthiness (attractiveness or dominance). Please rate your impression from score 1 to 7 on how trustworthy (attractive or dominant) the face appearsâĂİ; they then rated the stimuli for perceived trustworthiness (attractiveness or dominance) on a seven-point Likert-type scale labelled (1) very negative and (7) very positive, with the question on the top of each facial image being âĂIJhow trustworthy (attractive or dominant) does this face appear?âĂİ For attractiveness rating, participants were given the instruction âĂIJYou will make judgements regarding attractiveness. Please rate your impression of how attractive this face is from 1 to 7.âĂİ Participants rated apparent attractiveness on this seven-point scale.

4 METHODS

To solve this kind of problem that explores the relation between facial perception and social network situation, we proposed a framework named PSP (Facial Perception and Social Situation Prediction Framework) (shown in Figure 1). In this framework, we proposed an entropy-based data processing method to remove the noise in questionnaire data. Each part included in the framework is introduced as follows.

4.1 Problem Formulation

We assumed that there is a photo of student i and this photo is evaluated by thirty people from three aspects: attractiveness, trustworthiness and dominance. In other word, the photo of student i will get three scores $[s_{i1}, s_{i2}, s_{i3}]$. In addition, we calculated the degree centrality of student i in six different social networks$[d_{i1}, d_{i2}, d_{i3}, d_{i4}, d_{i5}, d_{i6}]$. Then, we compute the correlation between photo scores and degree centrality of each network and explore the predictability of degree centrality using the photo scores.

4.2 Network Analysis

We carried out a detailed analysis of six social networks through several parameters as follows, in order to get a deep understanding to sample's social situation.

4.2.1 Degree correlation and assortativity coefficient. The degree distribution, which is the probability that there are nodes in a network with the degree of i, is defined as

$$P(i) = \frac{n(i)}{N}, \tag{1}$$

where $n(i)$ is the number of nodes with degree i and N is the total numbers of nodes in the network. The joint probability distribution of the network is defined as the proportion of edges between nodes with degree i and j:

$$P(i,j) = \frac{m(i,j)\mu(i,j)}{2M}, \tag{2}$$

where $m(i,j)$ is the number of edges between nodes with degree i and j and M represents the total number of edges. If $i = j$, then $\mu(i,j) = 2$, otherwise $\mu(i,j) = 1$. Then, the excess degree distribution is defined as

$$P_n(i) = \sum_{i=j_{min}}^{j_{max}} P(i,j), \tag{3}$$

where j_{min} and j_{max} are the minimum and maximum of nodes' degree in the network. The excess degree distribution indicates the probability that of choosing a node with degree i from the neighbors of a node chosen randomly.

Denote the degree distribution $P(i)$ as p_i, the joint probability distribution $P(i,j)$ as e_{ij}, and the excess degree distribution $P_n(i)$ as q_i, then the assortativity coefficient is defined as

$$r = \frac{1}{\sigma_q^2} \sum_{i,j} ij(e_{ij} - q_i q_j), \tag{4}$$

where $\sigma_q^2 = \sum_i i^2 q_i^2 - [\sum_i i q_i]^2$ is the variance of the excess degree distribution q_i. The assortativity coefficient r ranges from -1 to 1. If $r > 0$, then the network is assortative, which means that nodes with bigger degree prefer to connect with nodes with bigger degree,

and vice versa. The absolute value of r reflects the strength of assortativity or disassortativity of the network.

We can also use excess average degree to quantify the degree correlation of network approximately. The excess average degree neighbors is defined as

$$\langle k_{nn} \rangle_i = \frac{1}{k_i} \sum_{j=1}^{k_i} k_{i_j}, \tag{5}$$

where $k_i k_{i_j}$ is the degree of number i_jth neighbor of node i.

4.2.2 Clustering coefficient. The clustering coefficient quantifies the probability that the neighbors of node i are connected with each other. It is a frequently used metric for the community structure of a network. The clustering coefficient of a node i with degree of k_i is defined as

$$C_i = \frac{E_i}{(k_i(k_i-1))/2} = \frac{2E_i}{k_i(k_i-1)}, \tag{6}$$

where E_i is the numbers of edges existing among the k_i neighbors of node i.

4.3 Correlation Coefficient

PearsonâĂŹs correlation is used to explore the relation among facial perception features and spearman's correlation is used to explore the relation between facial perception feature and the centrality of six social networks because of the different scale.

4.3.1 SpearmanâĂŹs correlation. SpearmanâĂŹs correlation, also known as SpearmanâĂŹs rank correlation, measures the correlation of rank between two populations. Here, we use it in the analysis of the relationships between the scores of photos and their centralities in different social networks. The SpearmanâĂŹs rank correlation coefficient is defined as

$$r_S = 1 - \frac{6 \sum_{i=1}^{N} d_i^2}{N(N^2-1)}, \tag{7}$$

where N is the number of students in our experiment, and $d_i = r(S_i) - r(C_i)$, with $r(S_i)$ and $r(C_i)$ being the ranks of students' photo scores and centralities respectively.

4.3.2 PearsonâĂŹs correlation. PearsonâĂŹs correlation coefficient quantifies the linear correlation between two groups of continuous variables. The Pearson correlation coefficient is defined as

$$r_{X,Y} = \frac{E[(X-\mu_X)(Y-\mu_Y)]}{\sigma_X \sigma_Y}, \tag{8}$$

where μ and σ are the mean value and standard deviation of random variable X and Y, and $E(\cdot)$ is the expectation. Here, we use the Pearson correlation coefficient to analyze the linear relationships among three kinds of scores of studentsâĂŹ photos.

4.4 Prediction

First, we proposed a novel method that using information entropy to remove the noise in questionnaire data. Then, we redesigned our prediction task as binary classification task and used four classical classification algorithms to predict student centrality.

4.4.1 Feature Processing. As mentioned before, each photo was evaluated by a certain number of participants. Some participants evaluated all photos with same score or score with low separating capacity, because they didnâĂŹt take these questionnaires seriously. As the noise, these scores will impact experiment result. Here we borrowed the concept of entropy in information theory to remove these meaningless data. We proposed a participant entropy which is calculated according to the score they gave to each photo.

$$E = -\sum p(x) \log p(x) \tag{9}$$

where $p(x)$ represents the probability of occurrence of sample x.

4.4.2 Prediction Models. In the experiment, we used four classical classification methods to solve the prediction problem. First, we tried the k-nearest neighbor (KNN) classifier [6], which finds the top k nearest neighbors of a test sample in the train set on the feature space and makes predictions by vote. The idea of this method is very naive, namely that if samples are closer in the feature space, they are more likely to be in the same class.

Then, we observed two linear classification modelsâĂŹ performance, linear support vector classifier (linear SVC) [3, 17] and logistic regression (LR) [7]. Both identify hyperplanes in the feature space to split samples into different classes. However, these two algorithms obtain the best partition in different ways. The linear SVC looks for a hyperplane that maximizes the interval between two classes, that is,

$$\begin{cases} max_{\mathbf{w},b} & \frac{2}{\|\mathbf{w}\|} \\ s.t. & y_i(\mathbf{w}^T x_i) \geq 1, \quad i = 1, 2, 3 \cdots, \end{cases} \tag{10}$$

where y_i and x_i are labels and features of ith sample in the train set, and $\mathbf{w}$ is the normal vector of the hyperplane.

Logistic regression estimates the relative logarithm odds of a sample as a positive one, that is

$$\mathbf{w}^T \mathbf{x} + b = ln \frac{y}{1-y}, \tag{11}$$

where y is the odds of sample being a positive one, $\mathbf{x}$ is its feature vector, and $\mathbf{w}$ is its corresponding coefficient.

We also used a probability model, a Naive Bayesian classifier, which is based on the attribute conditional independence assumption,

$$P(c|\mathbf{x}) = \frac{P(c)P(\mathbf{x}|c)}{P(\mathbf{x})} = \frac{P(c)}{P(\mathbf{x})} \prod_{i=1}^{d} P(\mathbf{x}_i|c), \tag{12}$$

where $P(c|\mathbf{x})$ is the probability of a sample belonging to class c under the condition that its feature vector equals $\mathbf{x}$. The Naive Bayesian classifier involves a prior assumption of the sample distribution. Here we used the Gaussian distribution due to the distribution of data.

5 RESULTS

5.1 Facial Perception Analysis

To explore the relationship between the centrality of social networks and perception, photos of participants were measured in three dimensions: attractiveness, trustworthiness, and dominance, and the distributions of data of each dimension are shown in Figure 2. The average score for trustworthiness was higher than the scores

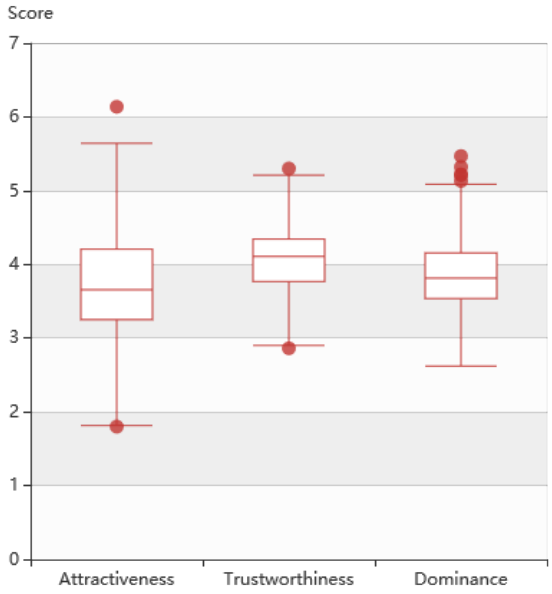

Figure 2: Box plot of attractiveness, trustworthiness, and dominance.

Table 1: Pearson's correlation coefficient

Score	Attractiveness	Trustworthiness	Dominance
Attractiveness	-	-	-
Trustworthiness	0.410**	-	-
Dominance	0.379**	0.179*	-

*p<0.05; **p<0.01

for other two aspects, and attractiveness scored lowest, which suggests that overall the freshmen prefer to trust strangers. For the dispersion level, the score for attractiveness was spread out further from its average value than others, as the span and interquartile range of attractiveness are much longer than the other two dimensions. For extreme outliers, compared with attractiveness and trustworthiness, participants give more extreme outliers on dominance. The distribution of data on these three dimensions has no significant skewness. In a word, Figure 2 suggests that students involved in our dataset covered almost all levels of facial appearance. Moreover, the correlations among attractiveness, trustworthiness, and dominance are shown in Table 1. Attractiveness has a relatively strong positive correlation with trustworthiness and dominance. The correlation between trustworthiness and dominance is also positive, but relatively weak. This means that people with high attractiveness can be trusted easily, and they can also be deemed to dominate.

5.2 Social Network Analysis

We built six directed networks defined by different types of relationships from our questionnaire. The nodes are all connected

Table 2: Correlation between three observed features and in-degree in six social networks

	Bad News	Friendship	Good News
Attractive	0.107	0.131	0.157*
Dominant	0.105	0.114	0.069
Trustworthy	0.152*	0.152*	0.143
	Social Advice	Academic Advice	Cooperation
Attractive	0.142	-0.055	0.084
Dominant	0.122	0.031	0.161*
Trustworthy	0.129	0.078	0.150*

* p<0.05

in these six directed networks. As we can see from Figure 3, the distributions of indegree for each of the six networks look like left-skewed bell-shaped curves. Due to the requirements of each questionnaire, most of the average indegree of the networks were about 6, except for the friendship network, with an average indegree of 6.72, which suggests that different friends meet different social requirement. For example, friends who are shopping together may not be suitable for starting a business together. However, in the bad news network, the average indegree is the lowest, and in most cases the indegree is around 5. This observation is consistent with general daily experience that bad news can only be shared with close friends. Moreover, about 75% of the indegrees are between 3 and 8, and the most frequent indegree is 5. Only a few individuals have a big indegree, which means that others prefer to choose them as listeners or helpers. In other words, few individuals occupy a center position in the social networks. This verifies the view that the Matthew Effect exists in social networks. Furthermore, four networksâĂŹ clustering coefficients are around 0.37, while they are about 0.33 in the cooperation and academic advice networks. Compared to some typical social networks, all these clustering coefficients are lower. This is probably because the individuals we researched are freshmen, and their social networks are still at an early stage. Their circles of friend are still narrow, so some friends may not know each other. As time goes by, more commonality will develop between students, and increasing links will appear, resulting in a higher clustering coefficient.

In Figure 4 we visualized the joint probability distribution of the indegree in all six networks. Note that nodes in all networks with a median indegree (with 8 to 10 nodes pointing to them) can have connections with higher probabilities (but no higher than 0.05, which is relatively very small), as there are more students in the social networks attracting 8 to 10 friends. We can also see this result from the indegree distribution and the excess degree distribution. Additionally, we computed the assortativity coefficient in these six networks, and we noticed that the values are all very low (less than 0.2). This result indicates that there are no obvious correlations between the connections of the indegree of node pairs.

Figure 5 shows the correlation between indegree and excess average degree, which is the average degree of their neighbors. There is an obvious negative correlation in all these six networks. This

indicates that students prefer to choose people who are different than themselves.

5.3 Correlation Analysis

To explore the relations between facial appearance and social situation, we performed an analysis on the correlation between the three observed features and the indegrees in six social networks. All findings are shown in Table 2.

The results show that trustworthiness is related to the indegrees in the bad news and friends networks, as shown in Figure 6 (both with a correlation coefficient of 0.152 and $p < 0.05$). For the choice of people as good friend, trustworthiness is more important than attractiveness and dominance (shown in Figure 7), which confirms a saying by Epicurus: without confidence, there is no friendship. People prefer to share bad news with people who get high scores in trustworthiness, which is consistent with common sense in that people would far rather show their bad side to trustworthy people than those with beautiful facial appearances. This also suggests that part of the role of a friend is to share pain.

When it comes to the good news spreading network, on the contrary, studentsâĂŹ attractiveness shows a significant correlation with indegree (with a correlation coefficient of 0.157 and $p-value < 0.05$). This means that the people with whom one can share bad news are not the same people with whom one can share good news. The purpose of sharing bad news is to share the pain and to get comfort. However, the purpose of sharing good news is not just sharing happiness, but also showing oneâĂŹs good side to the person with good facial appearance, possibly to reduce the psychological gap caused by facial appearance. [1]

Compared with the scenarios of choosing friends, sharing good news and sharing bad news, the following three scenarios are relatively rational. In the cooperation network, both dominance and trustworthiness are significant, which indicates that while people want to build a team, the one who shows enough dominant force and looks more trustworthy is more favorable. It is the only time that participants take dominance into account. In psychology, dominance is a measure of a personâĂŹs characteristic feelings of control and influence over his/her life circumstances versus feelings of being controlled and influenced by others or events. If attractiveness represents external competitiveness, then dominance represents inherent competitiveness, giving people confidence. In such a rational sense with a clear goal to complete a task, it suggests than students prefer to choose someone with inherent competitiveness over someone with a beautiful appearance. For social advice and academic advice, facial appearance does not have any effect statistically. In these two scenarios, the situation is so complicated, including making decisions on various questions, that it is difficult to make a decision solely according to facial appearance.

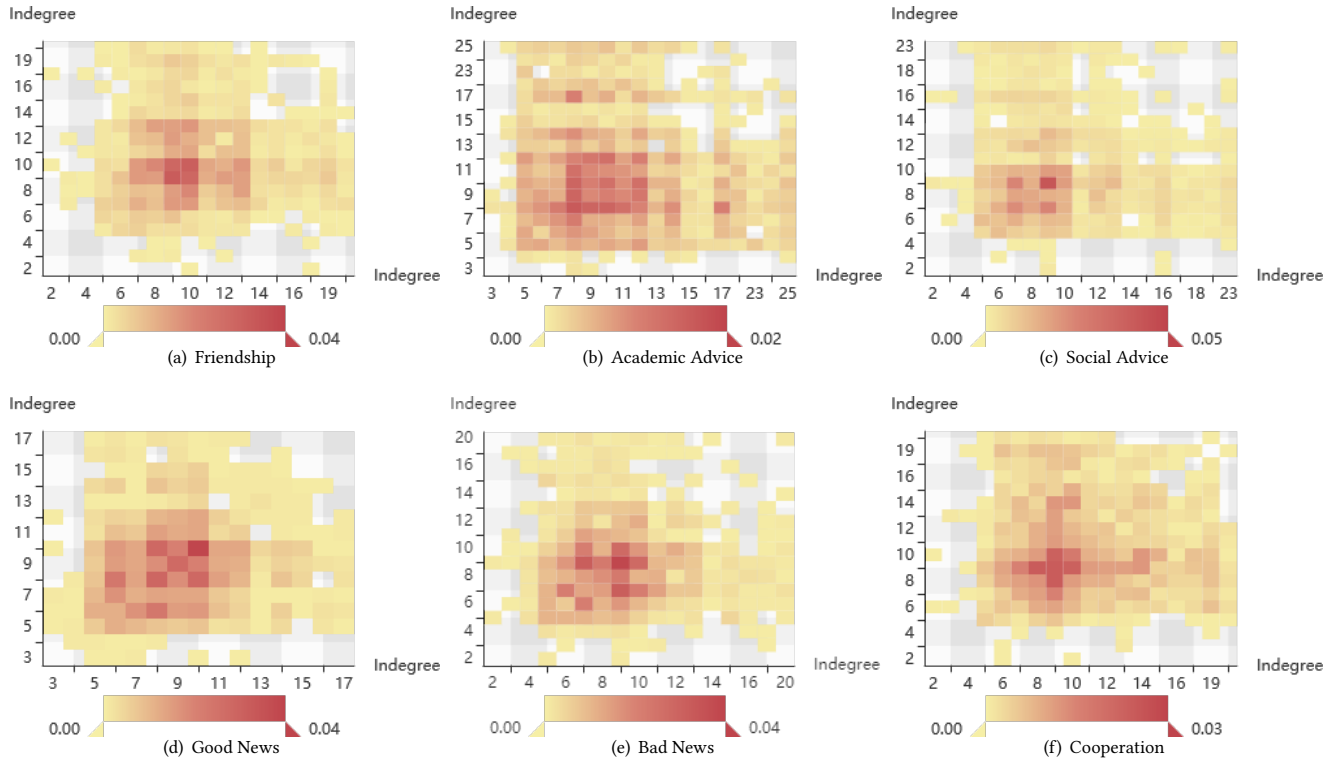

Figure 4: Joint probability distribution for the six social networks.

In addition, these findings also suggest that the main factors taken into account in various social scenarios differ. Finally, compared with attractive and dominance, trustworthiness is more important for peopleâĂŹs social lives, because three of these six social scenarios involve trust. In other words, being a trustworthy person will give you a good chance of being in a favorable social situation.

5.4 Prediction

The significant correlations imply that the three features extracted from facial appearance can predict studentsâĂŹ centrality in different social networks. To explore their predictive power, we carried out an experiment using the score of three aspects from studentâĂŹs facial appearance to predict their centrality in six different social networks. Excluding some incomplete or error data records, we got 185 samples in the experiment dataset. All three facial appearance quantification scores (attractiveness, dominance, and trustworthy) featured in the six observed networks. As every photo was quantified by 30 participants, we computed the average score from the final points. We performed our prediction task as a binary classification problem, which predicted whether a node could be high degree (with indegree higher than the median of population) or not.

We divided the dataset into two categories by degree of centrality: high and low. We used machine learning to predict the categories of the participants from their scores on the three dimensions. First, we removed 30 participants randomly from the dataset by stratified sampling to use as a test set, and we used the rest of the data as a train set. We performed a fivefold cross-validation on the train set to tune the super parameters of the predictive models, k-nearest neighbors, linear support vector classifier, naive Bayes classifier, and logistic regression, which are long-standing classical binary classification algorithms.

We calculated the participant entropy of each participant according to the score they gave to each photo. We assumed that there is a positive correlation between participant entropy and the validity of data given by participant. The higher the entropy gets, the more valid the data is. In this study, we removed 20%, 30% and 40% low entropy data respectively to remove the noise existed in data and the performances are shown in Figure 8.

Because the proportions of the positive and the negative are equal in the dataset, we used the accuracy value to evaluate the result of prediction. The accuracy value ranges from 0 to 1, with 0.5 being random chance in this condition; therefore, the predictive power is the extent to which the accuracy value exceeds 0.5.

Prediction results are shown in Figure 8. Obviously, it is notable that three features extracted from facial appearance are effective for predicting the centrality of four different networks (friendship network, bad news network, good news network and cooperation network) because all accuracy values exceed 0.5. The prediction result of removing 30% low-entropy data is the best. The result of removing 20% data is lower possibly because noise still exist in data, while the result of removing 40% data is lower possibly because

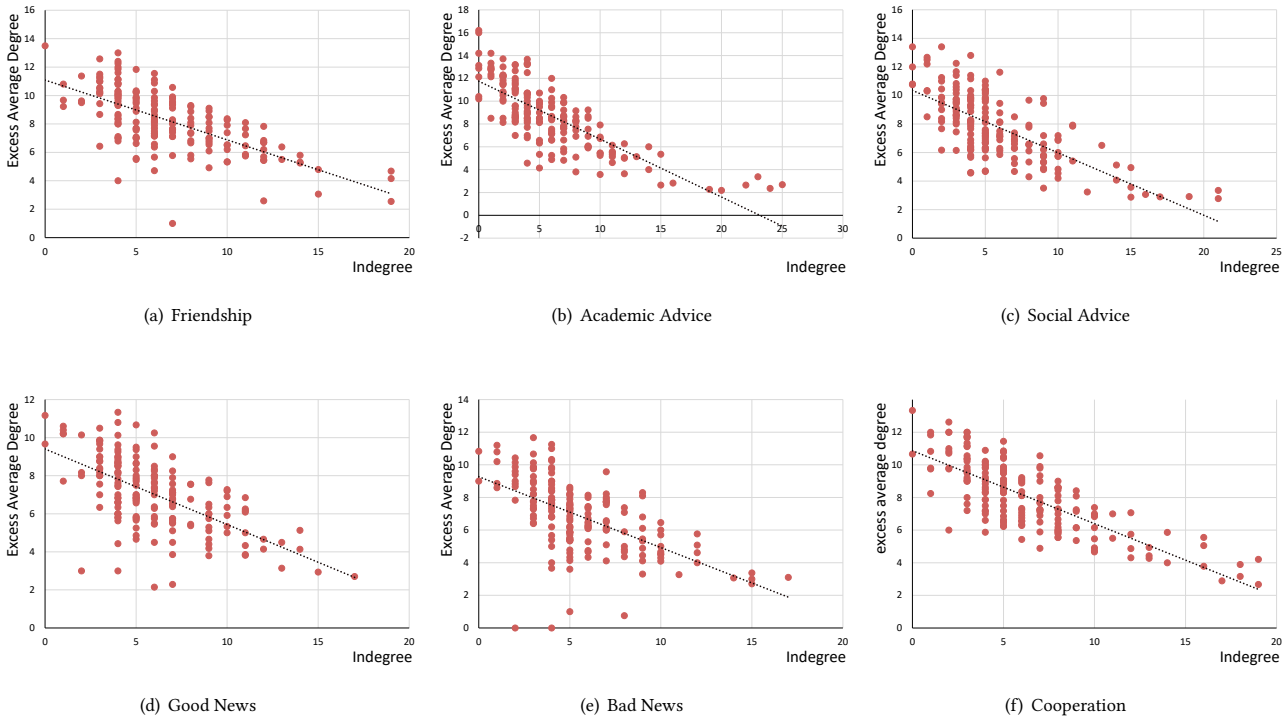

Figure 5: The correlation between indegree and excess average degree for each network.

some meaningful data is lost. In addition, accuracies of prediction in the social advice network and the academic advice network are relatively low, which is consistent with the previous findings about their correlation coefficients.

6 CONCLUSIONS

In this paper, we collected face perception data from freshmen in college to explore how appearance could impact the individualsâĂŹ

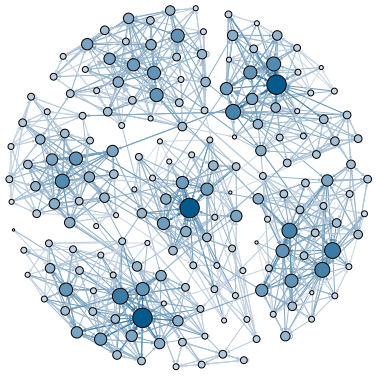

Figure 6: Sketch of the friendship network. The node represents student and the diameter of the nodes in the network indicates the trustworthiness score given by others.

centrality in different social networks. We selected six questions to capture their social relations in different scenarios, namely a friendship network, a good news network, a bad news network, a social advice network, an academic advice network, and a cooperation network. Experimental results show that perceived facial traits can predict the centrality of different networks. We proposed a PSP framework to discover the effect of facial perception on social situation and the experimental results verify its performance. Our

framework mechanism has a certain universality, which can be applied to the prediction of centrality in different social networks by reducing noise to improve the prediction accuracy. Our findings suggest that peopleâĂŹs appearance can impact their social situations at an early social stage in which people are not very familiar with each other. To the best of our knowledge, we are the first to explore the influence of facial appearance on centrality in social networks.

Our results also contribute to the psychological knowledge of facial perception, because they are consistent with previous research that facial appearance affects network-based social behaviors. Prior studies only examined the relationship between faces and behaviors in social network settings without using social network analysis and techniques, whose analysis might be limited and might lack depth. This paper sheds light on a novel approach by showing that apparent facial features can be evaluated and predicted by social network analysis and machine learning. In addition, our findings offer insights on a combination of psychological and social network techniques, and they highlight the function of facial bias in cueing and signaling social traits.

Our research is limited by the relatively small sample size, because obtaining a larger number of participants would be very challenging. The privacy and confidentiality of human participants was very important in this research, in that participantsâĂŹ photographs were taken and judged, and their social networks were reported. Accessing a large number of volunteers who are willing to participate such research is a challenge. However, a thorough analysis of social network from a novel, face-based perspective in this paper may remedy the limitations to some extent. Future work could obtaining a larger dataset to facilitate a more in-depth investigation.

ABSTRACT

Measuring the distances between vertices on graphs is one of the most fundamental components in network analysis. Since finding shortest paths requires traversing the graph, it is challenging to obtain distance information on large graphs very quickly. In this work, we present a preprocessing algorithm that is able to create landmark based distance sketches efficiently, with strong theoretical guarantees. When evaluated on a diverse set of social and information networks, our algorithm significantly improves over existing approaches by reducing the number of landmarks stored, preprocessing time, or stretch of the estimated distances.

On Erdos-Renyi graphs and random power law graphs with degree distribution exponent $2 < \beta < 3$, our algorithm outputs an exact distance data structure with space between $\Theta(n^{5/4})$ and $\Theta(n^{3/2})$ depending on the value of β, where n is the number of vertices. We complement the algorithm with tight lower bounds for Erdos-Renyi graphs and the case when β is close to two.

1 INTRODUCTION

Computing shortest path distances on large graphs is a fundamental problem in computer science and has been the subject of much study [27, 36, 37]. In many applications, it is important to compute the shortest path distance between two given nodes, i.e. to answer shortest path queries, in real time. Graph distances measure the closeness or similarity of vertices and are often used as one of the most basic metric in network analysis [29, 35, 39, 40]. In this paper, we will focus on efficient and practical implementations of shortest path queries in classes of graphs that are relevant to web search, social networks, and collaboration networks etc. For such graphs, one commonly used technique is that of *landmark-based labelings*: every node is assigned a set of landmarks, and the distance between two nodes in computed only via their common landmarks. If the set of landmarks can be easily computed, and is small, then we obtain both efficient pre-processing and small query time.

Landmark based labelings (and their more general counterpart, *Distance Labelings*), have been studied extensively [9, 36]. In particular, a sequence of results culminating in the work of Thorup and Zwick [37] showed that labeling schemes can provide a multiplicative 3-approximation to the shortest path distance between any two nodes, while having an overhead of $O(\sqrt{n})$ storage per node on average in the graph (we use the standard notation that a graph has n nodes and m edges). In the worst case, there is no distance labeling scheme that always uses sub-quadratic amount of space and provides exact shortest paths. Even for graphs with maximum degree 3, it is known that any distance labeling scheme requires $\Omega(n^{3/2})$ total space [26]. In sharp contrast to these theoretical results, there is ample empirical evidence that very efficient distance labeling schemes exist in real world graphs that can achieve much better approximations. For example, Akiba et al. [3] and Delling et al. [20] show that current algorithms can find *landmark based labelings* that use only a few hundred landmarks per vertex to obtain *exact distance*, in a wide collection of social, Web, and computer networks with millions of vertices. In this paper, we make substantial progress towards closing the gap between theoretical and observed performance. We show that natural landmark based labeling schemes can give exact shortest path distances with a small number of landmarks for a popular model of (unweighted and undirected) web and social graphs, namely the heavy-tailed random graph model. We also formally show how further reduction in the number of landmarks can be obtained if we are willing to tolerate an additive error of one or two hops, in contrast to the multiplicative 3-approximation for general graphs. Finally, we present practical versions of our algorithms that result in substantial performance improvements on many real-world graphs.

In addition to being simple to implement, landmark based shortest path algorithms also offer a qualitative benefit, in that they can directly be used as the basis of a social search algorithm. In social search [8], we assume there is a collection of keywords associated with every node, and we need to answer queries of the following form: given node v and keyword w, find the node that is closest to v among all nodes that have the keyword w associated with them. This requires an index size that is $O(L)$ times the size of the total social search corpus and a query time of $O(L)$, where L is the number of landmarks per node in the underlying landmark based algorithm; the approximation guarantee for the social search problem is the same as that of the landmark based algorithm. Thus, our results lead to both provable and practical improvements to the social search problem.

Existing models for social and information networks build on random graphs with some specified degree distribution [15, 22, 38], and there is considerable evidence that real-world graphs have power-law degree distributions [16, 23]. We will use the Chung-Lu

model [14], which assumes that the degree sequence of our graph is given, and then draws a "uniform" sample from graphs that have the same or very similar degree sequences. In particular, we will study the following question: *Given a random graph from the Chung-Lu model with a power law degree distribution of exponent β, how much storage does a landmark-based scheme require overall, in order to answer distance queries with no distortion?*

In the rest of the paper, we use the term "random power law graph" to refer to a graph that is sampled from the Chung-Lu model, where the weight (equivalently, the expected degree) of each vertex is independently drawn from a power law distribution with exponent β. We are interested in the regime when $\beta > 2$ — this covers most of the empirical power law degree distributions that people have observed on social and information networks [16]. Admittedly, real-world graphs have additional structure in addition to having power-law degree distributions [34], and hence, we have also validated the effectiveness of our algorithm on real graphs.

1.1 Our Results

Our first result corresponds to the "easy regime", where the degree distribution has finite variance ($\beta > 3$). We show that a simple procedure for generating landmarks guarantees exact shortest paths, while only requiring each node to store $\tilde{O}(\sqrt{n})$ landmarks. The same conclusion also applies to Erdős-Renyi graphs $G(n, \frac{c}{n})$ when $c > 1$, or when $c = 2 \log n$.

We then study the case where $2 < \beta < 3$. This is the most emblematic regime for power-law graphs, since the degree distribution has infinite variance but finite expectation. We present an algorithm that generates at most $\tilde{O}(n^{(\beta-2)/(\beta-1)})$ landmarks per node when $\beta \geq 2.5$; and $\tilde{O}(n^{(3-\beta)/(4-\beta)})$ landmarks per node when $2 < \beta < 2.5$. We obtain additional improvements if we allow an additive error of 1 or 2. See Figure 1 for an illustration of our results.

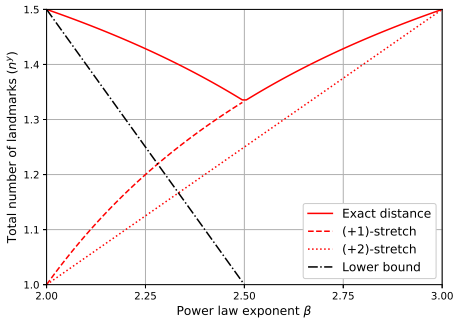

Figure 1: The x-axis is the exponent of the power law degree distribution and each value on the y-axis corresponds to a storage of $\tilde{O}(n^y)$. The lower bound is for exact distances.

While the dependence on β is complex, it is worth noting that in the entire range that we study ($\beta > 2$), the number of landmarks per node is at most $\tilde{O}(\sqrt{n})$ for *exact shortest paths*. This is in stark contrast to known impossibility results for general graphs, where no distance labeling with a multiplicative stretch less than 3 can use sub-linear space per node [26]. The query time of our algorithms is proportional to the number of landmarks per node, so we also get speed improvements.

Our algorithm is based on the pruned labeling algorithm of Akiba et al. [3], but differs in important ways. The pruned labeling algorithm initially posits that every node is a landmark for every other node, and then uses the BFS tree from each node to iteratively prune away unnecessary landmarks. In our approach, we apply a similar BFS with pruning procedure on a small subset of H (i.e. high degree vertices), but switch to lightweight local ball growing procedures up to radius l for all other vertices. As we show, the original pruned labeling algorithm requires storing $\tilde{\Omega}(n^2)$ landmarks on sparse Erdös-Rényi graphs. By growing local balls of size $\sqrt{n}$, our algorithm recovers exact distances with at most $\tilde{O}(n^{3/2})$ landmarks instead, for Erdös-Rényi graphs and random power law graphs with $\beta > 3$. Hence, our algorithm combines exploiting the existence of high-degree "central landmarks" with finding landmarks that are "locally important". Furthermore for $2 < \beta < 3$, by setting up the number of global landmarks H and the radius l suitably, we provably recover the upper bounds described in Figure 1. While the algorithmic idea is quite simple, the analysis is intricate.

We complement our algorithmic results with tight lower bounds for the regime when $\beta > 3$: the total length of any distance labeling schemes that answer distance queries exactly in this regime is almost surely $\tilde{\Omega}(n^{1.5})$. We also show that when $2 < \beta < 2.5$, any distance labeling scheme will generate labels of total size $\tilde{\Omega}(n^{3.5-\beta})$ almost surely. In particular, our algorithm achieves the optimal bound when β is close 2.

The parameter choice suggested by our theoretical analysis can be quite expensive to implement (as can earlier landmark based algorithms). We apply a simple but principled parameter tuning procedure to our algorithm that substantially improves the preprocessing time and generates a smaller set of landmarks at essentially no loss of accuracy. We conduct experiments on several real world graphs, both directed and undirected. First, compared to the pruned labeling algorithm, we find that our algorithm reduces the number of landmarks stored by 1.5-2.5x; the preprocessing time is reduced significantly as well. Next, we compare our algorithm to a variant of the distance oracle of Thorup and Zwick [37], which is believed to be theoretically optimal for worst-case graphs, as well as the distance sketch of Das Sarma et al [19] which has been found to be both efficient and useful in prior work [8]. For each graph, our algorithm substantially outperforms these two benchmarks. Details are in Section 5. It is important to note that the three algorithms we compare to also work much better on these real-world graphs than their theoretical guarantee, and we spend considerable effort tuning their parameters as well. Hence, the performance improvement given by our algorithm is particularly noteworthy.

It is worth mentioning that our technical tools only rely on bounding the growth rate of the breadth-first search. Hence we expect that our results can be extended to the related configuration model [22] as well. One limitation of our work is that the analysis does not apply directly to preferential attachment graphs, which correspond to another family of well known power law graphs. But we believe that similar results can be obtained there by adapting our analysis to that setting as well. This is left for future work.

Organizations: The rest of the paper is organized as follows. Section 2 introduces the basics of random graphs, reviews the pruned labeling algorithm and related work. Section 3 introduces our approach. We then present the analysis and experiments in Section 4 and Section 5. The lower bounds are presented in Section 6.

2 PRELIMINARIES AND RELATED WORK

2.1 Notations

Let $G = (V, E)$ be a directed graph with $n = |V|$ vertices and $m = |E|$ edges. For a vertex $x \in V$, denote by $d_{out}(x)$ the outdegree of x and $d_{in}(x)$ the indegree of x. Let $\mathcal{N}_{out}(x)$ denote the set of its out neighbors. Let $\text{dist}_G(x, y)$ denote the distance of x and y in G, or $\text{dist}(x, y)$ for simplicity. When G is undirected, then the outdegrees and indegrees are equal. Hence we simply denote by d_x the degree of every vertex $x \in V$. For an integer l and $x \in V$, denote by $\Gamma_l(x) = \{y : \text{dist}(x, y) = l\}$ the set of vertices at distance l from x. Denote by $N_l(x)$ the set of vertices at distance at most l from x.

We use notation $a \lesssim b$ to indicate that there exists an absolute constant $C > 0$ such that $a \leq Cb$. The notations $\tilde{O}(\cdot)$ and $\tilde{\Omega}(\cdot)$ hide poly-logarithmic factors.

2.2 Landmark based Labelings

In a landmark based labeling [21], each vertex x is assigned a set of forward landmarks $L_F(x)$ and backward landmarks $L_B(x)$. Each landmark set is a hash table, whose keys are vertices and values are distances. For example, if $y \in L_F(x)$, then the value associated with y would be $\text{dist}(x, y)$, which is the "forward" distance from x to y. Given the landmark sets $L_F(\cdot)$ and $L_B(\cdot)$, we estimate the distances as follows:

$$\min_{z \in L_F(x) \cap L_B(y)} \text{dist}(x, z) + \text{dist}(z, y), \forall x, y \in V. \tag{1}$$

If no common vertex is found between $L_F(x)$ and $L_B(y)$, then y is not reachable from x. In the worst case, computing set intersection takes $\Omega(\min(|L_F(x)|, |L_B(y)|))$ time.

Denote the output of equation (1) by $\hat{d}$. Clearly, we have $\hat{d} \geq \text{dist}(x, y)$ when y is reachable from x. The *additive stretch* of $\hat{d}$ is given by $\hat{d} - \text{dist}(x, y)$, and the *multiplicative stretch* is given by $\hat{d}/\text{dist}(x, y)$. When there are no errors for any pairs of vertices, such landmark sets are called *2-hop covers* [17].

There is a more general family of data structures known as labeling schemes [26], which associates a vector $\mathcal{L} : V \to \{0, 1\}^*$ for every vertex. When answering a query for a pair of vertices $x, y \in V$, only the two labels $\mathcal{L}(x)$ and $\mathcal{L}(y)$ are required without accessing the graph. The total length of $\mathcal{L}$ is given by $\sum_{x \in V} |\mathcal{L}(x)|$. It is clear from equation (1) that landmark sketches fall in the query model of labeling schemes.

2.3 The Pruned Labeling Algorithm

We review the pruned labeling algorithm [3] for readers who are not familiar. The algorithm starts with an ordering of the vertices, $\{x_1, x_2, \ldots, x_n\}$. First for x_1, a breadth first search (BFS) is performed over the entire graph. During the BFS, x_1 is added to the landmark set of every vertex.[1] Next for x_2, in addition to running BFS, a *pruning* step is performed before adding x_2 as a landmark. For example, suppose that a path of length l is found from x_2 to y. If x_1 lies on the shortest path fom x_2 to y, then by checking their landmark sets, we can find the common landmark x_1 to certify that $\text{dist}(x_2, y) = \text{dist}(x_2, x_1) + \text{dist}(x_1, y) \leq l$. In this case, x_2 is not added to y's landmark set, and the neighbors of y are pruned away. The above procedure is repeated on x_3, x_4, etc.

For completeness, we describe the pseudocode in Algorithm **??**. Note that the backward BFS procedure can be derived similarly. It has been shown that the pruned labeling algorithm is guaranteed to return exact distances [3].

Algorithm 1 PrunedLabeling (Akiba et al. [3])

Input: A directed graph $G = (V, E)$; An ordering of V, $\{x_1, x_2, \ldots, x_n\}$.

Let $O = \emptyset$, and $L_F(x) = L_B(x) = \emptyset$, for all $x \in V$
for $i = 1, \ldots, n$ **do**
    forwardBfs(x_i)
    backwardBfs(x_i)
    $O = O \cup \{x_i\}$
end for

procedure forwardBfs(x_i)
    Let Q be a priority queue and S be a hash set
    Set the priority of x_i to be zero
    while $Q \neq \emptyset$ **do**
        Let l be the minimum priority of Q
        Let u be the corresponding vertex
        $S = S \cup \{u\}$
        Let $\tilde{d} = \min_{y \in L_F(x_i) \cap L_B(u)} \text{dist}(x_i, y) + \text{dist}(y, u)$
        if $l < \tilde{d}$ **then** (otherwise u's neighbors are pruned)
            $L_B(u) = L_B(u) \cup \{x_i \to l\}$
            for $y \in \mathcal{N}_{out}(u)$ such that $y \notin O$ **do**
                Let q be the priority of y
                if $y \notin S$ and $l + 1 < q$ **then**
                    Decrease y's priority to $l + 1$
                end if
            end for
        end if
    end while
end procedure

2.4 Random Graphs

We review the basics of Erdös-Rényi random graphs. Let $G = G(n, p)$ be an undirected graph where every edge appears with probability p. It is well known that when $p \geq 2(\log n)/n$, G has only one connected component with high probability. Moreover, the neighborhood growth rate (i.e. $|\Gamma_{i+1}(x)| \,/\, |\Gamma_i(x)|$) is highly concentrated around its expectation, which is np. Formally, the following facts are well-known.

Fact 1 (Bollobás [10]). *Let $G = (V, E)$ be an undirected graph where every edge is sampled with probability $p = 2(\log n)/n$. Let $D = \lceil \frac{\log n}{\log(np)} \rceil$. Then the following are true with high probability:*

a) *The diameter of G is at most $D + 1$;*
b) *For any $x, y \in V$ and $l \leq D$, $\Pr(\text{dist}(x, y) \leq l) \leq \frac{(np)^{l+1}}{n(np-1)}$;*
c) *For any $x \in V$ and $l < D$, we have $\frac{1}{2} \leq \frac{|\Gamma_l(x)|}{(np)^l} \leq 2$.*

The Chung-Lu model: Let $p_x > 0$ denote a weight value for every vertex $x \in V$. Given the weight vector $\mathbf{p}$, the Chung-Lu model generalizes Erdös-Rényi graphs such that each edge is chosen independently with probability

$$\Pr[x \sim y] = \min\left\{\frac{p_x \cdot p_y}{\text{vol}(V)}, 1\right\}, \forall x, y \in V$$

[1] For directed graphs, there will be a forward BFS which looks at x_1's outgoing edges and its descendants, as well as a backward BFS which looks at x_1's incoming edges and its predecessors.

where $\text{vol}(V) = \sum_{x \in V} p_x$ denote the volume of V.

Random power law graphs: Let $f : [x_{\min}, \infty) \to \mathbb{R}$ denote the probability density function of a power law distribution with exponent $\beta > 1$, i.e. $f(x) = Zx^{-\beta}$, where $Z = (\beta - 1) \cdot x_{\min}^{\beta-1}$ [16]. The expectation of $f(\cdot)$ exists when $\beta > 2$. The second moment is finite when $\beta > 3$. When $\beta < 3$, the expectation is finite, but the empirical second moment grows polynomially in the number of samples with high probability. If $\beta < 2$, then even the expectation becomes unbounded as n grows.

In a random power law graph, the weight of each vertex is drawn independently from the power law distribution. Given the weight vector $\mathbf{p}$, a random graph is sampled according to the Chung-Lu model. If the average degree $\nu > 1$, then it is known that almost surely the graph has a unique giant component [15].

2.5 Related Work

Landmark based labelings: There is a rich history of study on how to preprocess a graph to answer shortest path queries [2, 4, 5, 11, 17, 37]. It is beyond our scope to give a comprehensive review of the literature and we refer the reader to survey [36] for references.

In general, it is NP-hard to compute the optimal landmark based labeling (or 2-hop cover). Based on an LP relaxation, a $\log n$ factor approximation can be obtained via a greedy algorithm [18]. See also the references [6, 7, 12, 21, 28] for a line of followup work. The current state of the art is achieved based on the pruned labeling algorithm [3, 20]. Apart from the basic version that we have already presented, bit-parallel optimizations have been used to speed up proprocessing [3]. Variants which can be executed when the graph does not fit in memory have also been studied [30]. It is conceivable that such techniques can be added on top of the algorithms that we study as well. For the purpose of this work, we will focus on the basic version of the pruned labeling algorithm. Compared to classical approaches such as distance oracles, the novelty of the pruned labeling algorithm is using the idea of *pruning* to reduce redundancy in the BFS tree.

Network models: Earlier work on random graphs focus on modeling the small world phenomenon [15], and show that the average distance grows logarithmically in the number of vertices. Recent work have enriched random graph models with more realistic features, e.g. community structures [31], shrinking diameters in temporal graphs [32].

Other existing mathematical models on special families of graphs related to distance queries include road networks [1], planar graphs and graphs with doubling dimension. However none of them can capture the expansion properties that have been observed on subnetworks of real-world social networks [34].

Previous work of Chen et al. [13] presented a 3-approximate labeling scheme requiring storage $\tilde{O}(n^{(\beta-2)/(2\beta-3)})$ per vertex, on random power law graphs with $2 < \beta < 3$. Our (+2)-stretch result improves upon this scheme in the amount of storage needed per vertex for $2 < \beta < 2.5$, with a much better stretch guarantee. Another related line of work considers compact routing schemes on random graphs. Enachescu et al. [24] presented a 2-approximate compact routing scheme using space $O(n^{1.75})$ on Erdös-Rényi random graphs, and Gavoille et al. [25] obtained a 5-approximate compact routing scheme on random power law graphs.

3 OUR APPROACH

In order to motivate the idea behind our approach, we begin with an analysis of the pruned labeling algorithm on Erdös-Rényi random graphs. While the structures of real world graphs are far from Erdös-Rényi graphs, the intuition obtained from the analysis will be useful. Below we describe a simple proposition which states that for sparse Erdös-Rényi graphs, the pruned labeling algorithm outputs $\tilde{\Omega}(n^2)$ landmarks.

Proposition 2. *Let $G = (V, E)$ be an undirected Erdös-Rényi graph where every edge appears with probability $p = 2(\log n)/n$. For any ordering of the vertices $V = \{x_1, x_2, \ldots, x_n\}$, with high probability over the randomness of G, the total number of landmarks produced by Algorithm **??** is at least $\tilde{\Omega}(n^2)$.*

Proof sketch. We first introduce a few notations. Let $r = np$ denote the growth rate of G. Let $\varepsilon = 1/\log n$. Consider a vertex x_i where $1 \le i \le \varepsilon n$. Denote by $X_{-i} = \{x_1, \ldots, x_{i-1}\}$. Consider any $u \in V$, if none of the shortest paths from x_i to u intersect with X_{-i}, then (x_i, u) is called a *bad* pair. Note that x_i must be added to u's landmark set by Algorithm **??**, because during the BFS from x_i, all estimates through X_{-i} will be strictly larger than $\text{dist}(x_i, u)$. Hence, to lower bound the total landmark sizes, it suffices to count the number of *bad* pairs. In the following, we show that in expectation for every x_i where $1 \le i \le \varepsilon n$, there are at least $n/(\log n)^3$ vertices u such that (x_i, u) are *bad*. It follows that Algorithm **??** requires at least $\varepsilon n^2/(\log n)^3 \ge \tilde{\Omega}(n^2)$ in expectation.

Let $D = \lfloor \log_r n - 2 \rfloor$. Consider $\Gamma_D(x_i)$, the set of vertices at distance equal to D from x_i. We count the number of *bad* vertices in $\Gamma_D(x_i)$ at follows. For each $1 \le k \le D$, consider the intersection $\Gamma_k(x_i) \cap X_{-i}$ and their subtree down to $\Gamma_D(x_i)$.

Starting from any $y \in \Gamma_k(x_i) \cap X_{-i}$, the subtree of y would result in *good* vertices in $\Gamma_D(x_i)$, whose distance from x_i can be correctly estimated (c.f. line 15-16 in Algorithm **??**). In expectation, the size of the intersection is $r^k\varepsilon$, because the probability that any two vertex has distance k on G is equal to r^k/n, and there are at most εn vertices in X_{-i}. Next, each y results in r^{D-k} vertices in its $(D-k)$-th level neighborhood. Combined together, the total number of *good* vertices which are covered by $\Gamma_k(x_i) \cap X_{-i}$ is at most $r^k\varepsilon \times r^{D-k} = \varepsilon r^D$. By summing over all $k \le D$, we obtain that the total number of *good* vertices in $\Gamma_D(x_i)$ is at most $D\varepsilon r^D$.

On the other hand, the size of $\Gamma_D(x_i)$ is r^D. Hence the total number of *bad* vertices is at least $(1 - D\varepsilon)r^D \ge n/\log^3 n$. To show that the the proposition holds with high probability, it suffices to apply concentration results on neighborhood growth in the arguments above. We omit the details.

□

The interesting point from the above analysis is that $\Theta(n)$ landmarks are added throughout the first εn vertices. The reason is that there are no high degree vertices in Erdös-Rényi graphs, hence the landmarks we have added in the beginning do not cover the shortest paths for many vertex pairs later.Secondly, a large number of distant vertices are added in the landmark sets, which do not lie on the shortest paths of many pairs of vertices.

Motivated by the observation, we introduce our approach as follows. We start with an ordering of the vertices. For the top H

vertices in the ordering, we perform the same BFS procedure with pruning. For the rest of the vertices, we simply grow a local ball up to a desired radius. Concretely, only the vertices from the local ball will be used as a landmark. Algorithm **??** describes our approach in full.[2] As a remark, when the input graph G is undirected, it suffices to run one of the forward or backward BFS procedures, and for each vertex, its forward and backward landmark sets can be combined to a single landmark set.

Algorithm 2 ApproximatePruning

Input: A directed graph $G = (V, E)$; An ordering of V $\{x_1, x_2, \ldots, x_n\}$; The number of global landmarks H; The set of radiuses $\{l_i\}_{i=H+1}^{n}$.

Let $O = \emptyset$, and $L_F(x) = L_B(x) = \emptyset$, for any $x \in V$.
for $i = 1, \ldots, H$ **do**
  forwardBfs(x_i)
  backwardBfs(x_i)
  $O = O \cup \{x_i\}$
end for
for $i = H + 1, \ldots, n$ **do**
  localForwardBfs(x_i, l_i)
  localBackwardBfs(x_i, l_i)
end for
procedure localForwardBfs(x_i, l_i)
  for y such that $\text{dist}(x_i, y) \le l_i - 1$ **do**
    $L_F(x_i) = L_F(x_i) \cup (y \to \text{dist}(x_i, y))$
  end for
  for y such that $\text{dist}(x_i, y) = l_i$ and $\exists z$ s.t. $\text{dist}(x, z) = l_i - 1$, $(z, y) \in E$, $d_{out}(z) \le d_{out}(y)$ **do**
    $L_F(x_i) = L_F(x_i) \cup (y \to \text{dist}(x_i, y))$
  end for
end procedure

Recall that the backward and forward BFS procedures do a breadth first search with a pruning step before enqueing a vertex (c.f. Algorithm **??**). For each x_i with $i > H$, the parameter l_i controls the depth of the local ball we grow from x_i. Furthermore, at the bottom layer, we only add vertices whose outdegree is higher than any of its predecessor to x_i's landmark set. The intuition is that vertices with higher outdegrees are more likely to be used as landmarks.

We begin by analyzing Algorithm **??** for Erdös-Rényi graphs, as a comparison to Proposition 2. The following proposition shows that without using global landmarks, local balls of suitable radius suffice to cover all the desired distances. The proof is by observing that for each vertex, if we add the closest $\sqrt{n}$ vertices to the landmark set of every vertex, then the landmark sets of every pair of vertices will intersect with high probability, i.e. we have obtained a 2-hop cover.

Proposition 3. *Let $G = (V, E)$ be an undirected random graph where each edge is sampled with probability $p = 2(\log n)/n$. By setting $H = 0$ and $l_i = l = \lceil \frac{\log n}{2 \log np} \rceil + 1$ for all $1 \le i \le n$, we have that Algorithm **??** outputs a 2-hop cover with at most $\tilde{O}(n^{3/2})$ landmarks with high probability.*

Proof. Denote by $L(x)$ the landmark set obtained by Algorithm **??**, for every $x \in V$. We will show that with high probability:

a) For all $x_i, x_j \in V$, $L(x_i) \cap L(x_j) \neq \emptyset$. This implies that $L(\cdot)$ is a 2-hop cover.
b) The size of $L(x_i)$ is less than $\tilde{O}(\sqrt{n})$, for all $x_i \in V$.

Claim a) follows because the diameter of G is at most $2l - 1$ with high probability by Fact 1. Note that $L(x_i)$ contains $N_{l-1}(x_i)$, the set of vertices with distance at most $l - 1$. If $\text{dist}(x_i, x_j) \le (l - 1) + (l - 1)$, $N_{l-1}(x_i)$ and $N_{l-1}(x_j)$ already intersect. Otherwise, since the diameter is at most $2l - 1$, these two neighborhoods must be connected by an edge e. Suppose between e's two endpoints, the one with a lower degree is on x_i's side, then the local BFS from x_i must add the other endpoint to $L(x_i)$, and vice versa. Therefore, $L(x_i)$ must intersect with $L(x_j)$.

Claim b) is because $L(x_i)$ is a subset of $N_l(x_i)$. By Fact 1, the size of $N_l(x_i)$ is at most $4(np)^l \lesssim \tilde{O}(\sqrt{n})$. Hence, the proof is complete. □

4 RANDOM POWER LAW GRAPHS

In this section we analyze our algorithm on random power law graphs. We begin with the simple case of $\beta > 3$, which generalizes the result on Erdös-Rényi graphs. Because the technical intuition is the same with Proposition 3, we describe the result below and omit the proof.

Proposition 4. *Let $G = (V, E)$ be a random power law graph with average degree $v > 1$ and power law exponent $\beta > 3$. For each $x_i \in V$, let l_i be the smallest integer such that the number of edges between $N_{l_i}(x_i)$ and $V \backslash N_{l_i}(x_i)$ is at least $\delta\sqrt{n}$, where $\delta = 5\sqrt{v \log n}$.*

*By setting $H = 0$ and $\{l_i\}_{i=1}^{n}$, Algorithm **??** outputs a 2-hop cover with high probability. Moreover, each vertex uses at most $O(\sqrt{n} \log^2 n)$ landmarks.*

Remark: The high level intuition behind our algorithmic result is that as long as the breadth-first search process of the graph grows neither too fast nor too slow, but rather at a proper rate, then an efficient distance labeling scheme can be obtained. Proposition 4 can be easily extended to configuration models with bounded degree variance. It would be interesting to see if our results extend to preferential attachment graphs and Kronecker graphs.

The case of $2 < \beta < 3$: Next we describe the more interesting case with power law exponent $2 < \beta < 3$. Here the graph contains a large number of high degree vertices. By utilizing the high degree vertices, we show how to obtain exact distance landmark schemes, (+1)-stretch schemes and (+2)-stretch schemes. The number of landmarks used varies depending on the value of β. We now state our main result as follows.

Theorem 5. *Let $G = (V, E)$ be a random power law graph with average degree $v > 1$ and exponent $2 < \beta < 3$. Let*

$$K = \begin{cases} \sqrt{n}, \text{for } 2.5 \le \beta \le 3 \\ n^{\frac{1}{(4-\beta)(\beta-1)}}, \text{for } 2 < \beta < 2.5. \end{cases}$$

Let H be the number of vertices whose degree is at least K in G. Let $\pi = \{x_i\}_{i=1}^{n}$ be any ordering of vertices V by their degrees in a non-increasing order. For each vertex $x_i \in V$, let l_i be the smallest integer such that the number of edges between $N_{l_i-1}(x_i)$ and $V \backslash N_{l_i-1}(x_i)$ is at least $\delta n^{(\beta-2)/(\beta-1)}$, where $\delta = 4v \cdot \log^2 n$.

*With ordering π, parameters H and $\{l_i\}_{i=H+1}^{n}$, Algorithm **??** outputs a 2-hop cover with high probability. Moreover, the maximum*

[2] Here we have omitted the details of the local backward BFS procedure, which can be derived similar to the local forward BFS procedure.

number of landmarks used by any vertex is at most

$$O\left(\max\left(n^{\frac{\beta-2}{\beta-1}}, n^{\frac{3-\beta}{4-\beta}}\right)\log^3 n\right).$$

The above theorem says that in Algorithm **??**, first we use vertices whose degrees are at least K as global landmarks. Then for the other vertices x_i, we grow a local ball of radius l_i, whose size is (right) above $n^{(\beta-2)/(\beta-1)}$. The two steps together lead to a 2-hop cover. We now build up the intuition for the proof.

Building up a +1-stretch scheme: First, it is not hard to show that G contains a heavy vertex whose degree is $n^{1/(\beta-1)}$, by analyzing the power law distribution. Note that $K \leq n^{1/(\beta-1)}$, hence we have added all such high degree vertices as global landmarks. This part, together with the local balls, already gives us a (+1)-stretch landmark scheme.

To see why, consider two vertices x_i, x_j. If their local balls (of size $n^{(\beta-2)/(\beta-1)}$) already intersect, then we can already compute their distances correctly from their landmark sets. Otherwise, since the bottom layers of x_i and x_j already have weight/degree $n^{(\beta-2)/(\beta-1)}$, they are at most two hops apart, by connecting to the heavy vertex with degree $n^{1/(\beta-1)}$. Recall that the heavy vertex is added to the landmark sets of every vertex. Hence, the estimated distance is at most off by one. As a remark, to get the (+1)-stretch landmark scheme, the number of landmarks needed per vertex is on the order of $n^{(\beta-2)/(\beta-1)}$. This is because we only need to use vertices whose degrees are at least $n^{1/(\beta-1)}$ as global landmarks (there are only $\log n$ of them), as opposed to H in Theorem 5.

Fixing the +1-stretch: To obtain exact distances, for each vertex on the boundary of radius $l_i - 1$, we add all of its neighbors with a higher degree to the landmark set (c.f. line 15-17 in Algorithm **??**). Whenever there is an edge connecting the two boundaries, the side with a lower degree will add the other endpoint as a landmark, which resolves the (+1)-stretch issue. For the size of landmark sets, it turns out that fixing the (+1)-stretch for the case $2 < \beta < 2.5$ significantly increases the number of landmarks needed. Specifically, the costs are $n^{(5-\beta)/(4-\beta)}$ landmarks per node.

Intuition for the +2-stretch scheme: As an additional remark, one can also obtain a (+2)-stretch landmark sketch by setting l_i in Algorithm **??** in a way such that every vertex stores the closest $\tilde{\Theta}(n^{(\beta/2)-1})$ vertices in its landmark set. This modification leads to a (+2)-stretch scheme, because for two vertices x, y, once the bottom layers of x, y have size at least $\tilde{\Theta}(n^{(\beta/2)-1})$, they are at most three hops away from each other. The reason is that with high probability, the bottom layer will connect to a vertex with weight $\Omega(\sqrt{n})$ in the next layer (which will all be connected), as it is not hard to verify that the volume of all vertices with weight $\sqrt{n}$ is $\Omega(n^{(4-\beta)/2})$. By a similar proof to Theorem 5, the maximum number of landmarks used per vertex is at most $\tilde{O}(n^{(\beta-2)/2})$.

We refer the reader to the full version for details of the full proof. The technical components involve carefully controlling the growth of the neighborhood sets by using concentration inequalities.

5 EXPERIMENTS

In this section, we substantiate our results with experiments on a diverse collection of network datasets. A summary of the findings are as follows. We first compare Algorithm **??** with the pruned labeling algorithm [3]. Recall that our approach differs from the pruned labeling algorithm by only performing a thorough BFS for a small set of vertices, while running a lightweight local ball growing procedure for most vertices. We found that this simple modification leads to 1.5-2.5x reduction in number of landmarks stored. The preprocessing time is reduced by 2-15x as well. While our algorithm does not always output the exact distance like the pruned labeling algorithm, we observe that the stretch is at most 1%, relative to the average distance.

Next we compare our approach to two approximate distance sketches with strong theoretical guarantees, Das Sarma et al. sketch [8, 19] and a variant of Thorup-Zwick's 3-approximate distance oracle [37], which uses high degree vertices as global landmarks [13]. We observe that our approach incurs lower stretch and requires less space compared to Das Sarma et al. sketch. The accuracy of Thorup-Zwick sketch is comparable to ours, but we require much fewer landmarks.

5.1 Experimental Setup

To ensure the robustness of our results, we measure performances on a diverse collection of directed and undirected graphs, with the datasets coming from different domains, as described by Table 1. Stanford, Google and BerkStan are all Web graphs in which edges are directed. DBLP (collaboration network) and Youtube (friendship network) are both undirected graphs where there is one connected component for the whole graph. Twitter is a directed social network graph with about 84% vertices inside the largest strongly connected component. All the datasets are downloaded from the Stanford Large Network Dataset Collection [33].

Table 1: Datasets used in experiments.

graph	# nodes	# edges	category	type
DBLP	317K	1.0M	Collaboration	Undirected
Twitter	81K	1.8M	Social	Directed
Stanford	282K	2.3M	Web	Directed
Youtube	1.1M	3.0M	Social	Undirected
Google	876K	5.1M	Web	Directed
BerkStan	685K	7.6M	Web	Directed

Implementation details: We implemented all four algorithms in Scala, based on a publicly available graph library.[3] The experiments are conducted on a 2.30GHz 64-core Intel(R) Xeon(R) CPU E5-2698 v3 processor, 40MB cache, 756 GB of RAM. Each experiment is run on a single core and loads the graph into memory before beginning any timings. The RAM used by the experiment is largely dominated by the storage needed for the landmark sets.

Parameters: In the comparison between the pruned labeling algorithm and our approach, we order the vertices in decreasing order by the indegree plus outdegree of each vertex.[4] Recall that there are

[3] https://github.com/teapot-co/tempest

[4] There are more sophisticated techniques such as ordering vertices using their betweenness centrality scores [20]. It is conceivable that our algorithm can be combined with such techniques.

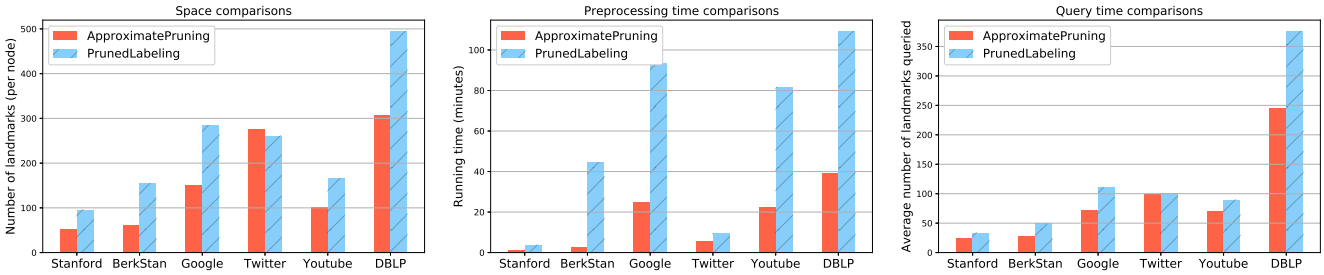

Figure 2: Comparing the efficiency of our approach to the pruned labeling algorithm.

Table 2: Measuring the accuracy of our approach.

	Stanford	BerkStan	Google	Twitter	Youtube	DBLP
Relative Average Stretch	0.37%	0.20%	0.51%	0.29%	0.33%	1.1%
Maximum Relative Stretch	21/10	10/7	8/5	4/3	4/3	7/5
Average Additive Stretch	0.046	0.030	0.060	0.014	0.018	0.075
Maximum Additive Stretch	11	3	3	1	2	2
Average Distance	12.3	14.6	11.7	4.9	5.3	6.8

two input parameters used in our approach, the number of global landmarks H and the radiuses of local balls $\{l_i\}_{i=H+1}^{n}$. To tune H, we start with 100, then keep doubling H to be 200, 400, etc. The radiuses $\{l_i\}_{i \geq H}$ are set to be 2 for all graphs.[5]

Benchmarks: For the Thorup-Zwick sketch, in the first step, $H = \sqrt{n}$ vertices are sampled uniformly at random as global landmarks. In the second step, every other vertex grows a local ball as its landmark set until it hits any of the $\sqrt{n}$ vertices. All vertices within the ball are used as landmarks. This method uses $O(n^{3/2})$ landmarks and achieves 3-stretch in worst case. In the follow up work of Chen et al. [13], the authors show a variant which uses high degree vertices as global landmarks and observe better performance. We implement Chen et al.'s variant in our experiment, and use the H vertices with the highest indegree plus outdegree as global landmarks. In the experiment, we start with H equal to $\sqrt{n}$. Then we report results for $\sqrt{n}$ multiplied by $\{2, 1/2, 1/4, 1/8\}$.

For the Das Sarma et al. sketch, first, $\log n$ sets S_i of different sizes are sampled uniformly from the set of vertices V, for $0 \leq i < \log n$, where the size of S_i is 2^i. Then a breadth first search is performed from S_i, so that every vertex $x \notin S_i$ finds its closest vertex inside S_i in graph distance. This closest vertex is then used as a landmark for x. The number of landmarks used in Dar Sarma's sketch is $n \log n$, and the worst case multiplicative stretch is $\log n$. If more accurate estimation is desired, one can repeat the same procedure multiple times and union the landmark sets together. We begin with 5 repetitions, then keep doubling it to be 10, 20 etc.

Our approach differs from the above two methods by using the idea of pruning while running BFS. This dramatically enhances performance in practice, as we shall see in our experiments.

Metrics: We measure the stretch of the estimated distances, and compute aggregated statistics over a large number of queries. For a query (x, y), if y is reachable from x, but the algorithm reports no common landmark between the landmark sets of x and y, then we count such a mistake as a "False disconnect error." On the other hand, if y is not reachable from x, then it is not hard to see that our algorithm always reports correctly that y is not reachable from x. In the experiments, we compute $\text{dist}(x, y)$ using Dijkstra's algorithm.

To measure space usage, we report the number of landmarks per node used in each algorithm as a proxy. Since the landmark sets are stored in Int to Float hash maps, the actual space usage would be eight bytes times the landmark sizes in runtime, with a constant factor overhead.

For the query time, recall that for each pair of vertices (x, y), we estimate their distance by looking at the intersection of $L_F(x)$ and $L_B(y)$ and compute the minimum interconnecting distance (c.f. equation 1). To find the minimum, we iterate through the smaller landmark set. Hence the running time is $\min(|L_F(x)|, |L_B(y)|)$ multiplied by the time for a hash map lookup, which is a small fixed value in runtime. A special case is when $y \in L_F(x)$ or $x \in L_B(y)$, where only one hash map lookup is needed. We will report the number of hash map lookups as a proxy for the query time.[6]

5.2 Comparisons to Exact Methods

We report the results comparing our approach to the pruned labeling algorithm. The pruned labeling algorithm is exact. To measure the accuracy of our approach, we randomly sample 2000 pairs of source and destination vertices. The number of global landmarks is set to be 400 for the Stanford dataset, 1600 for the DBLP dataset, and 800 for the rest of the datasets.

Figure 2 shows the preprocessing time, the number of landmarks and average query time used by both algorithms. We see that our approach reduces the number of landmarks used by 1.5-2.5x, except

[5]It follows from our theoretical analysis that the radiuses should be less than half of the average distance. As a rule of thumb, setting the radius as 2 works based on our experiments.

[6]It is conceivable that more sophisticated techniques may be devised to speedup set intersection. We leave the question for future work.

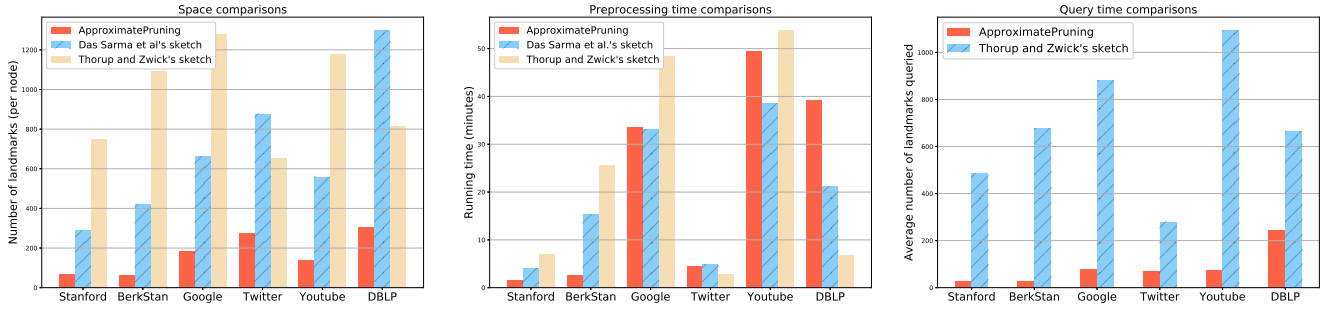

Figure 3: Comparing the efficiency of our approach to two well known distance sketches with strong theoretical guarantees.

Table 3: Measuring the stretch for all three methods.

	Stanford	BerkStan	Google	Twitter	Youtube	DBLP
DS et al. sketch	20.9%	17.2%	21.1%	11.1%	13.1%	5.4%
TZ sketch	0.30%	0.21%	0.36%	1.65%	0.03%	2.15%
Our approach	0.16%	0.20%	0.22%	0.29%	0.04%	1.1%

Table 4: Varying H in TZ sketch.

Youtube	$\sqrt{n}/2$	$\sqrt{n}/4$	$\sqrt{n}/8$	Ours
Stretch	0.04%	0.11%	0.07%	0.04%
# Landmarks	731	648	811	137
Preprocessing	37m	31m	35m	50m

on the Twitter dataset.[7] Our approach performs favorably in terms of preprocessing time and query time as well.

The accuracy of our computed estimate is shown in Table 2. We have also measured the median additive stretch, which turns out to be zero in all the experiments. To get a more concrete sense of the accuracy measures, consider the Google dataset as an example. Since the average additive stretch is 0.06 and there are 2000 pairs of vertices, the total additive stretch is at most 120 summing over all 2000 pairs! Specifically, there can be at most 120 queries with non-zero additive stretch and for all the other queries, our approach returns the exact answer. Meanwhile, among all the datasets, we observed only one "False disconnect error" in total. It appeared in the Stanford Web graph experiment, where the true distance is 80.

5.3 Comparisons to Approximate Methods

Next we compare our approach to Das Sarma et al.'s sketch (or DS et al. sketch in short) and the variant of Thorup and Zwick's sketch (or TZ sketch in short). Similar to the previous experiment, we sample 2000 source and destination vertices uniformly at random to measure the accuracy.

We start by setting the number of global landmarks to $\sqrt{n}$ in Thorup-Zwick sketch. To allow for a fair comparison, we tune our approach so that the relative average stretch is comparable or lower. Specifically, the Stanford, BerkStan and Twitter datasets use $H = 800$, the Google and DBLP datasets use $H = 1600$ and the Youtube dataset uses $H = 3200$.

Figure 3 shows the number of landmarks needed in each algorithm as well as the amount of preprocessing time consumed. Overall, our approach uses much fewer landmarks than the other two algorithms. In terms of preprocessing time, our approach is comparable or faster on all datasets, except on the DBLP network. We suspect that this may be because the degree distribution of the DBLP network is flatter than the others. Hence performing the pruning procedures on a small subset of high degree vertices are less effective in such a scenario.

We next report the relative average stretch for all three methods. As can be seen in Table 3, our approach is comparable to or slightly better than Thorup and Zwick's sketch, but much more accurate than Das Sarma et al's sketch. Note that the latter performed significantly worse than the other two approaches. We suspect that this may be because the sketch does not utilize the high degree vertices efficiently. Lastly, our approach performs favorably in the query time comparison as well. Note that the query time of Das Sarma et al.'s sketch are not reported because of the worse accuracy.

Effect of parameter choice: Note that in the above experiment, for Thorup and Zwick's sketch, we have set the number of global landmarks H to be $\sqrt{n}$. In the next experiment, we vary the value of H to $\sqrt{n}$ multiplied by $\{2, 1/2, 1/4, 1/8\}$.

First, we report a detailed comparison on the Google dataset in Figure 4. Note that when $H = 2\sqrt{n}$, the Thorup and Zwick's sketch requires over 2000 landmarks per node which is significantly larger than the other values. Hence, we dropped the data point from the plot. For our approach, we double H from 100 up to 1600. Overall, we can see that our approach requires fewer landmarks across different stretch levels.

Next, we report brief results on the Youtube dataset in Table 4 since the results are similar. The conclusions obtained from other datasets are qualitatively similar, and hence omitted.

[7] By setting the radiuses $\{l_i\}$ to be 1, we incur 0.72% relative additive stretch by using 173 landmarks per node, which improves over the pruned labeling algorithm by 1.5x.

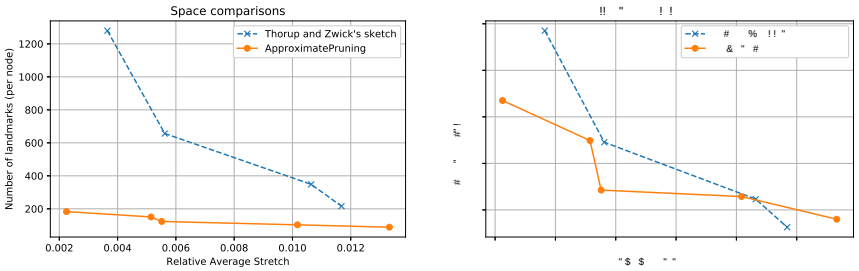

Figure 4: Varying H in TZ sketch and our approach, on the Google dataset.

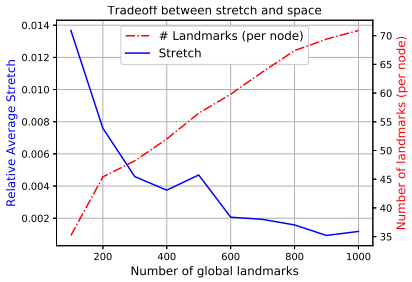

Figure 5: Tradeoff on the Stanford dataset.

5.4 More Experimental Observations

By varying the number of global landmarks used Algorithm **??**, it is possible to obtain a smooth tradeoff between stretch and number of landmarks used. As an example, we present the tradeoff curve for the Stanford Web dataset in Figure 5. Here we vary the number of global landmarks used from 100 to 1000. As one would expect, the relative average stretch decreases while the number of landmarks stored increases.

6 FUNDAMENTAL LIMITS OF LANDMARK SKETCHES

This section complements our algorithm with lower bounds. We begin by showing a matching lower bound for Erdös-Rényi graphs, saying that any 2-hop cover needs to store at least $\tilde{\Omega}(n^{3/2})$ landmarks. The results imply that the parameter dependence on n of our algorithm is tight for Erdös-Rényi graphs and random power law graphs with power law exponent $\beta > 3$. It is worth mentioning that the results not only apply to landmark sketches, but also work for the family of labeling schemes. Recall that labeling schemes associate a labeling vector for each vertex. To answer a query for a pair of vertices (x, y), only the labeling vectors of x, y are accessed. We first state the lower bound for Erdös-Rényi graphs.

Theorem 6. *Let $G = (V, E)$ be an Erdös-Rényi graph where every edge is sampled with probability $p = 2\log n/n$. With high probability over the randomness of G, any labelings which can recover all pairs distances exactly have total length at least $\Omega(n^{3/2}/\log^4 n)$.*

In particular, any 2-hop cover needs to store at least $\Omega(n^{3/2}/\log^4 n)$ many landmarks with high probability.

For a quick overview, we divide V into $\sqrt{n}$ sets of size $\sqrt{n}$ each. We will show that the total labeling length for each set of $\sqrt{n}$ vertices has to be at least $\tilde{\Omega}(n)$. By union bound over all the $\sqrt{n}$ sets, we obtain the desired conclusion. We now go into the proof details.

Proof. Denote by $r = np$. Let $d = \lfloor \frac{\log n}{2\log(np)} \rfloor - c$, where c is a fixed constant (e.g. $c = 2$ suffices). Divide V into groups of size $\sqrt{n}$. Clearly, there are $\sqrt{n}$ disjoint groups – let S be one of them. Denote by c_1 a fixed constant which will be defined later. We argue that

$$\Pr[\text{The total label length of } S \le c_1 \cdot r^{1-2c} n] \lesssim r^{1-2c}. \qquad (2)$$

Hence by Markov's inequality, with high probability except for $(\log n) r^{1-2c}\sqrt{n}$ groups, all the other groups will have label length at least $c_1 \cdot r^{1-2c} n \gtrsim \tilde{\Omega}(n)$, because $r \le 2\log n$. Hence we obtain the desired conclusion. For the rest of the proof, we focus on proving equation (2) for the group S.

Let $\{x_1, x_2, \ldots, x_{|S|}\}$ be an arbitrary ordering of S. We grow the neighborhood of each vertex in S one by one, up to level d. Denote by $G_1 = (V_1, E_1)$, where $V_1 = V$ and $E_1 = E$. For any $i \ge 1$, if $x_i \in V_i$, then we define define $T(x_i)$ to be the set of of vertices in V_i whose distance is at most d from x_i. Define $L(x_i) \subseteq T(x_i)$ to be the set of vertices in G_i whose distance is equal to d from x_i. On the other hand if $x_i \notin V_i$, then $T(x_i)$ and $L(x_i)$ are both empty. More formally,

$$T(x_i) := \begin{cases} \{y : \mathrm{dist}_{G_i}(x_i, y) \le d\}, & \text{if } x_i \in V_i \\ \varnothing, & \text{otherwise.} \end{cases}$$
$$L(x_i) := \{y \in T(x_i) : \mathrm{dist}_{G_i}(x_i, y) = d\}$$

We then define $F_i = \cup_{j=1}^{i} T(x_j)$. Denote by G_{i+1} to be the induced subgraph of G_i on the remaining vertices $V_{i+1} = V \backslash F_i$. We show that with high probability, a constant fraction of vertices $x_i \in S$ satisfy that $|L(x_i)| \ge \Omega((np)^d)$. □

Lemma 7 (Martingale inequality). *In the setting of Theorem 6, with high probability, at least $|S|/2$ vertices $x_i \in S$ satisfy that $|L(x_i)| \ge r^d/6$.*

Proof. For any $1 \le i \le |S|$, consider

$$X_i := \begin{cases} 1 & \text{if } x_i \notin V_i, \text{ or } |F_{i-1}| > |S| \cdot r^d \log n, \text{or } |L(x_i)| \ge r^d/6 \\ 0 & \text{otherwise.} \end{cases}$$

We claim that $\Pr[X_i = 1 \mid X_1, \ldots, X_{i-1}]$ with high probability. It suffices to consider the case $x_i \in V_i$ and $|F_{i-1}| \le |S| r^d \log n$. It is not hard to verify that $|F_{i-1}| \le n/\log n$ by our setting of d. Hence the size of V_i is at least $n(1 - 1/\log n)$. Note that the subgraph G_i is still an Erdös-Rényi random graph, and the number of vertices is at least $n(1 - 1/\log n)$. By Fact 1c), the size of $L(x_i)$ is at least

$$\frac{1}{2} r^d (1 - \log^{-1} n)^d \ge r^d/6,$$

since $d \le \log n$.

Thus by Azuma-Hoeffding inequality, $\sum_{i=1}^{|S|} X_i \ge 0.99\,|S|$ with high probability. We will show below that the contributions to $\sum_{i=1}^{|S|} X_i$ from $x_i \notin V_i$ and $|F_{i-1}| > |S| r^d \log n$ is less than $0.02\,|S|$. Hence by taking union bound, we obtain the desired conclusion.

First, we show that the number of x_i such that $x_i \notin V_i$ are at most $0.01|S|$ with high probability. Note that $x_i \notin V_i$ implies that

there exists some vertex x_j with $j < i$ such that $\text{dist}(x_i, x_j) \le d$. On the other hand, by Fact 1,

$$\Pr[\text{dist}(x, y) \le d] \le \frac{3r^d}{n}, \forall x, y \in S.$$

Hence, it is not hard to verify that the expected number of vertex pairs in S whose distance is at most d, is $O(|S|^2 r^{2d}/n) \lesssim |S| / \log n$, by the setting of d. By Markov's inequality, with probability $1 - 1/\log n$ only $0.01\,|S|$ vertex pairs have distance at most d in S. Hence there exists at most $0.01\,|S|$ i's such that $x_i \notin V_i$.

Secondly for all $1 \le i \le |S|$, the set of vertices T_i is a subset of $N_d(x_i)$, the set of vertices within distance d to x_i on G. By Fact 1c), the size of $N_d(x_i)$ is at most $2r^d$. Hence we have $|F_i| \le 2\,|S|\, r^d$ for all $1 \le i \le |S|$ with high probability. This proves the Lemma. □

Now we are ready to finish the proof. Given the labels of S, we can recover all pairwise distances in S. Let $\text{dist}_S : S \times S \to \mathbb{N}$ denote the distance function restricted to S. Consider the following:

a) $\exists\, |S|^2/9$ pairs (x_i, x_j) such that $\text{dist}_S(x_i, x_j) \le 2d + 1$. We know by Fact 1 that $\Pr[\text{dist}(x_i, x_j) \le 2d+1] \le 2r^{2d+1}/n$, for any $x_i, x_j \in S$. Hence the expected number of pairs with distance at most $2d+1$ in S, is at most $2\,|S|^2 \cdot r^{2d+1}/n \lesssim r^{1-2c}n$. By Markov's inequality, the probability that a random graph induces any such distance function is $r^{1-2c}n/(|S|^2/8) \lesssim r^{1-2c}$.

b) The number of pairs such that $\text{dist}_S(x_i, x_j) \le 2d + 1$ is at most $|S|^2/8$ in S. Let A denote

$$\left\{(x, y) \in S \times S \mid \text{dist}(x, y) > 2d + 1, \text{ and } |L(x)|, |L(y)| \ge r^d/6\right\}.$$

By Lemma 7 and our assumption for case b), the size of A is at least $\binom{|S|/2}{2} - |S|^2/8 \ge |S|^2/9$. For any $(x, y) \in A$, $L(x)$ and $L(y)$ are clearly disjoint. Note that the event whether there exists an edge between $L(x)$ and $L(y)$ is independent, conditional on revealing the subgraph for all $x \in S$ up to distance d. Hence

$$\begin{aligned}
&\Pr\left[\text{dist}_S(x, y) > 2d + 1,\ \forall (x, y) \in A\right] \\
&\le \prod_{(x,y)\in A} \Pr\left[\text{there is no edge between } L(x) \text{ and } L(y)\right] \\
&\le \prod_{(x,y)\in A} (1-p)^{|L(x)|\times|L(y)|} \\
&\le \exp\left(-p \times |A| \times r^{2d}/72\right) \qquad (\text{because } |L(x)|, |L(y)| \ge r^d/6) \\
&\le \exp(-c_1 r^{1-2c} n). \qquad (\text{because } |A| \ge n/9)
\end{aligned}$$

where $c_1 = 72 \times 9$ in the last line. Denote by $\kappa = c_1 \cdot r^{1-2c}n$. Note that the number of labelings of length (or number of bits) less than κ is at most 2^κ. For each labeling, the probability that it correctly gives all pairs distances is at most $\exp(-\kappa)$ by our argument above. Therefore by union bound, the probability that the total labeling length of $|S|$ is at most κ is at most $2^\kappa \cdot \exp(\kappa) \le r^{1-2c}$ for large enough n.

To recap, by combining case a) and b), we have shown that equation (2) is true. Hence the proof is complete.

Extensions to $\beta > 3$: It is worth mentioning that the lower bound on Erdös-Rényi graphs can be extended to random power law graphs with $\beta > 3$. The proof structure is similar because the degree distribution has finite variance, hence the number of high degree vertices is small. The difference corresponds to technical modifications which deal with the neighborhood growth of random graphs with constant average degree. We state the result below and leave the proof to the full version.

Theorem 8. *Let $G = (V, E)$ a random power law graph with average degree $\nu > 1$ and exponent $\beta > 3$. With high probability over the randomness of G, any labelings which can recover all pairs distances exactly have total length at least $\tilde{\Omega}(n^{3/2})$.*

In particular, any 2-hop cover needs to store at least $\tilde{\Omega}(n^{3/2})$ many landmarks with high probability.

Lower bounds for β close to 2: Next we show that the parameter dependence of our algorithm is tight when β is close to 2. Specifically, any 2-hop cover needs to store at least $\Omega(n^{3/2-\varepsilon})$ many landmarks when $\beta = 2 + \varepsilon$. Hence it is not possible to improve over our algorithm when β is close to 2. Furthermore, the lower bound holds for the general family of labeling schemes as well.

Theorem 9. *Let $G = (V, E)$ a random power law graph with average degree $\nu > 1$ and exponent $\beta = 2 + \varepsilon$ for $\varepsilon < 1/2$. With high probability over the randomness of G, any labelings which can recover all pairs distances exactly have total length at least $\Omega(n^{3/2-\varepsilon})$.*

In particular, any 2-hop cover needs to store at least $\Omega(n^{3/2-\varepsilon})$ many landmarks with high probability.

The proof is conceptually similar to Theorem 6, so we sketch the outline and leave the proof to the full version.

Let S_{high} be the set of vertices whose degrees are on the order of $\sqrt{n}$. Let S_{low} be a set of $\sqrt{n}$ vertices, where each vertex has weight between ν and 2ν. Such a set is guaranteed to exist because there are $\Theta(n)$ of them.

We first reveal all edges of G other than the ones between S_{high}. We show that at this stage, most vertices in S_{low} are more than 3 hops away from each other. If for some pair (x, y) in S_{low} whose distance is larger than three, and both x and y connect to exactly one (but different) vertex in S_{high}, then knowing whether $\text{dist}(x, y) = 3$ will reveal whether their neighbors in S_{high} are connected by an edge.

Based on the observation, we show that the total labeling length of S_{low} is at least $\tilde{\Omega}(n^{3-\beta})$. This is because the random bit between a vertex pair in S_{high} has entropy $\Omega(n^{2-\beta})$. Since there are $\Theta(n)$ pairs of vertices in S_{high}, the entropy of the labelings of S_{low} must be $\Omega(n^{3-\beta})$ (hence, its size must also be at least $\Omega(n^{3-\beta})$). Similar to Theorem 6, this argument is applied to $\sqrt{n}$ disjoint sets of "S_{low}", summing up to an overall lower bound of $\Omega(n^{7/2-\beta}) = \Omega(n^{3/2-\varepsilon})$.

7 CONCLUSIONS AND FUTURE WORK

In this work, we presented a pruning based landmark labeling algorithm. The algorithm is evaluated on a diverse collection of networks. It demonstrates improved performances compared to the baseline approaches. We also analyzed the algorithm on random power law graphs and Erdös-Rényi graphs. We showed upper and lower bounds on the number of landmarks used for Erdös-Rényi graphs and random power law graphs.

There are several possible directions for future work. One direction is to close the gap in our upper and lower bounds for random

power law graphs. We believe that any improved understanding can potentially lead to better algorithms for real world power law graphs as well. Another direction is to evaluate our approach on transportation networks, which correspond to another important domain in practice.

Acknowledgements. The authors would like to thank Fan Chung Graham, Tim Roughgarden, Amin Saberi and D. Sivakumar for useful feedback and suggestions at various stages of this work. Also, thanks to the anonymous referees for their constructive reviews. Hongyang Zhang is supported by NSF grant 1447697.

ABSTRACT

The understanding of talent flow is critical for sharpening company talent strategy to keep competitiveness in the current fast-evolving environment. Existing studies on talent flow analysis generally rely on subjective surveys. However, without large-scale quantitative studies, there are limits to deliver fine-grained predictive business insights for better talent management. To this end, in this paper, we aim to introduce a big data-driven approach for predictive talent flow analysis. Specifically, we first construct a time-aware job transition tensor by mining the large-scale job transition records of digital resumes from online professional networks (OPNs), where each entry refers to a fine-grained talent flow rate of a specific job position between two companies. Then, we design a dynamic latent factor based Evolving Tensor Factorization (ETF) model for predicting the future talent flows. In particular, a novel evolving feature by jointly considering the influence of previous talent flows and global market is introduced for modeling the evolving nature of each company. Furthermore, to improve the predictive performance, we also integrate several representative attributes of companies as side information for regulating the model inference. Finally, we conduct extensive experiments on large-scale real-world data for evaluating the model performances. The experimental results clearly validate the effectiveness of our approach compared with state-of-the-art baselines in terms of talent flow forecast. Meanwhile, the results also reveal some interesting findings on the regularity of talent flows, e.g. *Facebook becomes more and more attractive for the engineers from Google in 2016.*

analysis, the process of analyzing the phenomenon of job hopping among different regions or companies, always acts as a major component in market intelligence of modern companies. Indeed, with the help of talent flow analysis, many business insights and managerial initiatives can be achieved. For example, at the macro level, based on the talent flow among different countries, governments can monitor the brain drain, and carry out macroeconomic regulations for gaining and sustaining the global competitive advantage. At the micro level, companies can timely evaluate their employer brand, uncover the major competitors in the talent market, and conduct proactive talent management.

However, most of existing studies on talent flow analysis generally rely on subjective surveys, with a focus on qualitative causal inference from psychological, economic and cultural perspectives [2, 4]. Due to the lack of large-scale market data for quantitative analysis, there are limits for delivering fine-grained and predictive business insights through talent flow analysis [10, 20, 31]. Recently, the prevalence of online professional networks (OPNs) enables the accumulation of a large number of digital resumes, which contains rich information about the career path of talents. For example, as of the end of 2017, there are over 400 million resumes worldwide available at Linkedin. Indeed, these large-scale talent data provide unprecedented opportunities for conducting talent flow analysis.

To this end, in this paper, we aim to introduce a data-driven approach for fine-grained predictive talent flow analysis. Specifically, we first construct a time-aware job transition tensor by mining the large-scale job transition records of digital resumes, where each entry refers to a fine-grained talent flow rate of a specific job position between two companies, i.e., a tuple <Origin Company, Job Position, Destination Company, Time Slice>. Then, we design a dynamic latent factor based Evolving Tensor Factorization (ETF) model for predicting the future talent flows, where the origin company and the destination company are represented as the time-dependent vectors, the job position is represented as a time-independent low-dimension vector, and the time is used as the evolving signal. In particular, to model the evolving process of talent flows, we develop a job transition network based on the talent flows, where companies represent nodes, and the aggregated job transition between two companies represents the weight of edge. With this network, a novel evolving feature by jointly considering the influence of previous talent flows and global market is introduced for modeling the evolving principles of each company. Furthermore, to improve the predictive performance of ETF, we also integrate several representative attributes of companies as side information for regulating the model inference. Figure 1 illustrates the diagrammatic sketch of our approach. Finally, the extensive experiments conducted on a real-world dataset clearly validate the effectiveness of our approach compared with other state-of-the-art baselines in terms of talent flow forecast.

Specifically, the major contributions of this paper can be summarized as follows:

- We introduce a big data-driven approach for predictive talent flow analysis based on the large-scale online resume data. Our approach allows to identify fine-grained and predictive business insights.
- We propose a novel dynamic latent factor based evolving model for talent flow forecast, which consists of a novel evolving feature for jointly modeling the influence of previous talent flows and global market, and a company similarity based regularizer for enhancing model inference.
- We conduct extensive experiments on large-scale real-world data for evaluating the model performance. The experimental results not only validate the performance of our approach for talent flow forecast, but also reveal some interesting findings on the regularity of talent flows, such as *Facebook becomes more and more attractive for the engineers from Google.*

Overview. The rest of the paper is organized as follows. In Section 2, we describe the real-world data and formulate the problem. Section 3 shows the technical details of our dynamic latent factor model for talent flow forecast. Then, we introduce the experimental results in Section 4. After that, we summarize the important related works in Section 5. Finally, Section 6 concludes the work.

2 PRELIMINARIES

In this section, we first introduce the real-world dataset in our study, and then formulate the problem of fine-grained talent flow forecast.

2.1 Data Description

In this paper, we use a representative real-world dataset from one of the largest commercial OPNs, which contains more than 220 million professional resumes, to study the problem of talent flow forecast. Specifically, each resume contains a list of job experience records, where each record consists of the company name, job title with brief job description, and the working duration in a monthly granularity. An example is shown in Figure 2, more details of the dataset could be found in Section 4.

To extract the job transition records from the resumes, here we extend the methods introduced in [24] by allowing job overlaps since it is reasonable for an employee to start a new job a few months before the official resignation of her former job. Formally, a resume R contains a list of job experience records $[R_{c1}, R_{c2}, ..., R_{cn}]$, and each record R_{ci} contains a start date R^s_{ci} and an end date R^e_{ci}. Therefore, as long as the absolute difference between the end time of the former job and the start time of the successor job less than a predefined threshold θ, the transition from the former job to the successor job will be regarded as effective. Note that, in our settings, a former job may has multiple successor jobs. Furthermore, we formulate the effective job transition as a father-son relationship, and construct a career tree where each company represents a node. Intuitively, there may exist multiple paths from the root node to the leaf node, the length of which is set as the sum of corresponding work time. In particular, the longest path will be selected to represent the major career path of the employee, and the adjacent company node on the major path represents a job transition.

Specifically, we use the example shown in Figure 3 to illustrate how to extract job transition records from a resume. In the figure, we use line segments to represent work experiences and use letters to represent the corresponding company names. By checking the working durations of all the work experiences, we can get several job transitions records, including $a \rightarrow b$, $a \rightarrow c$ and $b \rightarrow c$. The corresponding career tree is shown in the right part of Figure 3.

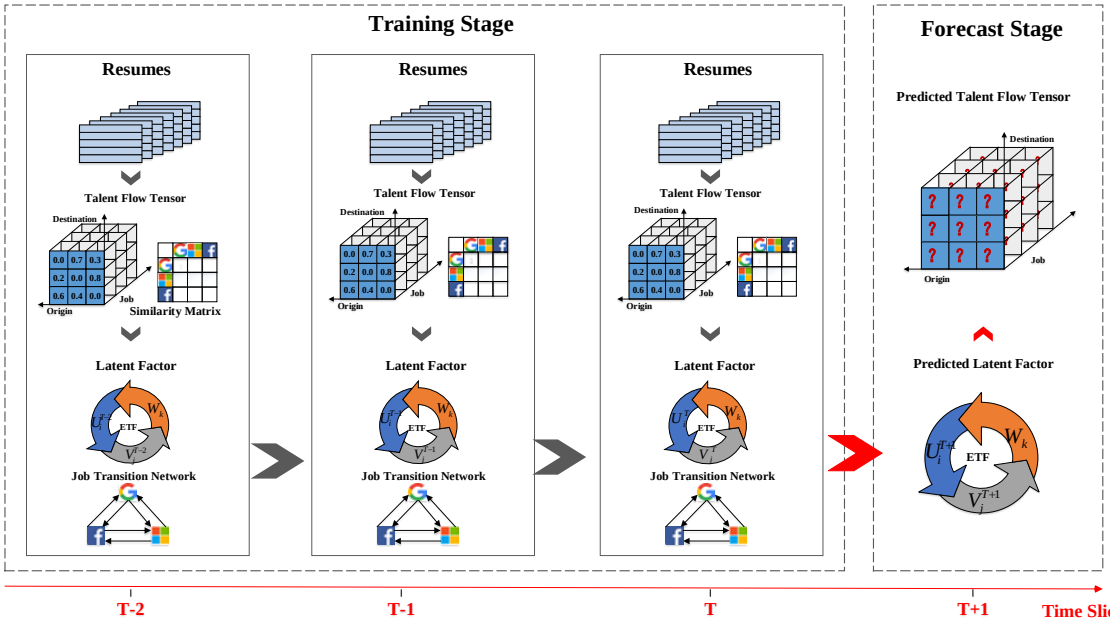

Figure 1: The diagrammatic sketch of our approach for talent flow forecast, where the dynamic latent factors are learned from the historical talent flows, and are used for forecasting the future talent flows.

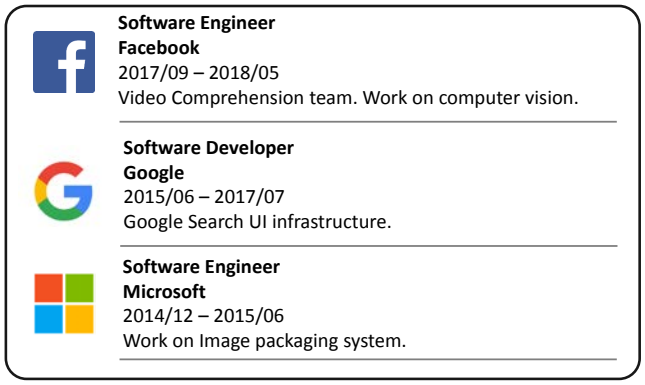

Figure 2: An example of the resume in our dataset.

Obviously, in this career tree there exist two paths, i.e., $\{a \rightarrow b \rightarrow e\}$ and $\{a \rightarrow c\}$. And because the first path is longer than the other one, we believe it is the major career path of this individual and just keep the job transitions in it, i.e., $[a \rightarrow b, b \rightarrow c]$. The job transition date is set as the start date of the successor and the job title is determined by the title of the predecessor.

2.2 Problem Formulation

Based on the extracted job transition records, here we introduce the problem formulation of talent flow forecast. For facilitating illustration, Table 1 lists some important mathematical notations used throughout this paper.

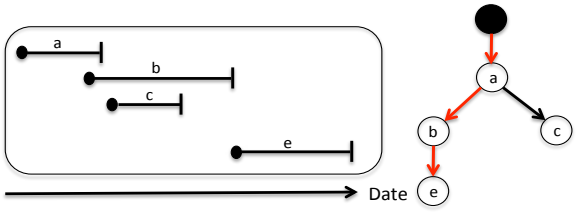

Figure 3: An example of transforming work experiences into job transition records.

Formally, we suppose there are N companies and M job positions. Based on the job transition records, we can construct talent flow tensor $\mathcal{R}^t \in \mathbb{R}^{N \times N \times M}$ for each time slice t, where each element $\mathcal{R}^t_{ijk}$ is defined as the normalized number of corresponding job transitions, i.e,

$$\mathcal{R}^t_{ijk} = \frac{Num^t_{i,j,k}}{\sum_{j=1}^{N} Num^t_{i,j,k}}, \tag{1}$$

where $Num^t_{i,j,k}$ denotes the aggregated job transitions from the job position k of company i to company j at time slice t. Along this line, the problem of talent flow forecast can be formulated as:

*Definition 2.1 (**Talent Flow Forecast**).* Given a set of talent flow tensors $\{\mathcal{R}^1, ..., \mathcal{R}^T\}$, which is constructed by the transition records as of time T, and the corresponding attributes of companies (e.g., industry, scale, and locations), the goal of talent flow forecast is to predict the value of $\mathcal{R}^{(T+1)}_{ijk}$.

Table 1: Mathematical notations.

Symbol	Description
$\mathcal{R}^t$	The talent flow tensor at time slice t;
U_i^t	The latent vector of origin company i at time slice t;
V_j^t	The latent vector of destination company j at time slice t;
W_k	The latent vector of job position k;
C	The set of companies;
S	The attribute similarity matrix of companies;
N	The number of companies;
M	The number of job position;
T	The number of time windows;
D	The dimension of latent vector.

3 TECHNICAL DETAILS

In this section, we first introduce a latent factor based model, named Basic Latent Factor based Evolving Tensor Factorization model (Basic-ETF), for talent flow forecast. Furthermore, we extend it by adding an attribute similarity based constraint for improving its performance.

3.1 Basic-ETF Model

Intuitively, given a talent flow at time slice t, i.e., $\mathcal{R}_{ijk}^t$, its value is influenced by three factors, namely talent outflow company i, talent inflow company j, and job position k. Here we represent them by latent vectors as follows:

- U_i^t represents the latent vector of the origin company i at time slice t.
- V_j^t represents the latent vector of the destination company j at time slice t.
- W_k^t represents the latent vector of the job position k at time slice t.

Without loss of generality, we assume the estimation of R_{ijk}^t equals to $f(U_i^t, V_j^t, W_k^t)$. Accordingly, the conditional distribution over the observed talent flow at time slice t is defined as

$$p(\mathcal{R}|U,V,W,\sigma) = \prod_{i=1}^{N}\prod_{j=1}^{N}\prod_{k=1}^{M}[\mathcal{N}(\mathcal{R}_{ijk}^t|f(U_i^t,V_j^t,W_k^t),\sigma^2)]^{I_{ijk}^t}, \tag{2}$$

where $\mathcal{N}(x|\mu,\sigma^2)$ is the probability density function of the Gaussian distribution with mean μ and variance σ^2, and I_{ijk}^t is the indicator function that equals to 1 if talent flow $\mathcal{R}_{ijk}^t > 0$ and equals to 0 otherwise. Specifically, we use interactions to model the relationships between talent flow R_{ijk}^t and latent vectors U_i^t, V_j^t, W_k^t. In other words, we have

$$f(U_i^t, V_j^t, W_k^t) = U_i^t V_j^t + U_i^t W_k^t + V_j^t W_k^t. \tag{3}$$

Next, we will introduce our assumptions about the time-aware relationships among U_i^t, V_j^t, and W_k^t.

As for W_k^t, in this paper, each job position represents a kind of jobs in all of time slices which play the similar function. Thus, we think it is generally time-independent and use W_k to denote the vector of job position k at all time slices. Here, we add zero-mean Gaussian priors on W, which is similar to the traditional matrix factorization [16]. Then, we have:

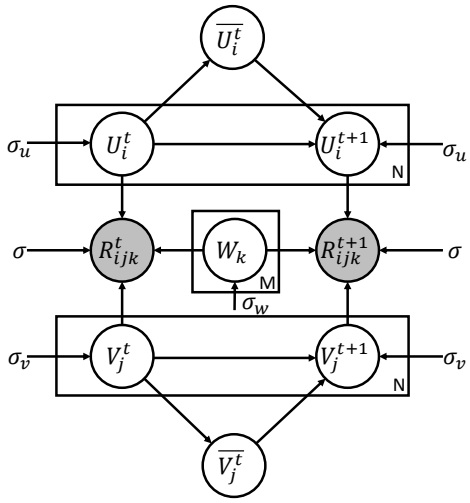

Figure 4: The graphical representation of Basic-ETF.

$$p(W|\sigma_w) = \prod_{k=1}^{M} p(W_k|\sigma_w) = \prod_{k=1}^{M} \mathcal{N}(W_k|0,\sigma_w^2 I), \tag{4}$$

where I is the D-by-D identity matrix.

As for the latent vectors of companies U_i^t and V_j^t, we think the talent preference of a company would evolve over time. Specifically, we assume there are two factors that influence companies' features in future. The first one is the **previous influence**. Intuitively, the features of company at time slice t are related to its features in the previous time slice $t-1$. In other words, the U_i^t (V_j^t) is related to $U_i^{t-1}(V_j^{t-1})$. The other one is the **market influence**, which means the company may evolve according to the general market tendency. Specifically, we assume those companies which have similar business construct the market together. And two companies are considered to have similar business when employees are very likely to move among them [3]. Therefore, here we define the business similarity of two companies based on the total number of talent transition between them. In particular, we construct a job transition network, where a node represents a company, a weighted edge represents the number of the corresponding job transitions. Then, for the target company i, at time slice t, we choose the neighbor companies that exist edges with the target company in the job transition network to represent its market, denoted by $\mathcal{M}_i^t$. And the impact of a neighbor node m to company i is denoted by P_{im}^t. In this paper, the P_{im}^t is set as follows:

$$P_{im}^t = \frac{E_{im}^t}{\sum_{m\in\mathcal{M}_i} E_{im}^t}, \tag{5}$$

where E_{im}^t denotes the total number of job transitions between company i and m. Now, we represent the market influence on the feature of origin company i by $\left(\sum_{m\in\mathcal{M}_i^{t-1}} P_{im}^{t-1} U_m^{t-1}\right)$ at time slice t, and for the destination company j by $\left(\sum_{m\in\mathcal{M}_j^{t-1}} P_{jm}^{t-1} V_m^{t-1}\right)$.

Intuitively, the companies may have their own decisions when balancing the two aspects. For example, some large companies prefer to follow their own historical state, while the small companies would like to follow the market. So we define two parameters for each company to balance the two aspects, namely α_i and β_j. Finally, the evolving process is modeled as:

$$\begin{aligned} &p(U_i^t) = \mathcal{N}(U_i^t|\bar{U}_i^t, \sigma_u^2 I), \quad p(V_j^t) = \mathcal{N}(V_j^t|\bar{V}_j^t, \sigma_v^2 I), \\ &where \quad \bar{U}_i^t = (1-\alpha_i)U_i^{t-1} + \alpha_i \sum_{m \in \mathcal{M}_i^{t-1}} P_{im}^{t-1} U_m^{t-1}, \\ &\qquad \bar{V}_j^t = (1-\beta_j)V_j^{t-1} + \beta_j \sum_{m \in \mathcal{M}_j^{t-1}} P_{jm}^{t-1} V_m^{t-1}, \\ &s.t.\ \forall i, j \in C,\ 0 \le \alpha_i \le 1,\ 0 \le \beta_j \le 1, \end{aligned} \tag{6}$$

where C denotes the company set. At the initial time $t = 1$, neither previous influence nor market influence is available. So we just assume zero-mean Gaussian distribution for the latent vectors of companies. To be specific,

$$p(U^1) = \prod_{i=1}^{N} \mathcal{N}(U_i^1|0, \sigma_u^2 I), \quad p(V^1) = \prod_{j=1}^{N} \mathcal{N}(V_j^1|0, \sigma_v^2 I). \tag{7}$$

Then, we summarize the prior over companies' latent feature matrix sequence as

$$\begin{aligned} p(U|\bar{U}, \sigma_u) &= \prod_{i=1}^{N} \mathcal{N}(U_i^1|0, \sigma_u^2 I) \prod_{t=2}^{T} \prod_{i=1}^{N} \mathcal{N}(U_i^t|\bar{U}_i^{t-1}, \sigma_u^2 I), \\ p(V|\bar{V}, \sigma_v) &= \prod_{j=1}^{N} \mathcal{N}(V_i^1|0, \sigma_v^2 I) \prod_{t=2}^{T} \prod_{j=1}^{N} \mathcal{N}(V_j^t|\bar{V}_j^{t-1}, \sigma_v^2 I). \end{aligned} \tag{8}$$

According to the graphical model shown in Figure 4, we can get the posterior distribution over U, V, W easily. To be specific,

$$\begin{aligned} &p(U, V, W|R, \sigma, \sigma_u, \sigma_v, \sigma_w) \propto \\ &p(U|\bar{U}, \sigma_u) p(V|\bar{V}, \sigma_v) p(W|\sigma_w) p(R|U, V, W, \sigma). \end{aligned} \tag{9}$$

We aim to find the value of U_i^t, V_j^t, W_k by maximizing the log-posterior of Equation 9, which is equivalent to minimizing the sum-of-squared-errors loss function:

$$\begin{aligned} \mathcal{L}_b = &\frac{1}{2} \sum_{t=1}^{T} \sum_{i=1}^{N} \sum_{j=1}^{N} \sum_{k=1}^{M} I_{ijk}^t \left(\mathcal{R}_{ijk}^t - f(U_i^t, V_j^t, W_k) \right)^2 \\ &+ \frac{\lambda_u}{2} \sum_{t=2}^{T} \sum_{i=1}^{N} \left\| U_i^t - \bar{U}_i^{t-1} \right\|_F^2 + \frac{\lambda_v}{2} \sum_{t=2}^{T} \sum_{j=1}^{N} \left\| V_j^t - \bar{V}_j^{t-1} \right\|_F^2 \\ &+ \frac{\lambda_w}{2} \sum_{k=1}^{M} \|W_k\|_F^2 + \frac{\lambda_u}{2} \sum_{i=1}^{N} \left\| U_i^1 \right\|_F^2 + \frac{\lambda_v}{2} \sum_{j=1}^{N} \left\| V_j^1 \right\|_F^2, \\ &s.t.\ \forall i, j \in C, 0 \le \alpha_i \le 1, 0 \le \beta_j \le 1, \end{aligned} \tag{10}$$

where $\lambda_u = \sigma^2/\sigma_u^2$, $\lambda_v = \sigma^2/\sigma_v^2$, $\lambda_w = \sigma^2/\sigma_w^2$ and $\|\cdot\|_F^2$ denotes the Frobenius norm.

3.2 Company Attribute Constraint

The basic model only considers the numerical job transition information, here we integrate some extra attribute information of companies into the basic model to further refine the performance of talent flow forecast, and the complete model is called ETF.

Specifically, first we extract some representative attributes for each company, which contain company's industry, scale, location, specialties, type and age. Next, these attributes of a company are integrated as a vector by using one hot encoding. To estimate the attribute similarity among companies, we choose the Cosine similarity of the corresponding vectors. Finally, we use a constraint to model the similarity between companies. We formulate the **Company Similarity Regularizer** as

$$\begin{aligned} \mathcal{L}c &= \sum_{t=1}^{T} \left(\sum_{i=1}^{N} \sum_{i'=1}^{N} S(i,i') \left\| U_i^t - U_{i'}^t \right\|_F^2 + \sum_{j=1}^{N} \sum_{j'=1}^{N} S(j,j') \left\| V_j^t - V_{j'}^t \right\|_F^2 \right) \\ &= \sum_{t=1}^{T} \sum_{i=1}^{N} \sum_{i'=1}^{N} \sum_{d=1}^{D} S(i,i') \left(U_i^t(d)^2 - U_i^t(d) U_{i'}^t(d) \right) \\ &+ \sum_{t=1}^{T} \sum_{j=1}^{N} \sum_{j'=1}^{N} \sum_{d=1}^{D} S(j,j') \left(V_j^t(d)^2 - V_j^t(d) V_{j'}^t(d) \right) \\ &= \sum_{t=1}^{T} \sum_{d=1}^{D} \left(U^t(d)^\top (\bar{S} - S) U^t(d) + V^t(d)^\top (\bar{S} - S) V^t(d) \right) \\ &= \sum_{t=1}^{T} \left(tr\left((U^t)^\top (\bar{S} - S) U^t \right) + tr\left((V^t)^\top (\bar{S} - S) V^t \right) \right), \end{aligned} \tag{11}$$

where $tr(\cdot)$ represents the matrix trace, and $S(i,i')$ is the attribute similarity between the origin company i and i'. $\bar{S}$ is the degree matrix of S, which is defined as

$$\bar{S} = \begin{cases} \sum_{i=1}^{N} S(i,i'), & i = i', \\ 0, & \text{otherwise.} \end{cases} \tag{12}$$

Here, we use the company attribute similarity matrices S to regularize the learning process of company latent matrix U^t and V^t, which guarantees the components of U^t (or V^t) should be similar if their corresponding company attributes are similar. By integrating the extra attribute information of companies into the basic model, we can obtain the final optimization objective of our model. To be specific, we have

$$min\mathcal{L} = min(\mathcal{L}_b + \lambda_c \mathcal{L}_c), \tag{13}$$

where λ_c denotes the parameter of company similarity constraint.

3.3 Model Learning and Forecasting

The coupling between U, V, W and the balance parameters make the above loss function $\mathcal{L}$ not-convex. However, a local minimum could be achieved by performing gradient descent on each parameter iteratively. Here, we introduce how to use the gradient descent approach to learn our model. The partial derivative of the balancing

Algorithm 1 Parameter Learning of the ETF

Require: $\mathcal{R} = \{\mathcal{R}^1, \mathcal{R}^2, ..., \mathcal{R}^T\}$, attribute matrix F, the learning rate η, the hypeparemeters $\lambda_u, \lambda_v, \lambda_w, \lambda_c$

8: Update latent vector V_j^t with Equation 17
9: Update bias vector α_i and β_j according to Equation 18
10: **end for**
11: **end while**

coefficient α_i and β_j are:

$$\begin{aligned}\frac{\partial \mathcal{L}}{\partial \alpha_i} &= \lambda_u \sum_{t=2}^{T}\sum_{i=1}^{N}(U_i^t - \bar{U}_i^{t-1})\left(\sum_{m\in\mathcal{M}_i^{t-1}} P_{im}^{t-1}U_m^t - U_i^{t-1}\right),\\ \frac{\partial \mathcal{L}}{\partial \beta_j} &= \lambda_v \sum_{t=2}^{T}\sum_{j=1}^{N}(V_j^t - \bar{V}_j^{t-1})\left(\sum_{m\in\mathcal{M}_j^{t-1}} P_{jm}^{t-1}V_m^t - V_j^{t-1}\right).\end{aligned} \tag{14}$$

The derivatives of job position vector W_k, the origin company's latent vector U_i^t, and destination company's vector V_j^t are

$$\frac{\partial \mathcal{L}}{\partial W_k} = \sum_{i=1}^{N}\sum_{j=1}^{N} I_{ijk}^t\left(\mathcal{R}_{ijk}^t - f(U_i^t, V_j^t, W_k)\right)(U_i^t + V_j^t) + \lambda_w W_k, \tag{15}$$

$$\begin{aligned}\frac{\partial \mathcal{L}}{\partial U_i^t} = &\sum_{j=1}^{N}\sum_{k=1}^{M} I_{ijk}^t\left(\mathcal{R}_{ijk}^t - f(U_i^t, V_j^t, W_k)\right)(V_j^t + W_k)\\ &+ \mathcal{I}[t=1]\cdot\lambda_u U_i^1 + I[t\geq 2]\cdot\lambda_u(U_i^t - \bar{U}_i^t)\\ &+ \lambda_u(1-\alpha_i)(\bar{U}_i^{t+1} - U_i^{t+1}) + \lambda_c(\bar{S} - S)U_i^t\\ &+ \lambda_u \sum_{i\in\mathcal{M}_m^t}\alpha_m \cdot P_{mi}^t(\bar{U}_m^{t+1} - U_m^{t+1}),\end{aligned} \tag{16}$$

$$\begin{aligned}\frac{\partial \mathcal{L}}{\partial V_j^t} = &\sum_{i=1}^{N}\sum_{k=1}^{M} I_{ijk}^t\left(\mathcal{R}_{ijk}^t - f(U_i^t, V_j^t, W_k)\right)(U_i^t + W_k)\\ &+ \mathcal{I}[t=1]\cdot\lambda_v V_j^1 + I[t\geq 2]\cdot\lambda_v(V_i^t - \bar{V}_i^t)\\ &+ \lambda_v(1-\beta_j)(\bar{V}_j^{t+1} - V_j^{t+1}) + \lambda_c(\bar{S} - S)V_j^t\\ &+ \lambda_v \sum_{i\in\mathcal{M}_m^t}\beta_m \cdot P_{mj}^t(\bar{V}_m^{t+1} - V_m^{t+1}),\end{aligned} \tag{17}$$

where $\mathcal{I}[x]$ is an indicator function that equals 1 if x is true and 0 otherwise. Because there is no constraint on U, V, and W at the updating step, we can directly update them by the Stochastic Gradient Descent (SGD) [1] method. As for α_i and β_j, they must be bounded between 0 and 1. So we employee the Projected Gradient (PG) [15] to achieve it. Specifically, by denoting the learning rate as η, the PG method updates α_i and β_j in $l+1$-iteration by the following rules:

$$\begin{aligned}\alpha_i^{l+1} &\leftarrow \mathcal{P}\left(\alpha_i^l + \eta\lambda_u(U_i^t - \bar{U}_i^t)(\sum_{m\in\mathcal{M}_i^{t-1}} P_{im}^{t-1}U_m^t - U_i^{t-1})\right),\\ \beta_j^{l+1} &\leftarrow \mathcal{P}\left(\beta_j^l + \eta\lambda_v(V_j^t - \bar{V}_j^t)(\sum_{m\in\mathcal{M}_j^{t-1}} P_{jm}^{t-1}V_m^t - V_j^{t-1})\right),\end{aligned} \tag{18}$$

where the function $\mathcal{P}(\cdot)$ is defined as follows:

$$\mathcal{P}(x) = \begin{cases}0, & \text{if } x \leq 0,\\ \alpha_i, & \text{if } 0 \leq x \leq 1,\\ 1, & \text{if } x \geq 1.\end{cases} \tag{19}$$

In conclusion, Algorithm 1 describes the optimization process of the ETF model. After learning the related parameters U, V, W, α, and β, we can forecast the $\mathcal{R}_{ijk}^{T+1}$ by:

$$\begin{aligned}U_i^{T+1} &\approx U_i^T + \alpha_i \sum_{m\in\mathcal{M}_i^T} P_{im}^T U_m^T,\\ V_j^{T+1} &\approx V_j^T + \beta_j \sum_{m\in\mathcal{M}_j^T} P_{jm}^T V_m^T,\\ \mathcal{R}_{ijk}^{T+1} &\approx f(U_i^{T+1}, V_j^{T+1}, W_k).\end{aligned} \tag{20}$$

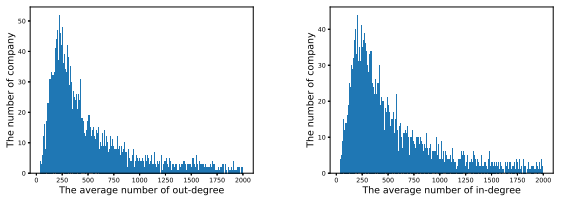
4 EXPERIMENTS

In this section, we introduce the experimental results for validating the effectiveness of our approach.

4.1 Data Pre-processing

There are three main steps of data pre-processing, namely *data filtering*, *job title categorization* and *Data Spliting*.



Data Filtering. In our real-world dataset, there are 670,260 unique companies. To avoid noise, we removed the companies that appeared in less than 1,000 resumes, and removed the resumes that contained only one company in the experience records (i.e., without job-hopping). After that, we finally retained 4,567 target

Table 2: Statistics of our dataset.

The number of resumes	2,176,157
The number of companies	4,567
The number of transition records	5,875,626

companies for experiments. Meanwhile, as shown in Figure 5, the frequency of job transition has a clear cycle of 12 months. Therefore, in the experiments, we set the length of time window as one year. Moreover, we also find that the frequency of job transition grows steadily before January 2016, while the frequency dropped significantly after then. It is because that, in most cases, the users in OPNs do not update their profiles immediately after changing the job. Therefore, the closer the date of job transition is to the time of data collection (e.g., January 2017 for our dataset), the more incomplete data is obtained. To guarantee the effectiveness of evaluation, we only selected the job transition records between January 2010 and January 2016 for experiments. The detailed statistics of our pre-processed dataset are shown in Table 2. In addition, Figure 6 shows the distribution of the number of companies with respect to different average number of out/in-flow of talents each year. From the results, we can find that both distributions are unbalanced, and most of the companies only have limited rate of talent flows, while only few companies have high rate of talent flows.

Job Title Categorization. In our dataset, there are total 448,309 unique job titles, which were filled in by users without specification. In our experiments, to normalize the job titles, we used an online API called MonkeyLearn [1] to categorize the original job titles into 26 classes according to the job descriptions written in the resumes. The detailed results of job title categorization in our dataset is shown in Table 3.

(a) Average Number of Out-degree (b) Average Number of In-degree

Figure 6: The distributions of the number of companies w.r.t the average number of in/out-flows of talents each year.

Data Spliting. After the above data-processing, we further standardized the date of job transitions into different time slices with year-based granularity. In the evaluation, we split four experimental datasets according to the time slice, the statistics of which are shown in Table 4. Specifically, we used the data as of time slice T for model training in the data splitting process, e.g., T=5 (T=3) in DATA10-15 (DATA12-15), and the data at the last time slice for test, e.g., T=6 (T=4) in DATA10-15 (DATA12-15). Finally, to initialize the talent flow tensor, we aggregated all transition records by the origin company, destination company, job category and time slice simultaneously.

4.2 Evaluation on Talent Flow Forecast

In this subsection, we introduce the evaluation of our approach in talent flow forecast.

Baselines. To evaluate the performance of our model in talent flow forecast, we selected a number of state-of-art methods as baselines. Specifically, we first chose two popular tensor factorization based approaches, and several latent factor based evolutionary approaches. Then, to further validate the performance of each component in our model, we also designed some simplified variants of our model.

- **CP (CANDECOMP/PARAFAC)** [11], which decomposes the tensor into same rank of latent factors, i.e., an n-dimensional tensor is factorized into a sum of outer products of n vectors.
- **Tucker** [5], which considers the tensor factorization problem as the high order PCA, i.e., an n-dimensional tensor is factorized into a small core tensor and n matrices.
- **BPTF** [22], which extends PMF [16] to tensor factorization for modeling the temporal relational data by creating an additional latent feature vector for each time slice.
- **CKF** [19], which models the temporal dynamics by allowing users' factors to evolve through the linear state space model.
- **BTMF** [28], which extends the conventional matrix factorization by assuming the user preferences change over time, and models the dynamics by learning a transition matrix for user latent vectors between consecutive time windows.
- **Pure-ETF**, which is a simple version of ETF, by ignoring the influence of neighbor when modeling the evolution process and the attribute information of company. It equals to minimizing the loss function defined in Equation 10 with $\alpha_i = \beta_j = 0$, for each $i, j \in C$.
- **Basic-ETF**, which is a simplified version of ETF, by considering the evolutionary process with loss function defined in Equation 10.

Evaluation Metrics. In our experiments, we chose two metrics for evaluating the performance of talent forecast, namely Root Mean Squared Error (RMSE) and Mean Absolute Error (MAE). Specifically, the two metrics are defined as

$$RMSE(y, \hat{y}) = \sqrt{\frac{1}{n}\sum_{t=1}^{n}(y_i - \hat{y}_i)^2}, \tag{21}$$

$$MAE(y, \hat{y}) = \frac{1}{n}\sum_{t=1}^{n}|y_i - \hat{y}_i|, \tag{22}$$

where y_i is the actual value, while $\hat{y}_i$ is the estimated value, and n is the number of test instances. Generally speaking, the best prediction has a value of 0 of both RMSE and MAE. And the lower values of these metrics are, the better forecast is obtained. Both metrics were selected since they are widely adopted in evaluating forecasting models [9]. Meanwhile, the RMSE is a part of our loss function (i.e., defined in Equation 10), so that it is suitable to validate whether our model is over-fitting in the training stage.

Evaluation Setup. In our experiments, each method was evaluated at four datasets, as shown in Table 4. Specifically, 10% records

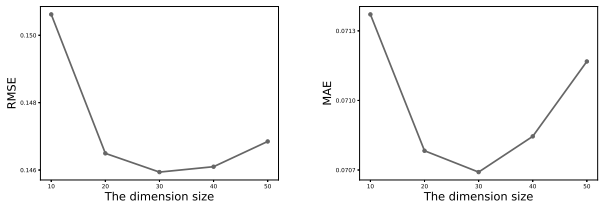
Table 4: The Statistics of Experimental Dataset

DataSet	Density	# Training	# Test
DATA10-15	9.5787 ‰	3,116,686	514,582
DATA11-15	9.2922 ‰	2,519,555	514,582
DATA12-15	8.6874 ‰	1,884,447	514,582
DATA13-15	7.6677 ‰	1,247,452	514,582

of the training data were selected randomly as validation data for parameter tuning. The rest part of training data were used to train models. And the final performance was evaluated on the test set.

For the tensor factorization based approaches to forecast, such as CP and Tucker, we trained these models on the training tensors directly. After getting the representation of each time slice in the training data, the average representation of each time slice, such as $1, 2, \ldots, T$, was used to denote the representation of $T+1$ [7]. Finally, we could predict the value at time $T+1$ based on the specific decomposition strategy of each method. For the evolution based approaches, such as BPTF, CKF and BTMF, which only consider two dimensions (e.g., user- and item-dimension) at a specific time, we changed the form of our dataset. Specifically, we merged the `Original Company` and `Job Position` dimensions of our tensor at time t to construct an extended matrix. Then in our experiments, we treated the job position of a original company as "user" and treated the destination company as the "item", for executing each method. In particular, all the parameters of models were tuned in the validation set to ensure the best performance.



Overall Performance. The overall RMSE and MAE results of different approaches are shown in Table 5 and 6 respectively. Obviously, our ETF method achieves the better performance than all the baselines in all cases. And from the results, we can have the following observations. First, the tensor factorization based models always get the worst performance, which is because they treat time as a separate element and ignore the evolutionary relationship of latent factors. Second, the Pure-ETF model, which is the simplified version of ETF achieves the better performance than the latent factor based evolutionary models. i.e., BPTF, CKF and BTMF. This

means considering the interaction of three factors is more effective than only considering two factors. Third, Basic-ETF outperforms Pure-ETF, which means that considering the market influence in evolution process is effective. Meanwhile, we find the attribute similarity based constraints can improve the model by 1% at least

(a) RMSE (b) MAE

Figure 8: The evaluation on the impact of the λ_u and λ_v.

(a) RMSE (b) MAE

Figure 9: The evaluation on the impact of the λ_w and λ_c.

in RMSE metric and 5% at least in MAE. Finally, the prediction performance of methods which model the evolutionary process is related to the length of time slices. The longer the length of time slices is, the better performance is obtained. It may because that the longer time slices can help to capture the regular pattern of evolution. Meanwhile the performance of ETF drops slowly than all baselines as the time slices decrease, which validates the robustness of our model.

4.3 Evaluation on Parameter Sensitivity

Here, we turn to discuss the sensitivity of parameters in our approach. Specifically, several parameters will be discussed, namely the dimension of latent factor D, the coefficient of original company vector λ_u, the coefficient of destination company vector λ_v, the coefficient of job vector λ_w and the coefficient of company similarity constraints λ_c. All the experiments were conducted on DATA11-15, and we executed the model for three times and used the average of result to represent the final performance.

First, we discuss the sensitiveness of the dimension of latent factor D, which is summarized in Figure 7. By setting D from 10 to 50, we find that the generally the increasing D will improve the performance, which could be reasonable as more dimensions may probably keep more useful information. However, the performance of the model drops a little, which may because that the more parameters cause the model over-fitting at the training stage. Second, we discuss the sensitiveness of the evolving parameter λ_u and λ_v, which is shown in Figure 8. By setting parameters from 0.01 to 0.05, we find that the model gets the best performance when $\lambda_u = 0.02$ and $\lambda_v = 0.04$ on both metrics. Finally, we set λ_w and λ_c from 0.01 to 0.05. As the result shown in Figure 9, we find that the model gets the best performance when $\lambda_w = 0.02$ and $\lambda_c = 0.02$.

4.4 Case Study

Here we introduce a case study of talent flow forecast for further validating our approach. Specifically, we trained the ETF model based on the job transition records from January 2010 to December 2015, and forecasted the out-flow for engineers (i.e., employees with engineering related jobs) of Google in 2016 by Equation 20. The ground truth results in 2015/2016 and the forecast results in 2016 are all shown in Figure 10, where the size of words are proportional to the number of talent flows (i.e., more attractive). Based on the results, we can obtain two findings. First, comparing with the ground truth in 2016, the forecast results have very similar distributions, which clearly validates the performance of our approach. Second, comparing the ground truth in 2015 and 2016, we can find that the distributions of companies have obvious difference, which indicates the dynamic characteristics of talent flows. For example, Facebook becomes more and more attractive for the engineers from Google. Indeed, our approach can clearly capture such change of talent flows, which validates the effectiveness of using dynamic latent factors for modeling the evolving of talent flows.

5 RELATED WORK

In this section, we will summarize the related works in the following three categories, namely the talent flow analysis, time-dependent collaboration filtering and tensor factorization.

Talent Flow Analysis. As a crucial issue of human resource management, talent management has attracted wide attention in the past decade. On the one hand, the studies of talent flow analysis, especially those designed by researchers with sociology background, mainly discussed the potential causes of talent flows. For instance, at the national level, [2] and [20] proposed several factors that might influence the decision to migrate, such as economic, family and so on. Besides, a few studies investigated the national talent flow issues with the consideration of "brain drain" in several countries [2], [10], [31]. In addition to these macro-level talent flow analysis, [8] analyzed the factors for influencing individual job hopping, such as the salary level, job satisfaction and so on. On the other hand, with the prevalence of online professional networks (OPNs), a large number of digital resumes of talents can be collected. With these kind of data, there emerges a tend of conducting talent-related studies with machine learning methods. For instance, [21] and [23] predicted the individual job changes for understanding the professional careers of talents. [27] aimed to find the professional similarity between talents. [3] predicted the salary at company level by using talent transition data. [24] proposed the concept of job transition network (JTN) and extracted talent circle for talent recruitment. Recently, [25] extended the JTN with a dynamic setting and focused on the prediction of edge weights in dynamic JTN. Different from the above literatures, in this paper, we aim to introduce a big data-driven approach for predictive talent flow analysis, i.e., forecasting the future talent flows in a fine-grained manner.

Time-Dependent Collaborative Filtering. Latent factor model are widely used [29] [30], and the technical solution of this paper follows the idea of the model based collaborative filtering, which maps both preferences of users and items into the low-dimensional vector space, and conducts recommendations based on the learned latent factors [13]. However, since user preferences usually change

(a) Ground Truth-2015 (b) Ground Truth-2016. (c) Forecast-2016.

Figure 10: (a)-(b) The ground truth of the most attractive companies to engineers of Google in 2015 and 2016. (c) The forecast of the most attractive companies to engineers of Google in 2016 by our model.

over time, it is important to take the dynamics of preferences into account [6] [18] [26]. For instance, [12] proposed the TimeSVD++, which modeled the temporal dynamics of user latent vectors by summarizing three factors. [14] assumed the users' preferences would change smoothly over time, and the current preference of a user was the prior to future preference. [28] proposed the BTMF, which modeled the dynamics by learning the transition matrix for each user's latent vector between consecutive time windows. [19] modeled the dynamics of user's latent vector through a linear state space model. In fact, it is equal to learning a shared transition matrix for all users' latent factors evolving while each user has a specific bias evolving vector. In this paper, we also try to learn the vectors for three components, i.e., origin company, destination company and job position. Meanwhile, we assume the vectors of companies are time-dependent. Different from the above works, we model the evolving process of companies' vector by considering two kinds of influence, i.e., previous influence and market influence, which is more suitable for the scenario of talent flow forecast.

Tensor Factorization. There are two kinds of popular tensor factorization models, namely the CANDECOMP/PARAFAC (CP) model [11] and the Tucker model [5]. Specifically, the CP model factorizes a tensor into the sum of outer products of n vectors, and the Tucker model factorized an n-dimensional tensor into a small core tensor and n matrices. In the literatures, there are some works on integrating the temporal information for tensor factorization. For instance, [22] created an additional latent feature vector for each time slice and modeled each entry of the tensor as the inner product of latent factors of user, item and time slice. [17] defined a new measure of user preference dynamics to capture the shifting rate for each user. And it further modeled users' preference dynamics and users' side information in coupled tensor factorization. [7] considered the bipartite graphs that evolved over time and demonstrated that tensor based methods were effective for temporal data with varying periodic patterns. Different from these methods, in this paper, we propose a novel approach to model the evolution of talent flows, instead of learning the vector of time slice directly.

6 CONCLUSION

In this paper, we studied the problem of talent flow forecast from a data-driven perspective. Specifically, we first constructed a time-aware job transition tensor by mining the large-scale job transition records of digital resumes in online professional networks (OPNs). Then, we designed a dynamic latent factor based Evolving Tensor Factorization (ETF) model for predicting the future talent flows. In particular, a novel evolving feature by jointly considering the influence of previous talent flows and global market was introduced for modeling the evolving principles of each company. Furthermore, to improve the predictive performance of ETF, we also integrated the company similarity as side information for regulating the model inference. Finally, extensive experiments conducted on a large-scale real-world dataset clearly validate the effectiveness of our approach.

ABSTRACT

Stance detection has gained increasing interest from the research community due to its importance for fake news detection. The goal of stance detection is to categorize an overall position of a subject towards an object into one of the four classes: *agree*, *disagree*, *discuss*, and *unrelated*. One of the major problems faced by current machine learning models used for stance detection is caused by a severe class imbalance among these classes. Hence, most models fail to correctly classify instances that fall into minority classes. In this paper, we address this problem by proposing a hierarchical representation of these classes, which combines the agree, disagree, and discuss classes under a new *related* class. Further, we propose a two-layer neural network that learns from this hierarchical representation and controls the error propagation between the two layers using the Maximum Mean Discrepancy regularizer. Compared with conventional four-way classifiers, this model has two advantages: (1) the hierarchical architecture mitigates the class imbalance problem; (2) the regularization makes the model to better discern between the related and unrelated stances. An extensive experimentation demonstrates state-of-the-art accuracy performance of the proposed model for stance detection.

1 INTRODUCTION

The quality of online news is usually less substantiated than that of traditional news services such as magazines or newspapers [1, 45, 47]. A large volume of fake news is being produced for political or economical purposes [8, 22, 41]. Fake news are those news articles that purport to be factual, but which contain misstatements of fact with intention to arouse passions, attract viewership, or deceive [25, 37, 44]. Verifying news content needs to retrieve *evidences* and determine their *stance* with respect to the *news claims*, which proposes new challenges for the conventional stance detection task [31, 36]. We specify evidence as text, e.g. web-pages and documents, that can be used to prove if news content is or is not true. Moreover, automatic stance detection has broad applications in information retrieval and text entailment [34, 42].

The task of stance detection is to identify the stance of an evidence towards a given news claim [12, 13]. Stances can be categorized into four classes: *agree*, *disagree*, *discuss* and *unrelated* [17]. Two characteristics make the stance detection task peculiar. On the one hand, news claims and evidences are often unrelated – generating a severe class imbalance problem; On the other hand, since the non-related classes are by definition related, intuitively, the identification of an evidence as related or unrelated to a news claim is semantically different from the identification of an evidence as belonging to one of the other three classes. These two characteristics suggests the natural presence of a hierarchical structure among stance classes.

Stance detection has been studied in areas of information extraction and natural language processing [11, 40]. However, previous methods tackle the task as a multiclass classification problem, neglecting the hierarchical structure in stance classes. Also, the commonly-used four-way classifiers are easily influenced by the class imbalance problem. In this paper, we address this issue by modeling the stance detection task as a two-layer neural network. The first layer aims at identifying the relatedness of the evidence, while the second layer aims at classifying, those evidences identified as related, into the other three classes: agree, disagree and discuss. Moreover, by studying various level of dependence assumptions between the two layers: (1) independent, when there is no error propagation between the two layers; (2) dependent, when the error propagation is left free, and; (3) learned, when the error propagation is controlled by Maximum Mean Discrepancy (MMD), we

show that when learned, the neural network (a) better separates the distributions of related and unrelated stances and (b) outperforms the state-of-the-art accuracy for the stance detection task.
The remainder of the paper is organized as follows: § 2 summarizes the related work; § 3 defines the stance detection task; § 4 details the proposed hierarchical classification model and the regularization term; § 5 describes the used datasets and experimental setup; § 6 is devoted to experimental results, and; § 7 concludes the paper.

2 RELATED WORK

Machine learning techniques are widely researched to tackle the stance detection task. Previous works focus on political or congressional floor debates [11, 40, 46] and online forums [2, 19, 27, 38, 39, 42]. Most of these works rely on content-based features, such as sentiment analysis and topic-specific features learned from labeled datasets for a closed set of topics.

Two methods only consider the agree, disagree and discuss classes: Bar-Haim et al. [7] split the stance detection task to three sub-tasks and propose a Contrast Classification Algorithm to distinguish agree and disagree classes; Augenstein et al. [4] build a neural network architecture based on bidirectional conditional encoding on a Tweeter dataset. A long-short term memory (LSTM) encodes the claim and another LSTM encodes the text with the encoded claim as initial states. These methods fail to consider the unrelated class.

Two other methods consider all the classes, but use two different models: Bourgonje et al. [10] use the lemmatized n-gram matching and a rule-based procedure to decide the evidence relatedness, and a three-way logistic regression classifier to distinguish among the relevant classes; Wang et al. [43] firstly develop a gradient boosted decision tree (GBDT) model [28] to determine the evidence relatedness, then another GBDT model is used to distinguish stances of the text towards the claim. These methods involve feature engineering in separate models and cannot be jointly optimized to achieve the best performance.

Other methods that also consider all the classes have been developed during the Fake News Challenge stage 1 (FNC-1) [18]. The winner team uses a 50%/50% weighted average between a GBDT model and a convolutional neural network (CNN) [5]. The second best performance is achieved by an ensemble of five multi-layer perceptrons (MLPs) where input features include bag-of-words, semantic analysis in addition to the baseline features developed by the challenge organizers [16]. Compared to the above two solutions, the third best team does not try ensemble methods. They use TF-IDF features and an MLP as a four-way classifier [33]. Zhang et al. [48] propose a ranking method to tackle the task and achieve empirical performance improvements. However, these methods all neglect the hierarchical structure among the four types of stances and suffer from class imbalance.

Deep learning-based methods have also been applied in the FNC-1. Bajaj [6] utilizes LSTM, CNN and their variants to detect stances. Bajaj finds that an attention-augmented CNN obtains the best performance. Rakholia and Bhargava [32] analyze the effectiveness of different ways of text coding, such as independent coding, bidirectional conditional encoding and attentive readers, and conclude that the attentive reader model is the most suitable for the task. Ma et al. [23] propose a multi-task learning algorithm that jointly detect rumours and stances. However, all these methods fail to achieve high accuracy for the agree and disagree classes.

There are three major defects in all the aforementioned methods: (a) they neglect the hierarchical relationships among the four stances; (b) they suffer from the class imbalance problem, and; (c) they fail to achieve acceptable detection performance for the agree and disagree classes.

3 STANCE DETECTION TASK

The stance detection task consists in classifying the stance of an evidence towards a claim as one of the four classes: agree, disagree, discuss and unrelated. Formal definitions of these four stances are:

agree – the evidence supports the claim;
disagree – the evidence denies the claim;
discuss – the evidence does not have a position about the claim;
unrelated – the evidence is not about the claim.

4 HIERARCHICAL CLASSIFICATION

In this section, we detail our proposed two-layer neural network for stance detection. § 4.1 outlines the model. In order to better differentiate between the related and unrelated classes, we design an MMD regularization term in § 4.2. This is then integrated into the two-layer neural network loss function in § 4.3. In Figure 1, we show the architecture of our model.

4.1 Two-Layer Neural Network

Let the input space be formed by m-dimensional real vectors in a neural network, denoted as $\mathbf{v} \in \mathbb{R}^m$. The four-class label can be transformed into a one-hot vector $\mathbf{y}$. The i-dimension of $\mathbf{y}$ (y_i) is 1 when the stance is the i-element in the label set $\{agree, disagree, discuss, unrelated\}$ and 0 otherwise. The hidden layer with parameters θ_u learns to map $\mathbf{v}$ to a k-dimensional hidden representation $\mathbf{u} \in \mathbb{R}^k$:

$$\mathbf{u} = f(\mathbf{v}; \theta_u). \tag{1}$$

For the two-layer classification, the first layer decides whether the evidence is related to a claim. Hence, the first classification layer is called *the relatedness layer*. This layer is parameterized by θ_r and learns to produce a 2-dimensional normalized vector $\hat{\mathbf{r}}$ as follows:

$$\hat{\mathbf{r}} = g(\mathbf{u}; \theta_r). \tag{2}$$

Note that the Softmax function is included in g to normalize the 2-dimensional vector, so each component of the vector $\hat{\mathbf{r}}$ denotes the probability that the neural network assigns $\mathbf{v}$ to the related and unrelated classes, i.e., $p(related)$ and $p(unrelated)$.

The second layer classifies the evidence into the related classes, i.e., agree, disagree, or discuss stances. Hence, the second classification layer is called *the stance layer*. The stance layer is parameterized by θ_s and learns to produce a 3-dimensional normalized vector $\hat{\mathbf{s}}$:

$$\hat{\mathbf{s}} = h(\hat{r} \cdot (1, 0); \theta_s), \tag{3}$$

where the vector multiplication $\hat{r} \cdot (1, 0)$ extracts the first element of $\hat{\mathbf{r}}$. Note that the Softmax function is also included in h to normalize the 3-dimensional vector, so that each component of the vector $\hat{\mathbf{s}}$ denotes the conditional probability that the neural network

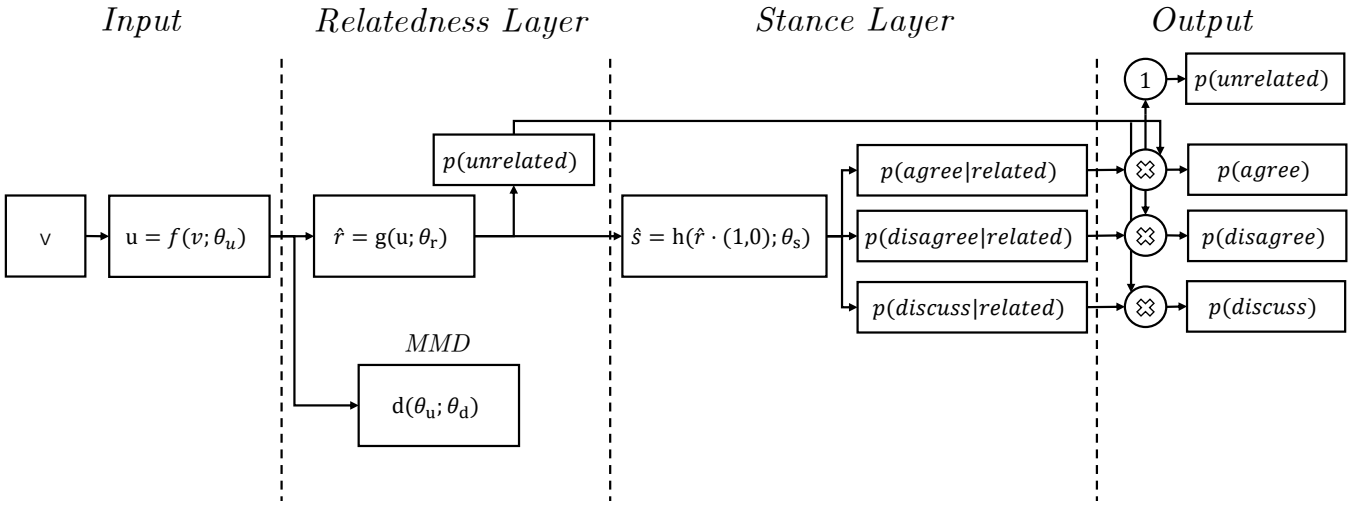

Figure 1: The architecture of our proposed two-layer neural network.

assigns $\mathbf{v}$ to agree, disagree and discuss given that $\mathbf{v}$ is related, i.e., $p(agree|related)$, $p(disagree|related)$, and $p(discuss|related)$.

We define the classification loss by the Kullback-Leibler (KL) divergence [21], which measures the difference between the network outputs and labels:

$$l^r(\theta_u, \theta_r) := \mathrm{KL}(\mathbf{r}||\hat{\mathbf{r}}), \tag{4}$$

where $\mathbf{r}$ is the ground-truth relatedness of the input data. $\mathbf{r}$ is computed from a label $\mathbf{y}$ as follows:

$$\mathbf{r} = (\mathbb{1}(\mathbf{y} \neq \mathbf{e}_4), \mathbb{1}(\mathbf{y} = \mathbf{e}_4)), \tag{5}$$

where $\mathbb{1}$ is the indicator function, $\mathbf{e}_4$ is a 4-dimensional one-hot vector with fourth element equal to 1. When $\mathbf{y} = \mathbf{e}_4$ is verified, it indicates that the label belongs to the unrelated class. Similarly, the stance classification loss can be defined as:

$$l^s(\theta_u, \theta_r, \theta_s) := \mathrm{KL}(\mathbf{s}||\hat{\mathbf{s}}), \tag{6}$$

where $\mathbf{s}$ is the ground-truth stance of the input data. $\mathbf{s}$ is computed from a label $\mathbf{y}$ as follows:

$$\mathbf{s} = (\mathbb{1}(\mathbf{y} = \mathbf{e}_1), \mathbb{1}(\mathbf{y} = \mathbf{e}_2), \mathbb{1}(\mathbf{y} = \mathbf{e}_3)), \tag{7}$$

where $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ are 4-dimensional one-hot vectors with first, second, and third elements equal to 1. When $\mathbf{y} = \mathbf{e}_1$ is verified, it indicates that the label belongs to the agree class, when $\mathbf{y} = \mathbf{e}_2$ is verified, it indicates that the label belongs to the disagree class, and when $\mathbf{y} = \mathbf{e}_3$ is verified, it indicates that the label belongs to the discuss class.

Finally, we now define the loss function for the two-layer neural network as the linear combination between the loss function of the relatedness layer (l^r) and the loss function of the stance layer (l^s):

$$l^c(\theta_u, \theta_r, \theta_s) := l^r(\theta_u, \theta_r) + \alpha \cdot l^s(\theta_u, \theta_r, \theta_s), \tag{8}$$

where α leverages the importance of the two classification layers.

4.2 Maximum Mean Discrepancy

The classification of related/unrelated stances is a different task from that of agree/disagree/discuss stances. Therefore, data representations from the relatedness layer and the stance layer can be seen as samples drawn from two different distributions. In order to measure distribution discrepancy between these two layers, we employ the Maximum Mean Discrepancy (MMD) [9] as a regularization term. The MMD does not involve density estimation and thus is a non-parametric way of measuring the difference between distributions. MMD has achieved success in face recognition and image annotation [15].

MMD is defined as follows:

Definition 4.1. Maximum Mean Discrepancy [9]: "Let p and q be two Borel probability distributions over a space $\mathcal{X}$ and let X and Z be sets with independent identically distributed samples drawn from p and q. The MMD is defined by a class Ψ of map functions ψ: $\mathcal{X} \to \mathcal{H}$ as:

$$MMD(p, q, \Psi) = \sup_{\psi \in \Psi} (\mathbf{E}_p[\psi(x)] - \mathbf{E}_q[\psi(z)]). \tag{9}$$

Here, x and z are samples from X and Z."

In other words, the MMD equation defines the largest possible distance between two expectations over the set of function Ψ. Moreover, "when $\mathcal{H}$ is the reproducing kernel Hilbert space (RKHS) [3], this means that for all $x \in \mathcal{X}$, the linear point evaluation function mapping $\psi \to \psi(x)$ exists and is continuous. When Ψ is the unit ball in a universal RKHS, it is guaranteed that $MMD(p, q, \Psi)$ will detect any discrepancy between p and q [9, 35]."

Let p denote the distribution for the first layer samples (unrelated hidden representations) in our model, with sample set $\mathcal{U}^1 = \{\mathbf{u}_1^1, \ldots, \mathbf{u}_{n_1}^1\}$ and according to Eq. (1) their generating set $\mathcal{V}^1 = \{\mathbf{v}_1^1, \ldots, \mathbf{v}_{n_1}^1\}$. And, q denotes the distribution for the second

layer samples (agree, disagree and discuss hidden representations), with sample set $\mathcal{U}^2 = \{\mathbf{u}_1^2, \ldots, \mathbf{u}_{n_2}^2\}$ and according to Eq. (1) their generating set $\mathcal{V}^2 = \{\mathbf{v}_1^2, \ldots, \mathbf{v}_{n_2}^2\}$. n_1 and n_2 are the number of samples in $\mathcal{U}^1$ and $\mathcal{U}^2$. Thus we have $\mathcal{X} = \mathcal{R}^k$ and $\mathcal{H} = \mathcal{R}^j$ with $\psi(x) = \theta_d x$, where θ_d is a $j \times k$ matrix in *the projection layer*. k and j are the space dimensions. According to Eq. (1), the hidden representation $\mathbf{u}$ is parameterized by θ_u, thus the empirical expression of MMD is parameterized by θ_u and θ_d:

$$d(\theta_u, \theta_d) = \frac{1}{n_1}\sum_{i=1}^{n_1}\theta_d \mathbf{u}_i^1 - \frac{1}{n_2}\sum_{i=n_1+1}^{n_1+n_2}\theta_d \mathbf{u}_i^2 \tag{10}$$

$$= \frac{1}{n_1}\sum_{i=1}^{n_1}\theta_d f(\mathbf{v}_i^1;\theta_u) - \frac{1}{n_2}\sum_{i=n_1+1}^{n_1+n_2}\theta_d f(\mathbf{v}_i^2;\theta_u). \tag{11}$$

By constantly changing *the projection layer* parameterized by θ_d, we find the maximum expectation difference between the representations of the two classification layers.

4.3 Optimization

The more different two distributions are, the larger the MMD is. Hence, in order to make the distributions easier to be distinguished, a larger MMD regularization term is preferred, and we treat the regularization term as an extra goal besides classification. We integrate the two-layer classification loss (see Eq. (8)) and the MMD regularization term (see Eq. (10)) into a single objective function (L). Specifically, we add these two sub-goals with a hyperparameter β as follows:

$$L(\theta_u, \theta_r, \theta_s, \theta_d) = l^c(\theta_u, \theta_r, \theta_s) - \beta \cdot d(\theta_u, \theta_d), \tag{12}$$

where β leverages the importance of the regularization. The larger the MMD regularization term is, the easier is for the classifier to distinguish between the related and unrelated stances. Thus, the sign of the regularization term is negative.

The optimization involves the minimization of the classification loss L with respect to θ_u, θ_r, θ_s, and θ_d as follows:

$$\min_{\theta_u, \theta_r, \theta_s, \theta_d} L(\theta_u, \theta_r, \theta_s, \theta_d). \tag{13}$$

Optimizing the model consists of two sub-goals. On the one hand, we want to maximize the distribution discrepancy between the two classification layers. On the other hand, we want to minimize the classification loss of both layers. Both of these two sub-goals involve the feature layer parameter θ_u update, but in opposite update directions. The optimization process will not stop until a saddle point (the feature layer parameters can be well applied in both sub-goals) is reached. Algorithm 1 shows the parameter update process, which is based on the mini-batch gradient descent algorithm.

4.4 Prediction
