As we know that the policy $\boldsymbol{\pi}^t$ is Lipschitz continuous w.r.t ϕ^t, this implies that $\boldsymbol{A}_\phi$ and $\boldsymbol{b}_\phi$ are also Lipschitz continuous w.r.t to ϕ. In other words, if $\frac{K}{2T} \leq C_0$ is sufficiently small and close to zero, then the norm term of $\left(\sup_{\boldsymbol{\phi}}||\boldsymbol{A}_\phi - \boldsymbol{A}_{\phi^*}||_2 + \sup_{\boldsymbol{\phi}}\frac{||\boldsymbol{b}_\phi - \boldsymbol{b}_\phi^*||_2}{||\boldsymbol{\phi} - \boldsymbol{\phi}^*||_2}\right)$ goes to zero. Considering near the equilibrium point ϕ^*, $\boldsymbol{A}_{\phi^*}$ is a negative definite matrix, the Eq. (16) tends to be negative definite as well, so the ODE in Eq.(15) is globally asymptotically stable and the conclusion of the theorem follows. □

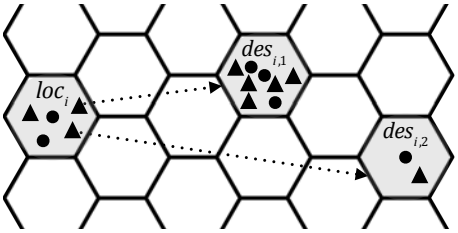

Figure 3: Illustration of the grid-based simulator. All location features are represented by the corresponding grid ID. The order origin $ori_{i,m}$ is the same as the driver location loc_i.

While in practice, we might break the linear condition by the use of nonlinear activation functions, the Lipschitz continuity will still hold as long as the nonlinear add-on is limited to a small scale.

3 EXPERIMENT

To support the training and evaluation of our MARL algorithm, we adopt two simulators with a grid-based map and a coordinate-based map respectively. The main difference between these two simulators is the design of the driver pick-up module, i.e., the process of a driver reaching the origin of the assigned order. In the grid-based simulator (introduced by Lin et al. [19]), the location state for each driver and order is represented by a grid ID. Hence, the exact coordinate for each instance inside a grid is shadowed by the state representation. This simplified setting ensures there will be no pick-up distance (or arriving time) difference inside a grid; it also brings an assumption of no cancellations before driver pick-up. Whereas in the coordinate-based simulator, the location of each driver and order instance is represented by a two-value vector from the Geographic Coordinate System, and the cancellation before pick-up is also taken into account. In this setting, taking an order within an appropriate pick-up distance is crucial to each driver, as the order may be canceled if the driver takes too long time to arrive. We present experiment details of the grid-based simulator in Section 3.1, and the coordinate-based simulator in Section 3.2.

3.1 Grid-based Experiment

3.1.1 Environment Setting. In the grid-based simulator, the city is covered by a hexagonal grid-world as illustrated in Fig. 3. At each simulation time step t, the simulator provides an observation $\boldsymbol{o}^t$ with a set of active drivers and a set of available orders. Each order feature includes the origin grid ID and the destination grid ID, while each driver has the grid ID as the location feature loc_i. Drivers are regarded as homogeneous and can switch between online (active) and offline via a random process learned from the history data. As the travel distance between neighboring grids is approximately 1.2 kilometers and the time step interval $t_\triangle$ is 10 minutes, we assume that drivers will not move to other grids before taking a new order, and define the order receiving area and the neighborhood as the grid where the agent stays. The order dispatching algorithm then generates an optimal list of driver-order pairs $\boldsymbol{a}^t$ for the current policy, where a_i is an available order $a_{i,m}$ selected from the order candidate pool $\mathcal{A}_i$. In the grid-based setting, the origin of each order is already embedded as the location feature loc_i in o_i, thus $a_{i,m}$ is parameterized by the destination grid ID $des_{i,m}$. After receiving the driver-order pairs from the algorithm, the simulator will then return a new observation $\boldsymbol{o}^{t+1}$ and a list of order fees. Stepping on this new observation, the order dispatching algorithm will calculate a set of rewards r^t for each agent, store the record $(\boldsymbol{o}^t, \boldsymbol{a}^t, \boldsymbol{r}^t, \boldsymbol{o}^{t+1})$ to replay buffer, and update the network parameters with respect to a batch of samples from replay buffer.

The data source of this simulator (provided by DiDi Chuxing) includes order information and trajectories of vehicles in three weeks. Available orders are generated by bootstrapping from real orders occurred in the same period during the day given a bootstrapping ratio p_{sample}. More concretely, suppose the simulation time step interval is $t_\triangle$, at each simulation time step t, we randomly sample p_{sample} orders with replacement from real orders happened between $t_\triangle * t$ to $t_\triangle * (t+1)$. Also, drivers are set between online and offline following a distribution learned from real data using a maximum likelihood estimation. On average, the simulator has $7K$ drivers and $136K$ dispatching events per time step.

The effectiveness of the grid-based simulator is evaluated by Lin et al. [19] using the calibration against the real data regarding the most important performance measurement: the accumulated driver income (ADI). The coefficient of determination r^2 between simulated ADI and real ADI is 0.9331 and the Pearson correlation is 0.9853 with p-value $p < 0.00001$.

3.1.2 Model Setting. We use the grid-based simulator to compare the performance of following methods.

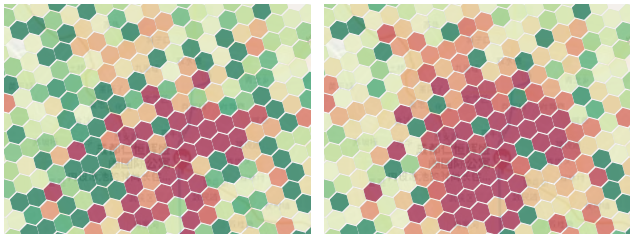
- **Random (RAN)**: The random dispatching algorithm considers no additional information. It only assigns all active drivers with an available order at each time step.
- **Response-based (RES)**: This response-based method aims to achieve higher order response rate by assigning drivers to short duration orders. During each time step, all available orders starting from the same grid will be sorted by the estimated trip time. Multiple orders with the same expected duration will be further sorted by the order price to balance the performance.
- **Revenue-based (REV)**: The revenue-based algorithm focuses on a higher ADI. Orders with higher prices will be given priority to get dispatched first. Following the similar principle as described above, orders with shorter estimated trip time will be assigned first if multiple orders have the same price.
- **IOD**: The independent order dispatching algorithm as described in Section 2.2. The action-value function approximation (i.e., the Q-network) is parameterized by an MLP with four hidden layers (512, 256, 128, 64) and the policy network is parameterized by an MLP with three hidden layers (256, 128, 64). We use the ReLU [27] activation between hidden layers, and transform the final linear output of Q-network and policy network with ReLU and sigmoid function respectively. To find an optimal parameter setting, we use the Adam Optimizer [14] with a learning rate of 0.0001 for the critic and 0.001 for the actor. The discounted factor γ is 0.95, and the batch size is 2048. We update the network parameters after every $3K$ samples are added to the replay buffer (capacity $5 * 10^5$). We use a Boltzmann softmax selector for all MARL

Table 1: Performance comparison regarding the normalized Accumulated Driver Income (ADI) on the test set with respect to the performance of RAN.

p_{sample}	100%	50%	10%
RES	−4.60 ± 0.01	−4.65 ± 0.04	−4.71 ± 0.03
REV	+4.78 ± 0.00	+4.87 ± 0.02	+5.24 ± 0.07
IOD	+6.27 ± 0.01	+6.21 ± 0.03	+5.73 ± 0.07
COD	**+7.78 ± 0.01**	**+7.76 ± 0.03**	**+7.52 ± 0.14**

Table 2: Performance comparison regarding the order response rate (OOR) on the test set. The percentage difference shown for all methods is with respect to RAN.

p_{sample}	100%	50%	10%
RES	+3.15 ± 0.01	+3.11 ± 0.02	+2.59 ± 0.04
REV	−6.21 ± 0.00	−6.14 ± 0.03	−5.22 ± 0.06
IOD	+4.67 ± 0.01	+4.68 ± 0.03	+4.53 ± 0.04
COD	**+5.35 ± 0.00**	**+5.38 ± 0.03**	**+5.42 ± 0.09**



methods and set the initial temperature as 1.0, then gradually reduce the temperature until 0.01 to limit exploration.

- **COD**: The cooperative order dispatching algorithm with mean field approximation as described in Section 2.3. The network architecture is identical IOD, except a mean action is fed as an addition input to the critic network as illustrated in Fig. 2b.

As described in the reward setting in Section 2.1.1, we set the regularization ratio ${}^1\alpha = 0.01$ for DP and ${}^2\alpha = 0$ for the order waiting time penalty as we don't consider the pick-up distance in the grid-based experiment. Because of our homogeneous agent setting, all agents share the same Q-network and policy network for efficient training. During the execution in the real-world environment, each agent can keep its copy of policy parameters and receive updates periodically from a parameter server.

3.1.3 Result Analysis. For all learning methods, we run 20 episodes for training, store the trained model periodically, and conduct the evaluation on the stored model with the best training performance. The training set is generated by bootstrapping 50% of the original real orders unless specified otherwise. We use five random seeds for testing and present the averaged result. We compare the performance of different methods by three metrics, including the total income in a day (ADI), the order response rate (ORR), and the average order destination potential (ADP). ORR is the number of orders taken divided by the number of orders generated, and ADP is the sum of destination potential (as described in Section 2.1.1) of all orders divided by the number of orders taken.

Accumulated Driver Income. As shown in Table 1, the performance of COD largely surpasses all rule-based methods and IOD in ADI metric. RES suffers from lowest ADI among all methods due to its preference of short distance trips with lower average order value. On the other hand, REV aims to pick higher value orders with longer trip time, thus enjoying a higher ADI. However, both RES and REV cannot find a balance between getting higher income per order and taking more orders, while RAN falls into a sub-optimal trade-off without favoring either side. Instead, our proposed MARL methods (IOD and COD) achieve higher growths in terms of ADI by considering each order's price and the destination potential concurrently. Orders with relatively low destination potential will be less possible to get picked, thus avoiding harming ADI by preventing the driver from trapping in areas with very few future orders. By direct modeling other agents' policies and capturing the interaction between agents in the environment, the COD algorithm with mean field approximation gives the best performance among all comparing methods.

(a) COD **(b) REV**

Figure 4: An example of the demand-supply gap in the city center during peak hours. Grids with more drivers are shown in green (in red if opposite) and the gap is proportional to the shade of colors.

Table 3: Performance comparison in terms of the average destination potential (ADP) on the test set. The percentage difference shown for all methods is with respect to RAN.

p_{sample}	100%	50%	10%
RES	+6.36 ± 0.15	+7.40 ± 0.54	+9.97 ± 0.43
REV	−20.55 ± 0.16	−20.23 ± 0.52	−20.55 ± 1.58
IOD	+54.33 ± 0.09	+54.71 ± 0.20	+53.33 ± 0.54
COD	**+66.74 ± 0.05**	**+66.90 ± 0.29**	**+64.69 ± 0.61**

Order Response Rate. In Table 2 we compare the performance of different models in terms of the order response rate (OOR), which is the number of orders taken divided by the number of orders generated. RES has a higher OOR than the random strategy as it focuses on reducing the trip distance to take more orders. On the other hand, REV aims to pick higher value orders with longer trip time, leading to sacrifice on OOR. Although REV has a relatively higher ADI than other two rule-based methods, its lower OOR indicates a lower customer satisfaction rate, thus failing to meet the requirement of an optimal order dispatching algorithm. By considering both the average order value and the destination potential, IOD and COD achieve higher OOR as well. High-priced orders with low destination potential, i.e., a long trip to a suburban area, will be less possible to get picked, thus avoiding harming OOR when trying to take a high-priced order.

Average Order Destination Potential. To better present our method on optimizing the demand-supply gap, we list the average order destination potential (ADP) in Table 3. Note that all ADP values

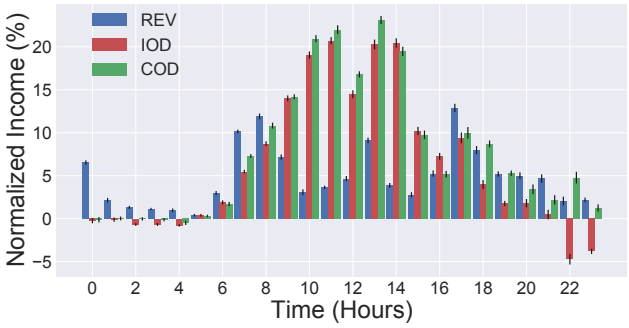


Figure 5: Normalized hourly income of REV, IOD and COD with respect to the average hourly income of RAN.

are negative, which indicates the supply still cannot fully satisfy the demand on average. However, IOD and COD largely alleviate the problem by dispatching orders to places with higher demand. As shown in Fig. 4, COD largely fills the demand-supply gap in the city center during peak hours, while REV fails to assign drivers to take orders with high-demand destination, thus leaving many grids with unserved orders.

Sequential Performance Analysis. To investigate the performance change of our proposed algorithms regarding the time of the day, Fig. 5 shows the normalized income of all algorithms with respect to the average hourly revenue of RAN. We eliminate RES from this comparison since it does not focus on getting a higher ADI and has relatively low performance. A positive value of the bar graph illustrates an increase in income compared to RAN, and vice versa. As shown in Fig. 5, MARL methods (IOD and COD) outperform RAN in most of the hours in a day (except for the late night period between 12 a.m. to 4 a.m., when very few orders are generated). During the peak hours in the morning and at night, MARL methods achieve a much higher hourly income than RAN. REV achieves a higher income than MARL methods between late night and early morning (12 a.m. to 8 a.m.) because of its aggressive strategy to take high-priced orders. However, this strategy ignores the destination quality of orders and assigns many drivers with orders to places with low demand, resulting in a significant income drop during the rest of the day (except for the evening peak hours when the possibility of encountering high-priced orders is large enough for REV to counteract the influence of the low response rate). On the other hand, IOD and COD earn significantly higher than RAN and REV for the rest of the day, possibly because of MARL methods' ability to recognize a better order in terms of both the order fee and the destination potential. As the order choice of MARL methods will prevent the agent from choosing a destination with lower potential, agents following MARL methods are thus enjoying more sustainable incomes. Also, COD outperforms IOD constantly, showing the effectiveness of explicitly conditioning on other agents' policies to capture the interaction between agents.

Effectiveness of Reward Settings. As described in Section 2.1.1, we use the destination potential as a reward function regularizer to encourage cooperation between agents. To show the effectiveness of this reward setting, we compare the ADI, OOR, and ADP of setting average income (AVE) and independent income (IND) as each agent's reward for IOD respectively. We also measure the performance of adding DP as a regularizer for both settings. For this experiment, we bootstrap 10% of the original real orders for the training and test set separately. As shown in Table 4, the performance of AVE in terms of all metrics is relatively lower than those of IND methods and RAN (even with DP added). This is possibly because of the credit assignment problem, where the agent's behavior is drowned by the noise of other agents' impact on the reward function. On the other hand, setting the individual income as the reward helps to distinguish each agent's contribution to the global objective from others, while adding DP as a regularizer further encourages the coordination between agents by arranging them to places with higher demand.

Table 4: Performance comparison of different reward settings applied to IOD with respect to RAN.

Method	ADI (%)	OOR (%)	ADP (%)
AVE	−0.36 ± 0.09	−0.14 ± 0.07	+1.11 ± 1.06
IND	+0.36 ± 0.10	+0.30 ± 0.09	−1.26 ± 0.87
AVE + DP	−0.26 ± 0.09	−0.10 ± 0.06	+1.17 ± 1.08
IND + DP	**+2.97 ± 0.02**	**+2.54 ± 0.03**	**+59.44 ± 1.33**

3.2 Coordinate-based Experiment

3.2.1 Environment Setting. As the real-world environment is coordinate-based rather than grid-based, we also conduct experiments on a more complex coordinate-based simulator provided by DiDi Chuxing. At each time step t, the coordinate-based simulator provides an observation $\boldsymbol{o}^t$ including a set of active drivers and a set of available orders. Each order feature includes the coordinate for the origin and the destination, while each driver has the coordinate as the location feature. The order dispatching algorithm works the same as described in Section 3.1.1. To better approximate the real-world scenario, this simulator also considers order cancelations, i.e., an order might be canceled during the pick-up process. This dynamic is controlled by a random variable which is positively related to the arriving time. The data resource of this simulator is based on historical dispatching events, including order generation events, driver logging on/off events and order fee estimation. During the training stage, the simulator will load five weekdays data with $350K$ dispatching events and generate $9K$ drivers. For evaluation, our model is applied on future days which are not used in the training phase.

3.2.2 Model Setting. We evaluate the performance of following MARL-based methods including IOD, COD, and a DQN variation of IOD (Q-IOD), i.e., without the policy network. We also compare these MARL methods with a centralized combinatorial optimization method based on the Hungarian algorithm (HOD). The HOD method focuses on minimizing the average arriving time (AAT) by setting the weight of each driver-order pair with the pick-up distance. For all MARL-based methods, the same network architecture setting as described in Section 3.1.2 is applied. Except that we use a mini-batch size of 200 because of the shorter simulation gap. The regularization ratio for pick-up distance is ${}^2\alpha = -0.1$ in this experiment.

Table 5: Performance comparison in terms of the ADI and the average arriving time (AAT) with respect to HOD.

Method	ADI1	ADI2	AAT
Q-IOD	−0.02%	−0.77%	+6.76%
IOD	+0.02%	−0.48%	+5.90%
COD	**+0.32%**	**+0.06%**	+5.49%

3.2.3 Result Analysis. We train all MARL methods for 400K iterations and apply the trained model in a test set (consists of three weekdays) for comparison. We compare different algorithms in terms of the total income in a day (ADI) and the average arriving time (AAT). ADI2 considers the cancellation while ADI1 doesn't. All the above metrics are normalized with respect to the result of HOD. As shown in Table 5, the result of COD largely outperforms Q-IOD and IOD in both ADI1 and ADI2, showing the effectiveness of direct modeling of other agents' policies in MARL. In addition, COD outperforms HOD in both ADI settings as well; this justifies the advantage of MARL algorithms that exploit the interaction between agents and the environment to maximize the cumulative reward. The performance improvement of ADI2 is smaller than that of ADI1 for MARL methods. This is possibly because that HOD works by minimizing the global pick-up distance and has a shorter waiting time. On the other hand, MARL methods only consider the pick-up distance as a regularization term, thus performing comparatively worse than HOD regarding AAT. As shown in Table 5, the AAT of all MARL methods are relatively longer than that of the combinatorial optimization method. However, as the absolute values of ADI are orders of magnitude higher than ATT, the increase in ATT is relatively minor and is thus tolerable in the order dispatching task. Also, MARL methods require no centralized control during execution, thus making the order dispatching system more robust to potential hardware or connectivity failures.

4 RELATED WORK

Order Dispatching. Several previous works addressed the order dispatching problem by either centralized or decentralized ruled-based approaches. Lee et al. [16] and Lee et al. [17] chose the pick-up distance (or time) as the basic criterion, and focused on finding the nearest option from a set of homogeneous drivers for each order on a first-come, first-served basis. These approaches only focus on the individual order pick-up distance; however, they do not account for the possibility of other orders in the waiting queue being more suitable for this driver. To improve global performance, Zhang et al. [45] proposed a novel model based on centralized combinatorial optimization by concurrently matching multiple driver-order pairs within a short time window. They considered each driver as heterogenous by taking the long-term behavior history and short-term interests into account. The above methods work with centralized control, which is prone to the potential "single point of failure" [23].

With the decentralized setting, Seow et al. [30] addressed the problem by grouping neighboring drivers and orders in a small multi-agent environment, and then simultaneously assigning orders to drivers within the group. Drivers in a group are considered as agents who conduct negotiations by several rounds of collaborative reasoning to decide whether to exchange current order assignments or not. This approach requires rounds of direct communications between agents, thus being limited to a local area with a small number of agents. Alshamsi and Abdallah [3] proposed an adaptive approach for the multi-agent scheduling system to enable negotiations between agents (drivers) to re-schedule allocated orders. They used a cycling transfer algorithm to evaluate each driver-order pair with multiple criteria, requiring a sophisticated design of feature selection and weighting scheme.

Different from rule-based approaches, which require additionally hand-crafted heuristics, we use a model-free RL agent to learn an optimal policy given the rewards and observations provided by the environment. Recent works by Xu et al. [41] and Wang et al. [38] proposed an RL-based dispatching algorithm to optimize resource utilization and user experience in a global and more farsighted view. However, they formulated the problem with the single-agent setting, which is unable to model the complex interactions between drivers and orders. On the contrary, our multi-agent setting follows the distributed nature of the peer-to-peer ridesharing problem, providing the dispatching system with the ability to capture the stochastic demand-supply dynamics in large-scale ridesharing scenarios. During the execution stage, agents will behave under the learned policy independently, thus being more robust to potential hardware or connectivity failures.

Multi-Agent Reinforcement Learning. One of the most straightforward approaches to adapt reinforcement learning in the multi-agent environment is to make each agent learn independently regardless of the other agents, such as independent Q-learning [36]. They, however, tend to fail in practice [24] because of the non-stationary nature of the multi-agent environment. Several approaches have been attempted to address this problem, including sharing the policy parameters [12], training the Q-function with other agent's policy parameters [37], or using importance sampling to learn from data gathered in a different environment [9]. The idea of centralized training with decentralized execution has been investigated by several works [8, 21, 29] recently for MARL using policy gradients [34], and deep neural networks function approximators, based on the actor-critic framework [15]. Agents within this paradigm learn a centralized Q-function augmented with actions of other agents as the *critic* during training stage, and use the learned policy (the *actor*) with local observations to guide their behaviors during execution. Most of these approaches limit their work to a small number of agents usually less than ten. To address the problem of the increasing input space and accumulated exploratory noises of other agents in large-scale MARL, Yang et al. [43] proposed a novel method by integrating MARL with mean field approximations and proved its convergence in a tabular Q-function setting. In this work, we further develop MFRL and prove its convergence when the Q-function is represented by function approximators.

5 CONCLUSION

In this paper, we proposed the multi-agent reinforcement learning solution to the order dispatching problem. Results on two large-scale simulation environments have shown that our proposed algorithms (COD and IOD) achieved (1) a higher ADI and OOR than three rule-based methods (RAN, RES, REV); (2) a higher ADI than

the combinatorial optimization method (HOD), with desirable properties of fully distributed execution; (3) lower supply-demand gap during the rush hours, which indicates the ability to reduce traffic congestion. We also provide the convergence proof of applying mean field theory to MARL with function approximations as the theoretical justification of our proposed algorithms. Furthermore, our MARL approaches could achieve fully decentralized execution by distributing the centralized trained policy to each vehicle through Vehicle-to-Network (V2N). For future work, we are working towards controlling ATT while maximizing the ADI with the proposed MARL framework. Another interesting and practical direction to develop is to use a heterogeneous agent setting with individual specific features, such as the personal preference and the distance from its own destination.

ABSTRACT

Many e-commerce platforms today allow users to give their rating scores and reviews on items as well as to establish social relationships with other users. As a result, such platforms accumulate heterogeneous data including numeric scores, short textual reviews, and social relationships. However, many recommender systems only consider historical user feedbacks in modeling user preferences. More specifically, most existing recommendation approaches only use rating scores but ignore reviews and social relationships in the user-generated data. In this paper, we propose TSNPF—a latent factor model to effectively capture user preferences and item features. Employing Poisson factorization, TSNPF fully exploits the wealth of information in rating scores, review text and social relationships altogether. It extracts topics of items and users from the review text and makes use of similarities between user pairs with social relationships, which results in a comprehensive understanding of user preferences. Experimental results on real-world datasets demonstrate that our TSNPF approach is highly effective at recommending items to users.

1 INTRODUCTION

Recommender systems are the core of today's personalized online e-commerce platforms like Amazon and Taobao. Such systems make use of user activities (e.g., ratings and reviews) and/or social relationships to generate features of items and identify user preferences.

The rating matrix based collaborative filtering [38] makes use of user activity to identify latent user-item factors to suggest products to a user. A representative realization of latent factor models is based on Matrix Factorization [27]. However, matrix factorization is confronted with a big challenge—computation complexity. When there are large numbers of users or items, the matrix factorization methods inevitably incur very high cost of latent factor identification from a huge user-item rating matrix. With the intensive mathematical computation required, such methods cannot handle large datasets. Some variants, e.g., Probabilistic Matrix Factorization [37], attempt to solve this problem. However, like most collaborative filtering methods, such variants often fail to identify the latent factors when a user or an item is associated with too few ratings. Consequently, the computation for recommendation falls apart due to data sparsity—too many zero ratings in a rating matrix. In contrast, the Hierarchical Poisson Factorization (HPF) [6, 15] only utilizes non-zero ratings to make scalable recommendations on large and sparse data.

In addition to user ratings on items, modern e-commerce platforms also generate other kinds of useful data such as social relationships and user reviews. By combining a rating matrix with additional data, better recommendations are expected. On the one hand, user textual reviews contain large amounts of information that often reflect concrete consumer experiences and many item attributes related to product quality. Some studies have utilized review text information for recommendation. By integrating ratings with review text or item contents, works [2, 9, 14, 28, 43] combine factors in ratings with topics in item reviews. On the other hand, the abundant social relationships provide an independent data source for recommendation and another possibility to improve recommended result quality. E.g., existing works [16, 31, 41] factorize rating matrix and social matrix simultaneously to improve recommendation performance.

In general, methods utilizing heterogeneous data tend to perform better than those using a single data source [45]. However, few studies take a rating matrix, social relationships and review text altogether into consideration. Work [20] is such an effort. However, it is simply a linear combination of two methods [2, 41]; it does not leverage the comprehensive implications of the latent factors in the completeness of a rating matrix, review text and social relationships.

In this paper, we propose an approach called Topic Soical Network Poisson Factorization (TSNPF for short). It integrates a rating matrix, review text and social relationships altogether in order

to enable high-quality recommendations. Overall, TSNPF aims to find item attributes and user preferences by exploiting all available heterogeneous data. Specifically, TSNPF merges all reviews on an item/user to generate the *document* for this item/user, in the hope of extracting topic intensities from such documents. When the topics of an item and a user are similar, the rating score of the user on that item tends to be high. However, item attributes and user preferences are not fully parameterized by their documents. To this end, we associate an attribute annex to each item and a preference annex to each user. As a result, the summation of topic intensities and corresponding annexes capture item attributes and user preferences to a greater extent. Rating of a user on an item is generated from the user's preferences and the item's attributes. In addition, most existing recommender systems that use social information assume that friends have similar preferences, which is however unrealistic in real life. In contrast, we utilize social relationships in a different way. Specifically, by assuming the similarity between two friends are generated from both users' preferences, we model the similarity with respect to the items they both have rated. The intuition behind is that a pair of friends who share similar (different) ratings on the same items naturally tend to have similar (different) preferences.

Our TSNPF exploits observations of multiple kinds, namely the ratings, the frequencies of words in the documents of items and users, and the similarity between a pair of friends on the items which they have both rated. In our model, each observation is represented as non-negative integers and generated from a Poisson distribution [25] that is in exponential family over non-negative integers. The latent item/user topic intensity, the item attribute annex and the user preference annex are all sampled from Gamma distributions—another exponential family distribution with shape and rate parameters. TSNPF only scans non-zero ratings, word frequencies and similarities, and factorizes them based on their posterior Gamma distributions. Therefore, TSNPF is able to capture features from sparse observations. By augmenting TSNPF with some auxiliary variables, we make TSNPF conditionally conjugate such that we can apply particular techniques to infer the parameters for it. To fit our TSNPF model, we use variational inference. It is an optimization-based strategy for efficiently approximating posterior distributions in large-scale complex probabilistic models [26, 42]. We propose a simple mean-field [36] variational inference method to update the parameters of TSNPF.

Our contributions are summarized as follows:

- We propose a method based on Gamma-Poisson distribution to extract the topic intensities of items and users from user-generated textual reviews. Compared to previous techniques, our method is able to address the usual problem of data scarcity.
- We propose TSNPF, a conjugate graphical model based on Poisson factorization which only models non-zero observations in ratings, reviews and social relations simultaneously via interpretable user preferences and item attributes. In addition, we propose a closed form mean-field variational inference method to train TSNPF.
- We evaluate the performance of TSNPF using three publicly available real datasets. The results show that TSNPF outperforms state-of-the-art alternatives.

The rest of this paper is organized as follows. Section 2 reviews the related work. Section 3 formulates the research problem and introduces the notations used throughout this paper. Section 4 describes our TSNPF model. Sections 5 details the variational inference for our TSNPF model. Experimental results are shown in Section 6. Section 7 concludes the paper and points out future work directions.

2 RELETED WORK

In this section, we mainly discuss the works which utilize heterogeneous data for recommendations.

Many existing works attempt to extract topics and features from user-generated reviews and learn latent factors from ratings using matrix factorization (MF) methods [10, 11, 18, 33, 40, 47, 52]. A general idea of these methods is to extract latent topics from reviews using topic models [10, 28, 33, 40, 47]. In particular, RMR [28] uses topic models on reviews to learns items' features and models rating using a maxiture of Gaussian. RBLT [40] and ITLFM [47] linearly combine the latent topics and latent factors to form the latent representations for users and items. TopicMF [2] and HPF [33] define a transform action function to link the latent topics and latent factors. He *et al.* [18] model the user-item-aspect relation with a tripartite graph to extract latent topics from reviews. JMARS [11] is an integrated graphical model that makes use of ratings and sentiments together for movie recommendation. However, with the rapid growth of user numbers, the increasing sparsity of the data becomes a critical concern [30]. Recently, neural networks are widely used to process reviews in recommender systems [7, 48, 49, 52]. DeepCoNN [52] first uses two CNNs to process reviews to learn users' and items' representations which are in turn concatenated and passed into a regression layer for rating predictions. However, neural network based methods often have the efficiency problem and their performance decrease greatly when reviews are scarce or unavailable in the testing phase [7].

There are also works [34, 35, 50] analyzing users' sentiments in reviews to improve the quality of recommendations. These works usually rely on the external NLP tools for sentiment analysis and thus are not self-contained.

Besides, item descriptions are also useful data for recommendations. Personalized articles recommendation methods such as CTR [43] and CTPF [14] assume that latent factors of items depend on the latent topic distributions from article contents. CTR [43] combines topic modeling using LDA [5] with Gaussian matrix factorization for one-class collaborative filtering [21]. CTPF [14] models both reader behavior and article texts with Poisson distributions, connecting the latent topics that represent the texts with the latent preferences that represent the readers. However, CTR is not conditionally conjugate and its inference algorithm depends on numerical optimization of topic intensities. Also, CTR and CTPF demand that the items themselves are articles or associated with descriptions. Thus, it is difficult to apply them in other scenarios.

In addition to textual data, social relations is another kind of heterogeneous data often used in recommender systems. LOCABAL [41] takes advantage of both local and global social contexts for recommendation. Ma *et al.* [31] propose a factor analysis approach based on probabilistic matrix factorization called "SoRec". It addresses the data sparsity and poor prediction accuracy problems

by employing both users' social network information and rating records. This idea is also applied in other works [24, 32]. Trust-based approach is another way to utilize social relations to make recommendation [23, 51]. This approach assumes a trust network among users and makes recommendations based on the ratings of the users that are directly or indirectly trusted by a user. Combining TopicMF [2] and LOCABAL [41], synthetic approach MR3 [20] utilizes ratings, social relations and reviews together for recommendation. However, MR3 is essentially a linear combination and it performs worse than our proposed approach according to our experimental results.

Moreover, Zhang *et. al* [46] and He *et al.* [17] consider the effect of visual content such as images when making recommendations. Bao *et. al* [1] and Do *et. al* [12] integrate metadata into their approaches.

3 NOTATIONS AND PROBLEM FORMULATION

Traditional recommender systems usually only use the rating matrix and ignore review text and social relationships. However, it is beneficial to take both of these two aspects into consideration [20]. On the one hand, social relationships often have impacts on a user's impression of items. On the other hand, a rating score can tell if a user likes or dislikes an item, but it cannot tell the reason behind the preference. In contrast, if this rating score is associated with some review text, the chance is better for us to understand why the user likes or dislikes the item. In addition, reviews offer abundant information about items' attributes. We intend to exploit the full combination of the rating matrix, the review text and the social relationships. We fuse three heterogeneous data types in one comprehensive data model to make high quality recommendations. The main notations used throughout the paper are shown in Table 1.

Table 1: Notations

R_{ui}	User u's rating on item i
D_i^I	Document of item i
D_u^U	Document of user u
C_{iw}^I	Count of word w in D_i^I
C_{uw}^U	Count of word w in D_u^U
S_{uvi}	Rating similarity between users u and v on item i
ε_w	latent topic rate for word w
ϵ_w	Latent topic intensities for word w
ϖ_i	latent topic rate for item i
π_i	Latent topic intensities for item i
α_i	latent popularity for item i
β_i	Latent attribute annex for item i
ς_u	Latent topic rate for user u
σ_u	Latent topic intensities for user u
ϑ_u	Latent activity for user u
θ_u	Latent preference annex for user u

Suppose there are U users numbered from 1 to U and I items numbered from 1 to I. The matrix of ratings given by users to items is denoted by $R \in \mathbb{R}^{U\times I}$, where R_{ui} is the rating by user u on item i. Each R_{ui} is an integer satisfying $0 \le R_{ui} \le M$, where M is the maximum rating score and 0 means currently the rating is unavailable. In addition to the rating matrix, the observed review on item i written by user u is denoted as D_{ui}, which is along with a rating score R_{ui}. For every item i, we merge all users' review comments together, generating a *document* D_i^I, i.e., $D_i^I = \bigcup_u D_{ui}$. Likewise, D_u^U denotes the document of a user u, i.e., $D_u^U = \bigcup_i D_{ui}$. We use D^I and D^U to denote the set of all documents of items and users, respectively. Furthermore, we use $G \in \mathbb{R}^{U\times U}$ to denote the user social network where $G_{uv} = 1$ means users u and v are friends and $G_{uv} = 0$ otherwise. Typically, R, D^I, D^U and G are all highly sparse, i.e., having many zero values.

For the recommendation purpose, we need to judge if a user will like an item that he/she has never consumed before. The problem statement for our research is as follows:

Problem Formulation: Given the rating matrix R, the document sets of items and users, i.e., D^I and D^U, and the social network G, estimate user u's rating on item i, i.e., R_{ui} that currently is 0.

4 TOPIC SOCIAL NETWORK POISSON FACTORIZATION

In this section, we describe the topic social network poisson factorization model (TSNPF). We model each user and each item by exploiting the rating matrix R, the documents sets D^I and D^U, and the social network G comprehensively.

Extracting topic intensities from documents. In TSNPF, there is a collection of K topics $\epsilon_{1:V,1:K}$ where each topic $\epsilon_{:,k}$ is composed of a vector of word intensities on the vocabulary and V is the size of the vocabulary. An item i is partly parameterized by the intensities of these topics denoted by $\pi_{i,1:K}$. The document D_i^I is generated by $\epsilon_{1:V}$ and π_i with C_{iw}^I, where C_{iw}^I is the count of word w in D_i and it is modeled by the inner product of ϵ_w and π_i, i.e., $C_{iw}^I \sim \text{Poisson}(\pi_i^\top \epsilon_w)$. Suppose $\sigma_{u,1:K}$ models the topics of user u, and C_{uw}^U is the word count of w in the document D_u^U. Likewise, C_{uw}^U is modeled using $\text{Poisson}(\sigma_u^\top \epsilon_w)$. When topic intensities of an item and a user are similar, the corresponding rating tends to be high. Using word intensities as topics is an widely-used technique [5]. Compared to existing work, our method of extracting topics is built on Poisson factorization which can take advantage of natural sparsity of user/item documents and is more efficient than Gaussian factorization based approaches [14].

Modeling ratings. The documents of items or users can not fully parameterize the items or users [14]. To this end, we make TSNPFassociate K latent attribute annexes $\beta_{i,1:K}$ to each item i and K latent preference annexes $\sigma_{u,1:K}$ to each user u. Such annexes capture the items' and users' deviations from their topic intensities. The rating R_{ui} is modeled by the inner product of the item attributes and user preferences, i.e., $R_{ui} \sim \text{Poisson}\Big((\sigma_u + \theta_u)^\top (\pi_i + \beta_i)\Big)$.

Modeling similarities. In addition, it is reasonable to believe that a user u's ratings on items are influenced by u's friends. When a pair of friends u and v have similar preferences, they are likely to give similar ratings on items. To incorporate this, we define the similarity between u and v on each item i on which they both give ratings, i.e., $S_{uvi} = M - |R_{ui} - R_{vi}|$ where M is the maximum rating score. In TSNPF, we model S_{uvi} using the inner product of users u and v's preferences, i.e., $S_{uv,i} \sim \text{Poisson}\Big((\sigma_u + \theta_u)^\top (\sigma_v + \theta_v)\Big)$. In this way, the distance of a pair of friends' preference vectors tends to be small when the users have similar ratings.

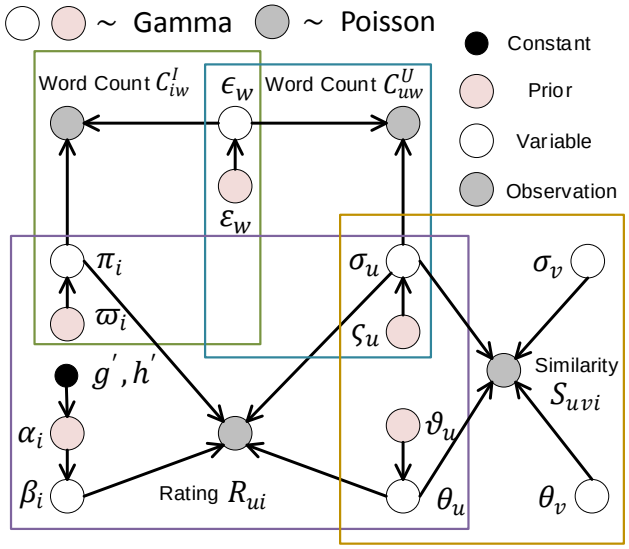

Figure 1: The directed graphical model representing TSNPF.

To deal with the sparsity of users and items, TSNPF also preserves the heterogeneity in the features by placing Gamma priors on ϵ_w, π_i, σ_u, β_i and θ_u [15]. The graphical model of TSNPF is illustrated in Figure 1. To avoid ambiguity, we only draw one constant node (g', h') in the example. More specifically, TSNPF's generative process is described as follows:

1. Generating documents of items and users
   1). For each word w:
      (a) Sample latent topic rate $\varepsilon_w \sim \text{Gamma}(a', b')$.
      (b) Sample word topic intensities $\epsilon_{wk} \sim \text{Gamma}(a, \varepsilon_w)$.
   2). For each item i:
      (a) Sample topic rate $\varpi_i \sim \text{Gamma}(c', d')$.
      (b) Sample document topic intensities $\pi_{ik} \sim \text{Gamma}(c, \varpi_i)$.
      (c) For every word w in D^I_i, sample word count
      $$C^I_{iw} \sim \text{Poisson}(\pi_i^\top \epsilon_w).$$
   3). For each user u:
      (a) Sample topic rate $\varsigma_u \sim \text{Gamma}(e', f')$.
      (b) Sample document topic intensities $\sigma_{uk} \sim \text{Gamma}(e, \varsigma_u)$.
      (c) For every word w in D^U_u, sample word count
      $$C^U_{uw} \sim \text{Poisson}(\sigma_u^\top \epsilon_w).$$
2. Generating ratings
   1). For each item i:
      (a) Sample latent popularity $\alpha_i \sim \text{Gamma}(g', h')$.
      (b) Sample attribute annex for each component k:
      $$\beta_{ik} \sim \text{Gamma}(g, \alpha_i).$$
   2). For each user u:
      (a) Sample latent activity $\vartheta_u \sim \text{Gamma}(m', n')$.
      (b) Sample preference annex for each component k:
      $$\theta_{uk} \sim \text{Gamma}(m, \vartheta_u)$$
   3). For each user u and item i, sample rating
      $$R_{ui} \sim \text{Poisson}\Big((\sigma_u + \theta_u)^\top (\pi_i + \beta_i)\Big).$$
3. Generating rating similarities between friends
   For a pair of users u and v with $G_{uv} = 1$, for every item they both have rated, sample rating similarity:
   $$S_{uvi} \sim \text{Poisson}\Big((\sigma_u + \theta_u)^\top (\sigma_v + \theta_v)\Big).$$

Given the observed rating matrix R, users similarity set S and word count sets C^I and C^U generated by document sets D^I and D^U, respectively, our goal is to infer the topics $\epsilon_{w,1:K}$, the item and user topic intensities $\pi_{i,1;K}$ and $\sigma_{u,1;K}$, the item attribute annex $\beta_{i,1:K}$, the user preference annex $\theta_{u,1:K}$ and their priors, i.e., to estimate the posterior distribution $p(\epsilon, \varepsilon, \pi, \varpi, \sigma, \varsigma, \beta, \alpha, \theta, \vartheta, |R, S, C^I, C^U)$ of these variables. Once the posterior is fit, TSNPF can be used to recommend items to users by ranking users' unconsumed items according to their scores based on the posterior expected Poisson parameters. Such a score for user u and item i is defined as follow:

$$\text{score}(u, i) = \mathbb{E}[(\sigma_u + \theta_u)^\top (\pi_i + \beta_i) | R, S, C^I, C^U]$$

5 INFERENCE FOR TSNPF

It is intractable to compute the exact posterior distribution $p(\epsilon, \varepsilon, \pi, \varpi, \sigma, \varsigma, \beta, \alpha, \theta, \vartheta | R, S, C^I, C^U)$ of TSNPF directly as variables are dependent on each other in p. We use variational inference [26] to approximate it. A family of distributions over latent variables indexed by a set of free parameters is introduced in variational inference. Those parameters are optimized to find the member of the family that is closest to the posterior. Previous studies [39, 44] have proved that the combination of simple distributions (*e.g.*, Poisson and Gaussian distribution) is able to approximate a very complex distribution. Thus, variational inference is reasonable. We use a distribution $q(\epsilon, \varepsilon, \pi, \varpi, \sigma, \varsigma, \beta, \alpha, \theta, \vartheta)$ in mean-field family [36], the simplest variational family, to approximate the exact posterior distribution p.

5.1 Complete Conditionals for TSNPF

We first augment TSNPF with auxiliary variables to make it conditionally conjugate, which means the complete conditional of each latent variable in p is in the exponential family and is in the same family as its prior [13]. A complete conditional is the conditional distribution of a latent variable given the observations and other latent variables. Following previous work [15], for word counts C^I_{iw} and C^U_{uw}, we add K latent variables $x^I_{iw,k} \sim \text{Poisson}(\epsilon_{wk}\pi_{ik})$ and K latent variables $x^U_{iw,k} \sim \text{Poisson}(\epsilon_{wk}\sigma_{uk})$, respectively, where $C^I_{iw} = \sum_k x^I_{iw,k}$ and $C^U_{uw} = \sum_k x^U_{uw,k}$. For rating similarity S_{uvi} that is non-zero, we add $2K$ latent variables $z_{uvi,k}$ which include two parts: $z^\sigma_{uvi,k}$ and $z^\theta_{uvi,k}$ such that $z^\sigma_{uvi,k} \sim \text{Poisson}(\sigma_{uk}\sigma_{vk})$ and $z^\theta_{uvi,k} \sim \textit{Poisson}(\theta_{uk}\theta_{vk})$, where $S_{uvi} = \sum_k (z^\sigma_{uvi,k} + z^\theta_{uvi,k})$ for every item i. For rating R_{ui}, $4K$ latent variables $y^1_{ui,k} \sim \text{Poisson}(\pi_{ik}\sigma_{uk})$, $y^2_{ui,k} \sim \text{Poisson}(\pi_{ik}\theta_{uk})$, $y^3_{ui,k} \sim \text{Poisson}(\beta_{ik}\sigma_{uk})$ and $y^4_{ui,k} \sim \text{Poisson}(\beta_{ik}\theta_{uk})$ are introduced such that $R_{ui} = \sum_k (y^1_{ui,k} + y^2_{ui,k} + y^3_{ui,k} + y^4_{ui,k})$. As a sum of independent Poisson random variables is itself a Poisson random variable with rate equal to the sum of the rates, the new latent variables preserve the marginal distribution of the observations. With the additional auxiliary variables, TSNPF is conditionally conjugate. We define the mean-field family that considers the latent variables

Table 2: TSNPF: latent variables, complete conditionals and variational parameters

Variable	Type	Complete Conditional	Variational Params
ε_w	Gamma	$a' + Ka,\ b' + \sum_k \epsilon_{wk}$	$\iota_w^{shp}, \iota_w^{rte}$
ϵ_{wk}	Gamma	$a + \sum_i x_{iw,k}^I + \sum_u x_{uw,k}^U,\ \varepsilon_w + \sum_i \pi_{ik} + \sum_u \sigma_{uk}$	$\mu_{wk}^{shp}, \mu_{wk}^{rte}$
ϖ_i	Gamma	$c' + Kc,\ d' + \sum_k \pi_{ik}$	$\zeta_i^{shp}, \zeta_i^{rte}$
π_{ik}	Gamma	$c + \sum_w x_{iw,k}^I + \sum_u (y_{ui,k}^1 + y_{ui,k}^2),\ \varpi_i + \sum_w \epsilon_{wk} + \sum_u (\sigma_{uk} + \theta_{uk})$	$\rho_{ik}^{shp}, \rho_{ik}^{rte}$
α_i	Gamma	$g' + Kc,\ h' + \sum_k \beta_{ik}$	$\tau_i^{shp}, \tau_i^{rte}$
β_{ik}	Gamma	$g + \sum_u (y_{ui,k}^3 + y_{ui,k}^4),\ \alpha_i + \sum_u (\sigma_{uk} + \theta_{uk})$	$\lambda_{ik}^{shp}, \lambda_{ik}^{rte}$
ς_u	Gamma	$e' + Ke,\ f' + \sum_k \sigma_{uk}$	ξ_u^{shp}, ξ_u^{rte}
σ_{uk}	Gamma	$e + \sum_w x_{iw,k}^U + \sum_i (y_{ui,k}^1 + y_{ui,k}^3) + \sum_{v,i,S_{uvi}\neq 0} z_{uvi,k}^{\sigma},$ $\varsigma_u + \sum_w \epsilon_{wk} + \sum_i (\pi_{ik} + \beta_{ik}) + \sum_{v,i,S_{uvi}\neq 0} \sigma_{v,k}$	$\nu_{uk}^{shp}, \nu_{uk}^{rte}$
ϑ_u	Gamma	$m' + Km,\ n' + \sum_k \theta_{uk}$	$\kappa_u^{shp}, \kappa_u^{rte}$
θ_{uk}	Gamma	$m + \sum_i (y_{ui,k}^2 + y_{ui,k}^4) + \sum_{v,i,S_{uvi}\neq 0} z_{uv,k}^{\theta},\ \vartheta_u + \sum_i (\pi_{ik} + \beta_{ik}) + \sum_{v,i,S_{uvi}\neq 0} \theta_{vk}$	$\gamma_{uk}^{shp}, \gamma_{uk}^{rte}$
x_{iw}^I	Mult	$\log \pi_{ik} + \log \epsilon_{wk}$	χ_{iw}^I
x_{uw}^U	Mult	$\log \sigma_{uk} + \log \epsilon_{wk}$	χ_{iw}^U
z_{uvi}	Mult	$\begin{cases} \log \sigma_{uk} + \log \sigma_{vk}, & \text{case } z_{uvi}^{\sigma} \\ \log \theta_{uk} + \log \theta_{vk}, & \text{case } z_{uvi}^{\theta} \end{cases}$	$\varphi_{uv}^{\sigma}, \varphi_{uv}^{\theta}$
y_{ui}	Mult	$\begin{cases} \log \pi_{ik} + \log \sigma_{uk}, & \text{case } y_{ui}^1 \\ \log \pi_{ik} + \log \theta_{uk}, & \text{case } y_{ui}^2 \\ \log \beta_{ik} + \log \sigma_{uk}, & \text{case } y_{ui}^3 \\ \log \beta_{ik} + \log \theta_{uk}, & \text{case } y_{ui}^4 \end{cases}$	$\phi_{ui}^1, \phi_{ui}^2, \phi_{ui}^3, \phi_{ui}^4$

to be independent and each governed by its own distributions.

$$
\begin{aligned}
q(\varepsilon, \epsilon, \varpi, \pi, \alpha, \beta, \varsigma, \sigma, \vartheta, \theta, x^I, x^U, z^{\sigma}, z^{\theta}, y) = & \prod_{w,k} q(\epsilon_{wk}|\mu_{wk}) \\
& \prod_w q(\varepsilon_w|\iota_w) \prod_{i,k} q(\pi_{ik}|\rho_{ik}) q(\beta_{ik}|\lambda_{ik}) \prod_i q(\varpi_i|\zeta_i) q(\alpha_i|\tau_i) \\
& \prod_{u,k} q(\sigma_{uk}|\nu_{uk}) q(\varsigma_u|\xi_u) q(\theta_{uk}|\gamma_{uk}) \prod_u q(\vartheta_u|\kappa_u) \\
& \prod_{i,w} q(x_{iw}^I|\chi_{iw}^I) \prod_{u,w} q(x_{uw}^U|\chi_{iw}^U) \prod_{u,v,i} q(z_{uvi}^{\sigma}, z_{uvi}^{\theta}|\varphi_{uv}^{\sigma}, \varphi_{uv}^{\theta}) \\
& \prod_{u,i} q(y_{ui}^1, y_{ui}^2, y_{ui}^3, y_{ui}^4|\phi_{ui}^1, \phi_{ui}^2, \phi_{ui}^3, \phi_{ui}^4) \qquad (1)
\end{aligned}
$$

The distributions of the variational variables (ε_w, ϵ_{wk}, ϖ_i, π_{ik}, α_i, β_{ik}, ς_u, σ_{uk}, ϑ_u and θ_{uk}) and the auxiliary variables (x^I, x^U, z and y) are all the same as their conditional distributions in p. The complete conditionals of all variables and the variational parameters that govern these variables in q are shown in Table 2. For more detailed derivation, please refer to Appendix A.1

The complete conditionals of ε_w, ϵ_{wk}, ϖ_i, π_{ik}, α_i, β_{ik}, ς_u, σ_{uk}, ϑ_u and θ_{uk} are all Gamma distributions, which are in the exponential family, with shape and rate variational parameters. We denote shape with superscript 'shp' and rate with 'rte'. For example, the variational distribution for the user preference θ_{uk} is Gamma($\gamma_{uk}^{shp}, \gamma_{uk}^{rte}$). For auxiliary variables x_{iw}^I, x_{uw}^U, z_{uvi} and y_{ui}, the complete conditionals are all free multinomials [25]. Specifically, χ_{iw}^I and χ_{uw}^U are all K-vectors that sum to one; $\varphi_{uv} = (\varphi_{uv}^{\sigma}, \varphi_{uv}^{\theta})$ and $\phi_{ui} = (\phi_{ui}^1, \phi_{ui}^2, \phi_{ui}^3, \phi_{ui}^4)$ are points in the $2K$ and $4K$-simplex, respectively.

5.2 Closed Form Variational Parameters Update

In this section, we give an coordinate ascent algorithm [4, 19] to update every variational parameter by holding all other parameters fixed. The detailed derivation can be found in Appendix A.2.

For all words and items, we initialize the word topic intensities ϵ_w using LDA [5]. These operations can be implemented by setting the point-wise ratio μ_w^{shp}/μ_w^{rte} to be ϵ_w. Subsequently, for all users and items, we initialize the user activity rate κ_u^{rte}, user preference γ_u, item popularity rate τ_i^{rte} and item feature λ_i with a small positive noise. We initialize the item topic intensities and attribute annexes i.e., ζ_i^{shp} and τ_i^{shp}, and the user topic intensities and preference annexes shapes, i.e., ξ_u^{shp} and κ_u^{shp}, according to the following equations:

$$
\begin{aligned}
\zeta_i^{shp} &= c' + Kc;\ \tau_i^{shp} = g' + Kg \\
\xi_u^{shp} &= e' + Ke;\ \kappa_u^{shp} = m' + Km
\end{aligned}
$$

Furthermore, the following steps are repeated until convergence:

1. Let

$$
f(r, s) = \exp\left(\Psi(r^{shp}) - \log r^{rte} + \Psi(s^{shp}) - \log s^{rte}\right)
$$

We use $\Psi(\cdot)$ to denote the digamma function. For each word/item such that $C_{iw}^I > 0$, each word/user such that $C_{uw}^U > 0$, each user pairs such that $S_{uvi} > 0$ for some items and each

user/item such that $R_{ui} > 0$, update the multinomials:

$$\hat{\chi}^I_{iw,k} = f(\rho_{ik}, \mu_{wk}) \; ; \; \chi^I_{iw,k} = \frac{\hat{\chi}^I_{iw,k}}{\sum_k \hat{\chi}^I_{iw,k}}$$

$$\hat{\chi}^U_{uw,k} = f(\sigma_{uk}, \mu_{wk}) \; ; \; \chi^U_{uw,k} = \frac{\hat{\chi}^U_{uw,k}}{\sum_k (\hat{\chi}^U_{iw,k})}$$

$$\hat{\varphi}^\sigma_{uv,k} = f(\nu_{uk}, \nu_{vk}) \; ; \; \hat{\varphi}^\theta_{uv,k} = f(\gamma_{uk}, \gamma_{vk})$$

$$\varphi^\sigma_{uv,k} = \frac{\hat{\varphi}^\sigma_{uv,k}}{\sum_k (\hat{\varphi}^\sigma_{uv,k} + \hat{\varphi}^\theta_{uv,k})} \; ; \; \varphi^\theta_{uv,k} = \frac{\hat{\varphi}^\theta_{uv,k}}{\sum_k (\hat{\varphi}^\sigma_{uv,k} + \hat{\varphi}^\theta_{uv,k})}$$

$$\hat{\phi}^1_{ui,k} = f(\rho_{ik}, \nu_{uk}) \; ; \; \hat{\phi}^2_{ui,k} = f(\rho_{ik}, \gamma_{uk})$$

$$\hat{\phi}^3_{ui,k} = f(\lambda_{ik}, \nu_{uk}) \; ; \; \hat{\phi}^4_{ui,k} = f(\lambda_{ik}, \gamma_{uk})$$

$$\phi^j_{ui,k} = \frac{\hat{\phi}^j_{ui,k}}{\sum_k (\hat{\phi}^1_{ui,k} + \hat{\phi}^2_{ui,k} + \hat{\phi}^3_{ui,k} + \hat{\phi}^4_{ui,k})} \; , \; j = 1, 2, 3, 4$$

2. For each item, update the topic prior and intensities, attribute prior and annex parameters:

$$\rho^{shp}_{ik} = c + \sum_w C^I_{iw} \chi^I_{iw,k} + \sum_u R_{ui} (\phi^1_{ui,k} + \phi^2_{ui,k})$$

$$\rho^{rte}_{ik} = \frac{\zeta^{shp}_i}{\zeta^{rte}_i} + \sum_w \frac{\mu^{shp}_{wk}}{\mu^{rte}_{wk}} + \sum_u (\frac{\nu^{shp}_{uk}}{\nu^{rte}_{uk}} + \frac{\gamma^{shp}_{uk}}{\gamma^{rte}_{uk}})$$

$$\lambda^{shp}_{ik} = g + \sum_u R_{ui} (\phi^3_{ui,k} + \phi^4_{ui,k})$$

$$\lambda^{rte}_{ik} = \frac{\tau^{shp}_i}{\tau^{rte}_i} + \sum_u (\frac{\nu^{shp}_{uk}}{\nu^{rte}_{uk}} + \frac{\gamma^{shp}_{uk}}{\gamma^{rte}_{uk}})$$

$$\zeta^{rte}_i = d' + \sum_k \frac{\rho^{shp}_{ik}}{\rho^{rte}_{ik}} ; \tau^{rte}_i = h' + \sum_k \frac{\lambda^{shp}_{ik}}{\lambda^{rte}_{ik}}$$

3. For each user, update the topic prior and intensities, preference prior and annex parameters:

$$\nu^{shp}_{uk} = e + \sum_w C^U_{uw} \chi^U_{uw,k} + \sum_i R_{ui} (\phi^1_{ui,k} + \phi^3_{ui,k}) + \sum_{v,i,S_{uvi} \neq 0} S_{uvi} \varphi^\sigma_{uv,k}$$

$$\nu^{rte}_{uk} = \frac{\xi^{shp}_u}{\xi^{rte}_u} + \sum_w \frac{\mu^{shp}_{wk}}{\mu^{rte}_{wk}} + \sum_i (\frac{\rho^{shp}_{ik}}{\rho^{rte}_{ik}} + \frac{\lambda^{shp}_{ik}}{\lambda^{rte}_{ik}}) + \sum_{v,i,S_{uvi} \neq 0} \frac{\nu^{shp}_{vk}}{\nu^{rte}_{vk}}$$

$$\gamma^{shp}_{uk} = m + \sum_i R_{ui} (\phi^2_{ui,k} + \phi^4_{ui,k}) + \sum_{v,i,S_{uvi} \neq 0} S_{uvi} \varphi^\theta_{uv,k}$$

$$\gamma^{rte}_{uk} = \frac{\kappa^{shp}_u}{\kappa^{rte}_u} + \sum_i (\frac{\rho^{shp}_{ik}}{\rho^{rte}_{ik}} + \frac{\lambda^{shp}_{ik}}{\lambda^{rte}_{ik}}) + \sum_{v,i,S_{uvi} \neq 0} \frac{\gamma^{shp}_{vk}}{\gamma^{rte}_{vk}}$$

$$\xi^{rte}_u = f' + \sum_k \frac{\nu^{shp}_{uk}}{\nu^{shp}_{uk}} ; \kappa^{rte}_u = n' + \sum_k \frac{\gamma^{shp}_{uk}}{\gamma^{shp}_{uk}}$$

4. For each word, update the word topic parameters:

$$\mu^{shp}_{wk} = a + \sum_i C^I_{iw} \chi^I_{iw,k} + \sum_u C^U_{uw} \chi^U_{uw,k}$$

$$\mu^{rte}_{wk} = \frac{\iota^{shp}_w}{\iota^{rte}_w} + \sum_i \frac{\rho^{shp}_{ik}}{\rho^{shp}_{ik}} + \sum_u \frac{\nu^{shp}_{uk}}{\nu^{shp}_{uk}} ; \iota^{rte}_w = b' + \sum_k \frac{\mu^{shp}_{wk}}{\mu^{shp}_{wk}}$$

Specifically, this algorithm only needs the non-zero observations in R, S, C^I and C^U. In step 1 above, we only need to update the variational parameters of the multinomials χ_{iw}, φ_{uv} and ϕ_{ui} for the non-zero word count, user similarity and rating observations, respectively. In steps 2, 3 and 4, all of the sums also only consider the non-zero observations. To judge if the distribution converges, we calculate the log probability of generating a validation rating matrix $\tilde{R}$ at every iteration:

$$\log p(\tilde{R} | \theta, \pi, \beta, \sigma, \theta) = \sum_{u,i,\tilde{R}_{ui} \neq 0} \log p(\tilde{R}_{ui} | \theta_u, \pi_i, \beta_i, \sigma_u, \theta_u)$$

$$= \sum_{u,i,\tilde{R}_{ui} \neq 0} \left(\tilde{R}_{ui} \log \left((\sigma_u + \theta_u)^\top (\pi_i + \beta_i) \right) - \log \tilde{R}_{ui}! \right)$$

$$- (\sum_u \sigma_u + \theta_u)^\top (\sum_i \pi_i + \beta_i)$$

When the change in the log probability is less than a very small threshold, we decide that the distribution converges and terminate the algorithm. The equation above implies that non-zero observations are not necessary when calculating the log probability. Therefore, this algorithm is able to handle sparse data.

6 EXPERIMENTS

In this section, we report on experimental studies that compare our TSNPF with existing methods and investigate the factors having impacts on the performance of TSNPF. In Section 6.1, we describe the settings of our experiments. Section 6.2 details the comparison results between our TSNPF and alternative methods. Section 6.3 reports on the impacts of reviews and social relations on the performance of TSNPF. Finally, Section 6.4 investigates how TSNPF performs as user activeness varies.

6.1 Experimental Settings

Datasets. We use the following open real datasets that are popular and used in the experiments of many recent works [20, 29, 33]:

- **PH-Restaurants** includes 204,887 users, 17,213 restaurants and 728,948 friend pairs. There are on average 1,180 words in the document of each restaurant. It is a part of the dataset of full Yelp data challenge[1] related to Phoenix.
- **LV-Restaurants** is also from Yelp data challenge. It contains 506,278 users, 26,809 restaurants located in Las Vegas and 3,109,068 friend pairs. The average word count of every document is 2,231.
- **Ciao** [2] is a dataset from a knowledge sharing and review website, on which users can rate items, give reviews and connect to others. This dataset includes 9,100 users, 23,432 items and 223,522 friend pairs. Each document contains 1,959 words on average.

[1] https://www.yelp.com/dataset/challenge
[2] https://www.cse.msu.edu/~tangjili/trust.html

The actual ratings on these datasets are all integers ranging from 1 to 5. For every dataset, we only keep top 20,000 words that appear most frequently .

Competing approaches. We compare our TSNPF with the following three typical approaches. They are the most recent representative approaches related to our TSNPF:

- **HPF** [15] factorizes the rating matrix based on Gamma-Poisson distribution. It is the first model in recommender systems that uses Poisson factorization.
- **CuPF** [12] is short for Coupled User Poisson Factorization that learns the couplings between users in the process of Poisson factorization. It is an improvement of HPF.
- **MR3** [20] is a synthetic approach combining ratings, social relationships and reviews. It integrates two other previous works [2, 41].

Evaluation Metrics. We randomly select 20% of the ratings with reviews in each dataset as testing set. Additionally, we set aside 1% of the training ratings and reviews as a validation set which is used to determine the algorithms convergence and to tune variational parameters. We define the relevant and recommended items for user u as those items on which the actual and predicted ratings by u are larger than 3.5, respectively. The following three metrics are used to evaluate the performance of the approaches in our experiments:

- **Normalized Mean Recall** (NMR) is a variant of recall-at-N which adjusts the denominator N'_u for a user u to be the $\min(N, I_u)$ where I_u denotes the most number of items the user u has rated in testing set. It is defined as

$$\text{NMR} = \frac{\sum_u \#\text{ of recommended and relevant items@}N'_u}{\sum_u \#\text{ of relevant items@}N'_u}$$

- **Normalized Mean Precision** (NMP) is a variant of precision-at-N with the denominator defined in normalized mean recall. Likewise,

$$\text{NMP} = \frac{\sum_u \#\text{ of recommended and relevant items@}N'_u}{\sum_u \#\text{ of recommended items@}N'_u}$$

- **Root-Mean-Square Error** (RMSE) is defined as

$$\text{RMSE} = \sqrt{\sum_{u,i}(R_{ui} - \hat{R}_{ui})^2/\mathcal{T}}$$

  Above, $\hat{R}_{ui}$ is the predicted rating of user u on item i and $\mathcal{T}$ is the number of ratings in testing set.

Parameter settings In our settings, the number of latent variables K is set to 100. The parameters a', b', a, c', d', c, e', f', e, g', h', g, m', n' and m in Section 4 are all set to 0.3 [15].

6.2 Overall Results and Analysis

We run top-20 recommendations using all the four approaches on all of the three datasets. Figure 2 reports the average results of the NMR, NMP and RMSE achieved by the four approaches. Overall, TSNPF outperforms the others on all three datasets. First, our TSNPF achieves considerably higher NMR than others, especially HPF and CuPF. This indicates that, compared to the items recommended by other approaches, a much higher fraction of all relevant items are indeed recommended by TSNPF to the respective users. Next, the NMP is high for all approaches and that of TSNPF is the highest. This indicates that all approaches are capable of returning high ratios of relevant items in their recommendations to users and TSNPF is overall the most effective one. Furthermore, the RMSE of TSNPF is also the best (smallest). Compared with HPF and CuPF, TSNPF gains clear RMSE improvements on all of the three datasets. MR3 outperforms HPF and CuPF, but is slightly better than TSNPF only in terms of NMP and RMSE on the Ciao dataset.

As recommender systems are more concerned about recommending more relevant items, i.e., achieving higher NMR, TSNPF performs best among all the four approaches in comparison. These experimental results demonstrate that TSNPF yields higher-quality recommendations.

Both HPF and CuPF use rating matrix only. More concretely, HPF only utilizes the ratings by individual users on items to generate user preferences and item attributes. CuPF attemps to capture the coupling relations between users and rating popularity. To predict the rating of user u on item i, CuPF requires that at least another user v and another item j exist in the training rating matrix such that both items i and j have been rated by user v. This is very demanding. According to our statistics, more than half of the testing ratings cannot be predicted by CuPF in all of the three datasets [3]. This indicates that CuPF is unsuitable for sparse data. Although MR3 utilizes all three types of data, it is simply a linear combination of two existing methods without sophisticated designs. The performance gain of TSNPF implies that jointly modeling the three types of data results in clearly better item recommendations.

6.3 Effects of Reviews and Social Relationships

Note that it is unnecessary for TSNPF that every rating is associated with a review, since we model the topic intensities of users/items based on all reviews related with users/items. Even if no review of a user/item is available, TSNPF is still able to process the relevant data. In case reviews are missing, there is no process of generating topic intensities. As a result, for an item, the ratings on it dominates its attributes. A user's preference is dominated by the ratings he/she post and his/her friends' preferences. To investigate the effect of each data type on TSNPF, we eliminate either reviews or social relationships, or both of them from TSNPF:

- **TSNPF\R** eliminates the effect of reviews by removing step 1 in the generative process (Section 4).
- **TSNPF\S** eliminates the effect of social relationships by removing step 3 in the generative process (Section 4).
- **TSNPF\R\S** eliminates the effect of both reviews and social relationships by removing steps 1 and 3 in the generative process (Section 4). As a result, it becomes HPF.

The recommendation results of TSNPF and its three variants are shown in Figure 3. TSNPF\R and TSNPF\S performs better than TSNPF\R\S on all three datasets, which suggests that both reviews and social relationships contain useful information for item recommendations. However, compared with TSNPF, the performance of a variant degrades when either reviews or social relationships are eliminated. The overall results indicate that TSNPF can make very good use of the heterogeneous information in reviews and social relationships.

[3] For testing data, we randomly decide the ratings from 1 to M.

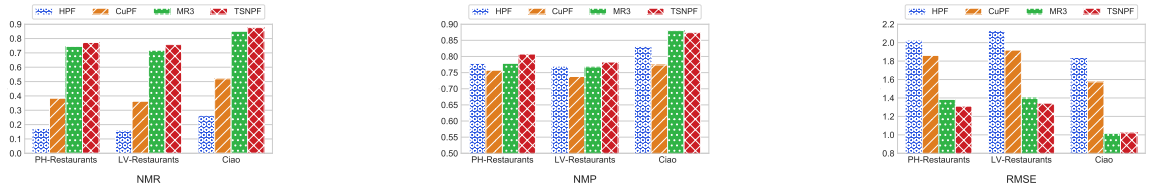

Figure 2: Performance of four approaches on three datasets

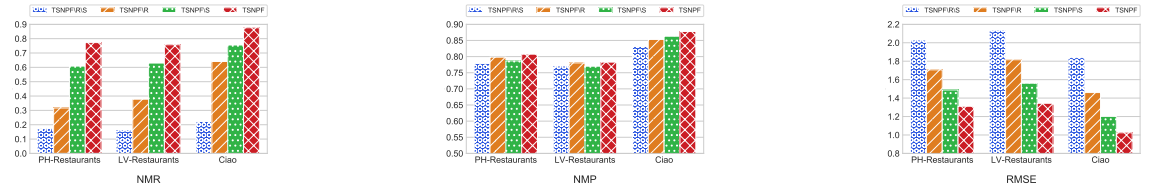

Figure 3: Effects of reviews and social relationships

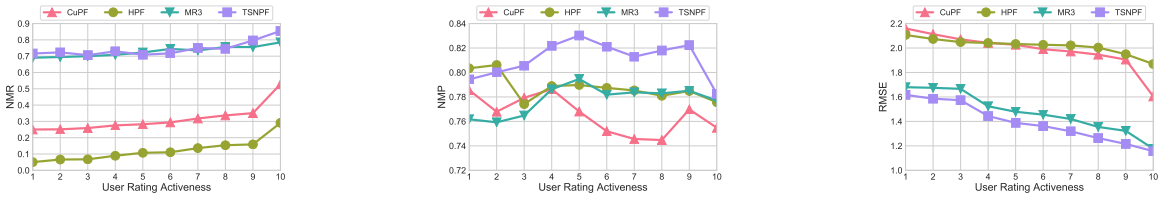

Figure 4: Effect of user rating activeness

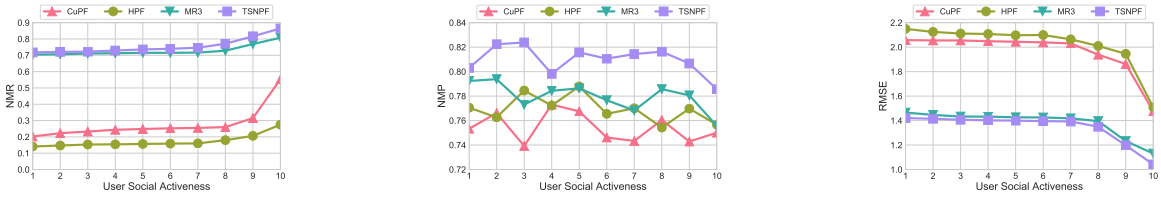

Figure 5: Effect of user social activeness

6.4 The Sensitivity of User Activeness

We treat NMR, NMP and RMSE as a function of user activeness and investigate how the recommendation performance varies across users of different types. We split all users in each of the three datasets into 10 groups ranked by user activeness. The first group is the bottom 10% users who are the least active, i.e., having rated fewest items. The 10th group contains the top 10% most active users. Figure 4 shows the performance results of NMR and NMP at top-20 recommendations and RMSE with different user types on the PH-Restaurants dataset. Due to the page limit, we omit the similar results on other datasets. The results show that all approaches tend to perform better on more active users as such users generate more data that can be used in the models. Again, we see that TSNPF outperforms the others in all but a few cases. This implies that TSNPF exploits larger amounts of user-generated data more effectively.

We also study the effect of the number of users' friends. Similarly, we split all users in each of the three datasets into 10 groups. The first group is the bottom 10% users who are the least sociable, i.e., having fewest friends. The 10th group contains the top 10% most sociable users. Figure 5 shows the performance results of NMR, NMP at top-20 recommendations and RMSE with different user types on the PH-Restaurants dataset.

The results show that all approaches tend to perform better on more sociable users as such users have more social relationships with other users that can be exploited by the models. Again, TSNPF outperforms the others.

7 CONCLUSIONS AND FUTURE WORK

We propose the Topic Social Network Poisson Factorization (TSNPF) to jointly model rating matrix, review texts and social relationships in a comprehensive manner. TSNPF extracts topics of users and

items reasonably as well as supports measuring of user similarities naturally. To address the data sparsity in high-quality recommendations, we use the Gamma-Poission generative process which only uses non-zero observations to model item attributes and user preferences. Experimental results show that TSNPF significantly outperforms alternative methods in item recommendation.

There are other kinds of heterogeneous data in addition to ratings, social relations and review, *e.g.*, metadata and visual content. A potential future work is to integrate them into our model to make even better recommendations. In addition, TSNPF only iterates over the non-zero observations. Thus, the coordinate ascent algorithm in our TSNPF is efficient. However, it is still difficult to fit TSNPF to very large datasets and therefore a stochastic variational inference algorithm [19] is needed in such cases. Furthermore, our approach uses a directed graphical model (Bayesian network) to capture user preferences and item features. Nevertheless, it is interesting to use a neural network instead of the graphical model, as studies show that neural networks can approximate arbitrarily complex functions [3] and thus have more powerful expression ability.

A APPENDIX

A.1 Derivation of the Complete Conditionals

To facilitate inference, we want to make TSNPF conditionally conjugate. To achieve this, we introduce some auxiliary vector variables (x^I_{iw}, x^U_{uw}, z_{uvi} and y_{ui}) in which each element is sampled from a Poisson distribution. Due to the given Poisson observations and Gamma priors of variables, the complete conditionals of these variables are still Gamma distributions. Hence, we use these auxiliary variables instead of actual observations to derive the complete conditionals of Gamma variables. Take ϵ_{wk} as an example, as described in the generative process, the conjugate prior of ϵ_{wk} is

$$\hat{p}(\epsilon_{wk}) = \frac{\varepsilon_w^a}{\Gamma(a)}\epsilon_{wk}^a \exp(-\varepsilon_w\epsilon_{wk})$$
$$= \overbrace{\hat{h}(\epsilon_{wk})}^{\text{Base measure}} \exp\Big((a-1,-\varepsilon_w)^\top(\log\epsilon_{wk},\epsilon_{wk}) - \overbrace{A\big((a-1,-\varepsilon_w)\big)}^{\text{Log-normalizer}}\Big).$$

Here, $(a-1,-\varepsilon_w)$ and $(\log\epsilon_{wk},\epsilon_{wk})$ are the natural parameters and sufficient statistics of this prior, respectively. Given the auxiliary variables x^I and x^U and other variables $\pi_{:,k}$ and $\sigma_{:,k}$, the conditional distribution is described as follows:

$$\begin{aligned}
&p(\epsilon_{wk}|x^I,x^U,\pi_{:,k},\sigma_{:,k})\\
&\propto \hat{p}(\epsilon_{wk})\prod_i p(x^I_{iw,k}|\epsilon_{wk},\pi_{ik})\prod_u p(x^U_{uw,k}|\epsilon_{wk},\sigma_{uk})\\
&\propto \hat{p}(\epsilon_{wk})\prod_i \frac{(\epsilon_{wk}\sigma_{uk})^{x^U_{uw,k}}\exp(-\epsilon_{wk}\sigma_{uk})}{x^U_{uw,k}!}\prod_u p(x^U_{uw,k})\\
&\propto \hat{p}(\epsilon_{wk})\prod_i\Big(\frac{1}{x^I_{iw,k}!}\exp\Big((\log\epsilon_{wk}+\log\sigma_{uk})x^U_{uw,k}-\epsilon_{wk}\sigma_{uk}\Big)\Big)\\
&\prod_u p(x^U_{uw,k})\\
&\propto \hat{h}(\epsilon_{wk})\prod_i\frac{1}{x^I_{iw,k}!}\exp\Big(\overbrace{\Big(a+\sum_i x^I_{iw,k}-1,-(\varepsilon_w+\sum_i\pi_{ik})\Big)}^{\eta}{}^\top\\
&(\log\epsilon_{wk},\epsilon_{wk}) - A(\eta)\Big)\prod_u p(x^U_{uw,k})\\
&\propto \overbrace{(\hat{h}(\epsilon_{wk})\prod_i\frac{1}{x^I_{iw,k}!}\prod_u\frac{1}{x^U_{uw,k}!})}^{\text{New base measure } h(\epsilon_{wk})}\\
&\exp\Big(\overbrace{\Big(a+\sum_i x^I_{iw,k}+\sum_u x^U_{uw,k}-1,-(\varepsilon_w+\sum_i\pi_{ik}+\sum_u\sigma_{uk})\Big)}^{\eta}{}^\top\\
&(\log\epsilon_{wk},\epsilon_{wk}) - \overbrace{A(\eta)}^{\text{New log-normalizer}}\Big)
\end{aligned}$$

Subsequently, $\Big(a+\sum_i x^I_{iw,k}+\sum_u x^U_{uw,k}-1,-(\varepsilon_w+\sum_i\pi_{ik}+\sum_u\sigma_{uk})\Big)$ are the natural parameters of the conditional distribution of $p(\epsilon_{wk}|x^I,x^U,\pi_{:,k},\sigma_{:,k})$. Thus,

$$\epsilon_{wk}|x^I,x^U,\epsilon_{:,k},\pi_{:,k},\sigma_{:,k} \sim \text{Gamma}(a+\sum_i x^I_{iw,k}+\sum_u x^U_{uw,k},\varepsilon_w+\sum_i\pi_{ik}+\sum_u\sigma_{uk}) \tag{2}$$

For conditional distribution of ε_w, the latent topic rate,

$$\begin{aligned}
&p(\varepsilon_w|\epsilon_{:,k}) \propto \hat{h}(\varepsilon_w)\exp\Big((a'-1,-b)^\top(\log\varepsilon_w,\varepsilon_w) - A(a',b')\Big)\\
&\prod_k\frac{(\epsilon_{wk})^{a-1}}{\Gamma(a)}\exp\Big((a,-\epsilon_{wk})^\top(\log\varepsilon_w,\varepsilon_w)\Big)\\
&\propto \Big(\hat{h}(\varepsilon_w)\prod_k\frac{(\epsilon_{wk})^{a-1}}{\Gamma(a)}\Big)\exp\Big(\Big(a'+Ka-1,-(b+\sum_k\epsilon_{wk})\Big)^\top\\
&(\log\varepsilon_w,\varepsilon_w)\Big)\\
&\Rightarrow\ \varepsilon_w|\epsilon_{:,k}\sim\text{Gamma}(a'+Ka,b'+\sum_k\epsilon_{wk})
\end{aligned}$$

The variational parameters in the conditional distributions of other variables (π_{ik}, ϖ_i, β_{ik}, α_i, σ_{uk}, ς_u, θ_{uk} and ϑ_u) are derived likewise.

The final latent variables are the auxiliary variables. Recall that each x^I_{iw} or x^U_{uw} is a K-vector of Poisson counts that sum to the observations C^I_{iw} or C^U_{uw}, respectively; each z_{uvi}, in the $2K$ simplex,

or y_{ui}, in the $4K$ simplex, is a vector of Poisson counts that sum to the observations S_{uvi} and R_{ui}, respectively. It is proved that the conditional distribution of a set of Poisson variables, given their sum, is a multinomial for which the parameters are their normalized set of rates [8, 25]. Thus, the complete conditionals for these vectors are

$$x^I_{iw}|\pi_i, \epsilon_w, C^I_{iw} \sim \text{Mult}(C^I_{iw}, \frac{\pi_i \epsilon_w}{\sum_k \pi_{ik}\epsilon_{wk}}) \tag{3}$$

$$x^U_{uw}|\sigma_u, \epsilon_w, C^U_{uw} \sim \text{Mult}(C^U_{uw}, \frac{\sigma_u \epsilon_w}{\sum_k \sigma_{uk}\epsilon_{wk}})$$

$$z_{uvi}|\sigma_u, \theta_u, \sigma_v, \theta_v, S_{uvi} \sim \text{Mult}\Big(S_{uvi}, \frac{(\sigma_u, \theta_u) \odot (\sigma_v, \theta_v)}{\sum_k (\sigma_{uk}\sigma_{vk} + \theta_{uk}\theta_{vk})}\Big)$$

$$y_{ui}|\pi_i, \beta_i, \sigma_u, \theta_u, R_{ui} \sim \text{Mult}\Big(R_{ui}, \frac{(\pi_i, \pi_i, \beta_i, \beta_i) \odot (\sigma_u, \theta_u, \sigma_u, \theta_u)}{\sum_k (\pi_{ik}\sigma_{uk} + \pi_{ik}\theta_{uk} + \beta_{ik}\sigma_{uk} + \beta_{ik}\theta_{uk})}\Big)$$

Above, $\odot$ denotes the element-wise multiplication operation.

A.2 Derivation of the Parameters Update

The objective of variational inference is to minimize the KL divergence between an exponential family member q and the posterior p. For similarity, we use $\boldsymbol{X}$ and $\boldsymbol{V}$ to denote the set of all observations and the set of all variational variables, respectively. Suppose $\boldsymbol{\Lambda}$ is the parameters of the distribution $q(\boldsymbol{V})$ that governs $\boldsymbol{V}$, and the distribution $q(\boldsymbol{V})$ and the conditional distribution $p(\boldsymbol{V}|\boldsymbol{X})$ are both in the exponential families. In this case, we let $\boldsymbol{\Lambda}$ be the natural parameters of $q(\boldsymbol{V})$. Thus,

$$\begin{aligned} p(\boldsymbol{V}|\boldsymbol{X}) &= h(\boldsymbol{V}) \exp\Big(\eta(\boldsymbol{V}|\boldsymbol{X}, p)^\top T(\boldsymbol{X}) - A(\eta(\boldsymbol{V}|\boldsymbol{X}, p))\Big) \\ q(\boldsymbol{V}) &= h(\boldsymbol{V}) \exp\Big(\boldsymbol{\Lambda}^\top T(\boldsymbol{V}) - A(\boldsymbol{\Lambda})\Big) \end{aligned}$$

Above, $\eta(\cdot)$, $T(\cdot)$, $h(\cdot)$ and $A(\cdot)$ are the functions of natural parameters, sufficient statistics, base measure and log-normalizer, respectively. Thus, $\boldsymbol{\Lambda} = \eta(\boldsymbol{V}, q)$. In practice, we often transfer this minimization into maximization of a lower bound on the logarithm of the marginal probability of the observations $\log p(\boldsymbol{X}, \boldsymbol{V})$ called the evidence lower bound (ELBO) [22] of q. It is defined as $\mathcal{L}(q) = \mathbb{E}_q[\log p(\boldsymbol{X}, \boldsymbol{V})] - \mathbb{E}_q[\log q(\boldsymbol{V})]$. The KL divergence is equal to the negative ELBO up to $\log p(\boldsymbol{X})$ which is a constant as it does not depend on q:

$$\begin{aligned} \text{KL}\Big(q(\boldsymbol{V})||p(\boldsymbol{V}|\boldsymbol{X})\Big) &= \mathbb{E}_q[\log q(\boldsymbol{V}) - \mathbb{E}_q[\log p(\boldsymbol{V}|\boldsymbol{X})] \\ &= \mathbb{E}_q[\log q(\boldsymbol{V})] - \mathbb{E}_q[\log p(\boldsymbol{X}, \boldsymbol{V})] + \log p(\boldsymbol{X}) \\ &= -\mathcal{L}(q) + \text{const} \end{aligned}$$

Besides,

$$\begin{aligned} \mathcal{L}(q) &= \mathbb{E}_q[\log p(\boldsymbol{X}, \boldsymbol{V})] - \mathbb{E}_q[\log q(\boldsymbol{V})] \\ &= \mathbb{E}_q[\log p(\boldsymbol{V}|\boldsymbol{X})] - \mathbb{E}_q[\log q(\boldsymbol{V})] + \text{const} \\ &= \mathbb{E}_q[\eta(\boldsymbol{V}|\boldsymbol{X}, p)^\top \nabla_{\boldsymbol{\Lambda}} A(\boldsymbol{\Lambda})] - \boldsymbol{\Lambda}^\top \nabla_{\boldsymbol{\Lambda}} A(\boldsymbol{\Lambda}) + A(\boldsymbol{\Lambda}) + \text{const} \\ &\quad \Big(\text{Because } \mathbb{E}_q[T(\boldsymbol{V})] = \nabla_{\boldsymbol{\Lambda}} A(\boldsymbol{\Lambda})\Big) \\ &\quad \Rightarrow \nabla_{\boldsymbol{\Lambda}} \mathcal{L} = \nabla^2_{\boldsymbol{\Lambda}} A(\boldsymbol{\Lambda}) \Big(\mathbb{E}_q[\eta(\boldsymbol{V}|\boldsymbol{X}, p)] - \boldsymbol{\Lambda}\Big) \end{aligned}$$

Setting the gradient $\nabla_{\boldsymbol{\Lambda}} \mathcal{L}$ to be zero, we get the closed form parameters update: $\boldsymbol{\Lambda} = \mathbb{E}_q[\eta(\boldsymbol{V}|\boldsymbol{X}, p)]$.

When $q(\boldsymbol{V})$ is a mean-field family member, the natural parameters of $q(\boldsymbol{V})$ are just the Cartesian product of its corresponding elements, respectively. Suppose $\boldsymbol{V} = \{v_1, ..., v_{|V|}\}$ and $\lambda_1, ...\lambda_V$ are the natural parameters of the distributions $q(v_1), ..., q(v_{|V|})$, respectively. Then $\boldsymbol{\Lambda} = (\lambda_1, ..., \lambda_{|V|})$. In addition, directly getting $\eta(\boldsymbol{V}|\boldsymbol{X}, p)$ is difficult as it involves all of the variable and observations. Thus we usually iteratively optimize every natural parameter λ_i for $1 \le i \le |V|$ using coordinate ascent algorithm by holding the parameters of all other variables fixed. Note that in this case these fixed variables become observations and the conditional distribution of a variable becomes the corresponding complete conditional. Each λ_i equals to the expected natural parameter (under q) of the complete conditional of v_i, i.e.,

$$\lambda_i = \mathbb{E}_q[\eta(v_i|\boldsymbol{X}, \boldsymbol{V}\backslash v_i, p)]$$

More details about coordinate ascent algorithm can be found in [4, 19].

By applying the derivations above into our TSNPF, we can easily derive the closed form variational parameters update in the main body of the paper. For simplicity, here we only give two examples: 1). μ_{wk}, the variational parameters of ϵ_{wk} which is sampled from a Gamma distribution and 2). χ^I_{iw}, the variational parameters of x^I_{iw} of which every element $x^I_{iw,k}$ is sampled from a Poisson distribution but the conditional distribution given other observations and variables is a multinomial. The updates for the variational parameters of the other Gamma and multinomial latent variables are similarly derived.

From Eq.(2), the natural parameters of the conditional distribution $p(\epsilon_{wk}|x^I, x^U, \pi_{:,k}, \sigma_{:,k}))$ and the distribution $q(\epsilon_{wk}|\mu_w k)$ are $\Big(a + \sum_i x^I_{iw,k} + \sum_u x^U_{uw,k} - 1, -(\varepsilon_w + \sum_i \pi_{ik} + \sum_u \sigma_{uk})\Big)$ and $(\mu^{shp}_{wk} - 1, -\mu^{rte}_{wk})$, respectively. As the natural parameters $(\mu^{shp}_{wk} - 1, -\mu^{rte}_{wk})$ are the affine transformation of shape and rate parameters—μ^{shp}_{wk} and μ^{rte}_{wk}, the update of variational parameters of gamma variable ϵ_{wk} are just the expectations of the shape and rate parameters of the complete conditional distributions under q, i.e.,

$$\begin{aligned} \mu^{shp}_{wk} &= \mathbb{E}_q[a + \sum_i x^I_{iw,k} + \sum_u x^U_{uw,k}] \\ &= a + \sum_i C^I_{iw}\chi^I_{iw,k} + \sum_u C^U_{uw}\chi^U_{uw,k} \\ \mu^{rte}_{wk} &= \mathbb{E}_q[\varepsilon_w + \sum_i \pi_{ik} + \sum_u \sigma_{uk}] \\ &= \frac{\iota^{shp}_w}{\iota^{rte}_w} + \sum_i \frac{\rho^{shp}_{ik}}{\rho^{shp}_{ik}} + \sum_u \frac{\nu^{shp}_{uk}}{\nu^{shp}_{uk}} \end{aligned}$$

Notice that the expectation of $x^I_{iw,k}$ equals to k-th probability of the multinomial $\chi^I_{iw,k}$ times the word count C^I_{iw}, i.e., $\mathbb{E}_q[x^I_{iw,k}] = C^I_{iw}\chi^I_{iw,k}$.

The natural parameters of $x^I_{iw,k}$ is $\log \chi^I_{iw,k}$. Due to the assumption of mean-field family, the natural parameters of x^I_{iw} are just the Cartesian product of every $\log \chi^I_{iw,k}$, i.e., $\eta(x^I_{iw}) = (\log \chi^I_{iw,1}, ..., \log \chi^I_{iw,K})$. From Eq. (3), the conditional distribution $p(x^I_{iw}|\pi_i, \epsilon_w, C^I_{iw})$ is a multinomial. The natural parameters of this conditional distribution are the logarithms of event probabilities, i.e., $\eta(x^I_{iw}|\pi_i, \epsilon_w, C^I_{iw})$ $= \Big((\log \pi_{i1} + \log \epsilon_{w1}) - r, ..., (\log \pi_{iK} + \log \epsilon_{wK}) - r\Big)$ where $r =$

$\log(\sum_k \pi_{ik}\epsilon_{wk})$. Thus,

$$\begin{aligned}\log \chi^I_{iw,k} &= \mathbb{E}_q[\log \pi_{ik} + \log \epsilon_{wk} - r] \Rightarrow \\ \chi^I_{iw,k} &= \exp(\mathbb{E}_q[\log \pi_{ik} + \log \epsilon_{wk} - r]) \\ &\propto \exp\left(\Psi(\rho^{shp}_{ik}) - \log \rho^{rte}_{ik} + \Psi(\mu^{shp}_{wk}) - \log \mu^{rte}_{wk}\right)\end{aligned}$$

Above, $\Psi(\cdot)$ is the digamma function. This update comes from the expectation of the log of a Gamma variable, e.g., $\mathbb{E}_q[\log \pi_{ik}] = \Psi(\rho^{shp}_{ik}) - \log \rho^{rte}_{ik}$. Let

$$\hat{\chi}^I_{iw,k} = \exp\left(\Psi(\rho^{shp}_{ik}) - \log \rho^{rte}_{ik} + \Psi(\mu^{shp}_{wk}) - \log \mu^{rte}_{wk}\right)$$

Then

$$\chi^I_{iw,k} = \frac{\hat{\chi}^I_{iw,k}}{\sum_k \hat{\chi}^I_{iw,k}}. \tag{4}$$

Eq. (4) guarantees that χ^I_{iw} is a K-vector whose elements sum to one.

ABSTRACT

Tips, as a compacted and concise form of reviews, were paid less attention by researchers. In this paper, we investigate the task of tips generation by considering the "persona" information which captures the intrinsic language style of the users or the different characteristics of the product items. In order to exploit the persona information, we propose a framework based on adversarial variational auto-encoders (aVAE) for persona modeling from the historical tips and reviews of users and items. The latent variables from aVAE are regarded as persona embeddings. Besides representing persona using the latent embeddings, we design a persona memory for storing the persona related words for users and items. Pointer Network is used to retrieve persona wordings from the memory when generating tips. Moreover, the persona embeddings are used as latent factors by a rating prediction component to predict the sentiment of a user over an item. Finally, the persona embeddings and the sentiment information are incorporated into a recurrent neural networks based tips generation component. Extensive experimental results are reported and discussed to elaborate the peculiarities of our framework.

CCS CONCEPTS

• **Computing methodologies** → **Natural language generation**; • **Information systems** → **Recommender systems**; **Personalization**.

1 INTRODUCTION

Tips, specifically defined by Yelp[1], as a compacted and concise form of reviews, have unique advantages for helping users get a quick insight over an item. Conventional reviews are extensively studied for rating prediction [26, 37] and review generation [6, 29, 35, 40], while tips are paid relatively less attention. In [21], the tip information was explored for tips generation and rating prediction for the first time. The rationality for performing the joint task can be attributed to "writing some tips and giving a numerical rating are two facets of a user's product assessment action, expressing the user experience and feelings". Moreover, compared with reviews, tips are likely more consistent with the rating score with respect to sentiment tendency, because of its intrinsic form, i.e. compacted and concise.

In this paper, we investigate another dimension, namely user persona, which is plausibly helpful for the task of tips generation and has not be considered in the previous work [21]. Here the term "**persona**" denotes the characteristics of the written text by users such as wording and style. Figure 1a shows some tips for a shower radio from different users. [2] These tips clearly show different styles, although all of them have the same ratings. Some users (e.g. 1, 4 and 5) prefer short sentences and direct wordings such as "great", "easy", and "excellent" to describe the product quality and their experience directly. On the other hand, some users (e.g. 2, 3, and 6) share their experience indirectly by talking about some facts with longer sentences. Therefore, different users indeed have different "persona" style when writing tips. Figure 1b shows a few tips with different ratings from the same user for different items, we can observe that the user prefers short sentences, and moreover he has his own style (i.e. preferred vocabulary) for writing tips of different sentiments/ratings (e.g. "perfect" and "excellent" for high rating tips, and "piece of crap" for low rating tips).

Tips	Rating
(1) Great fit and finish for shower.	5
(2) I selected this radio for myself several years ago and i have found that all claims for it are true.	5
(3) If your looking for a radio for your shower then look no further.	5
(4) Easy to set up stations.	5
(5) Excellent design and quality construction.	5
(6) First one lasted years just bought another one.	5

(a) Tips for the item "Sony Weather Band Shower Radio".

Tips	Rating
(1) Works perfectly in my msi wind.	5
(2) Perfect size for a home office.	5
(3) Excellent player for price.	5
(4) Wonderful docking speaker with full sound.	4
(5) I like it when it not dropping the signal.	4
(6) Works fine in a pinch.	3
(7) Piece of crap do bother.	1
(8) Revised star piece of crap.	1

(b) Tips for different items written by a particular user.

Figure 1: Example of tips.

Intuitively, the quality of abstractive tips generation can be improved if the model considers the user persona information when conducting the text generation. To do so, in this paper, we investigate an approach called **P**ersona-**A**ware **T**ips **G**eneration (**PATG**). There are two main challenges for the design of PATG: (1) How to capture and represent the persona information; (2) How to integrate the sentiment signal with the persona information to jointly control the style and the sentiment of the generated tips.

We distill persona information from all the historical tips and reviews of a user into the form of **Persona Embeddings**. Then the persona embeddings can be directly incorporated into the tips generation component as context information. Specifically, we employ variational auto-encoders (VAEs) [12] (which show strong capability in modeling latent random variables [20, 22]) to conduct persona modeling, and we regard the latent variables of VAEs as the persona embeddings. In the context of user behaviour analysis of online retailing, another indispensable party is the product item. Items also have their own intrinsic characteristics, such as product category in a coarser granularity, or specific features in a finer granularity. In this work, we personify the items and enable modeling them with "item persona", similar to modeling users. Besides distilling persona information using VAEs, we also design an external **Persona Memory** for the framework to store the persona related words for the current user and item. Pointer Networks [36] is used to retrieve appropriate words from the persona memory for generating tips.

Another obvious signal from the examples in Figure 1 is that the sentiment related wording is also bound to the sentiment ratings. For example, positive expressions are only used in tips with high ratings, no matter what persona the users have. To explore this signal for generating more accurate tips, our framework includes an auxiliary component: rating prediction with the information of users and items used for tips generation. The intuition is that if we can predict the rating of a user on an item accurately, the same input information should provide rich, if not complete, information for generating a tip satisfying that rating. Thus, in order to control the sentiment of the generated tips, we design a rating prediction component. The distilled persona embeddings are regarded as latent factors for users/items, and fed into the rating prediction component for detecting sentiment. A vectorization process is conducted on the predicted rating values and then the rating vectors are incorporated into the tips generation component as context information to control the sentiment of the generated tips.

The main contributions of our framework are summarized below:

- We develop a framework that tackles the task of persona-aware tips generation, where persona information, such as writing style and vocabulary preference, is considered for the first time to conduct the tips generation.
- In order to exploit the persona information, we design an adversarial variational auto-encoders (aVAE) based approach for persona modeling for users and items, i.e. generating persona embeddings. We employ an external memory based Pointer Networks to conduct the memory reading to retrieve more accurate persona information.
- In order to control the sentiment of the generated tips, we tightly couple an auxiliary component of rating prediction with the tips generation component. The distilled persona embeddings are used as latent factors of users and items for the sentiment rating prediction.
- Experimental results show that our framework achieves better performance than the state-of-the-art models on tips generation. Moreover, an additional observation is that the persona information can improve the performance of the auxiliary task, i.e. rating prediction.

2 FRAMEWORK DESCRIPTION

2.1 Overview

The data consists of users, items, ratings, review content, and tips. We denote the whole training corpus by $\mathcal{X} = \{\mathcal{U}, \mathcal{I}, \mathcal{R}, C, \mathcal{S}\}$, where $\mathcal{U}$ and $\mathcal{I}$ are the sets of users and items respectively, $\mathcal{R}$ is the set of ratings, C is the set of review documents, and $\mathcal{S}$ is the set of tips texts. We use C_u and $\mathcal{S}_u$ to denote all the historical reviews and tips respectively of the user u. For a quick reference, Table 1 lists all notations used in our paper.

As shown in Figure 2, our framework contains two major modules: persona modeling on the left and abstractive tips generation on the right. For modeling persona, our framework leverages the tips and reviews from each individual user or written by multiple users for the same item. Take the historical tips $\mathcal{S}_u$ of the user u as an example, we represent them using bag-of-words (BoWs) vectors $\mathbf{x}_u^s$. Then we feed $\mathbf{x}_u^s$ into the adversarial variational auto-encoders (aVAE^s) and obtain the persona embedding $\mathbf{z}_u^s$ for the user u. For the item i, we can also conduct similar persona modeling based on the historical tips $\mathcal{S}_i$ written by different users, and the obtained persona embedding is denoted as $\mathbf{z}_i^s$. The purpose of persona modeling for the item i is that when conducting tips generation for the user u, the model will also consider the tips from other users having similar interests with u, since they will disclose more characteristics of the item. We call this phenomenon *personalized collaborative*

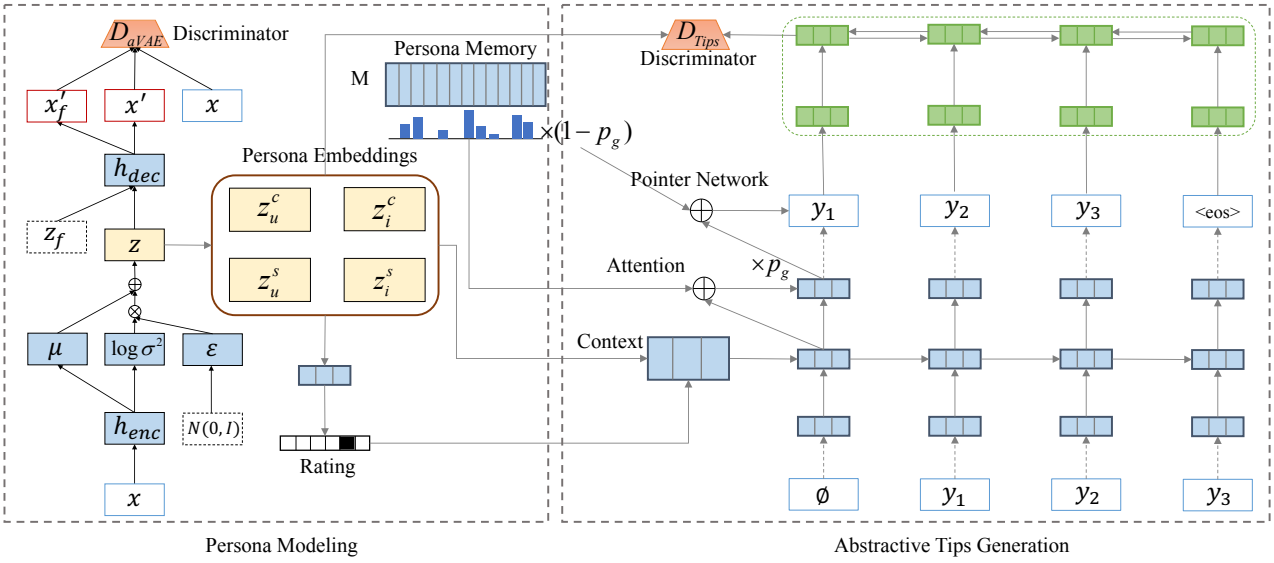

Figure 2: Our proposed framework for persona-aware abstractive tips generation.

Table 1: Glossary.

Symbol	Description
$\mathcal{X}$	training set
$\mathcal{V}$	vocabulary
$\mathcal{U}$	set of users
$\mathcal{I}$	set of items
$\mathcal{R}$	set of ratings
$\mathcal{C}$	set of reviews
$\mathcal{S}$	set of tips
$\mathcal{C}_u$	historical reviews for user u
$\mathcal{S}_u$	historical tips for user u
$\mathbf{M}$	external memory
$\mathbf{Z}$	persona embeddings
$\mathbf{E}$	word embeddings
$\mathbf{H}$	neural hidden states
$\mathbf{W}$	mapping matrix
$\mathbf{b}$	bias item
Θ	set of neural parameters
$r_{u,i}$	rating of user u to item j
σ	sigmoid function
ς	softmax function
$relu$	rectified linear unit
$tanh$	hyperbolic tangent function

influence. We also distill persona information from reviews with another aVAE model (aVAE^c) to map the historical reviews C_u and C_i to persona embeddings $\mathbf{z}_u^c$ and $\mathbf{z}_i^c$ for the user u and the item i respectively.

We design an external persona memory $\mathbf{M}$ for storing the persona related words for the current user and item which will be utilized in abstractive tips generation. In order to control the sentiment of the generated tips, the distilled persona embeddings are used as latent factors for users and items and are fed into a multilayer perceptron (MLP) based neural network component to predict the rating r. Then we transform r to a one-hot vector $\mathbf{r}$ which will be used as the sentiment controller when conducting the tips generation. For the step of tips generation, we design a sequence decoding model based on a neural network of Gated Recurrent Units (GRUs) [5]. Importantly, the persona embeddings and the rating vector are combined to construct a context vector which plays a significant role in the abstractive tips generation. In addition, Pointer Networks is used to retrieve relevant words from the persona memory $\mathbf{M}$, with a gate p_g to control the source of the next output word.

2.2 Persona Modeling

2.2.1 ***Persona Embedding Learning.*** The target of persona modeling is to distill the persona information from the users' historical tips and reviews. Some previous works in recommendation systems [26, 30, 37] employ topic modeling methods such as Latent Dirichlet Allocation (LDA) [2] or its variants to analyze the text corpus and use the latent topic distribution to represent each document. Considering the fact that our tips generation component is based on neural networks, existing topic modeling paradigms cannot be incorporated into our framework in an elegant manner. Instead, we employ the variational auto-encoders (VAEs) [12] for detecting the latent topics with neural modeling paradigm [4]. VAEs consists of two parts: inference (variational-encoder) and generation (variational-decoder). Recall that the dictionary is V. For historical tips based persona modeling, the input are the BoWs vectors $\mathbf{x}_u^s \in \mathbb{R}^{|V|}$ and $\mathbf{x}_i^s \in \mathbb{R}^{|V|}$ for the user u and the item i respectively. For convenience, we will use $\mathbf{x}$ to represent them in this section. As shown in the left part of Figure 2, for each input BoWs vector $\mathbf{x}$, the variational-encoder can map it to a latent variable $\mathbf{z} \in \mathbb{R}^K$, which can be used to generate a new variable $\mathbf{x}'$ via the variational-decoder component to reconstruct the original term vector. The target is to maximize the probability of each $\mathbf{x}$ in the dataset based

on the generation process according to:

$$p(\mathbf{x}) = \int p(\mathbf{x}|\mathbf{z})p(\mathbf{z})d\mathbf{z} \tag{1}$$

For the purpose of solving the intractable integral of the marginal likelihood, a model $q(\mathbf{z}|\mathbf{x})$ is introduced as the approximation to the intractable of the true posterior $p(\mathbf{z}|\mathbf{x})$. The aim of optimization is to reduce the Kulllback-Leibler divergence (KL) between $q(\mathbf{z}|\mathbf{x})$ and $p(\mathbf{z}|\mathbf{x})$ by maximizing the variational lower bound $\mathcal{L}_{VAE}$:

$$\mathcal{L}_{VAE} = \mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[\log p(\mathbf{x}|\mathbf{z})] - D_{KL}[q(\mathbf{z}|\mathbf{x})\|p(\mathbf{z})] \tag{2}$$

In order to differentiate and optimize the lower bound $\mathcal{L}_{VAE}$, following the core idea of VAEs, we use a neural network framework for the encoder $q(\mathbf{z}|\mathbf{x})$ for better approximation. Similar to previous works [12], we assume that both the prior and posterior of the latent variables are Gaussian, i.e., $p(\mathbf{z}) = \mathcal{N}(0, \mathbf{I})$ and $q(\mathbf{z}|\mathbf{x}) = \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}, \boldsymbol{\sigma}^2\mathbf{I})$, where $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ denote the variational mean and standard deviation respectively, which can be calculated with a multilayer perceptron (MLP). Precisely, given the BoWs vector $\mathbf{x}$ of the historical tips, we first project it to a hidden space:

$$\mathbf{h}_{enc} = relu(\mathbf{W}_{xh}\mathbf{x} + \mathbf{b}_{xh}) \tag{3}$$

where $\mathbf{h}_{enc} \in \mathbb{R}^{d_h}$, $\mathbf{W}_{xh}$ and $\mathbf{b}_{xh}$ are the neural parameters. $relu(\mathbf{x}) = max(0, \mathbf{x})$ is the activation function. Then the Gaussian parameters $\boldsymbol{\mu} \in \mathbb{R}^K$ and $\boldsymbol{\sigma} \in \mathbb{R}^K$ can be obtained via a linear transformation based on $\mathbf{h}_{enc}$:

$$\begin{aligned} \boldsymbol{\mu} &= \mathbf{W}_{h\mu}\mathbf{h}_{enc} + \mathbf{b}_{h\mu} \\ \log(\boldsymbol{\sigma}^2) &= \mathbf{W}_{h\sigma}\mathbf{h}_{enc} + \mathbf{b}_{h\sigma} \end{aligned} \tag{4}$$

In order to make the sampling operation differentiable, the latent variable $\mathbf{z} \in \mathbb{R}^K$ can be calculated using the reparameterization trick:

$$\boldsymbol{\varepsilon} \sim \mathcal{N}(0, \mathbf{I}), \quad \mathbf{z} = \boldsymbol{\mu} + \boldsymbol{\sigma} \otimes \boldsymbol{\varepsilon} \tag{5}$$

where $\boldsymbol{\varepsilon} \in \mathbb{R}^K$ is an auxiliary noise variable. This is the encoding process, and we denote all the parameters of this state as Θ_{Enc}.

Given the latent variable $\mathbf{z}$, a new vector $\mathbf{x}'$ is generated via the conditional distribution $p(\mathbf{x}|\mathbf{z})$ according to the variational-decoder:

$$\mathbf{h}_{dec} = relu(\mathbf{W}_{zh}\mathbf{z} + \mathbf{b}_{zh}) \tag{6}$$

$$\mathbf{x}' = \sigma(\mathbf{W}_{hx}\mathbf{h}_{dec} + \mathbf{b}_{hx}) \tag{7}$$

We denote all the parameters in the decoding stage using Θ_{Dec}. Finally, based on the reparameterization trick in Equation 5, we can get the analytical representation of $\mathcal{L}_{VAE}$:

$$\begin{aligned} \log p(\mathbf{x}|\mathbf{z}) &= \sum_{i=1}^{|V|} x_i \log x'_i + (1 - x_i) \cdot \log(1 - x'_i) \\ -D_{KL}[q(\mathbf{z}|\mathbf{x})\|p(\mathbf{z})] &= \tfrac{1}{2} \sum_{i=1}^{K} (1 + \log(\sigma_i^2) - \mu_i^2 - \sigma_i^2) \end{aligned} \tag{8}$$

For presentation clarity, we let:

$$\begin{aligned} \mathcal{L}_{Rec} &= -\log p(\mathbf{x}|\mathbf{z}) \\ \mathcal{L}_{KL} &= D_{KL}[q(\mathbf{z}|\mathbf{x})\|p(\mathbf{z})] \end{aligned} \tag{9}$$

and both of them need to be minimized.

We wish to employ the latent variable $\mathbf{z}$ as the distilled persona embeddings. So the quality of $\mathbf{z}$ will affect the performance of tips generation. Some previous works [9, 27, 43] have also shown that the performance of $\mathbf{z}$ is likely to be disturbed during the training procedure, especially when combining VAEs with the RNN based text generation framework. In order to enhance the performance of the typical VAEs, inspired by the ideas in [8] and [15], we employ the adversarial strategy for the training of VAEs. Generally, we design a discriminator network D_{aVAE} with a vector $\tilde{\mathbf{x}}$ as input, and the target is to recognize if $\tilde{\mathbf{x}}$ is from the true data $\mathbf{X}$ or from the generated samples $\mathbf{X}'$ by VAEs. VAEs will "fool" the discriminator D_{aVAE} by trying the best to produce high quality latent variables $\mathbf{z}$ as well as the generated sample $\mathbf{x}'$. Then the minimax game between the VAEs and the discriminator can be formulated as follows:

$$\begin{aligned} \min_{VAEs} \max_{D_{aVAE}} & \mathbb{E}_{\mathbf{x}\sim p_{data}(\mathbf{x})}[\log D_{aVAE}(\mathbf{x})] \\ & + \mathbb{E}_{\mathbf{z}\sim p(\mathbf{z}|\mathbf{x})}[\log(1 - D_{aVAE}(VAE_{Dec}(\mathbf{z})))] \\ & + \mathbb{E}_{\mathbf{z}_f\sim p(\mathbf{z})}[\log(1 - D_{aVAE}(VAE_{Dec}(\mathbf{z}_f)))] \end{aligned} \tag{10}$$

where VAE_{Dec} is the decoder component of the VAEs model. $\mathbf{z}$ is the latent variable from VAEs, and $\mathbf{z}_f$ is sampled from the prior distribution of $\mathbf{z}$.

For the design of the discriminator D_{aVAE}, we simply use a multilayer perceptron to process the data.

$$\begin{aligned} \mathbf{h}^{D_v} &= tanh(\mathbf{W}_{xh}^{D_v}\tilde{\mathbf{x}} + \mathbf{b}_{xh}^{D_v}) \\ y^{D_v} &= \sigma(\mathbf{W}_{hy}^{D_v}\mathbf{h}^{D_v} + b_{hy}^{D_v}) \end{aligned} \tag{11}$$

where $\mathbf{W}_{xh}^{D_v} \in \mathbb{R}^{d_h \times |V|}$, $\mathbf{W}_{hy}^{D_v} \in \mathbb{R}^{1 \times d_h}$, $\mathbf{b}_{xh}^{D_v} \in \mathbb{R}^{d_h}$, and $b_{hy}^{D_v} \in \mathbb{R}$. The output y^{D_v} is a real value in the range of $[0, 1]$ and the value 1 means that the sample $\tilde{\mathbf{x}}$ is from the true data. We denote all the parameters in D_{aVAE} using Θ_{D_v}. The optimization objective to be maximized for D_{aVAE} is formulated as:

$$\begin{aligned} \mathcal{L}_{D_{aVAE}} = & \log(D_{aVAE}(\mathbf{x})) \\ & + \log(1 - D_{aVAE}(VAE_{Dec}(VAE_{Enc}(\mathbf{x})))) \\ & + \log(1 - D_{aVAE}(VAE_{Dec}(\mathbf{z}_f))) \end{aligned} \tag{12}$$

Then the parameters Θ_{D_v} are updated using gradient methods:

$$\Theta_{D_v} \leftarrow \Theta_{D_v} - \nabla_{\Theta_{D_v}}(-\mathcal{L}_{D_{aVAE}}) \tag{13}$$

Conditioned on the aVAE framework, we will conduct the parameter learning for VAEs Encoder, VAEs Decoder, and discriminator D_{aVAE} using different loss functions respectively. Encoder transforms the input $\mathbf{X}$ to the persona embeddings $\mathbf{Z}$. On one side, $\mathbf{Z}$ are used to reconstruct the original input. On the other side, $\mathbf{Z}$ are used to conduct the persona-aware tips generation. So the loss signals from both the aVAE and the tips generation framework are used to conduct the optimization for Θ_{Enc}:

$$\Theta_{Enc} \leftarrow \Theta_{Enc} - \nabla_{\Theta_{Enc}}(\mathcal{L}_{KL} + \mathcal{L}_{Rec} + \mathcal{L}^z_{D_{aVAE}} + \mathcal{L}_{Tips}) \tag{14}$$

where $\mathcal{L}_{KL}$ and $\mathcal{L}_{Rec}$ are the KL divergence and reconstruction loss from Equation 8. $\mathcal{L}_{Tips}$ is the loss signal from the tips generation component. $\mathcal{L}^z_{D_{aVAE}}$ is the output of D_{aVAE}:

$$\mathcal{L}^z_{D_{aVAE}} = -\log(D_{aVAE}(VAE_{Dec}(VAE_{Enc}(\mathbf{x})))) \tag{15}$$

For the parameter optimization of VAEs Decoder, we use $\mathcal{L}_{Rec}$, $\mathcal{L}_{D_{aVAE}}$, $\mathcal{L}_{Tips}$ as the loss signals:

$$\Theta_{Dec} \leftarrow \Theta_{Dec} - \nabla_{\Theta_{Dec}}(\mathcal{L}_{\text{Rec}} + \mathcal{L}_{D_{aVAE}} + \mathcal{L}_{Tips}) \tag{16}$$

Finally, the training procedure of aVAE model is shown in Algorithm 1.

Algorithm 1 Persona embedding learning.

Input: BoWs vectors of historical tips and reviews $\mathbf{X}$.
Output: The persona embeddings $\mathbf{Z}$.

Initialize $\Theta_{Enc}, \Theta_{Dec}, \Theta_{D_v}$;
while not converged **do**
  Draw $\mathbf{x}$ from p_{data}.
  Draw $\mathbf{z}_f$ from prior $p(\mathbf{z})$.
  $\mathbf{z} = VAE_{Enc}(\mathbf{x})$
  $\mathbf{x}' = VAE_{Dec}(\mathbf{z})$
  $\mathbf{x}'_f = VAE_{Dec}(\mathbf{z}_f)$
  Get $\mathcal{L}_{Rec}$, $\mathcal{L}_{KL}$, $\mathcal{L}_{D_{aVAE}}$ according to Equation 8 and 12.
  Get $\mathcal{L}_{Tips}$ from tips generation.
  Update parameters using gradient methods:
  $\Theta_{Enc} \leftarrow \Theta_{Enc} - \nabla_{\Theta_{Enc}}(\mathcal{L}_{KL} + \mathcal{L}_{Rec} + \mathcal{L}^z_{D_{aVAE}} + \mathcal{L}_{Tips})$
  $\Theta_{Dec} \leftarrow \Theta_{Dec} - \nabla_{\Theta_{Dec}}(\mathcal{L}_{\text{Rec}} + \mathcal{L}_{D_{aVAE}} + \mathcal{L}_{Tips})$
  $\Theta_{D_v} \leftarrow \Theta_{D_v} - \nabla_{\Theta_{D_v}}(-L_{D_{aVAE}})$
end while
return $\mathbf{z}$.

Feeding the historical reviews and tips representations ($\mathbf{x}^c_u$, $\mathbf{x}^c_i$, $\mathbf{x}^s_u$, and $\mathbf{x}^s_i$) into $aVAE^c$ (for reviews) and $aVAE^s$ (for tips) respectively, we can obtain four persona embeddings $\mathbf{z}^c_u$, $\mathbf{z}^c_i$, $\mathbf{z}^s_u$, and $\mathbf{z}^s_i$. These persona embeddings will be integrated into the rating prediction component and the tips generation component later.

2.2.2 ***Sentiment and Rating Modeling.*** We regard the persona embeddings as the latent factors of users and items, and feed them into a multilayer perceptron to conduct the rating prediction. The predicted ratings will be used to control the sentiment of the generated tips.

Specifically, we first map the persona embeddings to a hidden space:

$$\mathbf{h}^r = tanh(\mathbf{W}^r_{uch}\mathbf{z}^c_u + \mathbf{W}^r_{ich}\mathbf{z}^c_i + \mathbf{W}^r_{ush}\mathbf{z}^s_u + \mathbf{W}^r_{ish}\mathbf{z}^s_i + \mathbf{b}^r_h) \quad (17)$$

where $\{\mathbf{W}^r_{uch}, \mathbf{W}^r_{ich}, \mathbf{W}^r_{ush}, \mathbf{W}^r_{ish}\} \in \mathbb{R}^{d_h \times k}$ are the mapping matrices. $\mathbf{b}^r_h \in \mathbb{R}^{d_h}$ is the bias term. $tanh$ is the hyperbolic tangent activation function. The superscript r refers to variables related to the rating prediction component. For better performance, we can add more layers of non-linear transformations into our model:

$$\mathbf{h}^r_l = \sigma(\mathbf{W}^r_{hh_l}\mathbf{h}^r_{l-1} + \mathbf{b}^r_{h_l}) \quad (18)$$

where $\mathbf{W}^r_{hh_l} \in \mathbb{R}^{d_h \times d_h}$ is the mapping matrix for the variables in the hidden layers. l is the index of a hidden layer. Assume that $\mathbf{h}^r_L$ is the output of the last hidden layer. The output layer transforms $\mathbf{h}^r_L$ into a real-valued rating $\hat{r}$:

$$\hat{r} = \mathbf{W}^r_{hr}\mathbf{h}^r_L + b^r \quad (19)$$

where $\mathbf{W}^r_{hr} \in \mathbb{R}^{1 \times d_h}$ and $b^r \in \mathbb{R}$. We formulate the optimization of the parameters Θ_r as a regression problem and the loss function is formulated as:

$$\mathcal{L}^r = \frac{1}{2|\mathcal{X}|}\sum_{u \in \mathcal{U}, i \in \mathcal{I}}(\hat{r}_{u,i} - r_{u,i})^2 \quad (20)$$

where $\mathcal{X}$ represents the training set. $r_{u,i}$ is the ground truth rating assigned by the user u to the item i.

The predicted rating is a real value, not a vector, for example, $\hat{r}_{u,i} = 4.321$. In order to incorporate the rating information into the tips generation component, we cast it into an integer 4, and add a vectorization process to obtain the vector representation of rating $\hat{r}_{u,i}$. If the rating range is $[0, 5]$, we will get the rating vector $\hat{\mathbf{r}}_{u,i} = (0, 0, 0, 0, 1, 0)^T$.

2.2.3 ***External Persona Memory.*** In addition to represent persona information using the latent embeddings from aVAE, we design an external persona memory for directly storing the persona related words for both the current user u and the current item i. To build the memory, we first collect all the words for the current user u and the current item t from their historical tips. We add a filtering process to remove the stop-words and the low-frequency words. Then we get a local vocabulary storing the indices of the persona words. Recall that we have a global word embedding $\mathbf{E}$. Then we can get a sub-matrix from $\mathbf{E}$ according to the word indices. We regard this sub-matrix as persona memory. We employ Pointer Networks to retrieve persona information from the memory when generating tips. The details are described in Section 2.3.3.

2.3 Abstractive Tips Generation

2.3.1 ***Overview of Tips Generation.*** The right part of Figure 2 depicts our tips generation model. The basic element is a RNN based sequence modeling component. Pointer Networks (attention modeling and copy mechanism) is introduced to conduct the memory reading. Context information plays an important role in the task of text generation. We combine the persona embeddings and the sentiment information as the context information and construct the context vector which can control the tips text generation. At the training state, we also design a discriminator D_{Tips} to assess the quality of the generated tips. The assess value will be propagated to the RNN models to assist the parameter learning. At the operational or testing stage, we use a beam search algorithm [13] for decoding and generating the best tips given a trained model.

2.3.2 ***Sequence Modeling.*** Assume that $\mathbf{h}^s_t$ is the sequence hidden state at the time t. It depends on the input at the time t and the previous hidden state $\mathbf{h}^s_{t-1}$:

$$\mathbf{h}^s_t = f(\mathbf{h}^s_{t-1}, s_t) \quad (21)$$

$f(\cdot)$ can be the vanilla RNN, Long Short-Term Memory (LSTM) [10], or Gated Recurrent Unit (GRU) [5]. Considering that GRU has comparable performance but with less parameters and more efficient computation, we employ GRU as the basic model in our sequence modeling framework. In the case of GRU, the state updates are processed according to the following operations:

$$\begin{aligned}
\mathbf{r}^s_t &= \sigma(\mathbf{W}^s_{sr}\mathbf{s}_t + \mathbf{W}^s_{hr}\mathbf{h}^s_{t-1} + \mathbf{b}^s_r) \\
\mathbf{z}^s_t &= \sigma(\mathbf{W}^s_{sz}\mathbf{s}_t + \mathbf{W}^s_{hz}\mathbf{h}^s_{t-1} + \mathbf{b}^s_z) \\
\mathbf{g}^s_t &= \tanh(\mathbf{W}^s_{sh}\mathbf{s}_t + \mathbf{W}^s_{hh}(\mathbf{r}^s_t \odot \mathbf{h}^s_{t-1}) + \mathbf{b}^s_h) \\
\mathbf{h}^s_t &= \mathbf{z}^s_t \odot \mathbf{h}^s_{t-1} + (1 - \mathbf{z}^s_t) \odot \mathbf{g}^s_t
\end{aligned} \quad (22)$$

where $\mathbf{s}_t \in \mathbf{E}$ is the embedding vector for the word s_t of the tips and the vector is also learnt from our framework. $\mathbf{r}^s_t$ is the reset gate, $\mathbf{z}^s_t$ is the update gate. $\odot$ denotes element-wise multiplication.

In order to conduct the persona-aware tips generation, we combine all the persona embeddings and the sentiment information as

the context information and construct the context vector. Specifically, we initialize the hidden state $\mathbf{h}_0$ using the persona embeddings and the sentiment information:

$$\mathbf{h}_0^s = tanh(\mathbf{W}_{uch}^s \mathbf{z}_\mathbf{u}^\mathbf{c} + \mathbf{W}_{ich}^s \mathbf{z}_\mathbf{i}^\mathbf{c} + \mathbf{W}_{ush}^s \mathbf{z}_\mathbf{u}^\mathbf{s} + \mathbf{W}_{ish}^s \mathbf{z}_\mathbf{i}^\mathbf{s} + \mathbf{W}_{rh}^s \hat{\mathbf{r}} + \mathbf{b}_h^s) \tag{23}$$

where $\{\mathbf{z}_*^*\}$ are the persona embeddings. $\hat{\mathbf{r}}$ is the vectorization for the predicted rating $\hat{r}$. $\mathbf{W}$ and $\mathbf{b}$ are the neural parameters.

After getting all the sequence hidden states based on GRU, we feed them to the final output layer to predict the word sequence in tips.

$$\hat{\mathbf{s}}_{t+1} = \varsigma(\mathbf{W}_{hs}^s \mathbf{h}_t^s + \mathbf{b}^s) \tag{24}$$

where $\mathbf{W}_{hs}^s \in \mathbb{R}^{d \times |\mathcal{V}|}$ and $\mathbf{b}^s \in \mathbb{R}^{|\mathcal{V}|}$. $\varsigma(\cdot)$ is the softmax function. Then the word with the largest probability is the decoding result for the step $t+1$:

$$w_{t+1}^* = \arg\max_{w_i \in \mathcal{V}} \hat{\mathbf{s}}_{t+1}^{(w_i)} \tag{25}$$

At the training stage, we use negative log-likelihood (NLL) as the loss function, where I_w is the vocabulary index of the word w:

$$\mathcal{L}_{Tips} = -\sum_{w \in Tips} \log \hat{\mathbf{s}}^{(I_w)} \tag{26}$$

Note that $\mathcal{L}_{Tips}$ is also used in the persona modeling component to train the aVAE models.

At the testing stage, given a trained model, we employ the beam search algorithm [13] to find the best sequence S^* having the maximum log-likelihood.

$$S^* = \arg\max_{S \in \mathcal{S}} \sum_{w \in S} \log \hat{\mathbf{s}}^{(I_w)} \tag{27}$$

2.3.3 ***Exploiting Persona Memory***. Recall that in Section 2.2.3, we build a local personal vocabulary V_{ui} for the user u and the item i. The persona memory $\mathbf{M}_{ui}$ is extracted from the word embedding $\mathbf{E}$ using the word indices in V_{ui}. Inspired by [1], we exploit the idea of attention modeling to conduct the addressing and reading operations on the memory $\mathbf{M}_{ui}$. We can obtain the GRU hidden state $\mathbf{h}_t^s$ according to Equation (21). Then the attention weights at the time step t are calculated based on the relationship between $\mathbf{h}_t^s$ with all the word embeddings in $\mathbf{M}_{ui}$. Let $a_{i,j}$ be the attention weight between $\mathbf{h}_i^s$ and $\mathbf{m}_j$, which can be calculated using:

$$\begin{aligned} a_{i,j} &= \frac{\exp(e_{i,j})}{\sum_{j'=1}^{|V_{ui}|} \exp(e_{i,j'})} \\ e_{i,j} &= \mathbf{v}_a{}^T \tanh(\mathbf{W}_{hh}^s \mathbf{h}_i^s + \mathbf{W}_{hh}^m \mathbf{m}_j + \mathbf{b}_a) \end{aligned} \tag{28}$$

where $\mathbf{W}_{hh}^s \in \mathbb{R}^{d_h \times d_h}$, $\mathbf{W}_{hh}^m \in \mathbb{R}^{d_w \times d_h}$, $\mathbf{b}_a \in \mathbb{R}^{d_h}$, and $\mathbf{v}_a \in \mathbb{R}^{d_h}$. The attention context is obtained by the weighted linear combination of all the word embeddings in $\mathbf{M}_{ui}$:

$$\mathbf{c}_t = \sum_{j'=1}^{|V_{ui}|} a_{t,j'} \mathbf{m}_{j'} \tag{29}$$

The final hidden state $\mathbf{h}_t^{s_2}$ is the output of the second decoder GRU layer, jointly considering the word $\mathbf{s}_t$, the previous hidden state $\mathbf{h}_{t-1}^{s_2}$, and the attention context $\mathbf{c}_t$:

$$\mathbf{h}_t^{s_2} = GRU_2(\mathbf{h}_{t-1}^{s_2}, \mathbf{s}_t, \mathbf{c}_t) \tag{30}$$

Then we can use $\mathbf{h}_t^{s_2}$ as the input to Equation (24) to conduct the decoding operation.

Besides using attention modeling to address and read the persona information from the the persona memory $\mathbf{M}$, we also employ the idea of Pointer Networks [36] to copy the target words from the memory to form the tips. At the state t, we can obtain the attention weights (distribution) $\mathbf{a}_{t,:}$ on the persona memory $\mathbf{M}_{ui}$. We project $\mathbf{a}_{t,:}$ to a $|V|$-sized vector $\hat{\mathbf{s}}_{t+1}^p$ according to the word indices in V_{ui}. Then we design a soft gate to decide that the word s_{t+1} should be generated or be copied from the memory:

$$p_g = \sigma(\mathbf{v}_p^T(\mathbf{W}_{hp}^s \mathbf{h}_t^{s_2} + \mathbf{W}_{sp}^s \mathbf{s}_t + \mathbf{W}_{cp}^s \mathbf{c}_t + \mathbf{b}_p)) \tag{31}$$

where $\mathbf{v}_p \in \mathbb{R}^{d_h}$ and $p_g \in (0,1)$. We merge the copy signal $\hat{\mathbf{s}}_{t+1}^p$ and the original output $\hat{\mathbf{s}}_{t+1}$ according to the gate p_g:

$$\hat{\mathbf{s}}'_{t+1} = p_g \times \hat{\mathbf{s}}_{t+1} + (1 - p_g) \times \hat{\mathbf{s}}_{t+1}^p \tag{32}$$

Then the tips sampling process can be conducted on $\hat{\mathbf{s}}'_{t+1}$.

2.3.4 ***Tips Quality Discriminator***. Some previous works [40, 41] show that adversarial training strategy is beneficial to the text generation problem. To further improve the performance, we also employ this training strategy in our framework.

The tips discriminator D_{Tips} is a multilayer perceptron with the persona embeddings, the rating information, and the tips sequence as the input. The input tips sequence can be the ground truth S or the tips $\hat{S}$ generated by the system. We propose a Bidirectional-GRU model to conduct the representation learning for S and $\hat{S}$:

$$\mathbf{h}^S = \overrightarrow{\mathbf{h}^S} || \overleftarrow{\mathbf{h}^S} \tag{33}$$

Then we combine all the information according to:

$$\mathbf{h}^q = \tanh(\mathbf{W}_{sh}^q \mathbf{h}^S + \mathbf{W}_{uch}^q \mathbf{z}_\mathbf{u}^\mathbf{c} + \mathbf{W}_{ich}^q \mathbf{z}_\mathbf{i}^\mathbf{c} + \mathbf{W}_{ush}^q \mathbf{z}_\mathbf{u}^\mathbf{s} + \mathbf{W}_{ish}^q \mathbf{z}_\mathbf{i}^\mathbf{s} + \mathbf{W}_{rh}^q \hat{\mathbf{r}} + \mathbf{b}_h^q)$$

Finally, we add a softmax output layer to let the model output a binary category variable:

$$\mathbf{y}^q = \varsigma(\mathbf{W}_{hy}^q \mathbf{h}^q + \mathbf{b}_y^q) \tag{34}$$

We treat the ground truth S as the positive instance and the sampled sequence $\hat{S}$ as the negative instance. So we directly let the first dimension of $\mathbf{y}^q$ represent the positive label. We define the value function as $V(S) = \mathbf{y}_{[0]}^q$. We utilize the REINFORCE [38] method to integrate the tips quality signal $V(S)$ into the tips generation framework to conduct the parameter learning. The details can be found in the existing works [18, 40, 41].

3 EXPERIMENTAL SETUP

3.1 Datasets

In our experiments, we use five datasets from different domains to evaluate our framework. The ratings of all these datasets are integers in the range of $[1, 5]$. There are four datasets from Amazon 5-core[3]: **Electronics**, **Movies & TV**, **Clothing, Shoes and Jewelry**, and **Home and Kitchen**. We regard the field "summary" as tips, and the number of tips texts is the same with the number of reviews. Another dataset is from **Yelp** Challenge[4]. It is also a large-scale dataset consisting of restaurant reviews and tips. We filter out the words with low term frequency in the tips and review texts,

[3]http://jmcauley.ucsd.edu/data/amazon
[4]https://www.yelp.com/dataset_challenge

Table 2: Overview of the datasets.

	Electr	Movies	Home	Clothing	Yelp
users	191,522	123,340	66,212	39,085	115,781
items	62,333	49,823	27,991	22,794	60,224
reviews	1,684,779	1,693,441	550,461	277,521	1,393,257
$\|\mathcal{V}\|$	37,999	82,805	23,950	16,297	82,805

and build a vocabulary $\mathcal{V}$ for each dataset. We show the statistics of our datasets in Table 2.

3.2 Evaluation Metrics

For the evaluation of abstractive tips generation, the ground truth s_h is the tips written by the user. We use *ROUGE* [24] as our evaluation metric with standard options[5]. It is a classical evaluation metric in the field of text summarization [24]. It counts the number of overlapping units between the generated tips and the ground truth written by users. Assuming that s is the generated tips, g_n is n-gram, $C(g_n)$ is the number of n-grams in $\tilde{s}$ (s_h or s), $C_m(g_n)$ is the number of n-grams that appear in both s and s_h, then the ROUGE-N score for s is defined as follows:

$$ROUGE\text{-}N(s) = \sum_{g_n \in s_h} C_m(g_n) / \sum_{g_n \in \tilde{s}} C(g_n) \tag{35}$$

When $\tilde{s} = s_h$, we can get $ROUGE_{recall}$, and when $\tilde{s} = s$, we get $ROUGE_{precision}$. We use Recall, Precision, and F-measure of ROUGE-1 (R-1), ROUGE-2 (R-2), ROUGE-L (R-L), and ROUGE-SU4 (R-SU4) to evaluate the quality of the generated tips.

For the evaluation of rating prediction, we employ two metrics: Mean Absolute Error (*MAE*) and Root Mean Square Error (*RMSE*). Both of them are widely used for rating prediction in recommender systems. Given a predicted rating $\hat{r}_{u,i}$ and a ground-truth rating $r_{u,i}$ from the user u for the item i, the RMSE is calculated as:

$$RMSE = \sqrt{\frac{1}{N} \sum_{u,i} (r_{u,i} - \hat{r}_{u,i})^2} \tag{36}$$

where N indicates the number of ratings between users and items. Similarly, MAE is calculated as follows:

$$MAE = \frac{1}{N} \sum_{u,i} |r_{u,i} - \hat{r}_{u,i}| \tag{37}$$

3.3 Comparative Methods

Abstractive tips generation: We compare our framework PATG with the following baseline and state-of-the-art methods:

- **NRT** [21]: It is a recent multi-task learning framework for rating prediction and abstractive tips generation achieving state-of-the-art performance. Latent factors for users and items are learnt during the training procedure, and are used as the context information for tips generation. NRT does not consider the persona information.
- **LexRank** [7] is a classical method in the field of text summarization. Because we have obtained all the historical tips for the current user and item, then the problem can be regarded as a multi-document summarization problem. LexRank can extract a sentence as the final tips. Note that we give an advantage of this method since the ground truth ratings are used to conduct the filtering.
- **CTR**$_t$: **C**ollaborative **T**opic **R**egression (CTR) [37] is proposed for rating prediction. It contains a topic model component and it can generate topics for items. Then the most topic-similar sentence from the item historical tips is extracted as the tips.
- **HFT**$_t$: **H**idden **F**actors and Hidden **T**opics [26] utilizes a topic modeling technique to model the review texts for rating prediction. Then we can design a tips extraction method HFT$_t$ using the similar technique in CTR$_t$.

Rating prediction: We compare of rating prediction performance with the following baseline methods:

- **NMF**: **N**on-negative **M**atrix **F**actorization [16]. It only uses the rating matrix as the input.
- **PMF**: **P**robabilistic **M**atrix **F**actorization [32]. Gaussian distribution is introduced to model the latent factors for users and items.
- **LRMF**: **L**earning to **R**ank with **M**atrix **F**actorization [34]. It combines a list-wise learning-to-rank algorithm with matrix factorization to improve recommendation.
- **SVD++**: It extends **S**ingular **V**alue **D**ecomposition by considering implicit feedback information for latent factor modeling [14].
- **URP**: **U**ser **R**ating **P**rofile modeling [25]. Topic models are employed to model the user preference from a generative perspective. It still only uses the rating matrix as input.
- The baseline methods used in tips quality evaluation: **NRT** [21], **CTR** [37], **HFT** [26].

Ablation experiments: In order to demonstrate the performance of each component of our framework, we conduct the ablation experiments on the dataset Home. We compare the performance of our integrated model PATG with the models without the some designed components. We set that "A" denotes the aVAE model, "M" represents the persona memory and the Pointer Networks, and "D" represents the tips quality discriminator D_{Tips}. Then the method "**PATG w/o A, M, D**" means that A, M, and D are all removed and we only use the standard VAE for persona modeling.

3.4 Experimental Settings

Each dataset is divided into three subsets: 80%, 10%, and 10%, for training, validation, and testing, respectively. All the parameters of our model are tuned with the validation set. After the tuning process, the number of latent factors k is set to 10 for NMF and SVD++. The number of topics K is set to 50 for the methods using topic models. The number of dimension for the persona embeddings is set to 100. The dimension of the hidden size is 400. In our framework, the number of layers for the rating regression model is 2, and for the tips generation model is 1. We set the beam size $\beta = 5$, and the maximum length $\eta = 20$. All the neural matrix parameters in hidden layers and RNN layers are initialized from a uniform distribution between $[-0.1, 0.1]$. We also regard the word embedding $\mathbf{E}$ used in the tips generation component as a neural parameter. Adadelta [42] is used for gradient based optimization.

4 RESULTS AND DISCUSSIONS

4.1 Research Questions

The research questions in our experiments are as follows:

- **RQ1**: What is the performance of PATG in persona-aware abstractive tips generation? (Section 4.2)
- **RQ2**: Can the persona embeddings improve the performance of rating prediction? (Section 4.3)
- **RQ3**: What is the performance of each component of PATG, such as VAEs, aVAE, and the persona memory? (Section 4.4)
- **RQ4**: Can the model generate tips that are complying with the persona information? (Section 4.5.)
- **RQ5**: Can the model generate tips that are really controlled by ratings? (Section 4.6.)

4.2 Abstractive Tips Generation (RQ1)

The evaluation results of tips generation of our model and the comparative methods are given in Table 3. In order to capture more details, we report Recall, Precision, and F-measure (in percentage) of ROUGE-1, ROUGE-2, ROUGE-L, and ROUGE-SU4. Our model achieves the best performance in most of the metrics among all the five datasets. NRT does not consider persona information when generating tips. It only utilizes the learnt latent factors for users and items as the context information. Compared with NRT, our proposed framework PATG obtains better performance on all the metrics, which demonstrates that the consideration of persona information can indeed improve the tips generation performance. We also conduct statistical significance test comparing PATG and NRT and the results indicate that the improvements are significant with $p < 0.05$.

From the results, we also find that our model obtains dramatic improvements on the metric of ROUGE Precision, especially compared with the methods of LexRank, HFT_t, and CTR_t. The main reasons are that those methods are all extraction-based which just extract some original sentences from the original reviews or tips as the final tips. Therefore, the obtained tips are much longer with more noisy and redundant information. In contrast, our framework PATG as well as NRT are abstractive tips generation methods. PATG can generate more concise sentences which not only guarantee the recall metric, but also obtain better precision performance. This also fits the essential spirit of Tips.

4.3 Rating Prediction (RQ2)

Recall that we also design an auxiliary component, i.e. **rating prediction** to capture the sentiment information and control the sentiment of the generated tips, which is also an important aspect of the task of tips generation. Therefore we design some experiments to evaluate the performance of this component. The rating prediction results are given in Table 4. Our model consistently outperforms the best under both MAE and RMSE metrics on all datasets, thus it verifies that the generated persona embeddings are not only effective for generating better tips in the main task, but also useful for predicting accurate ratings in the auxiliary task. Statistical significance of differences between the performance of PATG and the recent method NRT is tested using a two-tailed paired t-test. The result shows that PATG is significantly better than NRT.

4.4 Ablation Analysis (RQ3)

Considering that we design various of components to tackle the corresponding problems of our task, and different components play different roles on our framework. In order to demonstrate the necessity and the performance of each component, we conduct the ablation experiments on the dataset "Home". The results are shown in Table 5. Recall that "A" denotes the aVAE model, "M" represents the persona memory and the Pointer Networks, and "D" represents the tips quality discriminator D_{Tips}. It is obvious that persona modeling based on aVAE (A) can improve the tips generation performance. The persona memory and Pointer Networks (M) are very helpful to the effectiveness of our framework. The tips quality discriminator (D) can also contribute to the better performance. Among all the components, aVAE (A) as well as the persona memory and pointer network (M) contribute more to the improvements of the performance.

4.5 Persona Controlled Generation (RQ4)

The main problem setting of this work is to generate persona-aware tips. In order to demonstrate the quality of the generated tips, we selected some real cases generated by our PATG from different domains for some users and items. The results are listed in Table 6. Although our model generates tips in an abstractive way, tips' linguistic quality is quite good. The **persona properties** of the generated tips match well with the ground truth. For example, in the first case, the generated tips is "This is a great hat for the price.", and the ground truth is "Thanks nice quality excellent price great deal.". Both of the sentences contain the terms "great" and "price". In the third case, the generated tips and the ground truth have a large overlapping with the terms "replace my old", and "processor". Interestingly, sometimes the framework can select some synonyms when conducting tips generation. For instance, the generated tips of the fourth case contains terms "bought" and "for my husband". The ground truth contains "purchased" and "for a male". Moreover, we also choose some generated tips with negative sentiment to conduct the sentiment correlation analysis. Take the generated tips "Please do not buy this coffee maker." as an example (the last case in Table 6), our model predicts a rating of 2.01, which clearly shows a consistent sentiment. The ground truth tips of this example is " They are still overpriced and all but worthless.", which also conveys a negative sentiment. The generated tips "The bottom line of the thin man." and the ground truth "Pretty dark story in book or movie form." are just describing some facts, with a neutral rating 3. Sometimes the overlapping between the generated tips and the ground truth is small, but they still convey similar information.

4.6 Rating Controlled Generation (RQ5)

Recall that in addition to the persona embeddings as context information, rating information is also incorporated to control the sentiment of the generated tips. In order to show such ability of our framework, we design an experiment on the domain "Home" to demonstrate the rating controlled tips generation. Specifically, during the prediction, we manually set the rating from 1 to 5 as the sentiment context to control the generation, and meanwhile, we create a new user and a new item with **0** persona embeddings. This setting mimics a **cold start** case: what the tips will look like

without knowing any information of users and items. Then the manual rating and the **0** based persona embeddings are fed into the framework to conduct tips generation. The results are shown in Table 7. Here we set the beam size to 5 so we obtain 5 decoded tips ranked by the likelihood in descending order. It is obvious that when $r > 1$, our framework can generated reasonable tips controlled by ratings. The generated tips show monotone language style, which looks odd, but in fact it is not, because we did not give any persona information of users and items as input (refer to Table 6 for generated tips with rich text such as product information). Moreover, note that this is an artificial scenario which does not compile well with the real case. Table 7 shows that when $r = 1$, the framework does not generate negative tips. We investigate the training dataset and find that the proportion of rating-1 records is much smaller (e.g. a quarter of rating-4 and one-thirteenth of

rating-5), which may cause our model under-fitting for generating rating-1 tips.

5 RELATED WORK

Abstractive text generation is a challenging task. Recently, sequence modeling based on the gated recurrent neural networks such as Long Short-Term Memory (LSTM) [10] and Gated Recurrent Unit (GRU) [5] demonstrates high capability in text generation related tasks, such as abstractive summarization [19, 28, 31], dialogue systems [3, 33] and image caption generation [39].

In the area of recommendation systems, some researchers also apply LSTM or GRU based RNN models on abstractive text generation. Tang et al. [35] propose a framework to generate context-aware reviews. Sentiments and products are encoded into a continues semantic representation and use RNN to conduct the decoding and generation. Dong et al. [6] regard users, products, and rating as attribute information and employ a attention modeling based sequence modeling framework to generate reviews. Ni et al. [29] propose to combine collaborative filtering with generative networks to jointly perform the tasks of item recommendation and review generation. Low-dimensional user preferences and item properties are combined with a character-level LSTM model to conduct the review generation. Yao et al. [40] employ the adversarial strategy to make the generated review indistinguishable from human written

ones so that can improve the performance of review generation. Although research works have been proposed for review generation, there are very few works investigating tips generation. Li et al. [21] propose a unified framework to jointly conduct rating prediction and abstractive tips generation. Latent factors for users and items are learnt from the multi-task learning framework and are fed into the tips generation framework as context information.

However, few works consider persona modeling and sentiment detection jointly in their frameworks. Hu et al. [11], Liao et al. [23] revised the variational auto-encoders (VAEs) based text generation model and can control the sentiment and tense of the generated reviews. But they still do not consider persona information in their model. Li et al. [17] propose two methods to conduct the persona modeling for text generation in the area of dialog systems, but dialog systems have different characteristics with recommendation system. Moreover, they do not consider the sentiment information. Different with these previous works, our proposed framework can jointly consider the persona information and the sentiment signal when conducting the abstractive tips generation.

6 CONCLUSIONS

We propose a framework PATG to address the problem of persona-aware tips generation. A framework based on adversarial variational auto-encoders (aVAE) is exploited for persona modeling from the historical tips and reviews. We also design an external persona memory for directly storing the persona related words for the current user and item. The distilled persona embeddings are used as latent factors and are fed into the rating prediction component for detecting sentiment. Then the persona embeddings and the

sentiment information are incorporated into a recurrent neural networks (RNN) based tips generation component to control the tips generation. Experimental results show that our framework achieves better performance than the state-of-the-art models on abstractive tips generation.

ABSTRACT

Travel time estimation of a given route with respect to real-time traffic condition is extremely useful for many applications like route planning. We argue that it is even more useful to estimate the *travel time distribution*, from which we can derive the expected travel time as well as the uncertainty. In this paper, we develop a deep generative model – DeepGTT – to learn the travel time distribution for any route by conditioning on the real-time traffic. DeepGTT interprets the generation of travel time using a three-layer hierarchical probabilistic model. In the first layer, we present two techniques, amortization and spatial smoothness embeddings, to share statistical strength among different road segments; a convolutional neural net based representation learning component is also proposed to capture the dynamically changing real-time traffic condition. In the middle layer, a nonlinear factorization model is developed to generate auxiliary random variable *i.e.,* speed. The introduction of this middle layer separates the statical spatial features from the dynamically changing real-time traffic conditions, allowing us to incorporate the heterogeneous influencing factors into a single model. In the last layer, an attention mechanism based function is proposed to collectively generate the observed travel time. DeepGTT describes the generation process in a reasonable manner, and thus it not only produces more accurate results but also is more efficient. On a real-world large-scale data set, we show that DeepGTT produces substantially better results than state-of-the-art alternatives in two tasks: travel time estimation and route recovery from sparse trajectory data.

1 INTRODUCTION

Estimating travel time of a given route on a road network is an essential task for many applications, including route planning, taxi dispatching, and ride-sharing. Many online web apps (*e.g.,* Google Map and Uber) provide such service. Due to its great importance, significant research efforts have been made towards the accurate estimation of travel times [20, 38, 39, 41]. However, existing studies only focus on the estimation of *expected travel time*. We argue that it is much more helpful or even essential to estimate *travel time distribution* (the probability density function) of a given route, based on real-time traffic conditions. We illustrate this point through an example.

Motivating example. Mary has a time budget of 35 minutes to reach airport from home. She queries for the best route, and there are two candidates — route **A** and route **B**, denoted by $\mathbf{r}_A$ and $\mathbf{r}_B$, respectively. The travel time distributions of $\mathbf{r}_A$ and $\mathbf{r}_B$ are depicted in Figure 1a, with the expectation $\mathbb{E}[t_A] = 26$ (minutes), and $\mathbb{E}[t_B] = 30$ (minutes). If the system recommends route solely based on the expected travel time, then $\mathbf{r}_A$ is the best choice. However, as shown in the figure, $\mathbf{r}_A$ has a much larger variance. Therefore, Mary would have a high risk of missing her flight if taking $\mathbf{r}_A$. In contrast, the probability density function of t_B is much more concentrated, and it is much safer to take $\mathbf{r}_B$.

This example shows that it is more sensible to make decision based on the probability distribution of the travel time, instead of mere its expectation. In fact, estimating travel time distribution also addresses the issue of route recovery from the sparse trajectory [42]. Figure 1b shows two possible routes $\mathbf{r}_A, \mathbf{r}_B$ from a_3 to a_4 (due to the low sampling rate) in an observed trajectory $T_a = [a_1, \ldots, a_5]$.

As the sampling points usually carry timestamps, we could get the travel time cost from a_3 to a_4, denoted by t. The problem of inferring the most likely route can be expressed as

$$\underset{\mathbf{r}}{\text{argmax}}\ P(\mathbf{r}|t), \quad \mathbf{r} \in \{\mathbf{r}_A, \mathbf{r}_B\}.$$

Using the Bayes Rule, we have $P(\mathbf{r}|t) \propto P(t|\mathbf{r})P(\mathbf{r})$. That is, we need to access the value of travel time distribution $P(t|\mathbf{r})$ at any $t > 0$.

In this paper, we aim to learn the ***travel time distribution*** $P(t|\mathbf{r})$ for a given route $\mathbf{r}$, with the consideration of real-time traffic conditions. This problem is challenging due to a few reasons. First, data sparsity remains a key challenge. Even though we have access to a large number of trajectories, the trajectories demonstrate a skewed distribution in the space. Roads in central business district are frequently visited, while roads in rural or remote areas are rarely covered. It is reported that about 10% of paths cannot be estimated due to lack of neighbor trajectories [39]. Second, travel time heavily depends on real-time traffic conditions which are dynamic. Almost all existing methods [20, 25, 38, 39, 42] assume that traffic conditions in the same time slot (*e.g.,* 8:00am-9:00am on every Saturday) are temporally-invariant, when estimating travel times. The assumption does not hold because traffic conditions can be influenced by many random variables such as the daily activities of people, road works, and accidents. Considering real-time traffic conditions makes data sparsity issue even worse. Further, travel time is also influenced by spatial characteristics of a road *e.g.,* number of traffic lights, number of lanes, and speed limit. To the best of our knowledge, no existing study has incorporated these heterogeneous influencing factors (both spatial and temporal) into a single model for travel time estimation.

To address the aforementioned challenges simultaneously, we approach travel time distribution learning from deep generative perspective [23, 35]. Specifically, we propose a model named DeepGTT (Deep Generative Travel Time), a three-layer hierarchical probabilistic model [14]. Each layer in DeepGTT captures underlying dependencies among the relevant random variables in a principled way. In the first layer, we present two techniques, spatial smoothness embeddings and amortization [11], to share statistical strength among different road segments to address the data sparsity challenge. A representation ρ_i is learned for each road segment r_i. We further propose a convolutional neural network based representation learning component to address the second challenge. This learning component enables the encoding of dynamically changing real-time traffic conditions into a vector $\mathbf{c}$. In the middle layer, a nonlinear factorization model is developed to combine the road segment representation ρ_i and traffic condition $\mathbf{c}$ to generate the travel speed v_i for road segment r_i. This auxiliary random variable v_i allows us to separate the statical spatial road features from the dynamically changing traffic conditions, so as to address the third challenge. In the end layer, an attention mechanism [4] based function is proposed to generate the entire route travel time t by adaptively aggregating the road segment speed v_i. We derive a variational low bound [7] to train the entire model in an end-to-end fashion.

To the best of our knowledge, this is the first deep generative model developed for travel time distribution learning. A great advantage DeepGTT inherits from probabilistic methods [14], is that it is quite data-efficient [6, 12]; even only trained with a small fraction of data it could produce substantially better results than existing methods trained on much larger datasets. In summary, our contributions are as follows:

- For the first time, we develop a deep generative model, named DeepGTT, to learn travel time distributions. DeepGTT is designed to be data-efficient.The model utilizes spatial smoothness embeddings and amortization to model road segments, and a convolutional neural network based representation learning component to capture real-time traffic conditions.
- The carefully designed hierarchical architecture allows us to separate the dynamically changing traffic conditions from the static spatial features, and thus enables incorporating the heterogeneous influencing factors (both spatial and temporal) into a single model for travel time learning.
- We develop an attention mechanism based function to collectively aggregate road segment speeds to generate the observations. Then, a variational low bound is derived to enable the model to be trained in an end-to-end fashion. As DeepGTT optimizes the complete distribution rather than a single mean value, it could incorporate more variability for more accurate prediction.
- We conduct thorough experiments on a real world large traffic dataset. Experiments show that our model produces substantially better results than state-of-the-art methods in both travel time estimation and route recovery tasks.

The rest of the paper is organized as follows. The related work is discussed in Section 2. The definitions, problem statement and the overview of DeepGTT are presented in Section 3. Section 4 describes the details of our method. The experimental results are presented in Section 5. We conclude the paper and discuss the future work in Section 6.

2 RELATED WORK

We briefly review the related studies on *travel time estimation* and *deep generative models* in this section.

2.1 Travel time estimation

The road segment-based methods first estimate travel time on each individual road segment independently by using the speeds information collected by loop detectors. Then travel time on a given route is estimated by summing up the estimated times of the road segments traversed in the given route. Such methods fail to consider delays caused by traffic lights, and left/right turns, resulting in large estimation errors.

To address the weaknesses of road segment-based methods, route-based methods attempt to estimate the travel time of a route as a whole. There are two main threads for route-based methods, namely, nearest neighbors search [36, 39] and trajectory regression [20, 41, 48]. Nearest neighbors search estimates travel time of a route by averaging travel times of the historical trajectories that have the closed origin and destination with the query route. Trajectory regression methods, on the other hand, treat travel times of the road segments as unknown variables and solve a regression problem using the historical trajectories.

Several works also attempt to estimate the travel time distribution for a given route on road network. Hunter et al. [19] investigate travel time distribution of a path in arterial networks using Gaussian Markov Random Field. Wu et al. [42] propose a model named STRS, that seeks to recover the route from sparse trajectories. STRS comprises of a travel time distribution estimation component and a spatial transition inference component. Its travel time distribution estimation component first learns the mean value of travel time by trajectory regression, and then empirically study the relationship between the variance and mean value to derive the distribution. STRS has been shown to be the state-of-the-art route recovery algorithm. Raghu et al. [13] explore the prediction limits of different methods by estimating the entropy of the travel time distributions.

Almost all existing studies make the assumption that traffic conditions in the same time slot are temporally-invariant. In this paper, we relax this assumption by learning travel time distribution conditioned on the real-time traffic. Wang et al. [40] also attempt to estimate the travel time of a path based on the real-time traffic. They split the query path into multiple sub-paths and search them from the real-time trajectories. However this method seriously suffers from data sparsity issue, even tensor decomposition was used to mitigate it.

Very recently, two deep learning based travel time estimation models–DeepTTE [38] and WDR [41] are proposed. Our method differs from them in three aspects. First, both DeepTTE and WDR only learn to predict the expectation of travel time, whereas our model outputs a distribution. Second, DeepTTE and WDR both adopt the assumption that traffic conditions in a time slot are temporally-invariant (except that DeepTTE takes weather into consideration), while we learn the travel time distribution conditioned on the real-time traffic. Third, both of them employ an RNN to learn the travel time by brute force, which unavoidably leads to a data-hungry model. In contrast, our method is built on deep generative models which allow us to interpret the generation of travel time in a reasonable manner. As a result, our model not only produces more accurate results but also is data-efficient.

Li et al. [27] study the problem of estimating travel time of a *trip* defined by its origin and destination. We highlight that this problem actually is different from ours as we learn the travel time distribution for an entire *route*. Note that, a *trip* can be achieved through multiple routes. In many applications such as trip planning, ride-sharing, travel time estimation between two locations does not help much without knowing the routes to travel.

2.2 Deep Generative Models

Deep generative models or deep probabilistic methods are the hybrids of deep learning and Bayesian inference, which share the great advantages of two worlds. On the one hand, generative models [14] allow us to specify the relationships among random variables to incorporate our prior knowledge in a flexible way. On the other hand, the automatic-differentiation [5] permits us to perform inference on large-scale datasets.

Generative models have been widely adopted in text data mining [8], online recommendation [15, 16, 46], spatial data analytics [18, 45, 47] as well as air quality inference [9, 10]. They are usually trained with sampling-based methods [3, 32] which have the drawback of slow convergence, thus limits their usage to relative small datasets [17]. The emergence of VAE (Variational Auto-Encoders) [23, 35] makes training large-scale generative models possible by marrying Bayesian inference and the automatic-differentiation technique—the core ingredient in deep learning. Since then, deep generative models have been growing rapidly and achieved a range of state-of-the-art results in semi-supervised learning [22], multiple instances scene understanding [12], high quality images and audio synthesis [37, 43], large-scale online recommendation [28]. In contrast, deep generative models have been less explored in spatial-temporal data analysis field. To our knowledge, this is the first deep generative model developed for travel time distribution learning.

Table 1: Notation.

Symbol	Definition
T	Trajectory
$\mathbf{T}$	Trip
$\mathbf{r}$	Route
r_i	The i-th road segment in route $\mathbf{r}$
$\rho_i \in \mathbb{R}^{\lvert\rho_i\rvert}$	The learned representation of r_i
$v_i \in \mathbb{R}$	Travel speed of r_i
C	Real-time traffic indicator
$\mathbf{c} \in \mathbb{R}^{\lvert\mathbf{c}\rvert}$	The learned real-time traffic representation

3 PROBLEM DEFINITION AND DEEPGTT OVERVIEW

We start with definitions of *Road Network*, *Route*, *GPS Trajectory*, and *Trip*. We then formally define our research problem. For ease of reference, the notation used through the paper is given in Table 1.

Definition 3.1. **Road Network.** A road network is represented as a directed graph $G(V, E)$, in which V, E represents the vertices (crossroads) and edges (road segments) respectively.

Definition 3.2. **Route.** A route $\mathbf{r} = [r_i]_{i=1}^{n}$ is a sequence of adjacent road segments, where $r_i \in E$ represents the i-th road segment in the route.

Definition 3.3. **GPS Trajectory.** A GPS trajectory T is a sequence of sample points $\langle p_i, \tau_i \rangle_{i=1}^{|T|}$ from the underlying route of a moving object, where p_i, τ_i represents the i-th GPS location and timestamp respectively.

Definition 3.4. **Trip.** A trip $\mathbf{T}$ is a travel along a route $\mathbf{r}$ in the road network starting at time s. We use $\mathbf{T}.\mathbf{r}$ and $\mathbf{T}.s$ respectively, to denote the traveled route and starting time of trip $\mathbf{T}$.

In our study, all GPS trajectories are first mapped into the road network to get their underlying routes with a map matching algorithm [30].

The travel time distribution of a route $\mathbf{T}.\mathbf{r}$ highly depends on the real-time traffic condition and it is difficult to precisely define traffic condition. Intuitively, average speed of (sub-)trajectories could be considered as a measurement or sensing of the real-time traffic condition. Therefore, we propose to use all (sub-)trajectories

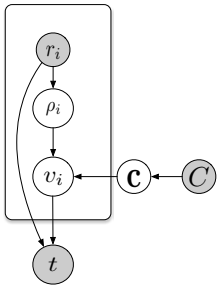

Figure 2: The graphical model of the generative process in which $\rho_i \in \mathbb{R}^{|\rho_i|}$, $v_i \in \mathbb{R}$, $\mathbf{c} \in \mathbb{R}^{|\mathbf{c}|}$ are latent variables and r_i, t are observed scalars.

collected during the time window $[\mathbf{T}.s - \Delta, \mathbf{T}.s)$ as the indicator of real-time traffic condition, denoted by C (or $\mathbf{T}.C$ for the route $\mathbf{T}.\mathbf{r}$). Here, Δ is a specified parameter *e.g.,* 30 minutes. We are now ready to formally define the research problem in this paper

Problem Statement. Given a road network $G(V, E)$ and a historical trajectory dataset $\mathcal{D} = \left\{T^{(m)}\right\}_{m=1}^{M}$, we aim to learn the travel time distribution $P(t|\mathbf{r}, C)$, for a given route $\mathbf{r}$ in the road network, conditioned on the real-time traffic condition indicator C.

DeepGTT Overview. The high-level idea of our proposed solution DeepGTT is that we treat the travel time of a route $\mathbf{r}$ as a random variable t and explain the generation of t using a three-layer hierarchical probabilistic model. The graphical model of the generative process is depicted in Figure 2.

Intuitively, the travel speed of a road segment r_i depends on two important factors: 1) the statical spatial features such as the road types (highway, secondary way), the number of lanes, etc., and 2) the dynamic temporal feature, *i.e.,* the real-time traffic condition. In our model, we learn a road representation ρ_i for road segment r_i to capture its statical spatial features and use $\mathbf{c}$ to model the real-time traffic condition. The generative process of travel time t for route $\mathbf{r} = [r_i]_{i=1}^{n}$ is as follows:

- Draw the traffic condition representation $\mathbf{c} \sim P(\mathbf{c}|C)$.
- For the i-th road segment r_i in the route $\mathbf{r}$,
  - Draw the road segment representation $\rho_i \sim P(\rho_i|r_i)$.
  - Draw the road segment speed $v_i \sim P(v_i|\rho_i, \mathbf{c})$.
- Draw the travel time $t \sim P(t|\mathbf{r}, \mathbf{v})$.

In this model, $\mathbf{v} = [v_i]_{i=1}^{n}$ and $\mathbf{c} \in \mathbb{R}^{|\mathbf{c}|}$, $\rho_i \in \mathbb{R}^{|\rho_i|}$ are fixed-length vectors.

Specifically, in the generative process, we first draw the real-time traffic representation $\mathbf{c} \sim P(\mathbf{c}|C)$. For every road segment r_i in route $\mathbf{r}$ we draw its representation $\rho_i \sim P(\rho_i|r_i)$ which only depends on the statical spatial features of r_i. The introduction of the auxiliary random variable v_i in the middle layer allows us to model both r_i's statical spatial features and the dynamically changing traffic conditions. In other words, probability distribution $P(v_i|\rho_i, \mathbf{c})$ depends on both road representation ρ_i and traffic condition $\mathbf{c}$. In the end, we collectively aggregate the road segment speeds v_i to generate the travel time for the entire route $\mathbf{r}$ by drawing t from $P(t|\mathbf{r}, \mathbf{v})$.

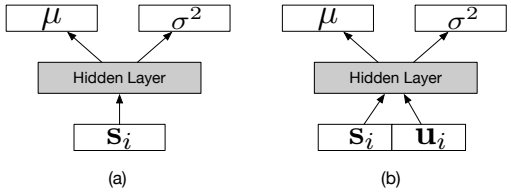

Figure 3: The parameterization of $P(\rho_i|r_i)$.

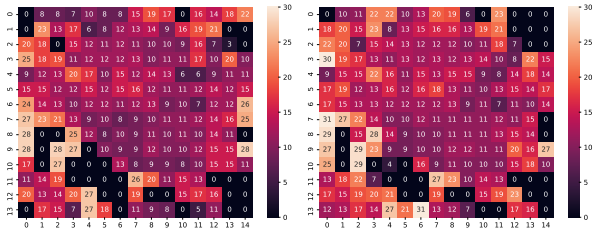
4 DEEPGTT MODELING

We next detail the modeling of road segment representation ρ_i (Section 4.1), traffic condition $\mathbf{c}$ (Section 4.2), speed (Section 4.3), and the aggregation (Section 4.4). Section 4.5 details the loss function and the learning algorithm. The prediction is discussed in Section 4.6.

4.1 Road Segment Representation ρ_i

As aforementioned, travel speed v_i is dominated by two main factors: the statical spatial features of road segment r_i and the dynamic temporal feature – real-time traffic condition. We model the impact of statical spatial features of r_i with distribution $P(\rho_i|r_i)$, where $\rho_i \in \mathbb{R}^{|\rho_i|}$ is the static road segment representation.

The high-level idea is to encode into ρ_i all spatial features that are indicative to travel speed via modeling $P(\rho_i|r_i)$ conditioned on such spatial features. In our model, we consider the following 5 types of statical spatial features:



(1) Road types: *e.g.,* primary, secondary, tertiary, residential, etc.;
(2) Number of lanes: how many marked traffic lanes;
(3) Whether it is a one way or not;
(4) The road shape, *e.g.,* straight, curve;
(5) Spatial smoothness, *e.g.,* congestion propagation makes neighboring roads likely to have similar congestion level.

To overcome data sparsity issue, we present two techniques– amortization and spatial smoothness embeddings. These two techniques enable the sharing of statistical strength among different road segments and impose spatial smoothness on modeling $P(\rho_i|r_i)$.

Amortization. The main idea of amortization [11] is to use a function $f(\cdot)$ to map a given observation to a set of parameters that are shared across all data-points. This allows us to share statistical strength among different road segments, in the sense that the knowledge learned from frequently traveled road segments is shared to those rarely traveled. In our setting, the observation corresponds to the (1)-(3) types of categorical features.

For easy exposition, let us use $n^{(\mathrm{t})}$, $n^{(\mathrm{l})}$, $n^{(\mathrm{o})}$ to represent the number of possible values in the first 3 types of categorical features, respectively. Then we use $\phi^{(\mathrm{t})}$, $\phi^{(\mathrm{l})}$, $\phi^{(\mathrm{o})}$ to map a road segment to its corresponding feature value. For example, assuming there are 5 road types in total and r_1 belongs to the third road type, then we have $n^{(\mathrm{t})} = 5$ and $\phi^{(\mathrm{t})}(r_1) = 3$.

We introduce three spatial feature embedding matrices, $S^{(\mathrm{t})}$, $S^{(\mathrm{l})}$, and $S^{(\mathrm{o})}$, with size $n^{(\mathrm{t})} \times d^{(\mathrm{t})}$, $n^{(\mathrm{l})} \times d^{(\mathrm{l})}$, and $n^{(\mathrm{o})} \times d^{(\mathrm{o})}$ respectively, for the three types of spatial categorical features. Here, $d^{(\mathrm{t})}$, $d^{(\mathrm{l})}$, and $d^{(\mathrm{o})}$ are their embedding dimensions. Each row in $S^{(\cdot)}$ corresponds to an attribute embedding, *e.g.,* $S^{(\mathrm{t})}[1]$ (the first row of $S^{(\mathrm{t})}$) is the embedding of the first type of road and $S^{(\mathrm{t})}[\phi^{(\mathrm{t})}(r_i)]$ is the

(a) Real-time traffic condition C at 7am (b) Real-time traffic condition C at 11pm

Figure 4: The real-time traffic condition C at 7am and 11pm, where the cell value indicates the average speed in that local area.

embedding of r_i's road type. For road segment r_i we define $\mathbf{s}_i$ as the concatenation of its spatial feature embeddings, *i.e.,*

$$\mathbf{s}_i = \left[S^{(\mathrm{t})}[\phi^{(\mathrm{t})}(r_i)], S^{(\mathrm{l})}[\phi^{(\mathrm{l})}(r_i)], S^{(\mathrm{o})}[\phi^{(\mathrm{o})}(r_i)]\right] \in \mathbb{R}^{d^{(\mathrm{t})}+d^{(\mathrm{l})}+d^{(\mathrm{o})}}$$

In the spirit of amortization, we model the distribution $P(\rho_i|r_i)$ with a high dimensional Gaussian distribution whose parameters are the outputs of a determined function taking $\mathbf{s}_i$ as input

$$P(\rho_i|r_i) = \mathcal{N}\left(\mu(\mathbf{s}_i), \mathrm{diag}\left(\sigma^2(\mathbf{s}_i)\right)\right) \tag{1}$$

Here, $\mu(\mathbf{s}_i)$ and $\sigma^2(\mathbf{s}_i)$ are parameterized by two MLPs (Multi-Layer Perceptron) with shared input and hidden layers as shown in Figure 3a.

Spatial Smoothness Embeddings. Amortization allows us to share the statistical strength of the categorical features among different road segments. However, it does not consider the impact of road shape and spatial smoothness *i.e.,* the last 2 types of road features. To remedy this, for every r_i we add an additional embedding $\mathbf{u}_i \in \mathbb{R}^{|\mathbf{u}_i|}$. This embedding aims to capture the complex factors (*e.g.,* road shape) that are specific to the road segment. Moreover, to impose spatial smoothness, we run DeepWalk [31] on the road network $G(V, E)$ to initialize the embeddings $\mathbf{u}_i$. Then we concatenate $\mathbf{s}_i$ and $\mathbf{u}_i$ as the input of the MLPs to parameterize the probability distribution $P(\rho_i|r_i)$ as following (also shown in Figure 3b).

$$P(\rho_i|r_i) = \mathcal{N}\left(\mu(\mathbf{s}_i, \mathbf{u}_i), \mathrm{diag}\left(\sigma^2(\mathbf{s}_i, \mathbf{u}_i)\right)\right) \tag{2}$$

The embeddings $S^{(\mathrm{t})}$, $S^{(\mathrm{l})}$, $S^{(\mathrm{o})}$, $\mathbf{u}_i$ and parameters of the two MLPs will be learned from data.

4.2 Real-time Traffic Representation c

In the generative process, we assume there exists a distribution $P(\mathbf{c}|C)$ from which we could draw a random variable $\mathbf{c}$ that captures the real time traffic condition. To realize this, we need to first find a way to construct C which could roughly reveal the real time traffic condition. To this end, we partition the space into cells and estimate the average vehicle speed in a cell by using real time trajectories. Each cell is considered as a sensing of the local traffic congestion level in that area. Figure 4(a) and 4(b) show the constructed C at 7am and 11pm respectively on the same example day, and the cell size is 2km × 2km.

To model $P(\mathbf{c}|C)$, a straightforward approach is to reshape C into a vector to get $\mathbf{c}$ and then build the condition probability table with each entry corresponding to a possible $\mathbf{c}$ value. However, such a table representation has several drawbacks. First, the space cost is prohibitively expensive. Even if we restrict the average speed into an integer with k possible values, there will be $k^{|\mathbf{c}|}$ states for $\mathbf{c}$ in total. Second, the table representation is sensitive to the spatial distribution of vehicles at that time. If there is no sensing vehicle passing the cell at that time, the cell value becomes zero, *e.g.,* $C[0, 13]$, $C[0, 14]$ are 18, 22 at 7am and they become zero at 11pm as shown in Figure 4. This is unreasonable because 7am is typically a peak hour in a day. Third, the table representation could not reveal similarity between two similar states. Even it only one cell value changes in C, the resulting state $\mathbf{c}$ will be considered to be different from the original one.

To overcome the above shortcomings, we propose to use a CNN (Convolutional Neural Net) to extract the abstract features from the rough estimation speed matrix C. The intuition is that similar traffic conditions generate similar travel times for a given path, which in turn results in close loss. We can then propagate such signals through gradients back to the CNN whose parameters will be tuned to being robust to missing values and being capable of producing similar representations for analogous traffic conditions.

$$\begin{aligned} \mathbf{f} &= \mathrm{CNN}(C) \\ P(\mathbf{c}|C) &= \mathcal{N}\left(\mu(\mathbf{f}), \mathrm{diag}\left(\sigma^2(\mathbf{f})\right)\right) \end{aligned} \tag{3}$$

Equation 3 presents the modeling of $P(\mathbf{c}|C)$, where $\mu(\mathbf{f})$, $\sigma^2(\mathbf{f})$ are parameterized by two MLPs with shared hidden layer. The convolutional neural net comprises of three connected convolution blocks and an average pooling layer. Each convolution block consists of three layers: Conv2d → BatchNorm2d → LeakyReLU.

Note that, the choice of making $\mathbf{c}$ being a random variable instead of being a deterministic one allows us to incorporate more variability in modeling complex traffic conditions and to produce a more reliable model.

4.3 Road Segment Speed v_i

Once we get the static road speed representation ρ_i and the dynamic traffic representation $\mathbf{c}$ we could use them to generate road travel speed v_i for r_i. One straightforward method is the linear factorization models [29], *i.e.,* travel speed v_i is interpreted as the linear interaction between ρ_i and $\mathbf{c}$ as

$$v_i = \langle \rho_i, \mathbf{c} \rangle \tag{4}$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product operation. However, this simple solution is limited by the linear assumption. We consider that travel speed on a road segment is very likely to be the result of nonlinear interaction between the static spatial features and the dynamic temporal traffic condition. Hence, we propose to model the generation of speed v_i in a nonlinear manner:

$$\begin{aligned} \mathbf{h}_i &= \mathrm{SELU}(W_1\rho_i + W_2\mathbf{c}) \\ \mu_i &= \langle \theta_\mu, \mathbf{h}_i \rangle, \ \sigma_i^2 = \langle \theta_\sigma, \mathbf{h}_i \rangle \\ P(v_i|\rho_i, \mathbf{c}) &= \mathcal{N}\left(\mu_i, \sigma_i^2\right) \end{aligned} \tag{5}$$

In the above equation, $\mathrm{SELU}(\cdot)$ is the self-normalizing nonlinear activation function [24] and W_1, W_2, θ_μ, θ_σ are parameters to be

learned and shared across all road segments. The Gaussian distribution is chosen due to the fact that travel speeds can be perfectly modeled by it [25]. The above generative process generalizes the classical linear factorization models. We actually can recover them by substituting the non-linear activation function SELU with the identity function.

4.4 Aggregating Road Segment Speeds

The Gaussian distribution of speed on road segment r_i naturally leads to Inverse-Gaussian distribution for travel time. The probability density function of Inverse-Gaussian distribution is given as follows:

$$p(t;\lambda,\mu) = \sqrt{\frac{\lambda}{2\pi t^3}} \exp\left\{\frac{-\lambda(t-\mu)^2}{2\mu^2 t}\right\} \tag{6}$$

where $\lambda, \mu > 0$ are parameters *i.e.,* mean μ and variance μ^3/λ. The Inverse-Gaussian distribution describes the first passage time of a Brownian random walk [1], and thus it is suitable for modeling travel time in our problem setting.

However, we cannot simply sum up the travel time distributions of r_i's to form the travel time distribution of the entire route $\mathbf{r}$, because Inverse-Gaussian distribution is not closed under addition. In other words, modeling $t = \sum_i \ell_i / v_i$ leads to an intractable model (here ℓ_i denotes the length of road segment r_i). Similar to [25], in our proposed solution, we consider the average speed of route $\mathbf{r}$, denoted by $v_\mathbf{r}$, as the weighted sum of v_i, *i.e.,*

$$v_\mathbf{r} = \sum_{i=1}^{n} w_i v_i, \quad w_i = \frac{\ell_i}{\sum_{j=1}^{n} \ell_j}.$$

Then we have

$$\mathbb{E}[v_\mathbf{r}] = \mathbb{E}\left[\sum_{i=1}^{n} w_i v_i\right] = \sum_{i=1}^{n} w_i \mu_i \tag{7}$$

$$\mathrm{Var}[v_\mathbf{r}] = \mathrm{Var}\left(\sum_{i=1}^{n} w_i v_i\right) = \sum_{i=1}^{n} w_i^2 \sigma_i^2 \tag{8}$$

Consequently, $P(t|\mathbf{r},\mathbf{v})$ will be a $\mathrm{IG}(\mu,\lambda)$ with

$$\mu = \frac{\sum_i^n \ell_i}{\mathbb{E}[v_\mathbf{r}]}, \quad \lambda = \frac{\mu^3}{(\sum_i^n \ell_i)^2 \mathrm{Var}[v_\mathbf{r}]}. \tag{9}$$

We scale route variance with the square of route length–$\sum_i^n \ell_i$ in Equation 9. This is to take into consideration travel time uncertainty is likely higher for longer route.

Note that Equation 8 holds only when v_i's are mutually independent. This may not be true in reality as speeds of spatially contiguous road segments are highly correlated. On the other hand, this equation offers us the insight that $\mathrm{Var}[v_\mathbf{r}]$ can be represented as a weighted sum of $\mathrm{Var}[v_i]$. Next, we present a better way to assign weights, *i.e.,* an attention mechanism-based method to adaptively assign weights for road segments.

The general idea of attention mechanism [4] is to learn the weights for a collection of inputs under a query vector $\mathbf{q}$. It assigns a relatively larger weight for the input which is more important under query $\mathbf{q}$. In our case, the inputs are the hidden states $\mathbf{h}_i$ in Equation 5, and the query vector is the traffic representation $\mathbf{c}$ because the uncertainty of a road segment is largely determined by the traffic condition. More formally, we have

$$\begin{aligned} a_i &= \langle W\mathbf{c}, \mathbf{h}_i \rangle \\ \mathrm{Var}[v_\mathbf{r}] &= \sum_{i=1}^{n} \mathrm{softmax}(a_i)\sigma_i^2 \end{aligned} \tag{10}$$

where W is the parameter matrix to be learned.

Notably, as we collectively aggregate v_i's to generate t, we actually amortize the delays caused at the crossroads into their adjacent road segments. Also note that we directly use the parameters of $P(v_i|\rho_i,\mathbf{c})$ to form $P(t|\mathbf{r},\mathbf{v})$. As a result, v_i becomes the virtual node in the graphical model (see Figure 2).

4.5 Variational Loss and Learning Algorithm

The generative process implies the following log-likelihood function

$$\mathcal{L}(\Theta) = \log \int_\mathbf{c} \int_\rho \mathrm{d}\mathbf{c}\, \mathrm{d}\rho \prod_{m=1}^{M} P(\mathbf{c}_m|C_m) \prod_{i=1}^{n_m} P(\rho_{mi}|r_{mi}) P(v_{mi}|\rho_{mi},\mathbf{c}_m) P(t_m|\mathbf{r}_m,\mathbf{v}_m)$$

in which Θ denotes all the parameters involved. Unfortunately, the log-likelihood is intractable due to the appearance of the latent variable integrals. Further, the MCMC based methods [3, 32] are not suitable for our case due to their slow convergence speed.

To circumvent this, we make an important observation that travel time t is actually a kind of reflection of the real-time traffic condition indicator C. Therefore, we can view $P(\mathbf{c}|C)$ as the encoder and $P(t|\mathbf{r},\mathbf{c})$ as the decoder of the real-time traffic condition. In the light of variational auto-encoder [23], the log-likelihood for one route could then be approximated as (lower bound)

$$\begin{aligned} \mathcal{L}(\Theta) &\geq \mathbb{E}_{\mathbf{c},\rho}[\log P(t|\mathbf{r},\mathbf{c})] \\ &= \mathbb{E}_{\mathbf{c},\rho}\left[\sum_{i=1}^{n} \log P(\rho_i|r_i) + \log P(v_i|\rho_i,\mathbf{c}) + \log P(t|\mathbf{r},\mathbf{v})\right] \end{aligned}$$

where $\mathbf{c} \sim P(\mathbf{c}|C)$ and $\rho_i \sim P(\rho_i|r_i)$.

This loss can be interpreted as the expected negative reconstruction error. Indeed, if we put a weak prior distribution for $\mathbf{c}$ and ρ_i respectively, we recover the well-known variational loss [7] as

$$\begin{aligned} \mathcal{L}_v(\Theta) = \mathbb{E}_{\mathbf{c},\rho}[\log P(t|\mathbf{r},\mathbf{c})] &- KL(P(\mathbf{c}|C)||P(\mathbf{c})) \\ &- \sum_{i=1}^{n} KL(P(\rho_i|r_i)||P(\rho_i)) \end{aligned} \tag{11}$$

where $KL(\cdot||\cdot)$ indicates KL divergence. We now can approximate the variational loss using the Monte Carlo method and propagate the gradients backward using the reparameterization trick [23]. In our case, we reparameterize the Gaussian random variable $\mathbf{z}$ ($\mathbf{c}$ and ρ_i) as:

$$\mathbf{z} \sim \mathcal{N}\left(\mathbf{z}|\mu,\sigma^2\right) \Leftrightarrow \mathbf{z} = \mu + \sigma\epsilon, \quad \epsilon \sim \mathcal{N}(0,1)$$

and calculate the gradient w.r.t the parameters θ as

$$\nabla_\theta \mathbb{E}_\mathbf{z}[f(\mathbf{z})] = \nabla_\theta \mathbb{E}_\epsilon[f(\mu+\sigma\epsilon)] = \mathbb{E}_\epsilon[\nabla_\theta f(\mu+\sigma\epsilon)]$$

where $f(\mathbf{z})$ represents the log-likelihood function of the parameters. In this sense, our model becomes the Variational Auto-Encoder

Algorithm 1: Learning Algorithm

(VAE) which is fully differentiable. The learning algorithm is presented in Algorithm 1.

We highlight that it is unnecessary to compute the traffic condition indicator C for every trajectory in training dataset (Line 3 in Algorithm 1). Instead, we discretize the temporal dimension into slots and let the trajectories whose start time fall into the same slot share the same C (see Section 5.1).

4.6 Prediction

Given the learned parameters Θ, a query route $\mathbf{r}$ along with its real-time traffic condition indicator C, we run the forward computation (Lines 2–5 in Algorithm 1) to predict the travel time distribution $P(t|\mathbf{r}, C)$.

Specifically, we compute the mean value $\mu(\mathbf{s}_i, \mathbf{u}_i)$ (in Equation 2) for each road segment r_i and $\mu(\mathbf{f})$ (in Equation 3) for traffic condition indicator C. Different from the training stage where we perform sampling operation to draw instances of ρ_i and $\mathbf{c}$, we simply feed these mean values into the subsequent computation to generate v_i (Equation 5) in prediction. Once we obtain v_i for each r_i, we aggregate them to output the parameters μ, λ (Equation 9) of the travel time distribution $P(t|\mathbf{r}, C)$.

5 EXPERIMENTS

We evaluate the effectiveness and scalability of DeepGTT on a real-world taxi dataset, against the state-of-the-art baselines.

5.1 Experimental setup

Dataset. The dataset was collected by 13,000 taxis during 28 days in a provincial capital city in China. It contains over 2.9 million trajectories. The sampling time interval between two consecutive points is around 30 seconds, and the map matching accuracy at this sampling rate can be as high as 99% [30]. We acquire the road network data from the Open Street Map [2]. There are 14,497 road segments in total and every road segment has the spatial features: the road type, the number of lanes, one way or not, and road length.

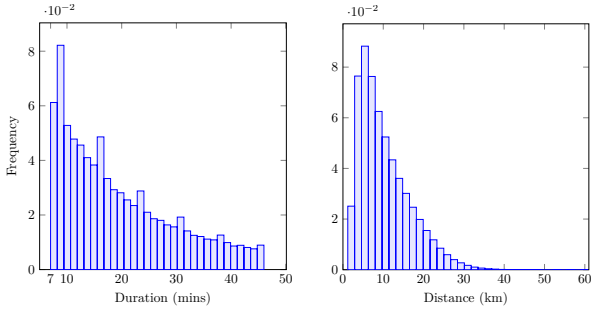

Figure 5 shows the spatial distribution of GPS points. As expected, routes at the central area of the city are frequently traveled whereas routes outside of the city are relatively less traveled by the vehicles. The average travel time is 19.4 minutes and average travel distance

Figure 5: The spatial distribution of the GPS points.

Table 2: Dataset statistics.

Measures	min	max	mean
Duration (mins)	7	46	19.4
Distance (km)	1.2	60	11.4

(a) Dist. of duration (minutes) (b) Dist. of travel distance (km)

Figure 6: The distributions of duration (minutes) and travel distance (km)

is 11.4 kilometers. Table 2 reports main statistics of the trips and Figure 6 plots distributions of trip duration and travel distance.

We use the first 18 days' trajectories as training dataset, the middle 3 days' trajectories as validation set. The remaining 7 days' trajectories are used for testing. The dataset size of training, validation, and testing is 1.7, 0.3, and 0.9 million respectively.

Baseline Methods. We evaluate DeepGTT on two tasks: (i) travel time estimation, and (ii) route recovery from sparse trajectories.

For travel time estimation, we compare DeepGTT with three baseline methods, namely, DeepTTE [38], WDR [41], and MURAT [27]. For route recovery from sparse trajectories, we demonstrate how we enhance the state-of-art route recovery method STRS [42] by simply changing its travel time distribution component to DeepGTT.

- DeepTTE and WDR are two leading travel time estimation models based on Deep Neural Nets. Both models treat road segments as tokens and compress a sequence of tokens (a route) to predict travel time by using RNN.

Table 3: Performance comparison of different methods.

Method	MURAT	WDR	DeepTTE	DeepGTT
RMSE (sec)	510.23	374.24	337.51	**193.04**
MAE (sec)	409.24	275.48	241.37	**141.75**

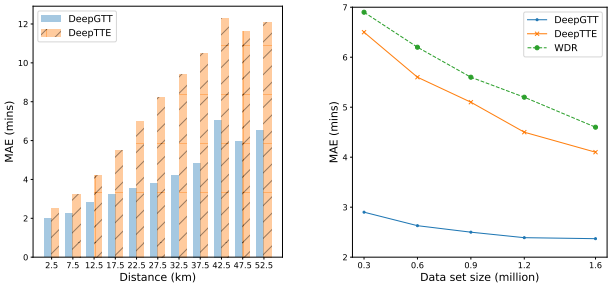
- MURAT is a multi-task representation learning based travel time estimation model. It only uses the origin-destination information.
- STRS is the state-of-the-art route recovery algorithm, which contains a travel time distribution learning component. The learning component first learns the mean value of travel time by trajectory regression, and then empirically study the relationship between the variance and mean value to derive the distribution.

Parameter settings. Our method[1] is implemented with PyTorch 0.4[2] and Julia 1.0[3], and trained with a Tesla K40 GPU. The platform runs on Ubuntu 14.04 OS with a Genuine Intel CPU.

The embedding sizes of $d^{(t)}$, $d^{(l)}$, $d^{(o)}$, $\mathbf{u}_i$ are set to 64, 32, 16, 200 respectively. The dimensions of the random variables are set as follows: $|\rho_i| = 256$, $|\mathbf{c}| = 400$, $|\mathbf{f}| = 600$, $|\mathbf{h}_i| = 500$. The space is partitioned into a 138×148 matrix C with cell size 200m $\times$ 200m, and $\Delta = 30$ minutes. We discretize the temporal dimension with a slot size 20 (minutes); two trips share the same traffic condition indicator C if their start time fall into the same slot. The batch size $|\mathcal{D}|$ in the training algorithm 1 is 150. The model is optimized by Amsgrad [21, 33] with an initial learning rate 0.001 for 10 epochs, and early stopping is used on validation dataset. We select the best hyperparameters for the baseline methods on valuation dataset.

5.2 Evaluation on travel time estimation

Overall performance. We evaluate all methods on this task by RMSE (Root Mean Square Error) and MAE (Mean Average Error),



$$\text{RMSE}(\mathbf{t}, \hat{\mathbf{t}}) = \sqrt{\frac{1}{|\mathbf{t}|}\|\mathbf{t} - \hat{\mathbf{t}}\|_2^2}, \quad \text{MAE}(\mathbf{t}, \hat{\mathbf{t}}) = \frac{1}{|\mathbf{t}|}\|\mathbf{t} - \hat{\mathbf{t}}\|_1$$

where $\mathbf{t}$, $\hat{\mathbf{t}}$ denote ground truth, estimated value respectively.

Reported in Table 3, simple model MURAT leads to relatively large errors, and WDR surpasses it by a fair margin. Among all the baselines DeepTTE achieves the best results. Our model DeepGTT outperforms all the baselines by a large margin, for three reasons: 1) DeepGTT interprets the generation of travel time in a logical way instead of learning by brute force; and 2) DeepGTT makes prediction based on the learned real-time traffic representation, rather than assuming that traffic conditions in the same time slot are temporally-invariant; 3) DeepGTT optimizes the full distribution rather than a single mean value, and thus it could incorporate more variability for more accurate prediction.

Remarkably, DeepGTT reduces MAE to 141.75 seconds for the trips with 19.4 minutes average duration which may potentially facilitate many existing web services.

[1]The code is available at https://github.com/boathit/deepgtt
[2]https://pytorch.org
[3]https://julialang.org

(a) Travel distance (b) Training dataset size

Figure 7: (a) MAE changes against travel distance, and over the training dataset size, respectively.

Impact of travel distance. We now study the impact of travel distance on the performance of different models. To this end, we group the trips in test dataset into subgroups by their lengths (in 5KM step), $[0, 5), [5, 10), \ldots, [50, 55)$, and study the performance of different models on these subgroups. Figure 7(a) plots MAEs of DeepTTE and DeepGTT against travel distance (we omit other baselines due to their large errors). Not surprisingly, MAEs increase with the travel distance. Longer trips typically involve more road segments and have larger uncertainty. It is worth noting that the performance difference between DeepTTE and DeepGTT grows with the travel distance. This result suggests that DeepGTT is more trustful for long trip estimation.

Impact of training data size. One of appealing properties of DeepGTT inherited from probabilistic models is that it is quite data efficient [6, 12]. To demonstrate this property, we study the change of MAE with different number of training data points from 0.3 to 1.7 million, reported in Figure 7(b). Observe that even trained with only 0.3 million data points, DeepGTT surpasses baseline methods that are trained with the full training data by a notable margin. This can be explained by the fact that DeepGTT interprets the generation of travel time in a more plausible manner, and thus it could reveal the hidden dependencies among relevant variables and explore training data in a more efficient way. The data efficient property enables DeepGTT to be trained in a much faster speed as well, making it attractive to the online web services that require frequent updates.

5.3 Performance on route recovery

In this subsection, we demonstrate how DeepGTT could enhance the existing leading route recovery algorithm, in which we need to access $P(t|\mathbf{r})$ for any $t > 0$. As described in Section 1, route recovery from sparse trajectories is formulated as

$$\underset{\mathbf{r}}{\text{argmax}}\, P(t|\mathbf{r})P(\mathbf{r}), \quad \mathbf{r} \in \{\text{candiate routes}\}.$$

The first term $P(t|\mathbf{r})$ describes the probability of a route $\mathbf{r}$ for an observed travel time t, namely, the temporal component. The second term $P(\mathbf{r})$ describes the probability from the spatial transition perspective, namely, the spatial component. Actually, these are the

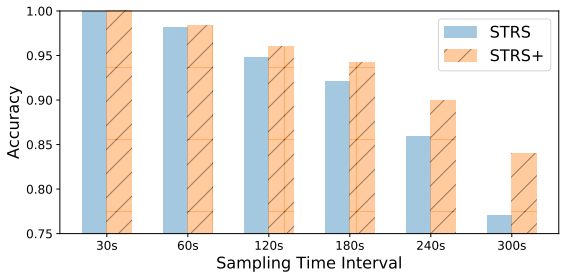


Figure 8: Accuracy comparison.

two main components in the state-of-the-art sparse route recovery algorithm STRS [42].

In this experiment, we replace STRS's temporal component with DeepGTT and refer to the new model as STRS+. The performance of route recovery is evaluated by route recovery accuracy [42]: the ratio of the length of correctly inferred road segments against the maximum value of the length of ground truth $\mathbf{r}_G$ and the length of inferred route $\mathbf{r}_I$.

$$\text{accuracy} = \frac{\text{length}(\mathbf{r}_G \cap \mathbf{r}_I)}{\max(\text{length}(\mathbf{r}_G), \text{length}(\mathbf{r}_I))}$$

We randomly select 10k trajectories from the test dataset and match these trajectories into the map. The matched results are used as ground truth. Then we down-sample these trajectories and recover the routes using STRS, and STRS+, respectively. Figure 8 reports the accuracy of STRS and STRS+, over different sampling time intervals (second). As sampling time interval increases, accuracy of both methods drop as expected. The reason is that larger sampling time interval leads to more possible candidate routes to be inferred between two sample points. Observe that accuracy of STRS+ is always higher than that of STRS. In particular, the difference between their accuracies becomes more evident when the sample time interval is larger. This result shows the superiority of STRS+.

5.4 The impact of real time traffic

In this paper, we relax the assumption that traffic conditions are temporally invariant for the same time slot. Instead, we propose to learn a real-time traffic representation $\mathbf{c}$, and by conditioning on which we generate the travel time. It is natural to ask the effectiveness of this real time traffic representation $\mathbf{c}$. We design two experiments to answer this question.

Experiment 1. We fill the traffic condition indicator C with a constant that is specific to the time slot. In this case, our model is forced to "assume" that traffic conditions are temporally invariant. The RMSE, MAE in travel time estimation increases from 193.04 to 272.45, and from 141.75 to 200.02, respectively. In other words, adopting the assumption that traffic conditions are temporally invariant in DeepGTT leads to a 41% performance drop in terms of MAE. This result implies that an appropriate modeling of $P(\mathbf{c}|C)$ is crucial for accurate travel time estimation.

Experiment 2. As a case study, we randomly select a route $\mathbf{r}_{102}$ with length 21.37km and evaluate the change of its travel time

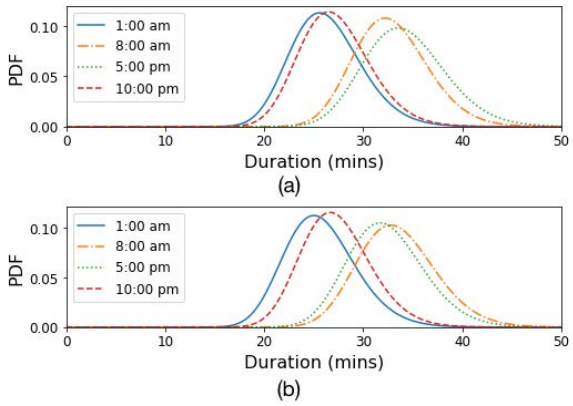

Figure 9: The travel time distributions of route $\mathbf{r}_{102}$ on Jan 03 (a) and Jan 17 (b), both of them are Saturday.

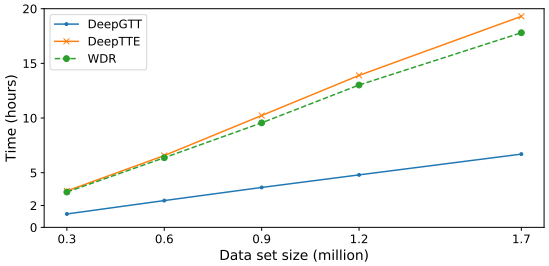

Figure 10: Time cost of all methods grows linearly with the training data size. However, DeepGTT has a much smaller constant term than its competitors.

distributions by taking different real-time traffic condition indicators C's. More specifically, we calculate C by using the (sub-) trajectories in different time slots and feed these C's into the model while keeping the route unchanged. Figure 9a and 9b plot the travel time distributions at different time slots on Jan 03, 2015 and Jan 17, 2015 respectively (both are Saturday). Two points are worth noting: I) The travel time distributions at 1:00am and 10:00pm exhibit smaller expectations and variances. This is reasonable because the traffic conditions at these time slots are less congested, compared with peak hours, *e.g.*, 8:00am and 5:00pm. II) Even both 8:00am and 5:00pm are peak hours, the traffic is more congested at 5:00pm on Jan 03, 2015 whereas it is more congested at 8:00am on Jan 17, 2015. Our observations suggest that traffic conditions in the same time slot are not invariant across the temporal dimension. The assumption made in previous studies does not hold [27, 38, 39, 41, 42].

5.5 Time Cost Study

The training time complexity of DeepGTT grows linearly with the number of trajectories. Figure 10 demonstrates that the training time of different methods vary with the data size. Even though the time cost of both DeepTTE and WDR grows linearly with the size of training data, they have larger constant terms compared with

DeepGTT. This is due to their employment of RNN which is more computationally expensive.

For prediction, DeepGTT can process over 0.9 million trajectories within 81 seconds with a mini-batch size 256. The fast running speed makes it ideal for online deployment.

6 CONCLUSION

For the first time, we develop a deep generative model DeepGTT for travel time distribution learning. We tackle the data sparsity challenge by presenting two techniques, amortization and spatial smoothness embedding, in the lower layer. We relax the assumption that traffic conditions are temporally-invariant by proposing a convolution neural net based real time traffic representation learning and a hierarchical structure. The introduction of an auxiliary random variable v_i in the middle layer enables separating the statical spatial features from the dynamically changing real-time traffic. As a result, we could incorporate these heterogeneous influencing factors into a single model. The further derived variational loss enables the model to be trained in an end-to-end fashion, and makes DeepGTT applicable to large-scale data sets. DeepGTT interprets the generation of travel time in a plausible manner rather than learning by brute force, thus it produces more accurate results and is data-efficient.

Evaluated on a real-world large-scale data set, we first demonstrate the superiority of DeepGTT over existing methods, including two recently proposed deep-neural-net-based approaches, in two tasks: travel time estimation and route recovery. Notably, even trained with a small fraction of data DeepGTT is able to produce substantially better results than the state-of-the-art baselines. We further design experiments to verify that an appropriate modeling of real-time traffic is crucial for accurate travel time distribution prediction, and the assumption made in previous studies that traffic conditions are temporally-invariant does not hold. Finally, we empirically compare the time cost of DeepGTT with the other two deep-neural-net-based approaches, which demonstrates that DeepGTT owns much faster training speed.

In the future work, we would like to enhance the performance of DeepGTT by investigating more rich posterior distribution for the real time traffic representation with the normalizing flows [34]. In the present solution, DeepGTT assumes that the travel times of longer routes tend to show higher variance which may not hold for highways, and we will attempt to address this in the future work. Due to space limitation, we also omit the analysis of the impact of different explanatory factors' dimensionality and cell size, and we would like to give a thorough study in the future version. It is also desirable to explore the usage of DeepGTT in the problems such as ride-sharing, taxi-dispatching, travel time-related trajectory anomaly detection and time-aware trajectory representation learning [26, 44].

ACKNOWLEDGEMENTS

This research was conducted in collaboration with Singapore Telecommunications Limited and partially supported by the Singapore Government through the Industry Alignment Fund - Industry Collaboration Projects Grant. This work was also supported in part by Singapore MOE Tier-2 grant MOE2016-T2-1-137, MOE Tier-1 grant RG31/17, and NSFC under the grant 61772537. The authors would like to thank the anonymous reviewers who give the thoughtful comments and helpful suggestions.

ABSTRACT

Crowd-sourcing is a cheap and popular means of creating training and evaluation datasets for machine learning, however it poses the problem of 'truth inference', as individual workers cannot be wholly trusted to provide reliable annotations. Research into models of annotation aggregation attempts to infer a latent 'true' annotation, which has been shown to improve the utility of crowd-sourced data. However, existing techniques beat simple baselines only in low redundancy settings, where the number of annotations per instance is low (≤ 3), or in situations where workers are unreliable and produce low quality annotations (e.g., through spamming, random, or adversarial behaviours.) As we show, datasets produced by crowd-sourcing are often not of this type: the data is highly redundantly annotated ($\geq$ 5 annotations per instance), and the vast majority of workers produce high quality outputs. In these settings, the majority vote heuristic performs very well, and most truth inference models underperform this simple baseline. We propose a novel technique, based on a Bayesian graphical model with conjugate priors, and simple iterative expectation-maximisation inference. Our technique produces competitive performance to the state-of-the-art benchmark methods, and is the only method that significantly outperforms the majority vote heuristic at one-sided level 0.025, shown by significance tests. Moreover, our technique is simple, is implemented in only 50 lines of code, and trains in seconds. [1]

1 INTRODUCTION

Large volumes of labelled data are crucial for machine learning, retrieval and search, both for training supervised methods and for evaluation. Ideally, ground truth labels are collected from experts, but such sources are often too slow or costly, motivating the use of data annotation by crowdsourcing [2, 7]. This has been shown to be highly effective for tasks which are difficult for machines to automate but relatively easy for humans, such as document categorization, image annotation, and sentiment analysis. Using non-expert labels for training machine learning algorithms can be as effective as using gold standard annotations from experts [16, 21], despite being much cheaper and faster to obtain.

Unfortunately, crowdsourced labels are often noisy or biased, which may be due to workers' lack of expertise, workers cheating or otherwise not performing the annotation task correctly [6]. This problem can be alleviated by filtering workers based on their profile and working history. However, this problem is not fully solved by simple quality control mechanisms currently provided by crowdsourcing platforms; consequently, most crowd data studies collect several labels for each item from different workers, which are aggregated post-hoc to infer an accurate consensus annotation.

Both the average number of labels per item (#labels/#items), and the quality of worker labels, are important factors in the performance of aggregation methods. Low-redundancy (e.g. #labels/#items ≤ 3) and/or low-quality scenarios (e.g. there are adversarial workers) are challenging and have attracted much attention. Such scenarios require methods to make full use of a few available labels by being able to interpret labels from different workers. Models which incorporate per-worker confusion matrices [3, 10, 18, 22] are flexible enough to capture different types of worker behaviour, and have shown to be effective in low-redundancy and/or low-quality scenarios.

However, the simplest aggregation technique, majority voting (MV), still predominates in practice. MV is an ensemble where every worker is given equal vote, based on the assumption that with increasing redundancy, the most common label will converge to the true label. Despite its simplicity, on many real-world crowdsourced datasets, MV outperforms most models of truth inference, as we show in our experimental evaluation, and the best method from prior work only outperforms MV by a small margin. To explain this observation, and the continued popularity of MV, we identify several misalignments between the experimental setup in previous papers and real-world scenarios:

Redundancy & worker quality. In practice #labels/#items is usually 5+ to ensure sufficient redundancy, and crowdsourcing platforms provide mechanisms to select high quality workers (e.g. in the collection of question answering dataset

SQuAD [17], workers were filtered based on the amount and acceptance rate of their prior work history). In such settings, MV is very competitive. Worryingly, our results show that confusion-matrix-based methods are inferior to MV in terms of mean accuracy across datasets, despite their utility in low-resource and/or low-quality scenarios.

Scale. Several datasets used in prior work were small with respect to the number of labels collected from crowd (#labels). But on large-scale datasets, like `senti` used in our experiment with 569k labels, the scalability of inference becomes critical. For example, GLAD [26], achieving the third highest mean accuracy among all existing methods in our experiment, takes more than 3 hours to train, while MV runs in 3.5 seconds.

This work is also motivated by qualitative considerations: ease of understanding, implementation, and hyper-parameter setting, for which MV is compelling, being parameter free. However, empirically the accuracy of MV is far from perfect, even for highly redundantly annotated datasets. We seek accurate, fast solutions to the high-resource high-quality scenario that are easy to implement. Our method is one such solution.

This paper presents a novel method for aggregating crowdsourced labels for classification. We propose a generative Bayesian model, relaxing a discrete binary problem to a continuous regression task, which we model using a normal likelihood and conjugate inverse-Gamma prior. Our method allows for straightforward inference using expectation-maximisation (EM; [5]), which is implemented in 50 lines of code (see Appendix A). The resulting update rules reveal a novel criterion for learning from crowds—namely the idea of minimizing the likelihood that "every worker is making mistakes".

Our base model has interpretable parameters and intuitive inference rules, which makes it easy to understand and use. We extend our base binary model in three ways: estimating different weights for each label, to capture both the reliability of a worker votes in favour and against an item belonging to a class; a means of correcting for model deficiency; and employing the one-versus-rest strategy to allow the model to operate in a multi-class setting. Our experimental results show our proposed methods achieve the highest mean accuracy over 10 real-world datasets drawn from several different application areas, with different sizes and differing degrees of label redundancy, and a total running time on the same datasets second only to MV.

2 RELATED WORK

Ever since Dawid and Skene [3] proposed a model (DS) to aggregate the clinical diagnoses of doctors, various methods have been proposed to aggregate worker labels and infer true annotations. The DS model uses the confusion matrix to capture the probabilities that a worker label is generated for an item conditioned on the item's true annotation. Extending the DS model by adding Dirichlet priors for the values in the confusion matrix, Kim and Ghahramani [10] then integrated the confusion matrix parameters out and used Gibbs sampling for inference. Simpson et al. [20] developed variational Bayesian inference for the model proposed in [10], which is computationally efficient and outperforms the Gibbs sampling method. Furthermore, they analysed the clusters naturally formed by the inferred workers' confusion matrices. Venanzi et al. [22] assumed there are a fixed number of clusters of workers, with workers in the same cluster possessing similar confusion matrices instead of modelling individual confusion matrices as done in previous works. In this way worker clusters are formed at inference-time instead of post-inference. Adding a Dirichlet process to the model to generate the Dirichlet priors on worker confusion matrices, Moreno et al. [14] also allowed workers to generate their own confusion matrices from the cluster's confusion matrix in order to increase model flexibility.

Unlike the above works, Whitehill et al. [26] didn't use confusion matrices, but borrowed ideas from Item Response Theory (IRT) and proposed an unsupervised version of previous IRT models. These estimate not only the true annotations and worker ability but also the difficulty of items. Zhou et al. [29] also developed an algorithm estimating the true annotations by using a minimax entropy principle, which assumes there are categorical distributions per worker-item pair and the worker labels are generated from those categorical distributions. The objective there is in finding the true annotations that minimize the maximum entropy of those categorical distributions. Such categorical distributions are more concentrated on worker labels and can be roughly considered as having higher likelihood of generating labels.

The database community has also independently studied the problem of resolving conflicts between information from different sources. Demartini et al. [4] developed a model similar to the DS model that also used EM but just modelled a single accuracy parameter instead of a full confusion matrix. Li et al. [12] adopted the Gaussian to model error between the truth and worker label, which is similar to our model but not a probabilistic model. They developed an iterative approach which alternatively estimated the truth based on variances, and set the variances to be the upper-bounds of their 95% confidence interval based on the estimated truth. Aydin et al. [1] adopted a two-step procedure that iteratively updates estimated truth and worker weights so that the sum of worker weight times the distance between worker label and estimated truth is minimized.

3 PROPOSED MODELS

In this section, we first define the crowdsourced annotation aggregation problem, then describe our proposed model, Bayesian Weighted Average (BWA), for binary classification tasks, followed by an extension to multi-class classification tasks, and strategies to set its hyper-parameters.

Problem statement. We assume that a task contains a number of homogeneous *instances* or *items*, where each item has its own *true label*. The true labels are drawn from a *label set*. All instances are uploaded to a crowdsourcing platform by requesters. Generally the requesters don't know the true labels, so they ask *workers* to label them. Workers need to choose a label from the label set per item. Typically a worker only labels a small fraction of all items in a task. The labels collected from workers are called *worker labels*. Finally, aggregation methods are used to infer the true annotations based on all worker labels.

Table 1: Mathematical notation.

Symbol	Description
N	number of items
i	item index, $i \in \{1, \ldots, N\}$
W	number of workers
j	worker index, $j \in \{1, \ldots, W\}$
K	number of classes
k, l	class/label index, $k, l \in \{0, \ldots, K-1\}$
W_i	set of workers who have labelled item i
N_j	set of items that worker j has labelled
	Binary setting
z_i	item i's latent true label (continuous), $z_i \in \mathbb{R}$
y_{ij}	worker j's observed label to item i (discrete), $y_{ij} \in \{0, 1\}$
	Multi-class setting
z_{ki}	score given to item i by model k which classifies items into class-k or not class-k, $z_{ki} \in \mathbb{R}$
y_{kij}	binary indicator, equalling 1 if worker j labels item i as class k otherwise 0

3.1 The Bayesian Weighted Average Model

We first consider binary classification tasks. Without loss of generality, let $y_{ij} \in \{0, 1\}$ be worker j's label to item i and let $z_i \in \mathbb{R}$ represent item i's true label. We model z_i's as continuous variables to make tractable the following optimization problem for inferring the truth, Z,

$$Z^* = \arg\max_Z P(Z|Y, \alpha), \tag{1}$$

where Z and Y are collections of their lowercase variables, α denotes all hyper-parameters, $P(Z|Y, \alpha)$ is the posterior distribution for Z, and Z^* is the maximum a posteriori (MAP) estimate of Z. Further discussion of our modelling choices is provided in Section 4.

After Z^* is computed, the discrete true label can be determined by rounding, i.e. the true label is 1 if $z_i^* > 0.5$, otherwise 0. Frequently used symbols are defined in Table 1.

3.1.1 The Generative Process and Joint Distribution. Our proposed models are all probabilistic generative models. We assume z_i is drawn from a Gaussian prior with mean μ and inverse variance λ, and y_{ij} is drawn from a Gaussian distribution with mean z_i and inverse variance v_j. Here v_j is a worker specific value for worker j and every v_j is drawn from Gamma($\frac{a_v}{2}, \frac{b_v}{2}$). The plate diagram for this model is shown in Figure 1.

The joint distribution $P(Z, Y, V|\mu, \lambda, a_v, b_v)$ can be factorized as

$$\begin{aligned} &P(Z, Y, V|\mu, \lambda, a_v, b_v) = P(Z|\mu, \lambda) \cdot P(Y|Z, V) \cdot P(V|a_v, b_v) \\ &= \prod_i \mathcal{N}\left(z_i \middle| \mu, \lambda^{-1}\right) \\ &\quad \cdot \prod_i \prod_{j \in W_i} \mathcal{N}\left(y_{ij} \middle| z_i, v_j^{-1}\right) \cdot \prod_j \text{Gamma}\left(v_j \middle| \frac{a_v}{2}, \frac{b_v}{2}\right), \end{aligned} \tag{2}$$

where $V = \{v_j\}_{j=1}^W$. λ and v_j model the inverse variance of $z_i - \mu$ and $y_{ij} - z_i$. The larger λ and v_j are, the smaller the corresponding errors are likely to be. In this way they can be interpreted as encoding worker reliability, a perspective we explore further in Section 3.1.3.

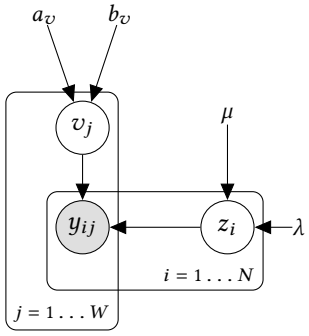

Figure 1: Plate diagram for our proposed BWA model (binary case).

Our proposed BWA model is deficient: data observations y_{ij} can only be binary, while the generative model has continuous support. We could force all y_{ij} to be binary variables ($\{0, 1\}$) then re-normalize the distributions accordingly to address the deficiency issue (Section 4.3). But the linking distribution between y_{ij}, z_i and v_j then becomes a logistic function, which is much more difficult to work with as no conjugate prior for v_j exists.

3.1.2 Inference. In order to find the most likely Z, we first integrate out V in Equation (2) to obtain $P(Z, Y|\alpha)$ where $\alpha = (\mu, \lambda, a_v, b_v)$ are the hyper-parameters.

$$\begin{aligned} &P(Z, Y|\alpha) = \int P(Z, Y, V|\mu, \lambda, a_v, b_v)\ \mathrm{d}V \\ &= \prod_i \mathcal{N}(z_i|\mu, \lambda^{-1}) \\ &\quad \cdot \prod_j \int \prod_{i \in N_j} \mathcal{N}\left(y_{ij} \middle| z_i, v_j^{-1}\right) \cdot \text{Gamma}\left(v_j \middle| \frac{a_v}{2}, \frac{b_v}{2}\right)\ \mathrm{d}v_j \\ &\propto \prod_i e^{-\frac{\lambda}{2}(z_i - \mu)^2} \cdot \prod_j \left(\frac{1}{2} b_v + \frac{1}{2} \sum_{i \in N_j} (z_i - y_{ij})^2\right)^{-\frac{a_v + |N_j|}{2}}. \end{aligned}$$

Since $P(Z, Y|\alpha) = P(Z|Y, \alpha)P(Y|\alpha)$ and $P(Y|\alpha)$ is independent from Z, maximising $P(Z, Y|\alpha)$ with respect to Z is equivalent to solving the program (1), i.e.

$$\arg\max_Z P(Z|Y, \alpha) = \arg\max_Z P(Z, Y|\alpha).$$

As we shortly show, λ, a_v, and b_v have intuitive meanings, and accordingly can be set manually, while μ can be optimized easily with Z. Therefore, the goal becomes to maximise $P(Z, Y|\alpha)$ with respect to Z and μ, which is equivalent to minimising the negative log likelihood $-\log P(Z, Y|\alpha)$ with respect to Z and μ:

$$\min_{Z, \mu} \sum_i \frac{\lambda}{2}(z_i - \mu)^2 + \sum_j \frac{a_v + |N_j|}{2} \log\left(b_v + \sum_{i \in N_j} (z_i - y_{ij})^2\right) + const., \tag{3}$$

where *const.* is the sum of values independent from Z and μ, and thus can be ignored during optimisation. We then use the EM

algorithm to minimize the above negative likelihood:

E step. $v_j|Z, Y, a_v, b_v \sim \text{Gamma}\left(\frac{a_v+|N_j|}{2}, \frac{b_v+\sum_{i\in N_j}(z_i-y_{ij})^2}{2}\right)$.

M step. Let $q(V) = P(V|Z^{\text{old}}, Y, a_v, b_v)$ and

$$Q(Z; Z^{\text{old}}) = \mathbb{E}_q \log P(Z, Y, V|\mu, \lambda, a_v, b_v) \ ,$$

then by setting the gradient of the Q function with respect to Z and μ to be zero, we obtain

$$z_i = \frac{\lambda\mu + \sum_{j\in W_i} \mathbb{E}_q v_j y_{ij}}{\lambda + \sum_{j\in W_i} \mathbb{E}_q v_j} \ , \tag{4}$$

where

$$\mathbb{E}_q v_j = \frac{a_v + |N_j|}{b_v + \sum_{i\in N_j}(z_i - y_{ij})^2} \ , \tag{5}$$

$$\mu = \frac{1}{N}\sum_i z_i \ .$$

3.1.3 Interpretations.

$\mathbf{z_i}$ *and its update rule.* In Equation (4), z_i is updated by a weighted arithmetic average of μ and $\{y_{ij}\}_{j\in W_i}$, weighted by λ and $\{\mathbb{E}_q v_j\}_{j\in W_i}$, respectively. Higher weights lead to a larger impact on average, so these weights can be considered as encoding worker reliability. In particular, λ is the weight for a "default worker" who always labels every item as μ.

$\mathbf{v_j}$ *and its estimation rule.* In Equation (5), $|N_j|$ is the number of items that worker j has labelled, $\sum_{i\in N_j}(z_i - y_{ij})^2$ is the sum of squared errors (SSE_j) that worker j has made. Note that $y_{ij} \in \{0, 1\}$ and $z_i \in [0, 1]$, thus $0 \le \text{SSE}_j \le |N_j|$. In the case that we know the true label, z_i is also binary just like y_{ij}, then SSE_j is simply the number of wrong judgements that worker j has made. The estimation of $\mathbb{E}_q v_j$ can be considered as a smoothed inverse error rate with a_v and b_v serving as the smoothing parameters. The larger the $\mathbb{E}_q v_j$, the smaller the worker j's smoothed error rate is.

Hyper-parameters. The values of a_v and b_v encode our belief that worker j has labelled a_v items before and b_v judgements were wrong, which naturally suggests $b_v \le a_v$ and further ensures $\mathbb{E}_q v_j \ge 1$. So when $b_v \le a_v$, even if all labels from worker j in task k are wrong, we still have $\mathbb{E}_q v_j \ge 1$. This mechanism guarantees everyone an unconditional minimum weight of 1 to vote for the truth. We may consider setting $b_v > a_v$ so that $\mathbb{E}_q v_j$ is allowed to be smaller than 1, however, in this setting, a worker who gets 10/10 wrong will be penalized more than another worker who gets 1000/1000 wrong due to the weaker smoothing effect on the latter. Hence both estimations are smaller than 1, but the estimation for the latter is closer to 1. As this is not the desired effect, we recommend the natural setting of $b_v \le a_v$. As 1 is the lower bound of $\mathbb{E}_q v_j$, we choose $\lambda = 1$ so that the "default worker" has limited ability to compete with other workers, but is most helpful in tie breaking.

3.2 Multi-class Extension

So far, our proposed models assume binary labels. However, it's easy to extend them to the multi-class setting by employing a one-versus-rest strategy, a commonly used reduction to binary classifiers such as SVMs.

Let K denote the number of classes, $k \in \{0, \ldots, K\}$ a class index, y_{kij} a binary indicator that equals 1 if worker j labels item i as class k otherwise 0, Y_k the collection of y_{kij}'s. Then our models can work on Y_k which is binary and output Z_k, a collection of z_{ki}'s, where z_{ki} is the score that our model gives to item i. The higher z_{ki} is, the more likely our model believes item i's true label is k. For item i, our model generates a score z_{ki} for each k value given different Y_k. Finally, $k^* = \arg\max_k z_{ki}$ is picked as the estimated true label for item i.

3.3 Hyper-parameter Settings

We discuss how to set b_v when a_v is given in this section. As a_v and b_v translate to our prior belief that every worker has labelled a_v items and made b_v mistakes, $b_v/a_v = \varepsilon$ is our assumed error rate. This error rate should depend on the quality of worker labels in a dataset, so we seek to estimate ε instead of setting it to be constant regardless of datasets. However, estimating ε requires true labels which we don't have, so a natural way is to estimate them by a simple aggregation method such as majority voting, then calculate ε based on the estimates.

We first consider the binary case. Let $\hat{z}_i = \frac{1}{|W_i|}\sum_{j\in W_i} y_{ij}$ to be the majority voting results, then the overall error rate ε is

$$\varepsilon = \frac{\sum_i \sum_{j\in W_i}(y_{ij} - \hat{z}_i)^2}{\sum_i |W_i|} \ .$$

To simplify ε, we define n_{i0} and n_{i1} to be the number of workers who have labelled item i as 0 or 1, respectively. Then $|W_i| = n_{i0}+n_{i1}$, $\hat{z}_i = \frac{n_{i1}}{n_{i0}+n_{i1}}$ and we obtain

$$\begin{aligned}\varepsilon =& \frac{\sum_i n_{i0}(0-\hat{z}_i)^2 + n_{i1}(1-\hat{z}_i)^2}{\sum_i n_{i0} + n_{i1}} \\ =& \frac{\sum_i n_{i0}(\frac{n_{i1}}{n_{i0}+n_{i1}})^2 + n_{i1}(\frac{n_{i0}}{n_{i0}+n_{i1}})^2}{\sum_i n_{i0} + n_{i1}} = \frac{\sum_i \frac{n_{i0}n_{i1}}{n_{i0}+n_{i1}}}{\sum_i n_{i0} + n_{i1}} \ .\end{aligned} \tag{6}$$

Then we can set $b_v = a_v\varepsilon$ to encode that every worker has already annotated a_v items, with $a_v\varepsilon$ mistakes, i.e. an error rate ε.

However, we find that the error rate is underestimated by Equation (6) in practice. We then derive that the error rate given by Equation (6) has an upper bound 1/4:

$$\begin{aligned}\varepsilon =& \frac{\sum_i \frac{1}{n_{i0}+n_{i1}} n_{i0}n_{i1}}{\sum_i n_{i0} + n_{i1}} \\ \le& \frac{\sum_i \frac{1}{n_{i0}+n_{i1}} \left(\frac{n_{i0}+n_{i1}}{2}\right)^2}{\sum_i n_{i0} + n_{i1}} = \frac{\sum_i \frac{n_{i0}+n_{i1}}{4}}{\sum_i n_{i0} + n_{i1}} = \frac{1}{4} \ .\end{aligned}$$

So given $\varepsilon \in [0, 1/4]$, setting $b_v = a_v\varepsilon$ means our prior belief is that every worker has an accuracy of 75% or higher even in the worst case, which is too optimistic and often doesn't reflect reality. We then propose doubling ε to extend its range to $[0, 1/2]$ to encode our belief that every worker is performing slightly better than random guessing.

For multi-class tasks, as there are K classes, we expect random guessing can achieve an accuracy of $1/K$, i.e. an error rate of $1 - \frac{1}{K}$. To encode that the prior belief that every worker is better than random guessing, we extend the range of ε to $[0, 1 - \frac{1}{K}]$ by multiplying ε with $4(1 - \frac{1}{K})$. This is consistent with the doubling strategy for binary tasks, as $4(1 - \frac{1}{K}) = 2$ when $K = 2$.

4 DISCUSSION

The primary motivation of modelling the truth Z as continuous variables is to make the optimization of finding the most likely Z tractable, i.e. $\arg\max_Z P(Z|Y,\alpha)$. We first describe the difference between this objective and other probabilistic models' objectives, then discuss some interesting findings due to the continuous modelling of Z.

4.1 An Objective Intractable for Other Models

Consider a graphical model defining joint $P(Z,Y,V|\alpha)$. It is often easy to sum out Z or integrate out V in $P(Z,Y,V|\alpha)$ to get $P(Y,V|\alpha)$ or $P(Z,Y|\alpha)$. Ideally, the most likely Z is computed by

$$Z^* = \arg\max_Z P(Z|Y,\alpha), \text{ or equivalently } Z^* = \arg\max_Z P(Z,Y|\alpha),$$

because $P(Z,Y|\alpha) \propto P(Z|Y,\alpha)$. However, when Z is discrete, as in most existing probabilistic models for truth inference, the above objective becomes an intractable discrete optimization task. Typical workarounds are:

(1) Solve $V^* = \arg\max_V P(Y,V|\alpha)$ first, then set $V = V^*$ into the joint distribution which naturally decouples z_i's, so $Z^* = \arg\max_Z P(Y,Z,V^*|\alpha)$ becomes tractable as z_i's can be optimized independently.

$$Z^* = \arg\max_Z P(Y,Z,V^*|\alpha)$$

where $V^* = \arg\max_V P(Y,V|\alpha)$. The compromise here is that although V^* is optimal, Z^* is only optimal when $V = V^*$, which does not capture uncertainty. Examples of methods taking this approach include DS [3] and LFC [18].

(2) Bayesian methods naturally use the posterior to make inference. In $P(Z,Y,V|\alpha)$, only Z is the variable of interest, so V is marginalized first, leaving $P(Z,Y|\alpha)$. The posterior of Z, $P(Z|Y,\alpha)$ is proportional to $P(Z,Y|\alpha)$, however, the normalizing constant $P(Y|\alpha)$ is typically intractable to compute. There are two common ways to deal with this intractability.
   - *Variational approaches* [8] approximate the posterior $P(Z|Y,\alpha)$ by another distribution $q(Z)$, which is then used to make inference. Mean-field variational inference is very popular and assumes $q(Z)$ is factorized into $\prod_i q(z_i)$, then the true label of item i is estimated as $\arg\max_{z_i} q(z_i)$, which approximates $\arg\max_{z_i} P(z_i|Y,\alpha)$ where $P(z_i|Y,\alpha)$ is the marginal distribution of z_i.
   - *Sampling techniques* generate samples from $P(Z|Y,\alpha)$. Markov chain Monte Carlo methods are commonly used to generate samples as they can work without knowing the normalizing constant $P(Y|\alpha)$. Then samples are used to approximate the marginal distribution over z_i, i.e. $P(z_i|Y,\alpha)$. Finally, $\arg\max_{z_i} P(z_i|Y,\alpha)$ is picked as the estimate of item i's true label.

   In summary, with either variational approaches or sampling, the goal of Bayesian methods is to solve

$$z_i^* = \arg\max_{z_i} P(z_i|Y,\alpha).$$

However, both approaches face the shortcoming that the variables of interest (z_i) must be optimized independently according to their marginal distributions, as joint optimization is intractable as Z is discrete. Examples include iBCC [10] and CBCC [22].

By contrast, our methods' objectives are ideal:

$$Z^* = \arg\max_Z P(Z|Y,\alpha).$$

The only compromise we make is that we have to model Z as continuous random variables.

4.2 A Novel Perspective on the Wisdom of Crowds

For our proposed BWA model, the negative log likelihood $-\log P(Z,Y|\alpha)$ defined in Equation (3) is reminiscent of a traditional sum-of-square-error objective as minimized in regression models, except that here the error terms are contained in separate log functions. Reorganizing the expression, and using the sum of squared errors defined as $\text{SSE}_j = \sum_{i\in N_j}(z_i - y_{ij})^2$, we obtain

$$\begin{aligned}&-\log P(Z,Y|\mu,\lambda,a_v,b_v)\\ &=\frac{\lambda}{2}\sum_i(z_i-\mu)^2 + \frac{1}{2}\sum_j \log\left(\frac{b_v+\text{SSE}_j}{a_v+|N_j|}\right)^{a_v+|N_j|} + const.\end{aligned}$$

The exponential of the RHS yields the equivalent objective

$$\begin{aligned}&\arg\min_{Z,\mu} -\log P(Z,Y|\mu,\lambda,a_v,b_v)\\ &=\arg\min_{Z,\mu}\prod_{\text{item } i} e^{\lambda(z_i-\mu)^2}\prod_{\text{worker } j}\left(\frac{b_v+\text{SSE}_j}{a_v+|N_j|}\right)^{a_v+|N_j|}.\end{aligned}$$

The first product over items serves as a regularization term for z_i. For μ, it simply means the minimum can be reached when μ is the mean of all z_i. The product over workers is more interesting. Note that $\frac{b_v+\text{SSE}_j}{a_v+|N_j|}$ also appears in $\mathbb{E}_q v_j$'s update rule, and can be considered as the smoothed error rate of worker j. The exponent, $a_v+|N_j|$, is just the smoothed number of items worker j has labelled. Accordingly, this factor measures the likelihood that all workers make all their annotations of the data incorrectly, with a uniform error rate per worker.

Therefore, the underlying principle behind our proposed BWA model is that *it's unlikely that all workers make mistakes for all their tasks*. Our proposed BWA model infers a truth that minimizes the likelihood of everybody performing incorrectly. This principle makes our model different from other models which seek to explain worker labels through maximising the likelihood of realizing these observations. Our principle is conservative, yet intuitively plausible, and a novel perspective on the *wisdom of crowds*.

4.3 A Novel Constraint on Worker Reliability

In the base model, if we were to force all y_{ij} and z_i to be binary variables ($\{0,1\}$) and then re-normalize the distributions accordingly, we obtain a new link function between y_{ij} and z_i,

$$\begin{aligned}P(y_{ij}=1|z_i,v_j) &= \frac{\sqrt{\frac{v_j}{2\pi}}\exp\left\{-\frac{v_j}{2}(z_i-1)^2\right\}}{\sqrt{\frac{v_j}{2\pi}}\exp\left\{-\frac{v_j}{2}z_i^2\right\}+\sqrt{\frac{v_j}{2\pi}}\exp\left\{-\frac{v_j}{2}(z_i-1)^2\right\}}\\ &= \frac{1}{\exp\left\{-v_j(z_i-\frac{1}{2})\right\}+1} \text{ for } z_i\in\{0,1\},\end{aligned}$$

or in an equivalent but more compact form,

$$P(y_{ij}|z_i, v_j) = \frac{\exp\left\{\frac{1}{2}v_j \mathbf{1}[y_{ij} = z_i]\right\}}{1 + \exp\left\{\frac{1}{2}v_j\right\}},$$

which means each worker has an accuracy of $\sqrt{e^{v_j}}/(1 + \sqrt{e^{v_j}})$, irrespective of the true label z_i. Such behaviour can be captured by a symmetric confusion matrix

$$\frac{1}{1 + \sqrt{e^{v_j}}} \begin{bmatrix} \sqrt{e^{v_j}} & 1 \\ 1 & \sqrt{e^{v_j}} \end{bmatrix}.$$

Due to v_j having a Gamma prior, v_j must be non-negative. Consequently the values on the diagonal must be larger than or equal to the values off diagonal. Accordingly our approach is capable of modelling: a perfect worker, $\left[\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right]$, a typical worker, $\left[\begin{smallmatrix} 0.7 & 0.3 \\ 0.3 & 0.7 \end{smallmatrix}\right]$, and a random worker, $\left[\begin{smallmatrix} 0.5 & 0.5 \\ 0.5 & 0.5 \end{smallmatrix}\right]$. However adversarial workers, e.g., $\left[\begin{smallmatrix} 0.2 & 0.8 \\ 0.8 & 0.2 \end{smallmatrix}\right]$, cannot be represented. This limitation arises from the choice of prior (Gamma), and does not feature in other confusion matrix based models.

This constraint means our models can't capture adversarial workers, however this limitation fits with empirical observations of crowd-workers: in practice adversarial workers are rare, and are largely filtered out based on performance history, which is a consequence of the data acquisition method, but it's possible that less carefully collected data with less rigorous quality control may not be a good fit to our model. Typically in a confusion matrix based probabilistic model, worker labels are assumed to be drawn from categorical distributions parameterized by rows in confusion matrices, and every row in a confusion matrix is assumed to be drawn from a Beta or Dirichlet distribution. For binary tasks, the constraint that values on the diagonal are larger than or equal to the values off the diagonal could be achieved by using a truncated Beta prior with a support $[0.5, 1]$, but at a much higher computational cost because the distributions will no longer be conjugate.

5 EXPERIMENTS

Initialization. Our techniques use the EM algorithm, and thus require initialization of either μ and $\mathbb{E}_q V$, or Z. We initialise Z, the easier of the two, using majority voting which allows for fast convergence. In some cases, from the MV initialization our algorithm doesn't converge to the global optimum (the highest likelihood). A common solution is to run the algorithm with random initialization multiple times and then find the best likelihood (including a majority voting run), but to obtain deterministic results, we only run our algorithm with the MV initialization in all experiments.

Since we use the released implementations of existing methods, we choose to keep their code unchanged. Implementations initializing parameters randomly (CATD, CRH) are run 10 times on every dataset and the mean accuracy of 10 runs is reported as its accuracy on that dataset.

Hyperparameter settings. Following the suggestions described in Section 3.1.3, we set $\lambda = 1$. We choose a_v and b_v in Section 5.1. We set the tolerance in the stopping criteria to 10^{-3}, such that iteration of the algorithm stops when the relative difference between every z_i and its last value is within 0.1%.

Methods. Zheng et al. [28][2] compared 17 existing aggregation methods and released their implementations, and 10 of them supporting the multi-class setting are used in our experiment including MV, ZC [4], GLAD [26], DS [3], Minimax [29], iBCC [10], CBCC [22], LFC [18], CATD [12], and CRH [1].

Datasets. There are 19 real-world datasets used in the experiments originating with four crowdsourcing dataset collections, namely the union of the CrowdScale 2013's shared task challenge [9][3] (2 datasets), the Active Crowd Toolkit project [23][4] (8 datasets), the Truth Inference in Crowdsourcing project [28][5] (7 datasets), and the GitHub repository for SpectralMethodsMeetEM paper [27][6] (5 datasets). Note that 3 datasets are in common between the last two collections. Table 2 presents some statistics about the 19 datasets.

The first two, `senti` and `fact`, are from the CrowdScale 2013's shared task challenge, and are the largest two in our experiment, with 569k and 217k labels respectively. The `senti` data asks the workers to judge the sentiment of a tweet discussing weather and label it within {Negative, Neutral, Positive, Unrelated, Can't tell}. The `fact` data requests workers to judge whether relational statements about public figures are correct, e.g. "Stephen Hawking graduated from Oxford". Workers may choose from {Yes, No, Skip}. Note that "Can't tell" or "Skip" may also appear as the true labels of some items due to the inherent ambiguity of some questions. None of the methods compared in our experiments explicitly model the unsure options, instead treating these as a standard label in a 5 and 3-class setting, respectively.

The next 8 datasets are all from the Active Crowd Toolkit project. `MS`, collected by Rodrigues et al. [19], asks workers to listen to short music samples and to classify the music into 10 music genres, {country, jazz, disco, pop, reggae, rock, blues, classical, mental, hip-hop}. `ZC_in` and `ZC_us`, provided by Demartini et al. [4], ask workers to judge if a provided Uniform Resource Identifier (URI) is relevant to a named entity extracted from news, where every URI describes an entity. `ZC_all` is a combination of `ZC_in` and `ZC_us`, and all `ZC` datasets share the same set of items. The two `SP`s are movie review datasets with binary sentiment labels. `CF` is just a small part of the full `senti`. `CF`* and `SP`* have the same items as `CF` and `SP`, but were reannotated.

The next 5 datasets are from the Truth Inference project Zheng et al. [28]. `prod`, collected by Wang et al. [24] for entity resolution, asks workers whether two product descriptions refer to the same product or not. `tweet`, collected by Zheng et al. [28], contains tweets where every tweet is related to a company. Workers are asked to identify if the tweet has positive sentiment towards the company in the tweet. `dog` contains dog images from ImageNet [11] and the task is to recognize a breed (out of Norfolk Terrier, Norwich Terrier, Irish Wolfhound, and Scottish Deerhound) for a given dog. `face`, provided by Mozafari et al. [15], contains face images, and workers are asked to judge whether the person in the image is happy, sad, angry, or neutral. `adult`, released by Mason and Suri [13], asks workers to determine the age appropriateness (P, PG, R, X) of a website given its link.

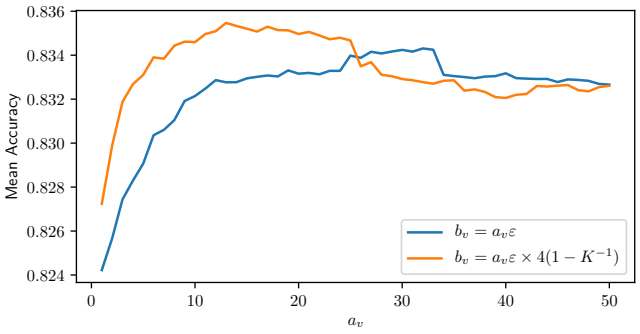

Figure 2: The performance of our proposed BWA model with b_v set by two different strategies.

The last five datasets are used in Zhang et al. [27]. bird, provided by Welinder et al. [25], is a dataset of bird images. The task is to determine whether an image contains at least one duck. The remaining three cover: recognising textual entailment, rte [21], assessing the quality of retrieved documents, trec (TREC 2011 crowdsourcing track)[7], judging the relevance of web search results, web [29].

5.1 Choosing a_v and b_v

Figure 2 shows the mean accuracy of our proposed BWA model across 19 datasets with b_v set by two different strategies described in Section 3.3, namely, using the original error rate ε and using the adjusted error rate $\varepsilon \cdot 4(1 - \frac{1}{K})$. For both strategies, the performance increases steeply when $a_v < 10$ as the prior becomes stronger and provides regularisation to workers who have labelled very few items. We also see both curves are flat around the optimum, so the performance is not very sensitive to the choice of a_v. Due to this reason, we pick a_v from the flat region and report results in both settings: BWA($a_v = 30$, original ε) and BWA($a_v = 15$, adjusted ε).

[7] https://sites.google.com/site/treccrowd/2011

5.2 Comparison against MV

In this section, we report the results of one-sided Wilcoxon signed rank test performed on every method against MV. We adopt the original version which discards the observations when two methods achieve the same accuracy on a dataset. The null hypothesis H_0 is that the performance difference between a method and MV follows a symmetric distribution around zero.

Table 3 summarizes the results showing whether every method is significantly better than MV and at which level, where significance levelsare denoted by asterisks, i.e. 0.1(*), 0.05(**), 0.025(***), respectively. N_r denotes the effective sample size, and W_- the statistic of a method summing up the ranks of datasets that this method is inferior to MV. Zencrowd and iBCC achieve 85.33% accuracy on the CF* dataset which is exactly the same performance as MV resulting, therefore their N_r's are reduced to 18.

The rightmost column in Table 3 shows the p-value calculated based on approximating the cumulative density function (cdf) of W_- given H_0 as a cdf of Gaussian. Due to the small N_r in our experiment (18 or 19), the approximation is somewhat inaccurate, but we keep them there as a reference, as they show ranking of the improvement achieved by all methods comparing to MV.

5.3 Discussion

Scalability. To measure the efficiency of all methods, we run all experiments on a modest desktop with a 7-th generation Intel i5 CPU and 8 GB memory. All methods including our proposed BWA model are implemented in Python, except for iBCC and CBCC

Table 3: One-sided Wilcoxon signed rank test results (all methods against MV)

Method	Mean accuracy	N_r	W_-	Sig. level	Approx. p-value
MV	0.8196				
ZC	0.8294	18	64		0.1746
GLAD	0.8305	19	47	**	0.0267
DS	0.8309	19	71		0.1671
Minimax	0.8141	19	81		0.2866
iBCC	0.8352	18	52	*	0.0723
CBCC	0.8291	19	71		0.1671
LFC	0.8338	19	69		0.1477
CATD	0.8334	19	56	*	0.0583

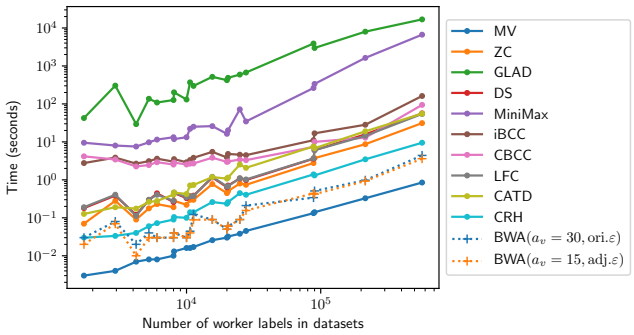

Figure 3: Running time (seconds) of all methods on 19 real-world datasets.

which are implemented in C#, and Minimax is implemented in MATLAB.

As shown in Figure 3, our proposed methods outperform the other existing methods (except MV) in terms of running time. For datasets other than the largest two (senti and fact), our method converged within one second. GLAD and Minimax are the two slowest methods, as they both require gradient-based optimization algorithms, and the required gradients are expensive to compute.

Accuracy. As shown in Table 3, although iBCC has the highest mean accuracy across all datasets, it outperforms MV only at a significance level of 0.1, which is insufficient to reject the null hypothesis. On the other hand, GLAD, whose mean accuracy is not outstanding, significantly outperforms MV at a significance level of 0.05, the best among all 9 benchmarks. In contrast, BWA achieves not only the highest mean accuracy, the same as iBCC, but also strongest significance of outperforming MV, at a level of 0.025.

As shown in Table 3, our proposed BWA($a_v = 15$, adjusted ε) model and iBCC achieve the highest mean accuracy of 83.52%, and our BWA model using another hyper-parameter setting ($a_v = 30$, original ε) which achieves 83.42%, followed by LFC 83.38% and CATD 83.34%. Interestingly, both our proposed methods and CATD model the latent truth z_i's as continuous variables, but in CATD the optimization objective is heuristic based, while in our models, the optimization objective is derived from explicit probabilistic models. Minimax is an interesting model in that it largely outperforms others on bird and web but performs the worst on MS, the three ZC datasets, and prod. This may be due to Minimax not being a probabilistic model thus its objective function is not well regularised and often too aggressive. This may also explain the results for CRH, another non-probabilistic model.

Figure 4 provides more details of the accuracies of all methods on the 19 real-world datasets. We roughly sort all methods into two categories: confusion-matrix-based methods (DS, MiniMax, iBCC, CBCC, LFC) and 1-coin models (ZC, GLAD, CATD, CRH, our proposed BWA). The name "1-coin" arises from these models only learning a single parameter per worker to capture their accuracy. face, bird, trec are three successful cases for confusion-matrix-based methods, because on those datasets workers behave very differently across classes, which "1-coin" models cannot capture. However, they perform not so well on senti, fact, MS, and ZC datasets due to either the data is overall insufficient to learn a $K \times K$ confusion matrix for every worker, or the class is imbalanced that for some minority classes worker behaviour can't be reliably estimated.

6 CONCLUSION

This paper presents a novel method for aggregating crowdsourced labels for classification. We propose a generative Bayesian model, relaxing a discrete binary problem to a continuous regression task, which we model using a normal likelihood and conjugate inverse-Gamma prior, and can be extended to work in multi-class settings by employing the one-versus-rest strategy.

Our models allow for straightforward inference using expectation-maximisation, which is implemented in 50 lines of code in the appendix. Our models have interpretable parameters and intuitive update rules, which make them easy to understand and use. We also provide detailed practical suggestions such as how to set the hyper-parameters.

Our experimental results show that our proposed method is the only one that significantly outperforms MV at significance level 0.025 and performs competitively to the state-of-the-art method in terms of mean accuracy, across all datasets drawn from several different application areas, with different sizes and differing degrees of label redundancy. Our proposed method also has a total running time on the same datasets second only to MV.

ABSTRACT

Sources in computer-based collaborative systems such as webpages can help employees to connect and cooperate with each other. It is natural to enable the systems to look not only for documents but also for experts. In this paper, we study the problem of expert retrieval in enterprise corpora: given a topic, also known as query containing a set of words, identify a rank list of candidate experts who have expertise on the topic. To tackle the problem, we propose an unsupervised semantic two-player minimax game, i.e., our unsupervised semantic generative adversarial networks (USGAN). Unlike almost all the previous generative adversarial networks-based algorithms that require ground truth training data, our USGAN is an unsupervised semantic expert retrieval algorithm that consists of a discriminative network and a generative network aiming at capturing the representations of words and experts in an unsupervised way. Candidates that have similar semantic representations to that of the topic are retrieved as relevant to the topic. Our USGAN would provide inspiration on how to extend the standard GAN and its variants by unsupervised ways to address other retrieval tasks where labelled data are missing. Experimental results on public datasets validate the effectiveness of the proposed expert retrieval algorithm.

1 INTRODUCTION

Computer-based collaborative systems have been widely used by many organizations these days. Sources in such systems, such as webpages, database records, agendas, employees' description files and technical reports, can help to connect employees for collaboration and information exchange in the organization. It is natural to enable the systems to look not only for documents, but for entities, such as answers, services, objects, and experts. Our interest is in one type of entity in particular: experts. Accordingly, in this paper, we aim at addressing the *expert retrieval task, also known as expert finding, expert retrieval, or expert search task: given a topic, also called a query containing a set of words, who are the experts with the most expertise on the topic?* Our goal is to retrieve a rank list of experts who have expertise on a specific topic described by an input query, given a set of candidates and a heterogeneous document repository of an organization.

The study of expert retrieval task has gained popularity in research community since the launch of the task at TREC 2005 enterprise track [14]. Algorithms for the task are either supervised or unsupervised. Supervised ones require great manual annotation efforts to obtain training data, resulting in the fact that a limited amount of training data may greatly hinder their applications. In contrast, unsupervised ones, such as those based on language models [8], do not require the training data, and can work well in many cases. In this paper we aim at improving the performance with no training data, and propose **U**nsupervised **S**emantic **G**enerative **A**dversarial **N**etworks (**USGAN** for short), i.e., an unsupervised semantic minimax game, for the expert retrieval task.

GAN (Generative Adversarial Networks [20]) works with a minimax game consisting of a discriminative network D that learns to distinguish whether a given data instance is real or not, and a generative network G that learns to confuse D by generating high quality data. GAN and its variants have been successfully applied into many applications such as those in artificial intelligence, e.g., abstract reasoning [28], clustering [42], and image and sequence generation [27, 57], and have shown their better performance compared to that of many maximum likelihood techniques and traditional deep learning models, e.g., convolutional neural networks [19]. However, they can not directly be applied to our task without labelled data, as they are supervised. Our USGAN is able to learn from raw textual evidence and document-expert associations in an unsupervised way and thus does not require any manual relevance judgements between topics and experts.

Additionally, most unsupervised expert retrieval algorithms are based on language models [15]. However, these unsupervised language model-based algorithms need to construct a language model for every document in the collections, and thus lack efficient query capabilities for large document collections, as each query term needs to be exactly matched against every document. They also suffer from term mismatch problem, which occurs due to the inability of widely used maximum-likelihood functions in the algorithms

and the different representations of queries and expert documents to describe the same concepts [50]. To address the problems, we represent all the words and candidate experts as semantic vectors obtained from our unsupervised USGAN algorithm such that we can avoid constructing language models for all documents in the collections and the the semantic similarities between words and experts can be effectively measured.

The purposes of this work are not only for improving the performance of unsupervised expert retrieval algorithms, but also, more importantly, for providing a new insight into training GAN and its variants, i.e., via unsupervised learning for a number of information retrieval applications. Our contributions can be summarized as:

(1) We propose unsupervised generative adversarial network algorithm that is a minimax game consisting of a discriminative network and a generative network for expert retrieval task.

(2) Our USGAN is semantic and is able to semantically measure the similarities between the representations of words and experts.

(3) To our knowledge, we are the first attempt to apply GAN framework *in an unsupervised way* to tackle the retrieval problems in information retrieval.

(4) Through USGAN as an example, we would provide insight and inspiration on how to extend supervised GAN model and its variants in unsupervised ways to tackle other tasks where labelled data is limited or missing.

(5) We systematically analyze the proposed algorithms and find that we achieve better performance compared to the state-of-the-art unsupervised algorithms.

The remainder of the paper is organized as: Section 2 discusses related work; Section 3 details the research problem; Section 4 describes the proposed USGAN model; Section 5 describes our experimental setup; Section 6 is devoted to our experimental results and we conclude the paper in Section 7.

2 RELATED WORK

In this section, we only discuss the most related work: previous generative adversarial networks, expert retrieval algorithms, and semantic models.

2.1 Generative Adversarial Networks

Generative adversarial networks are a class of GAN-based methods for learning from labelled data based on minimax game theory [20] that consists of a generative network G and a discriminative network D. The goal of GAN-based methods is to train a generator network $G(\boldsymbol{z}; \boldsymbol{\theta}^{(G)})$ that produces samples from the data distribution, $p_{\text{data}}(\boldsymbol{x})$, by transforming vectors of noise $\boldsymbol{z}$ as $\boldsymbol{x} = G(\boldsymbol{z}; \boldsymbol{\theta}^{(G)})$. The training signal for G is provided by a discriminator network D that is trained to distinguish between samples from the generator distribution and those from ground truth (real) data. The generator network G in turn is then trained to fool the discriminator into accepting its outputs as being real. After the first GAN model is introduced, many of its recent variants have been proposed and successfully applied to many applications. E.g., Boundary equilibrium GAN is proposed in [11], where a novel equilibrium method is applied for balancing adversarial networks and auto-encoder is applied as the discriminator. Rather than proposing a new GAN-based algorithm, IRGAN [51] assumes that ground truth data is available for training and directly applies GAN to document retrieval task. Energy-based GAN [58] views the discriminator as an energy function that attributes low energies to the regions near the data manifold and higher energies to other regions. [47] introduced a specific conditioning of convolutional GAN on texture and shape elements for generating fashion design images. Some work aims at improving training techniques for GAN-based algorithms. E.g., Wasserstein GAN [2] tries to improve the stability of learning in GAN, gets rid of problems like model collapse, and provides learning curves for debugging and hyper-parameter searches. In [46], a variety of new architectural features and training procedures are proposed and applied into GAN framework. Previous work has shown that GAN-based algorithms can perform better than most traditional deep learning models such as LSTM (Long Short Term Memory networks) and CNN (Convolutional Neural Networks) [19].

Surprisingly, as far as we know little attention has paid attention to training GAN and its variants *without labelled data* for tasks in information retrieval, and the lack of training data in previous supervised GAN based algorithms would greatly hinder their success in the tasks. To the best of our knowledge, ours is the first attempt to train GAN in an unsupervised way for expert retrieval and the first attempt to apply GAN to applications in information retrieval via unsupervised ways.

2.2 Expert Retrieval

After the launch of expert retrieval task at TREC 2005 enterprise track [14], a number of supervised and unsupervised algorithms for the task have been proposed, which can be categorized into either supervised or unsupervised ones. Supervised algorithms include the relevance-based expert retrieval learning algorithm [18], learning to find experts [52]. Of special relevance to us are the unsupervised algorithms. The most well-known unsupervised ones are the profile-centric (Model 1) and document-centric (Model 2) expert finding models [4, 8], which focus on raw textual evidence without incorporating collection-specific information, e.g., query modeling, document importance or document structure. Both the Model 1 and Model 2 expert finding algorithms are language retrieval models, and they differ each other by the way of computing the probabilities of a candidate having expertise on a given topic. Other unsupervised ones include thread-based model [55] where expert finding is performed in the context of social media, language model for finding bloggers as experts [7] in the context of blog documents, and shallow log-linear model [50] that learns distributed word representations in an unsupervised way for the expert finding task, probabilistic expert finding models [17] where candidate generation framework and topic generation framework are studied for the task, and language models for finding groups of experts [32, 34] that aim at retrieving a ranked list of groups of experts given a topic. All these supervised and unsupervised methods are not based on GAN, and except the shallow log-linear one they are non-semantic.

To better provide insight in how our unsupervised semantic GAN-based algorithm improves performance of expert retrieval, we follow the setting applied in many unsupervised expert retrieval methods, i.e., avoid explicit feature engineering and the incorporation of external evidence in our USGAN expert retrieval algorithm.

To the best of our knowledge, we are the first attempt to apply GAN techniques to tackle the task of expert retrieval.

2.3 Semantic Models

The mismatches between queries and documents pose one of the most critical challenges in many information retrieval tasks [29, 30, 40, 41], and a number of topic models have been proposed to alleviate the mismatch challenge. Topic models provide a suite of semantic algorithms to discover hidden thematic structure in a collection of documents. A topic model takes a set of documents as input, and discovers a set of "latent topics"—recurring semantic themes that are discussed in the collection—and the degree to which each document exhibits those semantic topics [12]. Since the well-known topic models, PLSI (Probabilistic Latent Semantic Indexing) [22] and LDA (Latent Dirichlet Allocation) [12] were proposed, various topic models and their applications in information retrieval have been widely studied. The author topic model [45] has been proposed to uncover latent semantic topics of authors; each author is associated with a multinomial distribution over topics and each topic is associated with a multinomial distribution over words. In [53], LDA-based document models have been proposed to perform semantic matching of documents and queries. Topic models were proposed for clustering short texts [39] and users [40] in streams, streaming short text diversifications [31, 38], diversified data fusion of rank lists [31, 33, 35–37]. In [56], a comparative study of utilizing topic models for document retrieval was provided. Besides topic models, other researchers tried to alleviate the mismatches between queries and documents in other ways. For instance, in [23] semantic matching between queries and documents was performed by leveraging click-through data optimizing for web document ranking. Deep learning models, e.g., position-aware representations for relevance matching model [24], deep relevance matching model [21], shallow log-linear model [50] and multiple instance deep learning model [13], have been proposed to alleviate the mismatch problem between queries and documents.

Except the shallow log-linear model [50], all the existing semantic models are for mismatch problem between queries and documents only but not for queries and candidate experts. Unlike all of the previous models, we tackle the problem of mismatch problem among queries, documents and candidate experts via an unsupervised GAN-based semantic model. To the best of our knowledge, we are the first attempt to address the semantic mismatch problem via an unsupervised GAN method.

3 PROBLEM FORMULATION

We aim at addressing the expert retrieval task defined at the TREC 2005–2008 enterprise tracks [3, 9, 14, 48] in an unsupervised way: given a topic (a topic is also called a "query" containing a set of words in the tracks), a set of candidate experts and the heterogeneous enterprise document corpora, identify a rank list of experts who have expertise on the topic. The expert retrieval algorithm is essentially a function f that satisfies the following:

$$q, \mathcal{E}, \mathcal{D}, \xrightarrow{f} \mathcal{L},$$

where $q = \{v_1, \ldots, v_{|q|}\}$ is a query (also called topic at the tracks), $\mathcal{E}$ is a set of candidate experts, $\mathcal{D}$ is an organization's heterogeneous document corpora, and $\mathcal{L}$ is the final rank list of the experts in response to the query (experts with larger retrieval probabilities are ranked higher in the final rank list). Here v is a word from a vocabulary $\mathcal{V}$ and $|q|$ is the length of the query q.

4 METHOD

In this section, we detail our proposed **U**nsupervised **S**emantic **G**enerative **A**dversarial **N**etworks (USGAN) that aim at addressing the expert finding problem.

4.1 The Minimax Game

Our proposed USGAN for expert retrieval is an unsupervised, semantic minimax two-player game that consists of a discriminative model $D_{\boldsymbol{\phi}}$ with parameter $\boldsymbol{\phi}$ and a generative model $G_{\boldsymbol{\theta}}$ with parameter $\boldsymbol{\theta}$. The generative model would try to generate (in our task, select) relevant experts to the query that look like the ground-truth relevant experts and therefore could fool the discriminative model, whereas the discriminative model would try to draw a clear distinction between the ground-truth experts and the generated ones made by its opponent generative model. Competition in this game drives both models to improve their expert retrieval abilities until the discriminative model is indistinguishable from the experts selected from the generative model.

Without loss of generality, let's suppose we have N queries. Inspired by many GAN-based algorithms [20], we can simply define our $D_{\boldsymbol{\phi}}$ and $G_{\boldsymbol{\theta}}$ and let them play the following two-player minimax game:

$$\begin{aligned} J^{G_{\boldsymbol{\theta}^*}, D_{\boldsymbol{\phi}^*}} &= \min_{\boldsymbol{\theta}} \max_{\boldsymbol{\phi}} \sum_{n=1}^{N} \Big(\mathbb{E}_{e \sim p_{GT}(e|q_n)} [\log D_{\boldsymbol{\phi}}(e \mid q_n)] + \\ &\qquad \mathbb{E}_{\mathbf{z} \sim p_{\mathbf{z}}(\mathbf{z}|q_n)} \left[\log \left(1 - D_{\boldsymbol{\phi}} \left(G_{\boldsymbol{\theta}}(\mathbf{z} \mid q_n) \mid q_n \right) \right) \right] \Big), \\ &= \min_{\boldsymbol{\theta}} \max_{\boldsymbol{\phi}} \sum_{n=1}^{N} \Big(\mathbb{E}_{e \sim p_{GT}(e|q_n)} [\log D_{\boldsymbol{\phi}}(e \mid q_n)] + \\ &\qquad \mathbb{E}_{e \sim p_{\boldsymbol{\theta}}(e|q_n)} \left[\log \left(1 - D_{\boldsymbol{\phi}} \left(e \mid q_n \right) \right) \right] \Big), \end{aligned} \tag{1}$$

where e is a candidate expert, $p_{GT}(e \mid q_n)$ is the ground truth distribution of experts to the n-th query q_n, and $\mathbf{z}$ and $p_{\mathbf{z}}(\mathbf{z} \mid q_n)$ are a noise vector and its corresponding distribution, respectively. As shown in (1), we directly represent the generator $G_{\boldsymbol{\theta}}$ as $p_{\boldsymbol{\theta}}(e \mid q)$ (see the comparison between the expectation term in the second line of (1) and the expectation term in the last line of (1)), and according to many supervised discriminative expert retrieval algorithms [18], $D_{\boldsymbol{\phi}}(e_i \mid q_n)$ in (1) can be defined as:

$$D_{\boldsymbol{\phi}}(e_i \mid q_n) = p_{\boldsymbol{\phi}}(r = 1 | e_i, q_n)^{r_{in}} p_{\boldsymbol{\phi}}(r = 0 | e_i, q_n)^{1 - r_{in}}, \tag{2}$$

where $p_{\boldsymbol{\phi}}(r = 1 \mid e_i, q_n)$ and $p_{\boldsymbol{\phi}}(r = 0 \mid e_i, q_n)$ are the probabilities of candidate e_i having and not having expertise on topic q_n, respectively, which can be directly obtained by the ground truth distribution $p_{GT}(e|q_n)$, and $r_{in} \in \{0, 1\}$ is the ground truth relevance score of candidate e_i having expertise on the topic q_n with $r_{in} = 1$ indicating that e_i is relevant to (has expertise on) the query q_n and $r_{in} = 0$ indicating the opposite.

Unfortunately, without ground truth distribution $p_{GT}(e \mid q_n)$ we can not play the minimax game defined in (1) to get the optimal discriminative model $D_{\boldsymbol{\phi}^*}$ and the optimal generative model $G_{\boldsymbol{\theta}^*}$.

Accordingly, we transfer (1) to the following unsupervised two-player minimax game:

$$J^{G_{\boldsymbol{\theta}^*}, D_{\boldsymbol{\phi}^*}} = \min_{\boldsymbol{\theta}} \max_{\boldsymbol{\phi}} \sum_{n=1}^{|\mathcal{S}|} \Big(\mathbb{E}_{e \sim p_{\boldsymbol{\phi}}(e|s_n)} [\log D_{\boldsymbol{\phi}}(e \mid s_n)] + \mathbb{E}_{e \sim p_{\boldsymbol{\theta}}(e|s_n)} \Big[\log \Big(1 - D_{\boldsymbol{\phi}}(e \mid s_n) \Big) \Big] \Big), \quad (3)$$

where $\mathcal{S} = \{s_n\}_{n=1}^{|\mathcal{S}|}$ is a set of word sequences (query can be regarded as a word sequence as well) extracted from all documents in $\mathcal{D}$ with $s_n = \{v_1, \ldots, v_{|s_n|}\}$ being the n-th word sequence, and the size of the sequence set is $|\mathcal{S}|$, i.e., the total number of word sequences in the set $\mathcal{S}$. Here $|s_n|$ is the size of the n-th sequence, i.e., the total number of words in the sequence s_n. Obviously, unlike queries that are manually defined in the ground truth, our set of word sequences $\mathcal{S}$ can be obtained by an unsupervised way. All the words in the sequences are supposed from a vocabulary $\mathcal{V}$. Note that both generative and discriminative networks with parameters $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$, respectively, are still modeled in (3), with the generative networks directly generate/select an expert from the distribution $p_{\boldsymbol{\theta}}(e \mid s)$. Later in this section, we will model each sequence as m-grams extracted from documents.

As we do not have ground truth during unsupervised learning, without loss of generality, as can be seen in (3) we replace N in (1), the number of ground truth queries, to be $|\mathcal{S}|$, and $p_{GT}(e \mid q_n)$ in (1) to be $p_{\boldsymbol{\phi}}(e \mid s_n)$, i.e., the probability of a candidate expert e having expertise on the topic underlying the sequence s_n, respectively.
In what follows, we present how we define $p_{\boldsymbol{\phi}}(e_i \mid s_n)$, $p_{\boldsymbol{\theta}}(e_i \mid s_n)$ and $D_{\boldsymbol{\phi}}$ in (3) via an unsupervised way, where we do not require topic-candidate ground truth assessments and manually defined queries for training. Recall that in (1) we directly represent $G_{\boldsymbol{\theta}}$ as $p_{\boldsymbol{\theta}}(e \mid q)$, and thus we do not need to redefine $G_{\boldsymbol{\theta}}$ at all.

Definition of $p_{\boldsymbol{\phi}}(e_i \mid s_n)$. According to unsupervised language model, we closely follow the work in [50] and rank all the candidate experts in $\mathcal{E}$ by the conditional probability of a candidate expert e_i given a topic/sequence $s_n = \{v_1, \ldots, v_{|s_n|}\}$:

$$p_{\boldsymbol{\phi}}(e_i \mid s_n) = \frac{1}{Z_1} \widetilde{p}_{\boldsymbol{\phi}}(e_i \mid v_1, \ldots, v_{|s_n|}) = \frac{1}{Z_1} \prod_{j=1}^{|s_n|} p_{\boldsymbol{\phi}}(e_i \mid v_j)$$
$$\overset{\text{rank}}{=} \frac{1}{Z_1} \exp\Bigg(\sum_{j=1}^{|s_n|} \log \Big(p_{\boldsymbol{\phi}}(e_i \mid v_j) \Big) \Bigg), \quad (4)$$

where $\widetilde{p}_{\boldsymbol{\phi}}(e_i | v_1, \ldots, v_{|s_n|})$ is the unnormalized score, $Z_1 = \sum_{i=1}^{|\mathcal{E}|} \exp(\sum_{j=1}^{|s_n|} \log(p_{\boldsymbol{\phi}}(e_i \mid v_j)))$ is the a normalization term (The transformation to log-space in (4) is a well-known trick to prevent floating point underflow [43]), $\overset{\text{rank}}{=}$ denotes that ranking according to the former equation is equivalent to ranking according to the latter one, and $p_{\boldsymbol{\phi}}(e_i \mid v_j)$ is the probability of a candidate having expertise on the topic specific to a word $v_j \in \mathcal{V}$, which can be defined as a log-linear learning model:

$$p_{\boldsymbol{\phi}}(e_i | v_j) = \frac{1}{Z_2} \exp(\mathbf{e}_i^{\boldsymbol{\phi}} \cdot \mathbf{v}_j^{\boldsymbol{\phi}\top} + b_i^{\boldsymbol{\phi}}), \quad (5)$$

where $\mathbf{e}_i^{\boldsymbol{\phi}}$ and $\mathbf{v}_j^{\boldsymbol{\phi}}$ are the expert e_i's and the word v_j's $1 \times c$ semantic representation vectors with c being the size of the vectors, respectively, $b_i^{\boldsymbol{\phi}}$ is a bias for the candidate expert e_i, $\mathbf{v}^{\boldsymbol{\phi}\top}$ is the transpose of $\mathbf{v}^{\boldsymbol{\phi}}$, and $Z_2 = \sum_{i=1}^{|\mathcal{E}|} \exp(\mathbf{e}_i \cdot \mathbf{v}_j^\top + b_i)$ is the normalization term. Obviously, the semantic representations of all the candidate experts, $\{\mathbf{e}_i^{\boldsymbol{\phi}}\}_{i=1}^{|\mathcal{E}|}$, the semantic representations of all the words, $\{\mathbf{v}_j^{\boldsymbol{\phi}}\}_{j=1}^{|\mathcal{V}|}$, and the corresponding biases $\{b_i^{\boldsymbol{\phi}}\}_{i=1}^{|\mathcal{E}|}$ constitute the parameter $\boldsymbol{\phi}$ of our discriminative model $D_{\boldsymbol{\phi}}$, i.e., $\boldsymbol{\phi} = \Big\{\{\mathbf{e}_i^{\boldsymbol{\phi}}\}_{i=1}^{|\mathcal{E}|}, \{\mathbf{v}_j^{\boldsymbol{\phi}}\}_{j=1}^{|\mathcal{V}|}, \{b_i^{\boldsymbol{\phi}}\}_{i=1}^{|\mathcal{E}|}\Big\}$. Note that we define a neural network in (5) with a log-linear model only. Adding more layers into the neural network defined in (5) is possible. But our experiments found that the shallow log-linear model defined in (4) performs well-enough in most cases and adding more layers will require more training times and lose the transparency of the model. Other neural networks such as CNN for defining $p_{\boldsymbol{\phi}}(e_i \mid s_n)$ are possible, but we want to be focused and leave these as future work.

Definition of $p_{\boldsymbol{\theta}}(e_i \mid s_n)$. To focus more on our USGAN, we define $p_{\boldsymbol{\theta}}(e_i \mid s_n)$ for our generative model in such a way that is the same as that in our discriminative model, i.e., via (4) and (5), but with different semantic parameters $\{\mathbf{e}_i^{\boldsymbol{\theta}}\}_{i=1}^{|\mathcal{E}|}$, $\{\mathbf{v}_j^{\boldsymbol{\theta}}\}_{j=1}^{|\mathcal{V}|}$ and $\{b_i^{\boldsymbol{\theta}}\}_{i=1}^{|\mathcal{E}|}$. Then, the parameter $\boldsymbol{\theta}$ in our generative model is set to be $\boldsymbol{\theta} = \Big\{\{\mathbf{e}_i^{\boldsymbol{\theta}}\}_{i=1}^{|\mathcal{E}|}, \{\mathbf{v}_j^{\boldsymbol{\theta}}\}_{j=1}^{|\mathcal{V}|}, \{b_i^{\boldsymbol{\theta}}\}_{i=1}^{|\mathcal{E}|}\Big\}$. Again, to keep focused, we leave using alternative neural networks for generative model in our USGAN as future work.

Definition of $D_{\boldsymbol{\phi}}$. Before we follow that in [50] and define our final $D_{\boldsymbol{\phi}}$, we construct a pseudo ground truth probability of candidate e_i having expertise on a document $d_k \in \mathcal{D}$, i.e., $p_{\widetilde{GT}}(e_i \mid d_k)$, based on document-candidate associations by an unsupervised way:

$$p_{\widetilde{GT}}(e_i \mid d_k) = \begin{cases} 0, & e_i \notin \mathcal{E}_{d_k}, \\ \frac{1}{|\mathcal{E}_{d_k}|}, & e_i \in \mathcal{E}_{d_k}, \end{cases} \quad (6)$$

where $\mathcal{E}_{d_k}$ and $|\mathcal{E}_{d_k}|$ are a set of candidates whose names or email addresses are observed in the document d_k and the total number of the observed candidates in the document d_k (i.e., the size of the set), respectively. For each document $d \in \mathcal{D}$, we extract a set of m-grams where m remains fixed during our unsupervised learning. Let $\mathcal{M}_{d_k}$ denote the set of the m-grams extracted from d_k with $d_k^{(l)} \in \mathcal{M}_{d_k}$ being the l-th m-grams. Let $\mathbf{p}_{\widetilde{GT}}(e_i \mid d_k) = \{p_{\widetilde{GT}}(e_i \mid d_k^{(l)})\}_{l=1}^{|\mathcal{M}_{d_k}|}$, where $|\mathcal{M}_{d_k}|$ is the size of the m-grams (i.e., word sequences) set extracted from d_k and let $p_{\widetilde{GT}}(e_i \mid d_k^{(l)}) = p_{\widetilde{GT}}(e_i \mid d_k)$ which can be obtained by (6). We also denote $\mathbf{p}_{\boldsymbol{\phi}}(e_i \mid d_k)$ to be $\mathbf{p}_{\boldsymbol{\phi}}(e_i \mid d_k) = \{p_{\boldsymbol{\phi}}(e_i \mid d_k^{(l)})\}_{l=1}^{|\mathcal{M}_{d_k}|}$. Here $p_{\boldsymbol{\phi}}(e_i \mid d_k^{(l)}) = p_{\boldsymbol{\phi}}(e_i \mid v_1^{d_k^{(l)}}, \ldots, v_m^{d_k^{(l)}})$ can be obtained by (4) with $v_x^{d_k^{(l)}}$ being the x-th word in the m-gram $d_k^{(l)}$. Accordingly, we define our discriminative model $D_{\boldsymbol{\phi}}(e_i \mid d_k)$ based on the cross-entropy $C\Big(\mathbf{p}_{\widetilde{GT}}(e_i \mid d_k), \mathbf{p}_{\boldsymbol{\phi}}(e_i \mid d_k)\Big)$ in an

unsupervised way as follows:

$$
\begin{aligned}
D_{\boldsymbol{\phi}}(e_i \mid d_k) =& \frac{1}{Z_3}\frac{|d_{\max}|}{|d_k|} C\left(\mathbf{p}_{\widetilde{GT}}(e_i \mid d_k), \mathbf{p}_{\boldsymbol{\phi}}(e_i \mid d_k)\right) \\
&+ \epsilon\left(\|\mathbf{e}_i^{\boldsymbol{\phi}}\|_2^2 + \frac{1}{|\mathcal{M}_{d_k}|}\sum_{j=1}^{|\mathcal{M}_{d_k}|}\|\mathbf{v}_j^{\boldsymbol{\phi}}\|_2^2\right) \\
=& -\frac{|d_{\max}|}{Z_3 \cdot |d_k| \cdot |\mathcal{M}_{d_k}|}\sum_{l=1}^{|\mathcal{M}_{d_k}|}\left(p_{\widetilde{GT}}(e_i \mid d_k^{(l)}) \cdot \log p_{\boldsymbol{\phi}}(e_i \mid d_k^{(l)})\right) \\
&+ \epsilon\left(\|\mathbf{e}_i^{\boldsymbol{\phi}}\|_2^2 + \frac{1}{|\mathcal{M}_{d_k}|}\sum_{j=1}^{|\mathcal{M}_{d_k}|}\|\mathbf{v}_j^{\boldsymbol{\phi}}\|_2^2\right),
\end{aligned} \tag{7}
$$

where $\|\mathbf{x}\|_2$ is the 2-norm of a vector $\mathbf{x}$, ϵ is a free regularization parameter, $d_{\max} = \arg\max_{d\in\mathcal{D}}|d|$ is the longest document in the collection, $|d_{\max}|$ and $|d_k|$ are the length of the corresponding documents, respectively, and Z_3 is a normalization constant that forces $D_{\boldsymbol{\phi}}(e \mid d)$ to be within the range $(0, 1]$, which can be defined to be the maximal score of $D_{\boldsymbol{\phi}}(e \mid d)$ before the normalization.

4.2 Optimizing the Discriminative Model

The objective of the discriminative model is to maximize the log-likelihood of correctly distinguishing the candidate experts from $p_{\boldsymbol{\phi}}(e \mid s)$ and those generated from $p_{\boldsymbol{\theta}}(e \mid s)$. As (7) is built on (4) and thus maximizing (7) for all candidates and documents means to maximizing (4) for all the candidates and documents in collection, and with the candidate experts sampled from the current optimal generative model $p_{\boldsymbol{\theta}^*}(e \mid s)$, we can obtain the optimal parameters for the discriminative model defined in (3) as:

$$
\begin{aligned}
\boldsymbol{\phi}^* =& \arg\max_{\boldsymbol{\phi}}\sum_{k=1}^{|\mathcal{D}|}\Big(\mathbb{E}_{e\sim p_{\boldsymbol{\phi}}(e|d_k)}[\log D_{\boldsymbol{\phi}}(e \mid d_k)] + \\
&\mathbb{E}_{e\sim p_{\boldsymbol{\theta}}(e|d_k)}\left[\log(1 - D_{\boldsymbol{\phi}}(e \mid d_k))\right]\Big) \\
=& \arg\max_{\boldsymbol{\phi}}\sum_{k=1}^{|\mathcal{D}|}\Big(\frac{1}{|\mathcal{E}|}\sum_{i=1}^{|\mathcal{E}|}\log D_{\boldsymbol{\phi}}(e_i \mid d_k) + \\
&\mathbb{E}_{e\sim p_{\boldsymbol{\theta}}(e|d_k)}\left[\log(1 - D_{\boldsymbol{\phi}}(e \mid d_k))\right]\Big).
\end{aligned} \tag{8}
$$

As can be seen in (7), $D_{\boldsymbol{\phi}}(e \mid d)$ is differentiable with respect to the parameter $\boldsymbol{\phi}$, and thus we can obtain the optimal parameter $\boldsymbol{\phi}^*$ in (8) by stochastic gradient descent. For convenient discussion in later part of the paper, we denote $\frac{1}{|\mathcal{E}|}\sum_{i=1}^{|\mathcal{E}|}\log D_{\boldsymbol{\phi}}(e_i \mid d_k) + \mathbb{E}_{e\sim p_{\boldsymbol{\theta}}(e|d_k)}\left[\log(1 - D_{\boldsymbol{\phi}}(e \mid d_k)\right]$ in (8) as $J^{D_{\boldsymbol{\phi}}(d_k)}$ and thus (8) can be simplified as $\boldsymbol{\phi}^* = \arg\max_{\boldsymbol{\phi}}\sum_{k=1}^{|\mathcal{D}|}J^{D_{\boldsymbol{\phi}}(d_k)}$.

4.3 Optimizing the Generative Model

In contrast, the objective of the generative model $G_{\boldsymbol{\theta}}$ with the form of $p_{\boldsymbol{\theta}}(e \mid d)$ is to minimize the log-likelihood of $1 - D_{\boldsymbol{\phi}}$ such that the model can fit the underlying relevance distribution over candidate experts, $p_{\widetilde{GT}}(e \mid d)$. The generative model samples candidates from the whole candidate expert set $\mathcal{E}$ based on the distribution $p_{\boldsymbol{\theta}}(e \mid d)$ and tries to fool the discriminative model $D_{\boldsymbol{\phi}}$.

It is worth mentioning that unlike most GAN-based models [1, 58], we let our generative model $G_{\boldsymbol{\theta}}$ directly generate known candidate experts but not their features, because our work here intends to directly select relevant experts from a given candidate set $\mathcal{E}$. Note that as presented in (1), it is feasible to first generate features as denoted by $\mathbf{z}$ and then generate candidate experts from $G_{\boldsymbol{\theta}}(\mathbf{z} \mid s)$ by USGAN. However, to be focused, we leave this as future work.

After we obtain the optimal parameter $\boldsymbol{\phi}^*$ from (8), we then optimize the generative model $G_{\boldsymbol{\theta}}$ via performing the following minimization:

$$
\begin{aligned}
\boldsymbol{\theta}^* =& \arg\min_{\boldsymbol{\theta}}\sum_{k=1}^{|\mathcal{D}|}\Big(\underbrace{\mathbb{E}_{e\sim p_{\boldsymbol{\phi}}(e|d_k)}[\log D_{\boldsymbol{\phi}}(e \mid d_k)]}_{\text{Partial derivative of this term w.r.t } \boldsymbol{\theta} \text{ is 0}} + \\
&\mathbb{E}_{e\sim p_{\boldsymbol{\theta}}(e|d_k)}\left[\log(1 - D_{\boldsymbol{\phi}}(e \mid d_k)\right]\Big) \\
=& \arg\min_{\boldsymbol{\theta}}\sum_{k=1}^{|\mathcal{D}|}\underbrace{\mathbb{E}_{e\sim p_{\boldsymbol{\theta}}(e|d_k)}\left[\log(1 - D_{\boldsymbol{\phi}}(e \mid d_k)\right]}_{\text{Denoted this term as } J^{G_{\boldsymbol{\theta}}(d_k)}},
\end{aligned} \tag{9}
$$

where we denote the term $\mathbb{E}_{e\sim p_{\boldsymbol{\theta}}(e|d_k)}\left[\log(1 - D_{\boldsymbol{\phi}}(e \mid d_k)\right]$ as $J^{G_{\boldsymbol{\theta}}(d_k)}$ and thus it can be simplified to be $\boldsymbol{\theta}^* = \arg\min_{\boldsymbol{\theta}}\sum_{k=1}^{|\mathcal{D}|}J^{G_{\boldsymbol{\theta}}(d_k)}$. As the sampling $e \sim p_{\boldsymbol{\theta}}(e \mid d_k)$ is discrete in the objective function (9) and unlike many GAN-based algorithms [20], we can not simply optimize our $\boldsymbol{\theta}$ by gradient descent. We utilize policy gradient based reinforcement learning (REINFORCE) [49, 54, 57] for obtaining the optimal $\boldsymbol{\theta}^*$ in (9), and the gradient is derived as:

$$
\begin{aligned}
&\nabla_{\boldsymbol{\theta}}J^{G_{\boldsymbol{\theta}}(d_k)} \\
&= \nabla_{\boldsymbol{\theta}}\left(\mathbb{E}_{e\sim p_{\boldsymbol{\theta}}(e|d_k)}\left[\log(1 - D_{\boldsymbol{\phi}}(e \mid d_k)\right]\right) \\
&= \sum_{i=1}^{|\mathcal{E}|}\nabla_{\boldsymbol{\theta}}\left(p_{\boldsymbol{\theta}}(e_i \mid d_k)\log(1 - D_{\boldsymbol{\phi}}(e_i \mid d_k))\right) \\
&= \sum_{i=1}^{|\mathcal{E}|}p_{\boldsymbol{\theta}}(e_i \mid d_k)\nabla_{\boldsymbol{\theta}}\left(\log p_{\boldsymbol{\theta}}(e_i \mid d_k)\log(1 - D_{\boldsymbol{\phi}}(e_i \mid d_k))\right) \\
&= \mathbb{E}_{e\sim p_{\boldsymbol{\theta}}(e|d_k)}\left[\nabla_{\boldsymbol{\theta}}\left(\log p_{\boldsymbol{\theta}}(e_i \mid d_k)\log(1 - D_{\boldsymbol{\phi}}(e_i \mid d_k))\right)\right] \\
&\simeq \frac{1}{H}\sum_{i=1}^{H}\nabla_{\boldsymbol{\theta}}\left(\log p_{\boldsymbol{\theta}}(e_i \mid d_k)\log(1 - D_{\boldsymbol{\phi}}(e_i \mid d_k))\right),
\end{aligned} \tag{10}
$$

where in the last step we sample H candidates from the current version of generative model $p_{\boldsymbol{\theta}}(e \mid d_k)$ to approximate the partial derivative of $J^{G_{\boldsymbol{\theta}}(d_k)}$ with regards to the parameter $\boldsymbol{\theta}$. According to reinforcement learning [49, 54], the term $\log(1 - D_{\boldsymbol{\phi}}(e_i \mid d_k))$ in the last step of (10) acts as the reward for the policy $p_{\boldsymbol{\theta}}(e \mid d_k)$ taking an action e_i in the environment d_k. Other ways, e.g., categorical reparameterization with Gumbel-Softmax [25], to derive the gradient $\nabla_{\boldsymbol{\theta}}J^{G_{\boldsymbol{\theta}}(d_k)}$ are possible, but we leave this for future investigation.

To reduce variance during the REINFORCE learning, we replace the reward term $\log(1 - D_{\boldsymbol{\phi}}(e_i \mid d_k))$ by its advantage function as:

$$
\log(1 - D_{\boldsymbol{\phi}}(e_i \mid d_k)) - \mathbb{E}_{e\sim p_{\boldsymbol{\theta}}(e|d_k)}\left[\log(1 - D_{\boldsymbol{\phi}}(e \mid d_k))\right],
$$

where the term $\mathbb{E}_{e\sim p_{\boldsymbol{\theta}}(e|d_k)}\left[\log(1 - D_{\boldsymbol{\phi}}(e \mid d_k))\right]$ acts as the baseline function in policy gradient based reinforcement learning [49].

4.4 Overview, Example and Discussion

Overview of USGAN. The overview of our proposed unsupervised semantic USGAN expert retrieval model is shown in Algorithm 1. We initialize the semantic representations of all words, $\{\mathbf{v}_j^{\phi}\}_{j=1}^{|\mathcal{V}|}$ and $\{\mathbf{v}_j^{\theta}\}_{j=1}^{|\mathcal{V}|}$, in both the discriminative and generative models, with pre-trained word representations trained on Wikipedia 2014 dataset [1] [44], respectively. The dimension of both words' and candidates' semantic representations is set to be $c = 300$. We sample initial vectors uniformly in the range $[-\frac{1}{\sqrt{300}}, \frac{1}{\sqrt{300}}]$ for all the candidates as their initial semantic representations, and let all the initial biases be 0. (step 1 in Algorithm 1). We pre-train our $\boldsymbol{\phi}$ by maximizing (7) using batched gradient descent. After the pre-training of $\boldsymbol{\phi}$, we let $\boldsymbol{\theta} = \boldsymbol{\phi}$. (step 2 in Algorithm 1). We iteratively perform the minimax game where we update the parameters $\boldsymbol{\phi}$ and $\boldsymbol{\theta}$ at each iteration and terminate the game once it converges. Obviously, we can perform the unsupervised training for our USGAN offline, whereas the USGAN with optimal parameters $\boldsymbol{\phi}$ and $\boldsymbol{\theta}$ after training can be directly applied online for expert retrieval.

After we obtain the optimal parameters $\boldsymbol{\phi}^*$ of the discriminative neural-network and $\boldsymbol{\theta}^*$ of the generative neural-network in USGAN, given a query q, we produce a rank list of the candidate experts $\mathcal{L}$ by their relevance probabilities to the query, i.e., either by $p_{\boldsymbol{\phi}^*}(e \mid q)$ with parameter $\boldsymbol{\phi}^*$ of the discriminative model or by $p_{\boldsymbol{\theta}^*}(e \mid q)$ with parameter $\boldsymbol{\theta}^*$ of the generative model. See (4) for computing $p_{\boldsymbol{\phi}^*}(e \mid q)$ and $p_{\boldsymbol{\theta}^*}(e \mid q)$. Obviously, the unsupervised training for USGAN can be performed offline, whereas the USGAN with optimal parameters $\boldsymbol{\phi}^*$ and $\boldsymbol{\theta}^*$ after the training can be directly applied online for the expert retrieval task.

An Example. Here we provide an example to further illustrate the underlying idea of our proposed USGAN model. We are given a corpora of documents (any formats, e.g., Code docs, Emails, web pages, Wiki web pages etc.), a set of test queries, a set of candidate experts, and the ground truth. Suppose the corpora only contains two Wiki documents: d_1 and d_2, the content of which are: d_1={"*Turing was influential in development of theoretical computer science, providing a formalization of the concepts of algorithm and computation.*"}, d_2={"*Washington was an American statesman who served as the first president of the United States.*"}, respectively, and no other information of the documents is available. We further suppose there is only one test query, q_1={"algorithm"}, and the ground truth for evaluation is: {q_1–Turing–1; q_1–Washington–0} where the "1" indicates that the expert is relevant to the query; whereas "0" indicates non-relevant. Thus, the ground truth denotes that Turing is an expert on topic q_1, whereas Washington is not an expert on topic q_1. The goal of our USGAN is to obtain embeddings (semantic vectors) of both the candidate experts and the words in the corpora, where we assume that the ground truth is not available during training (the ground truth can only be used for evaluation). According to (6), we have $p_{\widetilde{GT}}(\text{Turing} \mid d_1) = 1$, $p_{\widetilde{GT}}(\text{Washington} \mid d_1) = 0$, $p_{\widetilde{GT}}(\text{Turing}|d_2) = 0$, $p_{\widetilde{GT}}(\text{Washington}|d_2) = 1$. All of these probabilities are obtained in an unsupervised way (just identify if the names can be observed in the documents) and are used as the pseudo relevance signals during the unsupervised training of our USGAN. We use m-grams during the training. Suppose $m = 1$ and thus we have probabilities (signals) of each word in the document for the unsupervised training, e.g., $p_{\widetilde{GT}}(\text{Turing} \mid \text{"computer"}) = 1$, (as $p_{\widetilde{GT}}(\text{Turing} \mid d_1) = 1$ and the word "computer" is within d_1), $p_{\widetilde{GT}}(\text{Turing}|\text{"algorithm"}) = 1$, etc. These signals will be used during the unsupervised training. Once the training is done, we will obtain the embeddings. Given a test query={"algorithm"}, we rank the experts by $p_{\boldsymbol{\phi}^*}(e \mid q)$ or $p_{\boldsymbol{\theta}^*}(e \mid q)$ computed by (4), which will result in a ranking, and will be evaluated by the ground truth.

[1] Publicly available from https://nlp.stanford.edu/projects/glove/.

Algorithm 1: Overview of USGAN for expert retrieval.

Input : $\mathcal{D}$, $\mathcal{E}$, ϵ
Output: Optimal $\boldsymbol{\phi}^*$ of $D_{\boldsymbol{\phi}^*}$, and Optimal $\boldsymbol{\theta}^*$ of $G_{\boldsymbol{\theta}^*}$

1 Initialize $\boldsymbol{\phi}$ of $D_{\boldsymbol{\phi}}$ and $\boldsymbol{\theta}$ of $G_{\boldsymbol{\theta}}$
2 Pre-train $p_{\boldsymbol{\phi}}(e \mid d)$ and $p_{\boldsymbol{\theta}}(e \mid d)$ with all documents in $\mathcal{D}$ by (7)
3 **repeat**
4 **for** *g-steps* **do**
5 **for** $k = 1, \ldots, |\mathcal{D}|$ **do**
6 Sample top-H candidate experts from the current version of generative model $p_{\boldsymbol{\theta}}(e \mid d_k)$ for document d_k
7 Update $\boldsymbol{\theta}$ in the generator $G_{\boldsymbol{\theta}}$, i.e., (9), by descending its stochastic gradient with REINFORCE learning: $\nabla_{\boldsymbol{\theta}} \sum_{k=1}^{|\mathcal{D}|} J^{G_{\boldsymbol{\theta}}(d_k)} = \sum_{k=1}^{|\mathcal{D}|} \nabla_{\boldsymbol{\theta}} J^{G_{\boldsymbol{\theta}}(d_k)}$
8 **for** *d-steps* **do**
9 **for** $k = 1, \ldots, |\mathcal{D}|$ **do**
10 Sample top-H candidate experts from the current version of generative model $p_{\boldsymbol{\theta}}(e \mid d_k)$ for document d_k
11 Update $\boldsymbol{\phi}$ in the discriminative $D_{\boldsymbol{\phi}}$, i.e., (8), by ascending its stochastic gradient: $\nabla_{\boldsymbol{\phi}} \sum_{k=1}^{|\mathcal{D}|} J^{D_{\boldsymbol{\phi}}(d_k)} = \sum_{k=1}^{|\mathcal{D}|} \nabla_{\boldsymbol{\phi}} J^{D_{\boldsymbol{\phi}}(d_k)}$
12 **until** USGAN *converges*

Discussions. To our knowledge, there is only one GAN-based algorithm for information retrieval – IRGAN [51]. Our USGAN differs from IRGAN in at least four aspects: (1) The main difference between IRGAN and our USGAN lies in the fact that IRGAN requires ground truth data to train the model, which will hinder its applications in the scenarios that no labelled data is available, whereas our USGAN is an unsupervised GAN-based algorithm and can work without labelled data. (2) IRGAN directly defines its discriminative networks using ground truth data – the samples from the generative networks can be directly distinguished with the labelled data in the ground truth, whereas we define an unique discriminative function for the expert retrieval task in an unsupervised way (see (7)). (3) Our USGAN is semantic retrieval networks and in which we avoid feature extractions, whereas IRGAN requires to extract features for query-entity pairs for training the networks. (4) It is impossible to directly apply IRGAN to the task of expert retrieval even if we assume that the labelled data is available, as there is no direct connection between a relevant expert and a query. In addition, a state-of-the-art UESM (unsupervised, efficient and semantic expertise model) model [50] is just proposed, and has

shown its good performance on the expert retrieval task. Our USGAN differs from UESM in at least three aspects: (1) The strategy to obtain optimal parameters in USGAN is different compared to that in UESM. USGAN utilizes reinforcement learning to update the parameters; whereas UESM directly apply stochastic gradient descent to obtain them. (2) The frameworks are absolutely different. USGAN is a GAN-based algorithm, whereas UESM is a common neural network-based language model. (3) USGAN captures two parameters: ϕ from its discriminative network and θ from its generative network. The competitions between the two networks drive both networks to improve their semantic representations; whereas UESM is built on one network only and no competitions in it.

5 EXPERIMENTAL SETUP

In this section, we describe our experimental setup.

5.1 Research Questions

The research questions guiding the remainder of the paper are: **(RQ1)** How is the expert retrieval performance of USGAN compared to other state-of-the-art methods? **(RQ2)** What is the effect of the window size (m-grams) on the performance of our USGAN expert retrieval method? **(RQ3)** What is the effect of the sampling size (parameter H in (10)) on the performance of our USGAN? **(RQ4)** What is impact of number of iterations on the retrieval performance of our generative model G_θ and discriminative model D_ϕ? **(RQ5)** Does our USGAN outperform the best unsupervised baseline method on each query?

5.2 Dataset

For evaluation purposes we use datasets made available at the 2005 and 2006 editions of the TREC enterprise tracks [14, 48]. Note that for both of these two years' tracks, the document collections [2] are the same but with different testing queries. The document collection contains a crawl of the World Wide Web Consortium (W3C) – a heterogenous document repository containing a mixture of document types, which include lists (from email forum), dev, www, esw, other, and people (personal homepages). Statistical information of the dataset is as follows: total number of documents: 331,037, average document length: 1,237.23, total number of candidates: 1092, total number of document-candidate associations: 200,939 (an association indicates that name or email address of a candidate expert appears in a document), average number of associations per document (Only documents with at least one association are considered): 2.14, average number of associations per candidate: 281.03, 50 test queries were created for the 2005 track with all of their ground truths provided, and 55 test queries were created for the 2006 track with only 50 of their ground truths provided. Other datasets, such as the CSIRO Enterprise Research Collection (CERC) dataset that was a dump of the intranet of Australia's national science agency and was built in the TREC 2007 and 2008 enterprise tracks [9] for testing and the employee dataset of the Tilburg University that consists of bi-lingual, heterogeneous documents [10], are impossible to be used for evaluating expert retrieval algorithms, because they are no longer publicly distributed. [3]

[2]Publicly available from http://trec.nist.gov/data/enterprise.html.
[3]Details can be found at http://trec.nist.gov/data/enterprise.html.

5.3 Baselines

As our goal is to improve performance of the expert retrieval task in an unsupervised way with no labelled data, we only consider unsupervised baselines for comparisons. As IRGAN is a supervised method, it is inappropriate to be taken as baseline. We make comparisons among our USGAN and the following unsupervised non-neural networks-based and neural networks-based algorithms:

Term Frequency and Inverse Document Frequency (TF-IDF). It weights a term by considering both its frequency and inverse document frequency in a given document [15].

Latent Dirichlet Allocation (LDA). This model [12] infers semantic topic distributions specific to each document and each word via the LDA model.

Author Topic Model (AuthorT). This model [45] infers semantic topic distributions specific to each candidate, each document and each word.

Profile-Centric Language Model (Model 1). It is an unsupervised, non-semantic language model for expert finding. It amasses all the term information from all the documents associated with the candidate for a given query and uses this to represent that candidate [4, 8].

Document-Centric Language Model (Model 2). It is an unsupervised, non-semantic language model for expert finding. It first selects documents associated with the candidate, using either the so-called document-centric or the candidate-centric language model. It then considers whether the query can be generated from those documents [4, 8].

Unsupervised, Efficient and Semantic Model (UESM). It is a state-of-the-art unsupervised, semantic, neural expert finding model based on neural networks, exclusively employs textual evidence from document-expert associations for learning representations of terms and experts in an unsupervised way [50].

In terms of the baselines, TF-IDF, LDA and AuthorT, we represent experts, documents and queries by their semantic vector spaces inferred from the corresponding models, and then adapt a generic framework proposed in [16] to rank experts in response to a query, respectively. For Models 1 & 2, we apply Dirichlet smoothing method with parameter β equal to the average document length [5]. We only include the state-of-the-art deep learning model, UESM, for comparisons. Traditional deep learning models, e.g., CNN, Recurrent Neural Network (RNN), LSTM and their state-of-the-art variants [19], are supervised learning algorithms, and thus they are inappropriate to be included as our baselines. There are some unsupervised deep learning models, but they mainly aim at encoding and decoding for generating semantic features in unsupervised ways and serve for different purposes [19]. Thus these unsupervised deep learning models can not be directly applied to expert finding task and used as our baselines.

Later for convenient discussion, we denote our methods that produce the retrieval results by the discriminative model $p_{\phi^*}(e \mid q)$ and the generative model $p_{\theta^*}(e \mid q)$ as USGAN$_D$ and USGAN$_G$, respectively.

5.4 Evaluation Metrics and Settings

The evaluation metrics used to assess the performance of the expert retrieval algorithms are the ones widely used in TREC enterprise

tracks [14, 48]: MAP (Mean Average Precision), R-Prec, MRR (Mean Reciprocal Rank) and P@k (Precision at k) [15]. R-Prec is the precision after R documents have been retrieved, where R is the total number of relevant documents for the query. We also use NDCG@k (Normalized Discounted Cumulative Gain at k [26]). For P@k and NDCG@k, we set k to 5 and 10, respectively, to align with the cut-off used in the TREC enterprise tracks.

For our USGAN (both USGAN$_D$ and USGAN$_G$) and the baseline UESM, we use a 70%/20%/10% split of the queries for unsupervised training, validation and test sets, respectively. We optimize the objectives during the unsupervised training using different values of the parameters, e.g., the size of m-grams in the methods, and the sampling size in USGAN. The best values are then chosen on the validation set, and evaluated on the test queries. The *g-steps* and *d-steps* epochs in USGAN (see Algorithm 1) keep running until the parameters $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ updated by the corresponding stochastic gradients converge, respectively. Other settings, e.g., the initialization for $\boldsymbol{\phi}$ and $\boldsymbol{\theta}$ etc., can be found in subsection 4.4. The train/validation/test splits are permuted until all the queries were chosen once for the test set. We repeat the experiments 10 times and report the average results. The statistical significance of the observed differences between the performance of two ranking algorithms across the queries is tested using a two-tailed paired t-test and is denoted using $^{\blacktriangle}$ (or $^{\blacktriangledown}$) for $\alpha = .01$, and $^{\triangle}$ (and $^{\triangledown}$) for $\alpha = .05$.

Table 1: Retrieval performance of USGAN and the baselines on MAP, R-Prec, MRR, P@5, 10, NDCG@5, 10, respectively. Statistically significant differences between USGAN$_G$ and best baseline model, UESM, and between USGAN$_D$ and USGAN$_G$ are marked in the upper right hand corner of USGAN$_G$'s and USGAN$_D$'s scores, respectively.

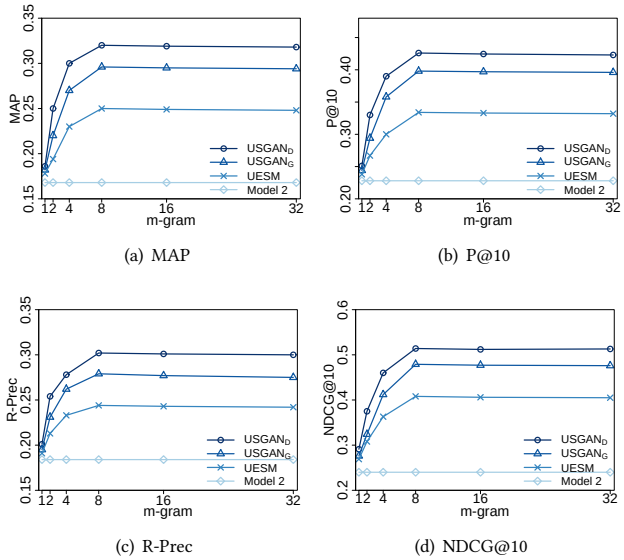
6 RESULTS AND ANALYSIS

In what follows, we discuss and analyze our experimental results and answer the research questions. Subsection 6.1 report the overall performance of USGAN and the baseline methods (**RQ1**); subsection 6.2 investigates how the size of the window (m-grams) impacts the performance of USGAN (**RQ2**); subsection 6.3 investigates the effect of the sampling size, i.e., the value of the parameter H in (10) on the performance of USGAN (**RQ3**); subsection 6.4 illustrates the impact of iterations on the retrieval performance of our generative and discriminative models (**RQ4**); finally, subsection 6.5 shows the performance of USGAN on different test queries (**RQ5**).

6.1 Overall of Experimental Results

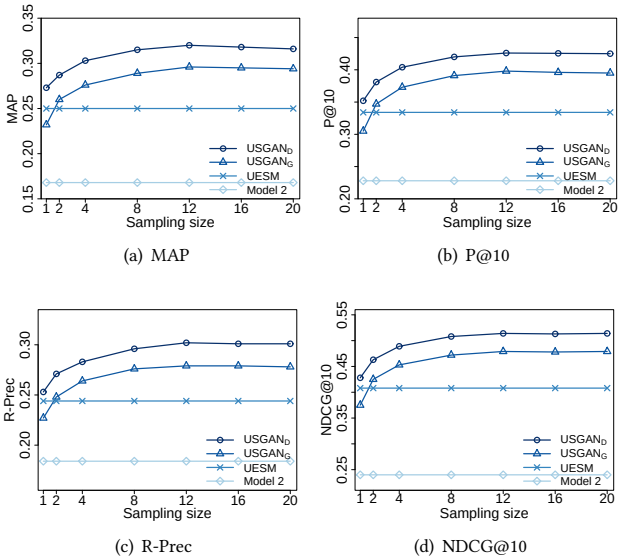


RQ1: We compare the retrieval performance of our USGAN with the baseline methods on the TREC enterprise 2005 and 2006 tracks.

Table 1 reports the performance on all the evaluation metrics. For all these two years' tracks, we have the following findings from Table 1: (i) Both our discriminative model, USGAN$_D$, and our generative model, USGAN$_G$, are able to statistically significantly outperform all the baselines on all the metrics and in both of the two tracks, which confirms the effectiveness of our unsupervised generative adversarial networks for the expert retrieval task and the fact that utilizing the REINFORCE policy gradient can help to obtain optimal parameters during our unsupervised training in Algorithm 1. (ii) All the semantic methods, i.e., USGAN$_D$, USGAN$_G$, UESM, AuthorT, and LDA, outperform non-semantic baseline TF-IDF, which demonstrates that representing experts and words in semantic ways can help to improve the retrieval performance, compared to those directly representing them by words. (iii) Both USGAN$_D$ and USGAN$_G$ outperform the state-of-the-art semantic UESM model, which demonstrates the fact that semantic representations of experts and words obtained by GAN-based algorithms are better than those obtained by traditional deep learning models for the task of expert retrieval. (iv) USGAN$_D$ works somewhat better than USGAN$_G$, which demonstrates that our discriminative model outperforms our generative model. The main reason is because we can directly update the parameter $\boldsymbol{\phi}$ in USGAN$_D$ by stochastic gradient descent, whereas we can only approximately update the parameter $\boldsymbol{\theta}$ in USGAN$_G$ by REINFORCE learning where we need to select top-H discrete candidates.

6.2 Effect of Window Size

RQ2: We vary the size of the window, i.e., the length of m-grams applied in (7) and see how it contributes to the overall retrieval performance. We only report the performance on MAP and P@10 for the TREC 2005 enterprise track as representative, as the plot patterns on other metrics and for the TREC 2006 track are similar. Fig. 1 shows how the expert retrieval performance on MAP and P@10 for the TREC 2005 enterprise track varies against the window size $m = 2^i (0 \leq i \leq 5)$, respectively.



As can be seen from the figures in Fig. 1, there is a significant retrieval performance increase on the metrics with the size of the m-grams from $m = 1$ to $m = 8$ on our models USGAN$_D$, USGAN$_G$, and the baseline UESM, which underlines the importance of the size of m-grams applied in the models. The increase on the metrics implies that the retrieval performance of our models and the baseline model UESM achieved is not solely due to initialization with pre-trained representations of candidate experts and words, but that the models efficiently learn the representations tailored to the problem domain. As the window size of the m-grams increases beyond $m = 8$ the performance of our models, USGAN$_D$

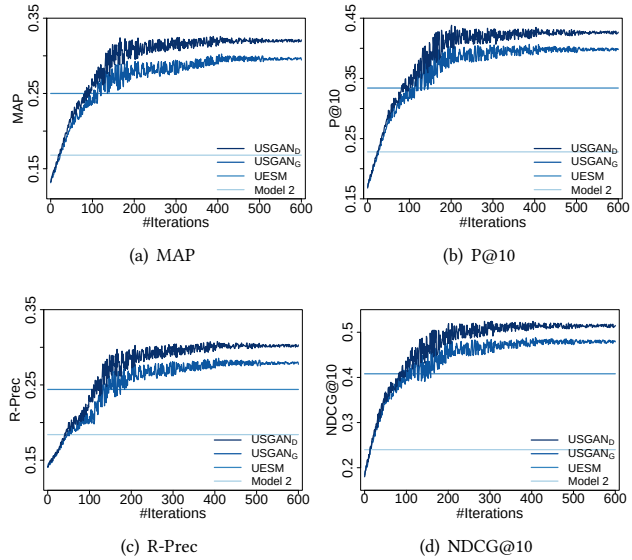
and USGAN$_G$, and the baseline model UESM seems to be level-off. These demonstrate one merit of our USGAN expert retrieval models: they are not sensitive to the window size of m-grams when m is large enough. Other retrieval models, e.g., Model 2, do not consider m-grams for retrieval and thus their performance is consistent over different scales of m-grams. In the next subsection, we report the experimental results with different sampling sizes.

6.3 Effect of Sampling Size



RQ3: To understand the effect of the sampling size, i.e., the parameter H in (10), on the performance of our proposed retrieval model, we vary the size of the samplings H during the REINFORCE learning for updating the parameter $\boldsymbol{\theta}$ in USGAN. In the experiments, as our goal is to yield better expert retrieval performance and to make the iterations converge as fast as possible, for each iteration during the unsupervised training, we choose top-H candidates as the samplings for updating $\boldsymbol{\theta}$.

Fig. 2 shows how the expert retrieval performance varies against the size of the samplings from $H = 1$ to $H = 20$. According to the figures, USGAN$_G$ with the size of samplings being 1 performs a little poorly compared to the baseline UESM that does not need to sample candidates for optimization. This is because one sample is not able to provide enough information for updating the parameter $\boldsymbol{\theta}$ during the REINFORCE learning in our USGAN. USGAN$_D$ with the size of samplings being 1 still can outperforms UESM, and this is because USGAN$_D$ can directly update the parameter $\boldsymbol{\phi}$ by stochastic gradient decent without sampling candidates. There is an obvious performance ascent when tuning the size of samplings from 1 to the optimal value 12, which illustrates the fact that utilizing more top-H samplings for updating the parameter $\boldsymbol{\theta}$ does help to improve the performance when $H \leq 12$. The performance reaches a plato after the optimal number of the samplings $H = 12$. These findings show another merit of our USGAN model: we do not need to sample too many discrete scores, i.e., the top-H candidate experts, at each iteration for the REINFORCE learning, while the model can still perform well. Once again, in Fig. 2 we observe that the retrieval performance of USGAN$_D$ outperforms that of USGAN$_G$ on all the different sampling sizes. This is, again, because the parameter updating strategy of USGAN$_D$ is different from that of USGAN$_G$: USGAN$_D$ directly optimize its parameter $\boldsymbol{\phi}$ with its objective function, whereas USGAN$_G$ needs to leverage REINFORCE learning to update its parameter $\boldsymbol{\theta}$. The baseline model UESM that works with a common neural network does not need to sample candidate experts for parameter updating.

6.4 Impact of Numbers of Iterations

RQ4: To figure out the impact of the number of iterations on the retrieval performance, we plot the expert retrieval performance curves of our USGAN$_D$ and USGAN$_G$ models with different number of iterations from 0 to 600 on representative evaluation metrics MAP, P@10, R-Prec and NDCG@10 in Fig. 3.

As is shown in Fig. 3 before we start the iterations, i.e., the number of iterations being 0, we can still get not too bad retrieval performance that is somewhat a litter worse than that of the baseline language model, i.e., Model 2. This is because we pre-train our USGAN$_D$ and USGAN$_G$ with all documents in $\mathcal{D}$ by (7) (step 2 in Algorithm 1) before we perform the iterations. The performance of both USGAN$_D$ and USGAN$_G$ gradually increase with the iterations increase from 0 to 20. In addition, we can observe that after about 50 iterations, USGAN$_D$ consistently outperforms USGAN$_G$ and such performance gap between them seems to increase with more iterations. These findings again confirm the fact that our updating strategies, i.e., the REINFORCE updating strategy for obtaining the optimal parameter $\boldsymbol{\theta}$ in USGAN$_G$ applied in USGAN and the

stochastic gradient descent updating strategy for obtaining the optimal parameter $\boldsymbol{\phi}$, are effective. The performance of both USGAN$_D$ and USGAN$_G$ dramatically changes up and down between about 120 iteration and 200 iterations. The performance of both models reaches a plato after about 400 iterations, which illustrates another merit of the proposed USGAN: it is not sensitive to the number of iterations once we have performed enough iterations.

6.5 Query-Level Analysis

RQ5: Last, we take an in-depth view of the improvements of USGAN$_G$ over the best baseline (UESM) and USGAN$_D$ over USGAN$_G$ on a per query basis, respectively. We only report the result on MAP and P@10 for the TREC 2005 enterprise track, as the results on other metrics have similar performance patterns. Fig. 4(a) and Fig. 4(b) show the per query AP performance differences between USGAN$_G$ and the best baseline UESM, and between our discriminative model USGAN$_D$ and our generative model USGAN$_G$, respectively; whereas Fig. 4(c) and Fig. 4(d) show the per query P@10 performance differences, respectively. As can be seen in Fig. 4(a), the number of queries on which USGAN$_G$ outperforms UESM is absolutely more than the number of queries on which UESM outperforms USGAN$_G$. Similar patterns can be found in Fig. 4(b) and Fig. 4(d), where the number of queries on which USGAN$_D$ outperforms USGAN$_G$ is more than that the number of queries on which USGAN$_G$ outperforms USGAN$_D$ on the metrics, respectively. These findings further support the conclusion that our unsupervised generative adversarial networks, USGAN$_D$ and USGAN$_G$, are able to retrieve more relevant experts for a given query compared to that of the best baseline model, UESM, and our discriminative model, USGAN$_D$, works better than our generative model, USGAN$_G$.

(a) USGAN$_G$ v.s. UESM on MAP (b) USGAN$_D$ v.s. USGAN$_G$ on MAP

(c) USGAN$_G$ v.s. UESM on P@10 (d) USGAN$_D$ v.s. USGAN$_G$ on P@10

Figure 4: Per-query MAP retrieval performance differences on the 2005 track (a) between USGAN$_G$ and UESM on MAP, (b) between USGAN$_D$ and USGAN$_G$ on MAP, (c) between USGAN$_G$ and UESM on P@10, and b) between USGAN$_D$ and USGAN$_G$ on P@10, respectively. A bar above the line $y = 0$ indicates the former model outperforms the latter model, while the opposite is true for bars below $y = 0$, respectively.

7 CONCLUSIONS

We have studied the problem of expert retrieval in enterprise corpora. We have proposed an unsupervised semantic minimax two-player game, i.e., unsupervised semantic generative adversarial networks (USGAN), for the expert retrieval. Our USGAN consists of a discriminative model and a generative model, and semantically represent both candidate experts and words to alleviate the mismatch problems among queries, documents and candidate experts. The unsupervised training signal for our semantic generative network G is provided by our semantic discriminator network D that is trained to distinguish between candidate experts from G and other potential better candidates. Competition in the game drives both models to improve their exert retrieval performance. Unlike most previous generative adversarial networks-based algorithms that require a large amount of labelled data, we train our USGAN in an unsupervised way to obtain the semantic representations of both experts and words, where we consider the candidate-document associations for the optimization during the training. To obtain optimal parameters in our generative model, we apply REINFORCE policy gradient during the iterations. Importantly, our USGAN goes beyond tackling the expert retrieval task in unsupervised way, as it may provide insight and inspiration on how to extend supervised GAN-based models in unsupervised ways to tackle other tasks where labelled data is missing. We found that our proposed USGAN outperforms all the state-of-the-art unsupervised expert retrieval algorithms, including both semantic or non-semantic ones.

Looking forward, there are many unexplored avenues. For instance, how to extend the supervised standard GAN and its variants

via unsupervised ways to tackle other tasks where no manually labelled data is available? Can we use implicit signals such as clicks of documents into our USGAN to improve performance of document retrieval? Can we apply our USGAN for expert profiling [6, 8, 30, 41] in enterprise corpora?

ABSTRACT

We study the problem of estimating the total volume of queries of a specific domain, which were submitted to the Google search engine in a given time period. Our statistical model assumes a Zipf's law distribution of the population in the reference domain, and a non-uniform or noisy sampling of queries. Parameters of the distribution are estimated using nonlinear least square regression. Estimations with errors are then derived for the total number of queries and for the total number of searches (volume). We apply the method on the *recipes and cooking* domain, where a sample of queries is collected by crawling popular Italian websites specialized on this domain. The relative volumes of queries in the sample are computed using Google Trends, and transformed to absolute frequencies after estimating a scaling factor. Our model estimates that the volume of Italian recipes and cooking queries submitted to Google in 2017 and with at least 10 monthly searches consists of 7.2B searches.

1 INTRODUCTION

The problem of computing the total number of searches (volume) of queries belonging to a specific domain is extremely relevant and, at the same time, challenging. From a business perspective, the total volume $\mathcal{V}$ of queries quantifies the potential market of search engine advertising in the domain. An even more interesting quantity is the total volume $\mathcal{V}_v$ of queries searched at least v times. $\mathcal{V}_v$ quantifies the potential market of queries worth to bid on. Related to the above, the total number of queries N in the domain, or of queries N_v searched at least v times, are also gold nuggets. However, the stream of queries submitted to a search engine is so massive that it is impractical to keep frequency counts of every possible query, particularly of those in the long tail of the distribution.

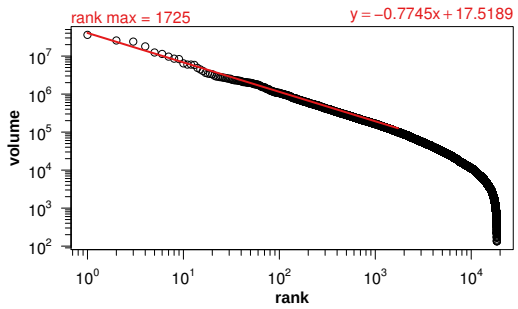

Figure 1: Empirical rank-volume distribution (scaled Google Trends estimates). Best view in color.

Here we study the problem of estimating the total volume of queries submitted to the Google search engine for a specific domain in a given time period. While our method is in principle general, in this paper we apply it to data in the domain of *recipes and cooking*. Such a domain consists of queries with the name of the recipe of a dish, excluding drinks. The advantage over other domains is that it is relatively easy to collect sample recipes and to validate whether a given text is a recipe or not. In particular, we crawled popular websites of Italian recipes and cooking, collecting a sample of more than 120K queries. We then resorted to Search Engine Optimization (SEO) tools, and in particular to Google Trends[1], for obtaining estimates of the volume of each query in the sample for the whole year 2017.

The motivation for the model adopted in this paper comes from the evidence of Figure 1, which shows the empirical rank-volume distribution obtained using estimates of Google Trends. Actually, Google Trends provides relative volumes, not absolute frequencies, thus to find absolute volumes we need to estimate an appropriate scaling factor. This is done by correlating relative volume with ground truth continuous data. We rely on query impression summaries provided by the Google Search Console of a top-ranked website. Indeed Figure 1 reports absolute volumes obtained by rescaling relative ones. The most difficult task in our problem is to estimate the volume of the queries in the population which do *not* belong to the empirical sample. For this reason we do a precise statistical assumption on the rank-volume distribution of the whole population of queries (i.e. observed and unobserved). Our statistical model assumes a Zipf's law distribution of the population, as suggested by the empirical distribution of Figure 1 and previous related work [16]. In order to cope with computational issues, SEO tools may adopt sampling strategies and/or approximated counting techniques, e.g., *count-min sketch* summaries [6, 8], that favor volume

[1] https://trends.google.com

estimation of popular queries against the ones in the long tail of the distribution. This yields the visible drop in volume in the tail of the empirical distribution of Figure 1, with only 18.5K queries being assigned a non-zero volume estimate by Google Trends. We are able to model this behavior by assuming that empirical sampling from the population is not uniform, but it depends on the true rank of a query (*non-uniform* sampling). Moreover, in order to account for approximations in the SEO tool data, we additionally assume that the estimates are noisy, and discuss two specific sampling schemes (*noisy* and *sketchy* sampling). Parameters of the Zipf distribution are estimated using Nonlinear Least Square (NLS) regression. Simulations show such estimators perform better than an alternative approach based on Power law parameter estimation. We derive then estimators of total volumes $\mathcal{V}$ and $\mathcal{V}_v$, and total number of queries N and N_v, including closed formula for statistical errors of such estimators.

In summary, this paper makes the following contributions:

- we formalize the problem of estimating the total volume of queries submitted to a search engine, propose a statistical model which is consistent with empirical data, and infer parameters of the statistical model that perform well under simulated conditions;
- we design a procedure for estimating relative volumes of a set of queries that overcomes the rounding error introduced by Google Trends, and devise a statistical model for scaling relative volumes to absolute ones starting from ground truth SEO data;
- we apply the approach to the domain of recipes and cooking for queries in Italian, and produce estimations for the volume $\mathcal{V}_v$ of queries searched at least v times in 2017.

This paper is organized as follows. First, we report on related work in Section 2. Next, Section 3 states the main problem by modelling the rank-volume distribution of queries as Zipf's law. Section 4 first discusses the impact of non-uniform sampling from a Zipf's law, which is consistent with empirical data. Then, estimators of the parameters of the Zipf's law are introduced, and adopted for estimating the number and total volume of queries in the population. Section 5 describes the approximation introduced by computing relative volumes from Google Trends data, and presents a statistical model for scaling relative volumes to absolute ones. Section 6 describes the available empirical data obtained by collecting Google Trends relative volumes, and applies the scaling method of Section 5 and the estimators of Section 4 to the empirical data. Conclusions summarize the contribution of the paper.

2 RELATED WORK

Pareto distributions and Zipf's laws are ubiquitous in empirical data of many fields [5, 14], and in information retrieval in particular [16]. Several works [2, 3, 10, 16] have observed that the probability that a query is searched v times in a query log is approximately Power law distributed, namely $P(V = v) \propto 1/v^{\alpha}$. This implies (see e.g., [1, 4]) that the the probability that a query is ranked i-th follows a Zipf's law $P(R = i) \propto 1/i^{\beta}$ for $\beta = 1/(\alpha - 1)$. This information on query frequencies/ranks has been used to optimize caching and distribution strategies in search engines and peer-to-peer systems.

There is a huge literature on the estimation of parameters of Power law distributions and Zipf's law. Popular methods [16] have relied on: graphical methods, straight-line approximation, maximum-likelihood estimation. The estimated tail exponent, even in simulated data, significantly depends on the adopted method [12]. A major breakthrough was the method proposed in [5], which consists in a maximum-likelihood estimation, with a cutoff for the fitting region determined with a Kolmogorov-Smirnov test. This method is implemented in the `powerLaw` package [11] of R, which we used extensively in our analyses.

A related stream of literature considers the *unseen species* problem. As originally stated, the problem asks how many biological species are present in a region, given that in an observation campaign a certain number of species with their relative frequency have been observed. In our case, the problem is that we have (noisy) estimates of the frequency of a certain number of queries, and we want to estimate the number of unobserved queries and their frequency. Despite there are several estimators for the unseen species problem (for example, the Good-Toulmin estimator and its extensions [15]), the problem tackled here is different in an important aspect. In the unseen species problem, it is often assumed that in the sample used to build the estimator, the observed frequencies are proportional to the true frequencies in the population. In other words, there is no bias in the construction of the sample. In our approach, the elements of the sample are chosen *ex-ante* and not necessarily the probability of being in the sample is proportional to true frequency.

Google Trends has been widely used for correlating search trends with offline indicators of economic activity, business performance, disease spreading, brand value and awareness, box-office revenue and audience, stock market variability, etc. [17] presents a brief review of the literature. To the best of our knowledge, all works make use of relative volumes only. Their conclusions are stated in relative terms, such as increase/decrease of a searched topic. Here, we first attempt at determining absolute volumes of sample queries, and at inferring how they aggregate over all queries in a domain.

In general, there is little documentation on how SEO tools collect query logs for providing estimates of search frequencies. Google Trends and Google AdWords can rely on Google search engine logs. Similarly for services provided by other search engines. Independent SEO tools (Searchvolume.io, Ubersuggest, Semrush, Keywordkeg, etc.) rely on a more limited user base. [17] compares Google Trends and Baidu Index (restricted to searches from China only), and finds that their estimates are highly correlated. An advantage of Baidu Index over Google Trends is that it provides absolute estimates, not relative ones. For reference domains restricted to searches from China, by using Baidu Index instead of Google Trends, one would save the task of scaling relative to absolute volumes described in Section 5.

3 PROBLEM STATEMENT

Let us assume the population of queries in the reference domain is composed by N queries, and that the rank-volume distribution of such population follows a Zipf's law. Formally, the volume V_i of the i-th most popular query q_i, for $i \in [1, N]$, is:

$$V_i = \frac{c}{i^{\beta}}. \tag{1}$$

The parameters c and β are called the *intercept* and the *coefficient* respectively. The total volume over the population is thus:

$$\mathcal{V} \equiv \sum_{i=1}^{N} \frac{c}{i^{\beta}} = c[\zeta(\beta) - \zeta(\beta, N+1)] \tag{2}$$

where $\zeta(x)$ and $\zeta(x, y)$ are the Riemann zeta and Hurwitz functions, respectively. If N, c, and β are known one can easily determine $\mathcal{V}$. As discussed in the introduction, however, there are several reasons that make this impossible in practice. The problem that we investigate in this paper consists of estimating $\mathcal{V}$ starting from an empirical sample of volumes $v_1, \ldots, v_n$, for $n < N$ sample queries. Without any loss of generality, we assume that the observations are ranked, namely $v_1 \geq v_2 \geq \ldots \geq v_n$.

The problem can be decomposed in two parts: (1) since true absolute volumes V_i are not observable, even for the subset of n queries, we propose a method for estimating them; (2) having a possibly noisy estimation v_i for V_i in a possibly non-uniform sample subset, we consider the problem of estimating the total query volume $\mathcal{V}$, including also the volume of the unobserved queries. Problem (2) is tackled first in the next section, while problem (1) is discussed in Section 5.

4 MODELLING AND ESTIMATION

4.1 Sampling from a Zipf

Starting from the assumption that the volume of the query population follows a Zipf distribution (see Eq. 1), we observe that the empirical distribution in Figure 1 shows a drop of volume in its tail. We intend here to investigate on this. We will consider the effects of different sampling methods from a Zipf's law, and check whether the conclusions are consistent with our empirical data.

Clearly, uniform sampling from a Zipf's law cannot explain the drop of volume in the tail of the empirical distribution. In fact, queries in an empirical sample are rarely chosen uniformly. The approach followed in our reference domain, for instance, relies on collecting recipe names from specialized websites. These typically conduct a keyword research effort in targeting high-volume keywords. As a consequence, our empirical data suffers from an unavoidable selection bias in favor of high-volume queries. A similar bias against very low volume queries is introduced by SEO tools (e.g., Google Trends) used to obtain volume estimates of queries in a sample. In summary, our empirical data is likely to be a non-uniform sampling of the query population. We assume here that sampling depends on the true rank, and call this *non-uniform sampling*. Formally, we assume that the i-th query q_i is sampled with a probability $p(i)$. We want to check whether the observed rank plot obtained by a sample of the population is different from a Zipf's law. To this end, we consider a geometric sampling $p(i) \propto p(1-p)^{i-1}$, i.e., the sampling probability decays exponentially with the rank. For example, if $p = 0.01$, the probability that the query with the largest volume in the population is observed is p, then the second, third, fourth, etc. query in terms of volume will be observed (i.e. sampled) with probability $0.99p$, 0.99^2p, 0.99^3p, etc. Figure 2 shows a numerical simulation with the following parameters[2] of

[2]The choice of β, in particular, has been driven by the empirical distribution of Figure 1.

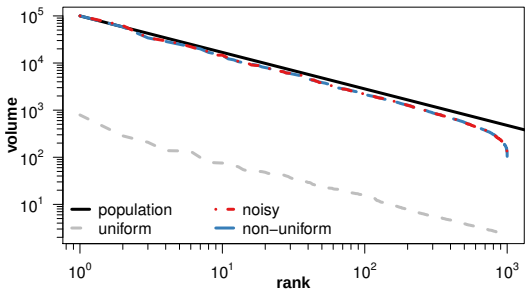

Figure 2: Simulation of sampling from a Zipf's law.

the population:

$$N = 10^6, \quad c = 10^5, \quad \beta = 0.7745. \tag{3}$$

Samples consist of $n = 1000$ queries, and $p = 0.001$ is set for the geometric sampling. The black line is the whole population, the blue line is obtained with geometric sampling while the grey line is obtained with uniform sampling. The non-uniform sampling is consistent with the tail of the empirical distribution in Figure 1.

As a second aspect worth to be considered, we have mentioned that SEO tools typically provide approximated values of the true volume of queries, due to their sampling strategy and computational heuristics in frequency counting. Another source of approximation will be discussed in Section 5.1. Therefore, our empirical data is drawn from noisy values X_i's of the true V_i's. We assume that:

$$X_i = V_i \epsilon_i$$

where ϵ_i are independent noise with common distribution characterized by the same mean μ and variance σ_i^2. Clearly, the presence of noise scrambles the frequencies, thus the most frequent according to X is not necessarily the most frequent according to V. Figure 2 includes also a noisy and non-uniform sample (red line) generated assuming ϵ_i normally distributed, but truncated to 0 to avoid negative V_i's. Parameters are set as follows: $\mu = 1$, i.e., noise is unbiased, and $\sigma_i^2 = 0.01/9$, i.e., 99.7% of noise is in the range $\pm 3\sigma = \pm 10\%$ of the true value. Noisy and non-uniform sampling (hereafter *noisy sampling*) produces an empirical distribution very close to the one of non-uniform sampling and that is also consistent with our empirical data.

A yet another way to model computationally approximated counting, as provided by count-min sketches [6, 8], is to set:

$$X_i = V_i + \gamma_i c$$

where γ_i is uniformly distributed in the range $[0, \gamma]$. In such case, the noise overestimates V_i up to a fraction γ of the top volume $V_1 = c/1^{\beta} = c$. For low volumes, the noise may considerably increase the observed value. However, for a sufficiently low γ, the non-uniform sampling alleviates from this problem, since low volumes are sampled with low probability. We set $\gamma = 0.001$ in simulations. The empirical distribution generated lies in between the ones of non-uniform and noisy sampling. For readability reasons, it is not shown in Figure 2. We call such model the sketchy and non-uniform sampling, hereafter *sketchy sampling*.

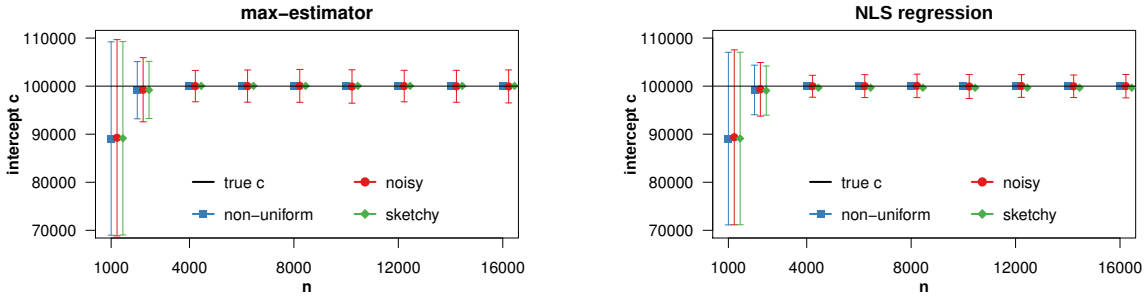

Figure 3: Simulations on estimation of c: error bars (mean ± stdev).

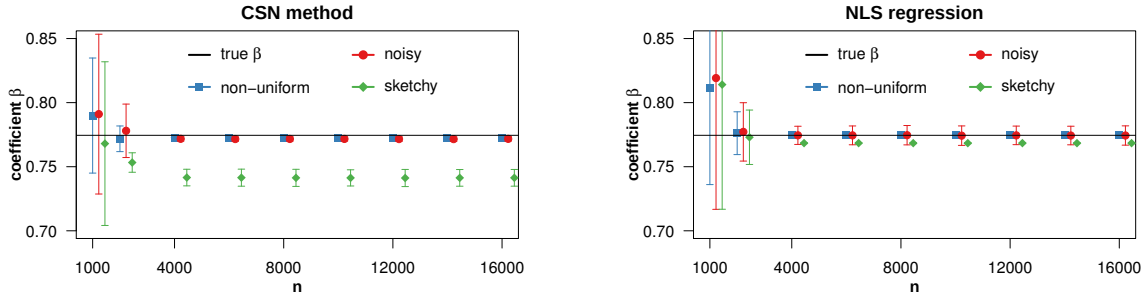

Figure 4: Simulations on estimation of β: error bars (mean ± stdev).

4.2 Estimating β and c

We consider now the estimation of the coefficient β and intercept c in Eq. 1 by exploring two alternative methods for each of them. Regarding the coefficient, we observe that β is the same coefficient of the p.d.f. of the continuous Zipf's law:

$$p_i = \frac{1}{\zeta(\beta)\ i^{\beta}}$$

Thus, we can use the well-known method of Clauset, Shalizi and Newman [5] (hereafter, the CSN method) for estimating the β parameter in Eq. 1. Strictly speaking, [5] is a maximum-likelihood estimator $\hat{\alpha}$ of the α exponent of the Power law of volume distribution, $P(V = v) \propto 1/v^{\alpha}$, from the high-volume tail of empirical data $v_{max} \leq \ldots \leq v_1$. Since in many empirical data the Power law tail is observed only for a range of values, [5] uses a Kolmogorv-Smirnov like test to determine v_{max} which is the optimal value after which the distribution is Power law tailed. Using the well-known relation $\beta = 1/(\alpha - 1)$ between exponents of Power law and continuous Zipf's law (see [1, 4]), we obtain the estimate $\hat{\beta} = 1/(\hat{\alpha} - 1)$ of the coefficient of the rank-volume distribution for top ranks 1 to *max*. The theoretical advantage of this method is that it automatically selects the rank *max* from which to regress the coefficient.

The second estimator of β is to use standard Nonlinear Least Square (NLS) regression of the volume V_i from the rank i. This means that the parameters c and β are those minimizing the sum of squares: $\sum_{i=1}^{M} \left(V_i - \frac{c}{i^{\beta}}\right)^2$, where M is the maximal rank considered in the regression[3]. Since the empirical data follows such distribution for the top ranks, we regress only the top $M = max$ rank-volume data, where *max* is the rank returned by the CSN method. NLS has two advantages over CSN. First, intercept c and coefficient β are estimated together in the same procedure. Second, the regression directly estimates β, while in the CSN method β is estimated with a formula involving the estimator of α. Finally, the second estimator of the intercept that we consider here is the maximum observed value, namely v_1. We call it the *max-estimator* of c. This is motivated by observing that $V_1 = c/1^{\beta} = c$, namely the intercept c is the volume of the top ranked query in the population.

Let us now investigate how these estimators are affected by the non-uniform, noisy, and sketchy sampling from a Zipf's law. Numerical simulations with parameters as in (3), are repeated at the variation of the sample size n for 1000 times and results averaged.

Figure 3 shows that both the max-estimator and the NLS regression converge to the true value of the intercept c. For noisy data, however, there is some error, which is proportional to the noise level (set to ±10%). Variability is slightly lower for NLS regression. Larger error bars can be observed for small values of n. They are due to the chances of not having the highest volume of the population included in the sample. This chance is controlled by the $p = 0.001$ parameter in the geometric sampling. Smaller values lead to larger standard deviation, and, symmetrically, larger values to smaller standard deviation. Thus, in practical settings, the selection of the sample queries must carefully consider the issue of including the most popular queries in the empirical sample. This has been

[3]NLS regression requires to specify initial values for β and c to start with. We compute them using ordinary (linear) least squares (OLS) of the log, i.e. minimizing $\sum(\log V_i - \log c - \beta \log i)^2$. This method cannot be used as an alternative to NLS since it gives too much importance to deviations of low rank queries with respect to high rank queries.

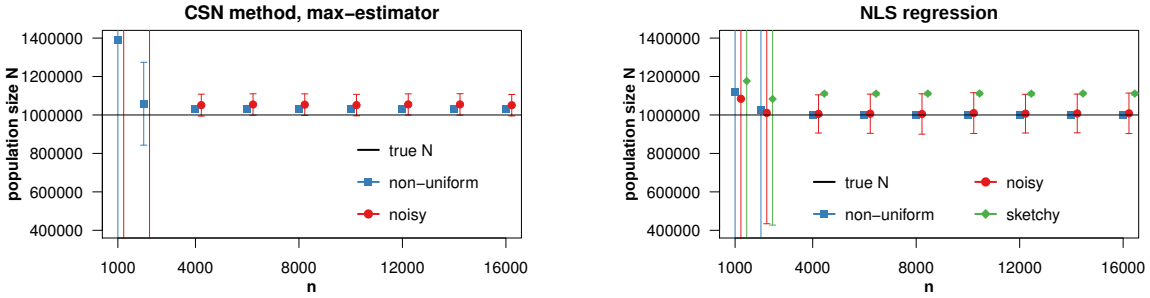

Figure 5: Simulations on estimation of the population size N: error bars (mean ± stdev).

one of our main concerns in collecting queries in the recipe and cooking domain.

Figure 4 shows some differences in the estimation of β. Regarding the CSN method, the estimated values for non-uniform and noisy samplings are slighly lower than the true β. Underestimation in the sketchy sampling case is, instead, considerable. Regarding the NLS regression, it is unbiased for non-uniform and noisy sampling. For sketchy sampling, β is slightly underestimated. Estimations rapidly converge for increasing n's, except for noisy sampling in the case of NLS, and for sketchy sampling in the case of CSN.

Finally, all estimations are weakly dependent on n: starting for samples of 0.4% of the population, they become stable.

4.3 Estimating N

In the following, we will focus on a simple but effective estimator of the size N of the query population. We assume to know V_N, namely the smallest volume of a query in the population. This assumption is realistic for absolute frequencies, since $V_N \simeq 1$. From Eq. 1, for $i = N$, we have $N = (c/V_N)^{1/\beta}$. This motivates the following estimator:

$$\hat{N} = \left(\frac{\hat{c}}{V_N}\right)^{\frac{1}{\hat{\beta}}} \tag{4}$$

where $\hat{c}$ is an estimator of c and $\hat{\beta}$ is an estimator of β. Eq. 4 can be extended to an estimator of the number of queries whose volume is greater or equal than a given value v as:

$$\hat{N}_v = (\hat{c}/v)^{1/\hat{\beta}} \tag{5}$$

Numerical simulations with parameters as in (3) are shown in Figure 5 for: (1) $\hat{\beta}$ obtained by the CSN method and $\hat{c}$ obtained by the max-estimator; and (2) $\hat{\beta}$ and $\hat{c}$ obtained by NLS regression. The first method is biased, showing a slight overestimation for non-uniform and noisy sampling and a large overestimation for sketchy sampling (not shown because exceeding the y-axis limits). The second method converges to the true value of N for non-uniform and noisy sampling (on average), and it slightly overestimates it for sketchy sampling. These findings are intuitive. They follow from Eq. 4, by observing that, if $\hat{c}$ is unbiased (as shown in Figure 3), then the estimator $\hat{N}$ has a bias proportional to the power of $1/\hat{\beta}$. We know from Figure 4 that $\hat{\beta}$ underestimates β for the CSN method or for the sketchy sampling. The only advantage of first method over the second one, is a smaller variability of the estimates in the case of noisy sampling. Again, this is a direct consequence of the smaller variability of β estimates (see Figure 4).

4.4 Estimating $\mathcal{V}$

Building on the estimators and simulations conducted so far, the proposed procedure for estimating the total volume $\mathcal{V}$ is composed of the following steps:

- estimate β and c, as described in Section 4.2;
- use the estimated $\hat{\beta}$ and $\hat{c}$ as inputs for estimating N as shown in Section 4.3;
- the estimator of $\mathcal{V}$ is obtained from Eq. 2 as follows:

$$\hat{\mathcal{V}} = \hat{c}[\zeta(\hat{\beta}) - \zeta(\hat{\beta}, \hat{N} + 1)]$$

Notice that by Eq. 4, the estimator $\hat{\mathcal{V}}$ can be stated using only $\hat{\beta}$ and $\hat{c}$:

$$\hat{\mathcal{V}} = \hat{c}[\zeta(\hat{\beta}) - \zeta(\hat{\beta}, \left(\frac{\hat{c}}{V_N}\right)^{\frac{1}{\hat{\beta}}} + 1)] \tag{6}$$

These estimators can be generalized to estimators of the total volumes of queries with minimum volume v by replacing V_N by v:

$$\hat{\mathcal{V}}_v = \hat{c}[\zeta(\hat{\beta}) - \zeta(\hat{\beta}, (\hat{c}/v)^{1/\hat{\beta}} + 1)] \tag{7}$$

Let us continue the previous numerical simulations. With the settings in (3), it turns out $\mathcal{V} = 9,609,224$. First consider using the NLS regression method in the first step of the procedure. Figure 6 shows that $\hat{\mathcal{V}}$ converges to $\mathcal{V}$ for non-uniform and noisy sampling, and overestimates it for sketchy sampling. For noisy sampling, there is some variability, which is in the order of the noise introduced during sampling (±10%). The overestimation in the case of sketchy sampling follows from the overestimation of N (see Figure 5).

Consider now the case of using in the first step of the procedure the CNS method coupled with the max-estimator. The total volume is slightly overestimated for non-uniform sampling and for noisy sampling. In the latter case, there is some variability, which appears lower than for the CSN method. This can be tracked back to lower variability in the estimation of β (see Figure 4). For sketchy sampling, the overestimation is very large: it is out of the bounds of the plot in Figure 6. Again, this can be traced back to a larger underestimation of β compared to the CSN method.

The impact of biased $\hat{\beta}$ on the estimated total volume $\hat{\mathcal{V}}$ can be readily explained when $\hat{c} = c$ – which holds in simulations, as shown in Figure 3. In Figure 7 we plot Eq. 6 as a function of $\hat{\mathcal{V}}$, under the assumption that V_N is known. The left plot shows

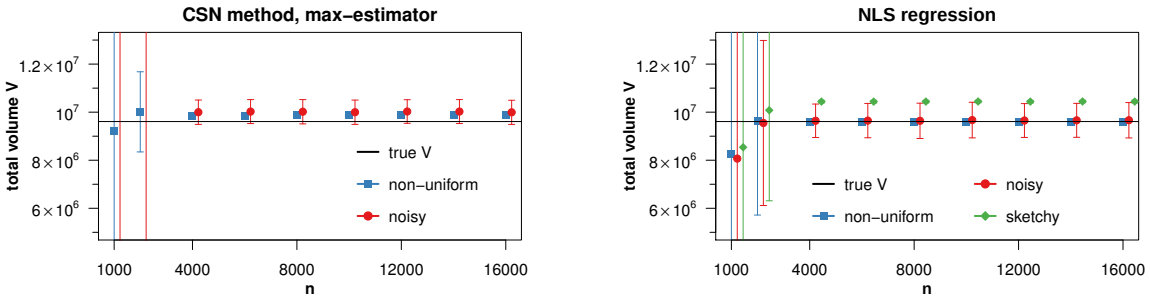

Figure 6: Simulations on the estimation of the total volume $\mathcal{V}$: error bars (mean ± stdev).

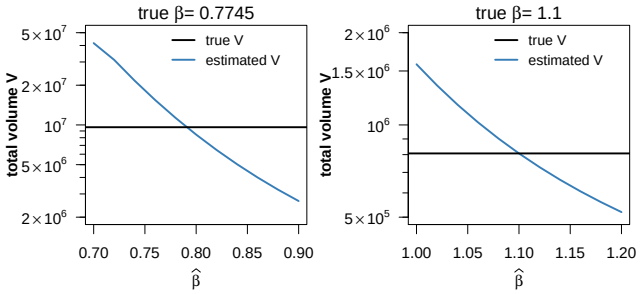

Figure 7: Estimated volume (Eq. 6) as a function of $\hat{\beta}$, assuming $\hat{c} = c$. Simulation parameters: $N = 10^6$, $c = 10^5$, β in title.

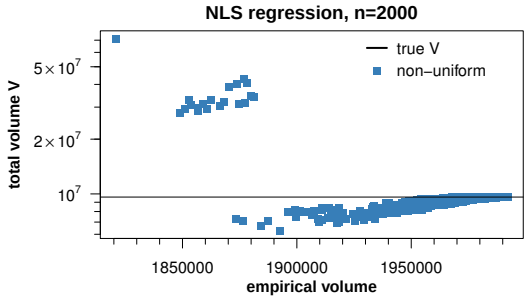

Figure 8: Scatterplot of empirical vs estimated total volume.

simulations for the parameters in (3) used so far. The right plot uses the same N and c, but a β greater than 1. In both cases, the bias of $\hat{\mathcal{V}}$ is inversely proportional to bias of β. Note the log scale in the y-axis, which comes from the fact that β appears as exponent in Eq. 6. For β's lower than 1, error (or variability) of the estimator $\hat{\beta}$ has a greater impact on error (or variability) of $\hat{\mathcal{V}}$ than for β's greater than 1.

In all three sampling models, the performances become stable from $n = 4,000$ on, which is 0.4% of the population. Let us now focus on small sample sizes, for which instead there is a large standard deviation over the experimental runs. Fix $n = 2,000$, and consider NLS regression and uniform sampling. The estimated $\hat{\mathcal{V}}$ is approximately $\mathcal{V} \pm 3.9 \times 10^6$, i.e., the standard deviation is 4 times the (unbiased) average. What is the source of such variability? Figure 8 shows the scatter plot of empirical volume vs estimated total volume over the 1,000 experimental runs. Runs where the generated sample has a low total empirical volume exhibit most of the variability (notice that the y-axis is in logscale). If the total empirical volume is sufficiently large, even small samples converge to the true volume. This reinforces our previous conclusion that, in practical settings, the selection of sample queries must carefully include popular ones, especially for small size samples.

As a summary of the simulations, we therefore recommend using the NLS regression method for estimating c and β, and, using Eqs. 6–7, for estimating $\mathcal{V}$ and $\mathcal{V}_v$.

4.5 Errors on the estimates

We now compute the error on the estimated N obtained from Eq. 4. Using the propagation of errors under the assumption that the errors on β and c are independent, the error on $\hat{N}$ is:

$$\Delta N = \sqrt{\left(\frac{\partial \hat{N}}{\partial \hat{c}}\Delta c\right)^2 + \left(\frac{\partial \hat{N}}{\partial \hat{\beta}}\Delta \beta\right)^2}$$

To have a more conservative estimate of ΔN, taking into account correlations between errors, one can replace the previous formula with the sum of the absolute values:

$$\Delta N = \left|\frac{\partial \hat{N}}{\partial \hat{c}}\Delta c\right| + \left|\frac{\partial \hat{N}}{\partial \hat{\beta}}\Delta \beta\right| \tag{8}$$

The partial derivatives in the previous expressions are:

$$\frac{\partial \hat{N}}{\partial \hat{c}} = \left(\frac{\hat{c}}{V_N}\right)^{\frac{1}{\hat{\beta}}} \frac{1}{\hat{\beta}\hat{c}} = \frac{\hat{N}}{\hat{\beta}\hat{c}}$$

$$\frac{\partial \hat{N}}{\partial \hat{\beta}} = -\left(\frac{\hat{c}}{V_N}\right)^{\frac{1}{\hat{\beta}}} \frac{1}{\hat{\beta}^2} \log\frac{\hat{c}}{V_N} = -\frac{\hat{N}}{\hat{\beta}^2} \log\frac{\hat{c}}{V_N}$$

From these values and the knowledge of Δc and $\Delta \beta$ (obtained from the NLS regression), it is possible to compute ΔN.

The computation of the error on the total volume is a bit more involved. Consider $\hat{\mathcal{V}}$ as a function of $\hat{c}$ and $\hat{\beta}$ (see Eq. 6). To find the error on $\hat{\mathcal{V}}$ we compute its derivatives with respect to $\hat{c}$ and $\hat{\beta}$. We find:

$$\frac{\partial \mathcal{V}}{\partial \hat{c}} = \frac{\hat{\mathcal{V}}}{\hat{c}} + \hat{N}\zeta\left(\hat{\beta}+1, \hat{N}+1\right)$$

$$\frac{\partial \mathcal{V}}{\partial \hat{\beta}} = \hat{c}\left(\zeta'(\hat{\beta}) - \zeta^{(1,0)}\left(\hat{\beta}, \hat{N}+1\right) - \frac{\hat{N}\log\left(\frac{\hat{c}}{V_N}\right)\zeta\left(\hat{\beta}+1, \hat{N}+1\right)}{\hat{\beta}}\right)$$

where $\zeta'(x)$ is the derivative[4] of the Riemann Zeta function and $\zeta^{(1,0)}(s,a)$ is the partial derivative of the Hurwitz function with respect to s. In summary, the error on the total volume is:

$$\Delta\mathcal{V} = \sqrt{\left(\frac{\partial \hat{\mathcal{V}}}{\partial \hat{c}}\Delta c\right)^2 + \left(\frac{\partial \hat{\mathcal{V}}}{\partial \hat{\beta}}\Delta\beta\right)^2}$$

or, more conservatively:

$$\Delta\mathcal{V} = \left|\frac{\partial \hat{\mathcal{V}}}{\partial \hat{c}}\right|\Delta c + \left|\frac{\partial \hat{\mathcal{V}}}{\partial \hat{\beta}}\right|\Delta\beta \tag{9}$$

5 GOOGLE TRENDS: DATA COLLECTION AND SCALING

Google Trends has several advantages over other SEO tools. First, the volumes provided are computed from the Google search engine query logs, and not from unspecified sources which may have unknown forms of bias. Second, data can be aggregated for arbitrary ranges of time and user agent languages. Most of the other tools, instead, provide monthly averages at the time of request, making it impossible to extend an experiment incrementally to new queries. Third, estimates by Google Trends are ratio-scaled, while other SEO tools provide binned values, i.e., ranges of volumes.

On the negative side, the volume provided by Google Trends is relative, not absolute. We then fix one specific query to the conventional volume of 1, and collect estimates of the volume of any other query in comparison to the specific query. Next, we scale the relative volumes to absolute volumes. In the rest of this section, we discuss some approximation introduced by relative volume calculation, and the scaling from relative to absolute volumes.

5.1 Relative volume calculation

A source of approximation in the calculation of the volume from Google Trends raw data is introduced by the computation of the ratio between the volume of a query q and the volume of the pre-fixed query f. In fact, Google Trends provides $v_f^1, \ldots, v_f^{52}$ relative volumes for f, and $v_q^1, \ldots, v_q^{52}$ relative volumes for q, namely two values for each week in our reference time period (the whole year 2017). The largest value among v_f^i's or v_q^i's is conventionally set to 100, and all the others are integers from 0 to 100 set on the basis of their fraction w.r.t. the largest value (hence, the name *relative* volume). In the following, we assume $v_f^1 = 100$ (similar reasonings apply when $v_q^1 = 100$). We aim at defining an estimator for the ratio:

$$r = \frac{\sum_{i=1}^{52} V_q^i}{\sum_{i=1}^{52} V_f^i} = \frac{\sum_{i=1}^{52} 100 \cdot V_q^i/V_f^1}{\sum_{i=1}^{52} 100 \cdot V_f^i/V_f^1}$$

where V_f^i's and V_q^i's are the true absolute volumes of f and q in the i-th week of the year, and $100 \cdot V_q^i/V_f^1$'s and $100 \cdot V_f^i/V_f^1$'s are the true relative (percentage) volumes of q and f respectively. Intuitively, r is the ratio of the total volume of q over the total volume of f. Recall that v_f^i's and v_q^i's are integer numbers. We further assume they round down[5] the true relative volume, namely $v_q^i = \lfloor 100 \cdot V_q^i/V_f^1 \rfloor$ and $v_f^i = \lfloor 100 \cdot V_f^i/V_f^1 \rfloor$. Bounds for the ratio r above are then:

$$\frac{\sum_{i=1}^{52} v_q^i}{51 + \sum_{i=1}^{52} v_f^i} \le r \le \frac{52 + \sum_{i=1}^{52} v_q^i}{\sum_{i=1}^{52} v_f^i} \tag{10}$$

An estimator for r is the central value between the bounds:

$$\hat{r} = \frac{1}{2}\left(\frac{52 + \sum_{i=1}^{52} v_q^i}{\sum_{i=1}^{52} v_f^i} + \frac{\sum_{i=1}^{52} v_q^i}{51 + \sum_{i=1}^{52} v_f^i}\right)$$

Figure 9 (left panel) shows a numerical simulation consisting of 10,000 repetitions. For each repetition, true relative volumes for 52 weeks are generated for $100 \cdot V_f^i/V_f^1$'s and $100 \cdot V_q^i/V_f^1$'s. Then, they are rounded down to obtain v_f^i's and v_q^i's respectively. Finally, the estimator $\hat{r}$ is compared to the true value r. As a parameter of the simulations, while $100 \cdot V_f^i/V_f^1$'s are uniformly generated in $[0, 100]$ (hence, the assumption $v_f^1 = 100$ is satisfied), the values $100 \cdot V_q^i/V_f^1$'s are randomly generated in $[0, 100]$ with total sum equal to a fraction of $\sum_{i=1}^{52} 100 \cdot V_f^i/V_f^1$, namely so that r is set to a desired value. In particular, Figure 9 (left panel) shows lines for $r = 0.8$ (black line), $r = 0.2$ (blue line), and $r = 0.05$ (red line). For non-small r's, the estimator $\hat{r}$ is very close[6] to the true r on average. Variance is small for larger r's. For small values of r, however, the estimator has a positive bias and very large variance. Intuitively, the weight of rounding in the bounds for r in Eq. 10 becomes considerable. Such weight can be kept low if the volumes of q and f are close to each other. For such a reason, our implementation computing the relative volume of a candidate query q consists of first comparing q with the pre-fixed query f. If their estimated ratio $\hat{r}$ is lower (resp., higher) than a given threshold, then another query f' with lower (resp., higher) relative volume is chosen such that the estimated ratio is within an expected range. The search for f' follows a binary search pattern among all queries whose relative volume has been already estimated. If no f' satisfies the condition, the estimation for q is suspended, until some other query f' will subsequently be estimated that meets the constraint. Finally, the volume of q relative to f is calculated as the product of the volume of q relative to f' multiplied by the volume of f' relative to f. Figure 9 (right panel) shows the benefits of this two-steps procedure against the single step comparing q to f. Here, $r = 0.01$ and f' is chosen with relative volume of 0.2, which is 20 times the one of q. In our actual implementation, we are even more strict. We look for an f' such that the ratio of q relative to f' is is between $4/5 = 0.8$ and $5/4 = 1.25$.

5.2 From relative to absolute volume

We tackle now the problem of transforming the relative volumes computed using Google Trends into absolute frequencies. Basically,

[4] $\zeta'(x)$ is available in R, while $\zeta^{(1,0)}(s,a)$ must be computed numerically or with other tools, e.g., Mathematica.

[5] Rounding to the closest integer is another option, which seems not consistent with the results of Google Trends. E.g., in any week series there is only one estimate of 100. Other estimated values are strictly lower.

[6] Strictly speaking, a t-test at 95% confidence level rejects the hypothesis that the mean of $\hat{r}/r$ is equal to 1. The values are however very close for the whole region of explored parameters.

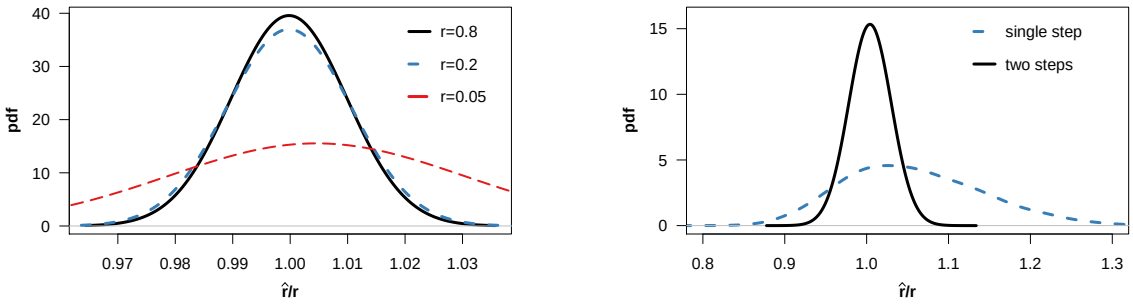

Figure 9: Simulation on estimation $\hat{r}$ of relative volume r of Google Trends. Left: at variation of r. Right: single step vs two steps procedure for $r = 0.01$.

we rely on correlating with absolute volumes provided by an external "ground truth" source. For instance, many SEO tools provide absolute estimations. Commercial tools are supposed to be more reliable than free tools, yet their fees are expensive for a large sample of queries. Moreover, in most cases such tools provide binned absolute estimations. This complicates the statistical correlation model. We consider in this sub-section the case of SEO tools with *continuous* absolute estimations.

As before we consider a sample of n queries, and for the i-th query q_i, let V_i be its true absolute volume. We cannot observe V_i, but we have two related quantities: (1) Google Trends provides a rescaled estimate $X_i = V_i/g$, but g is not known; (2) another SEO tool provides an absolute estimate of the volume of V_i, which we call Y_i. Our objective is to estimate g and therefore the absolute volume V_i. The problem is complicated by two facts: measurements computed from Google Trends are actually estimations of relative volumes (see previous subsection); and, values provided by the other SEO tool are noisy estimates of the true volume. A sensible model taking into account the two sources of noise is:

$$X_i = \frac{V_i}{g\xi_i}, \qquad Y_i = V_i\eta_i$$

where ξ_i are independent and positive error terms due to relative volume estimation[7] and are characterized by a mean value $\mathbb{E}[\xi_i] = \bar{\xi} \simeq 1$ and variance $Var[\xi_i] = z_i^2$. Similarly η_i are independent and positive random variables with mean 1 (i.e., we assume that the other SEO tool is not biased) and variance s_i^2. Note that we are not excluding the possibility that the variance of ξ_i and/or η_i depends on the rank and/or on the volume of a query – since volume of popular queries is easier to estimate. Finally, we will assume that ξ_i and η_j are mutually independent for any i and j. Combining the two expressions we obtain a relation between observable quantities:

$$Y_i = gX_i\xi_i\eta_i \tag{11}$$

Let us consider different estimators of the constant g. In the case of continuous data we compare three of them:

(1) The ratio based estimator defined as:

$$\hat{g}_1 = \frac{1}{n}\sum_{i=1}^{n}\frac{Y_i}{X_i} \tag{12}$$

[7]With the terminology of Section 5.1, ξ_i^{-1} is the rounding error, whose density is shown in Figure 9.

It is easy to show that it has the property:

$$\mathbb{E}[\hat{g}_1] = \bar{\xi}g; \qquad Var[\hat{g}_1] = \frac{g^2}{n^2}\sum_{i=1}^{n}\left(z_i^2s_i^2 + z_i^2 + \bar{\xi}^2s_i^2\right)$$

This estimator has a bias given by $\bar{\xi}$, which can be assumed very small as shown in the previous subsection. Moreover when the sample size $n \to \infty$ it is $Var[\hat{g}_1] \to 0$, i.e. the error on the estimator asymptotically vanishes.

(2) The estimator from the linear regression over the logarithms of the values:

$$\log Y_i = a + b\log X_i + \epsilon_i \tag{13}$$

and then setting $\hat{g}_2 = e^a$.

(3) The estimator from the regression:

$$\log X_i = A + B\log Y_i + \epsilon_i \tag{14}$$

given by $\hat{g}_3 = e^{-A/B}$

In the numerical simulations below we will assume that η_i follows a lognormal distribution, which is positive and has relatively large fluctuations. Given the parameters μ and σ characterizing the lognormal distribution, it is $\mathbb{E}[\eta_i] = \exp(\mu + \sigma^2/2)$ and $Var[\eta_i] = (e^{\sigma^2} - 1)(\mathbb{E}[\eta_i])^2$. In order to have $\mathbb{E}[\eta_i] = 1$, it must be $\mu = -\sigma^2/2$. Moreover we assume for simplicity that $\bar{\xi} = 1$ and $Var[\xi_i] = 0$, i.e. we neglect the approximation error in the calculation of relative volume from Google Trends data. As data generating process, we consider a Zipf's law distribution of the volumes V_i's, with parameters as in (3), and a non-uniform random sampling from it. Also, we consider two noise levels: $\sigma = 0.03$, which leads to a standard deviation of η_i equal to $s \simeq 0.03$; and $\sigma = 0.3$, which leads to $s \simeq 0.31$. Then, we fix $g = 2.75$ and estimate it using the above three estimator for 10,000 runs. Figure 10 shows the densities of the estimated g with the three methods. The ratio based estimator of Eq. 12 performs much better than the ones based on regression and this advantage is larger when the noise term has large variance.

6 EMPIRICAL ANALYSIS

We generated a sample of 120K queries by crawling popular Italian websites about recipes and cooking. The list of websites was compiled with the help of web marketing experts and by looking at

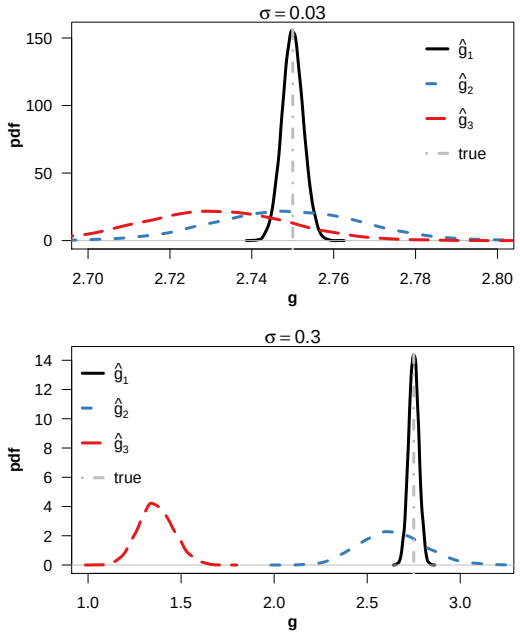

Figure 10: Density estimation of the estimated parameter g. Top plot: small noise. Bottom plot: large noise.

the rankings of SEO tools[8]. We then submitted the 120K queries to a few SEO tools to collect the estimated volume of each query for the reference year 2017 and for Italian user agents. Considering a whole year prevents seasonal bias in data. Query crawling, cleaning, and collection of Google Trends volumes took about 2 months. The process required manual inspection of crawled queries, with a few iterations to correct bugs, to support new hypotheses, etc. Even though the collection of Google Trends data was automated in a script[9], there is a daily bound on the number of invocations to the Google Trends service, which makes such a step time-consuming.

6.1 Google Trends with absolute volumes

We obtained non-zero estimates by Google Trends for about 18.5K queries out of the 120K in the sample. The resulting rank-volume distribution is shown in Figure 1. The remaining queries belong to the long tail, for which Google Trends returns a relative (hence, absolute) estimated volume of zero.

The estimators of the scaling factor g discussed in Section 5.2 require that the absolute estimates provided by an external ground truth are not biased. This assumption cannot be verified in general, e.g., SEO tools do not disclose sufficient information due to IPR restrictions. Since the bias of such tools is unknown, the choice of which one to use for estimating g relies only on the trustworthiness on one specific tool over the others.

Google Search Console[10] (GSC) is a tool that provides to website owners (a.k.a., publishers) summary statistics about the number of impressions and the ranking of the website in Search Engine Result Pages (SERPs). We considered a specific website for which

[8]E.g., https://serpstat.com
[9]We used PyTrends APIs (https://github.com/GeneralMills/pytrends).
[10]https://www.google.com/webmasters

v	$v/12$	$\hat{N}_v$	ΔN_v	$\hat{\mathcal{V}}_v$	$\Delta\mathcal{V}_v$
12	1	269,214,520	± 18,507,467	14,169.58 M	± 827.70 M
120	10	13,770,732	± 815,062	7,171.15 M	± 353.96 M
1,200	100	704,394	± 33,959	3,591.35 M	± 145.83 M
12,000	1,000	36,031	± 1,444	1,760.23 M	± 56.86 M
120,000	10,000	1,843	± 56	823.63 M	± 20.30 M
600,000	50,000	231	± 5	457.12 M	± 9.06 M

Table 1: Estimated N_v and $\mathcal{V}_v$ for queries with at least v searches in 2017. $v/12$ is the monthly average of v.

we had access to its GSC statistics. The website ranked about first in 2017 for 41 queries belonging to our sample. For such queries, the absolute volume is then equivalent to the number of impressions reported by GSC. In summary, we have ground truth volumes (or very close to it) for such set of queries. Using the estimator of Eq. 12, we found $\hat{g}_1 = 6,466.6$, that is the pre-fixed query with relative volume 1 was searched 6,466.6 times in the whole 2017 year, i.e., an average of 538.9 times per month. Figure 1 shows the rank-volume distribution where relative volume X_i has been scaled to $V_i = X_i \cdot \hat{g}_1$.

A drawback of using GSC is the low number of ground truth queries, only 41. As a second option, we consider the well-recognized SemRush[11] tool. We were able to collect volume estimates for 1,688 queries in our sample, using the paid service version of the tool. The resulting estimated scaling factor $\hat{g}_1 = 6,114$ is very close to the one obtained from GSC data.

6.2 Estimation of total query volume

Let us now apply the estimation model designed in Section 4 to the empirical data of Google Trends volumes scaled using GSC data. As shown by the red line fit in Figure 1 (left panel), the NLS regression estimates[12] are:

$$\hat{\beta} = 0.7745085 \quad \hat{c} = e^{17.5189} = 40,584,860.$$

Their statistical errors are moderately low:

$$\Delta\beta = 0.002490065 \quad \Delta c = 199,263.$$

We can now use Eq. 4 for estimating the number N_v of queries having a volume of at least v, using Eq. 8 for calculating the statistical error ΔN_v. Similarly, Eq. 7 can be used for estimating the total volume $\mathcal{V}_v$ of queries having a volume of at least v, and Eq. 9 for calculating its statistical error $\Delta\mathcal{V}_v$. Table 1 reports the estimates for a few values of v. As a means of comparison, the total empirical volume of the 18.5K queries in our sample amounts at 1,057M searches. Such a large number is consistent with the fact that the sample is not uniform, but highly ranked queries are more likely to be in the sample. Moreover, it also gives confidence that the sample is sufficiently large (as per empirical volume) to correctly estimate the true volume. According to the simulations of Section 4, the values $\hat{N}_v$ and $\hat{\mathcal{V}}_v$ may overestimate the true N_v and $\mathcal{V}_v$ respectively, if some sketchy approximation is introduced in the query volume data by Google Trends (or by any other SEO tools we might haved used in place of it). In case of noisy data,

[11]https://www.semrush.com
[12]The figure also shows the rank $max = 1725$ determined with the CSN method. The NLS fit is considered for the top max queries.

instead, under or overestimation may occur. The amount of such errors depend on the unknown amount of approximation or noise in the Google Trends data. Moreover, it is worth to stress that the reported statistical errors do not take into account such noise, but only the error of the parameter estimation procedures (assuming noiseless data).

7 CONCLUSIONS

We studied the problem of estimating the total search volume of queries belonging to a specific domain. By doing the sensible assumption that the unobserved rank distribution of absolute volumes follows a Zipf's law, our method can be decomposed in two parts. First, by comparing Google Trends data with results from SEO tools, we convert the relative volumes obtained from Google Trends for a subset of queries into absolute volumes. Second, we use the estimated absolute volumes of the subset of queries to infer the total volume of the queries of the domain. In doing this, we carefully took into account different sources of error (round-off by Google Trends and observational noise). We were also able to find the total number and the total volume of the queries in the domain which have been searched at least v times in a given time period. A large set of numerical simulations have supported the validity of our methods. Finally, we presented an empirical application to the estimation of the volume of the domain *recipes and cooking*, providing also error bars for the estimates. This kind of information is extremely useful in web marketing research and advertising.

The *first critical issue* for extending our analysis to other domains consists of checking the hypothesis that the population of queries in the domain is Zipfian. As shown in Figure 1, empirical data on the domain of recipes and cooking appears to be Zipfian. This motivated our assumption that the reference population, namely the queries searched in a reference domain, follows a Zipf's law. Ref. [9] points out that the granularity and extent of a reference population should exhibit a "coherence" property. This is particularly relevant, since splitting or merging two Zipfian sets does not necessarily yield another Zipfian set, hence the actual definition of what is and what is not in a domain is essential in meeting our assumption. The domain considered in this paper has well-defined boundaries that make it reasonably coherent.

The *second critical issue* is the construction of the sample set of queries. As shown by the numerical simulations, the capability of inferring the total volume significantly depends on the ability of selecting in the investigated sample queries which have likely high rank in the population (this is related to the parameter p in the non-uniform sampling). This set can be constructed either by resorting to domain's experts or, as we did in this paper, by crawling a set of specialized websites. Finding estimators which are (more) robust to the choice of the sample of queries is certainly an interesting potential extension of our approach to the case when it is costly or unfeasible to construct controlled samples.

The *third critical issue* is concerned with understanding which type of noise is likely to be present in empirical data provided by Google Trends or other SEO tools. In this paper, we considered three possible scenarios: uniform sampling alone, or together with normally distributed noise (noisy sampling), or together with count-min sketch like approximation (sketchy sampling). Other scenarios can be conceived, e.g., noise due to data anonymization [7, 13]. Further work is necessary to test which scenario fits better for a given SEO tool.

Finally, the *fourth critical issue* in our approach is which SEO tool to use for collecting volume of queries in the empirical sample. We relied on Google Trends, which provides relative volumes, and had to resort to GSC or other SEO tools as ground truth for determining a scaling factor. An alternative is to use SEO tools directly for collecting empirical absolute volumes. There are limitations of such tools which motivated our choice of using Google Trends – see beginning of Section 5. One of the issues is that they provide binned data. This means that the estimators of c and β might have to be reconsidered, e.g., by resorting to extensions of the CSN method to binned data [18].

ABSTRACT

Roughly one in ten Americans move every year, bringing significant social and economic impact to both the places they move from and places they move to. We show that migration intent mined from internet search queries can forecast domestic migration and provide new insights beyond government data. We extract from a major search engine (Bing.com) 120 million raw queries with migration intent from 2014 to 2016, including origin and destination geographies, and the specific intent for migration such as whether the potential migration is housing or employment related. Using these queries, we map U.S. state level migration flows, validate them against government data, and demonstrate that adding search query-based metrics explains variance in migration prediction above robust baseline models. In addition, we show that the specific migration intent extracted from these queries unpack the differential demands of migrants with different demographic backgrounds and geographic interests. Examples include interactions between age, education, and income, and migration attributes such as buying versus renting housing and employment in technology versus manual labor job sectors. We discuss how local government, policy makers, and computational social scientists can benefit from this information.

1 INTRODUCTION

Every year over 32 million Americans, about 10% of the total population, migrate from one location in the United States to another [34]. The inflow and outflow of domestic migration can have substantial economic, political, and social impact. Because of this, many cities and states track and analyze migration data closely, looking to inform policies designed to retain existing residents and attract domestic migrants from other regions. For example, the Vermont General Assembly recently passed legislation that pays remote workers $10,000 if they move to Vermont from other states [50]. Even among states such as Texas and Arizona that have no difficulty attracting migrants, improved migration measurement and forecasts can aid development and planning related to local housing and job markets.

To track domestic migration in the United States, state governments and other interested parties rely almost exclusively on two migration datasets from the federal government [48], one from the American Community Survey (ACS) and another from the Internal Revenue Service (IRS). Both have limitations that might be mitigated by incorporating signals from large scale, naturalistic sources such as internet search queries. Most importantly, ACS and IRS data typically take two years to collect, prepare, and publish, forcing the consumers of these data to base current decisions on past, rather than fresh, measurements. Also, because ACS utilizes survey methods, the resulting data are based on a comparatively small samples, resulting in larger margins of error for smaller regions. IRS migration data, on the other hand, are derived from tax return records. People filing tax returns from a different state than they did the year prior are assumed to have migrated. While this method has a considerably larger sample size than ACS, it is subject to population biases, as it underestimates the migration of poorer, wealthier, and elderly citizens, all of whom may file taxes less frequently [29].

In terms of why people move, in over a century of research on migration, scholars have identified *housing* and *employment* as the two key motivators for moving [4, 30, 35, 69]. Prior research has demonstrated the predictive power of internet search in forecasting housing and jobs related measures. For instance, Wu and Brynjolfsson enhanced prediction of housing demand using Google searches [68]. Likewise, search queries have been used to "nowcast" unemployment rates [3] and job search interests [13]. Thus given how central the internet is in helping people find both jobs and housing, we explore whether internet search data can be used as a signal for forecasting and explaining domestic migration, with a focus on housing and employment as primary drivers of intent to migrate.

Using data from Microsoft's Bing search engine, we extracted and assessed the value of search queries from people researching potential moves. Drawing on theories from migration studies and the web search literature, we designed a highly accurate migration query filter that performs two tasks: it retrieves queries expressing the intent to migrate with F_1 score of 0.880, and it categorizes each query into specific types of migration intent, such as whether it indicates housing or employment needs. Using 120 million raw queries containing migration intent from 2014 to 2016, we show that these internet search data provide a meaningful measurement of migration when validated against core government migration

statistics. We further show that adding search-based variables to a model can improve its predictive power at forecasting future net migration flow at the U.S. state level, compared to two well-established and strong baseline models from migration literature. Finally, we examine the explanatory power of migration search data through the lenses of demography and geography, showing how an analysis of the different categories of migration queries (e.g., housing versus job, renting versus buying, technology versus manufacturing jobs) offers new insights beyond what government data provide.

In summary, this paper contributes a novel approach to domestic migration measurement and forecasting that utilizes search query data that are larger in scale, more timely, and more nuanced in explanation than current government migration data. Although we focus our analysis on the United States, we expect the approach would generalize to any region with reasonable internet penetration.

2 RELATED WORK

2.1 Motivation for Domestic Migration

Theories from migration studies have suggested that the needs for housing and employment are two forces that drive domestic migration. Researchers have conceptualized migration as a search and matching process [19, 48, 59] in that prior to actual moving, migrants are constantly searching for places that maximize the net benefit of moving. In particular, housing and employment are two of the most important factors when considering the benefits of moving [4, 30, 35, 69]. That is, on the one hand, people are willing to move to places with better job opportunities [15, 38], while on the other hand, the costs of housing could motivate or limit migration to certain areas [9, 36]. Although there has been debate on whether housing leads employment in motivating migration or vice versa [45, 49, 62], the consensus is that migrants almost inevitably need to search for both of them in their migration activities [48].

Empirical results from census surveys reaffirm that migrants are motivated by housing and jobs. According to the latest *Reason for Moving* report published by Census Bureau [33], employment-related reasons and housing-related reasons motivate nearly 68% domestic migrants. Although the report also shows that family-related reasons motivate 30% migrants, closer examination [32] reveals that some of the family-related reasons directly involve housing activities, including "To Establish Own Household."

As such, given how housing and employment are central in domestic migration, we consider housing and job as the most relevant topics when defining search queries with migration intent.

2.2 Macroeconomic Forecasting Using Search

With the internet becoming the default channel to search for information, economists and computer scientists have used search queries to model macroeconomic measurements that previously were available only through government and financial agencies, including phenomena such as car sales [16] and the stock market volumes [5, 54, 55]. Housing and employment demand, again two macroeconomic factors highly relevant to migration, have also been successfully modeled with internet searches. Most prior work relies on Google Trends, which are normalized, aggregated query volumes for particular keywords and entities. Google Trends data have also been used, for example, to forecast unemployment rate for both U.S. [16, 20, 22] and other countries [52].

Similar work has been done to predict housing trends. Wu and Brynjolfsson [68] have shown that search frequencies from Google could enhance the prediction of the Housing Price Index (HPI) on both national scale and local scale. McLaren and Shanbhogue [46] have used a similar approach to nowcast housing market dynamics in UK. Finally, other projects have sought to go beyond predicting macroeconomic measures to understanding socioeconomic drivers and effects, such as the relationship between searches for different types of jobs and searchers' demographics [13].

Taken together, this body of work provides us confidence about the applicability of search query based data to accurately model demand for housing and employment, the two key motivations related to migration. Methodologically, we were also able to leverage keyword dictionaries established in this prior work to distinguish employment and job related migration search queries.

2.3 Identifying Migrants with Internet Data

Most relevant to our work, a number of studies from computational social science have used internet data to identify migrants. The first type of work does so by mining personal digital traces on social media platforms. Using Twitter data, Zagheni et. al. [70] identified migrants as those whose geolocated tweets exhibit several distinct geographic clusters chronologically. Later work by Fiorio et. al. [24] also used Twitter data to identify and distinguish between short-term movers and long-term migrants. The location field in online profiles from other social network platforms, including Google+ [47], Facebook [51] and LinkedIn [2], have also been exploited to identify migrants. Finally, by using IP address data from Yahoo!'s 100 million email users, researchers identified international migrants and studied their migration patterns across many demographic attributes [67, 71].

However, as the data collected from this prior work only identified migrants *after* they moved, they only shed light on existing migration trends and will be less useful in forecasting migration. Decision makers who rely on this information can not prepare themselves beforehand. Moreover, previous methods that use open-access data from Twitter can only collect data for a small percentage of migrants, which limits their ability at accurately predicting national level migration statistics. [70].

By mining large scale search queries, our approach has two advantages over prior work. First, search queries usually precede actual migration, offering a unique advantage for prediction. Second, the content of the search queries offers additional insights into the specific types of demand (e.g., housing or job related) that can indicate economic impact to local markets.

3 MIGRATION QUERIES FILTER

In this section, we define *migration queries* in the context of this paper. We then describe how we design a filter to accurately extract migration queries from a larger pool of search queries.

3.1 Defining Migration Queries

Formally, we define migration queries as *housing or employment queries that explicitly target a destination geographic unit different*

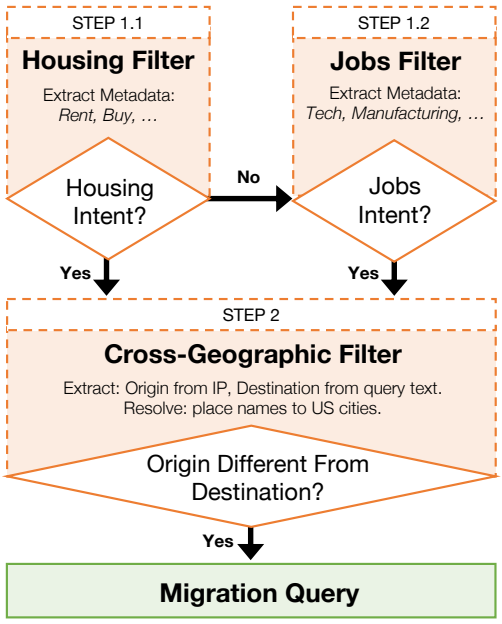

Figure 1: Simplified flowchart of our migration query filter.

from the origin of the query. Our emphasis on housing and employment queries is driven by the theories from migration literature (see Related Work) in which housing and jobs are two major reasons for moving. In the context of search queries, housing and employment keywords make the intent to migrate more apparent. For instance, the housing related term "apartments" in a query such as "apartments in Boston" that originated from Phoenix raises the likelihood of an intended move from Phoenix to Boston.

An important component of our definition is the notion of "geographic unit". Migration researchers usually select relatively large geographic units, including county, metropolitan statistical area (MSA), core-based statistical area (CBSA) and state [48]. However, empirically we observed that housing and employment queries often mention the more specific geographic units (e.g. "apartment to rent in DC", "software engineer job in San Francisco") than those that are used in migration studies. This trend is particularly prominent for housing queries that target a big metropolitan area where certain cities or even neighborhoods within that MSA function as residential areas. As such, we decide to focus on *county*, *city*, and *zip code* in the migration query retrieval process (detailed below) and then later aggregated them to larger geographic units (states) used in the analyses. We also note that our definition requires an explicit mention of the geographic unit in the query. We do so because housing or job queries without mentioning geography, such as "data scientists jobs", "apartment near me" are more likely to be local rather than migration related.

3.2 Design of the Filter

Before we detail the implementation of the migration query filter, we discuss two high-level challenges that influence many specific design choices. First, our task requires identifying *both* the topic and the destination geography of the query, a problem not seen in previous work. As such, we can't leverage a readily available search trend product such as Google Trends since its statistics are not segmented by query destination, and instead must filter raw queries. This presents the second challenge: processing an enormous amount of data.

To address the first challenge, we divide the task into extracting housing and jobs topics and extracting place names. We leverage prior studies that use housing and jobs related search queries (e.g. [13, 16, 68]) to guide our selection of keywords. For extracting geography, we turn to the literature of toponym disambiguation [7, 8, 60]. While different approaches exist, an external knowledge source, such as gazetteers or Wikipedia, usually serves as the foundation to more advanced methods [18, 66], and often times provide a competitive baseline accuracy [60]. As such, we adopt a straightforward gazetteer approach to build our geography extractor which will be detailed below. To address the second challenge of large data volume, our design prioritizes *run time* over complexity and *precision* over recall. As such, we employ rule-based filters and avoid machine learning approaches whenever possible. However, we show that our accuracy is comparable to prior work that implements machine learning based filters.

Figure 1 presents the detailed implementation of our migration query filter. After filtering out abnormally long queries, each raw query is first passed through a housing query filter (Step 1.1). To implement this filter, we leverage the keywords from prior work that uses housing search queries to forecast housing sales [68], which includes "real estate", "apartment", "property", "house" etc. Notably, we expanded these keywords by adding the names of popular housing websites such as "zillow" and "redfin." Known as "navigational queries" in the web search literature [6], search queries containing these websites also indicate users' intention for housing information. Specifically, we added the names for the top ten housing websites according to rankings from Alexa.com. If a query is identified as a housing query, our filter identifies whether the user's intent is to *buy* or *rent* housing by looking for the existence of terms such as "prices", "sale" (for buying) and "rent", "rental" (for renting). These housing queries are saved for location extraction, which will be described below.

Non-housing queries are subsequently processed by a jobs query filter (Step 1.2). We took a similar approach to construct a set of keywords to identify job related migration searches. First, we obtained the specific keywords for 14 job categories that were used in [13]. In a later analysis, we focus our attention on four of these categories: Science, Technology, Manufacturing, and Transportation. Similar to the housing query filter, these topical keywords were expanded with navigational search terms that refer to top 10 job search websites from Alexa.com, including "indeed", "monster" etc.

If a query is either a housing query or job query, it's transferred to Step 2 to extract and compare the origin and the destination geography. While the origin of the query is contained in the reverse-IP look up results, which was provided to us as part of the query data sample, extracting the destination of the query is non-trivial. As we discussed earlier, we leveraged a gazetteer to identify the reference of cities, counties and zip codes in the query. While the zip code and county names are straightforward to obtain, cities are ambiguously defined in U.S. geography. We adopt the Census definition of "place", which is most similar to scale of a colloquial "city" [26] and includes

	#	%	Example queries
Housing	100,123,000	83	"condo in san francisco", "home for sale in maricopa county", "apartment in santa clara, ca"
↪ **Buy**	39,095,000	39	"home for sale in maricopa county", "house price 20500", "duplex for sale in chicago"
↪ **Rent**	32,144,000	32	"apartment for rent in seattle", "house for rent in texas city, texas", "apartment for rent 60231"
Jobs	20,890,000	17	"jobs in st paul", "software engineer jobs in mountain view", "accounting jobs in cook county"
↪ **Sci/Tech**	204,000	1	"software engineer jobs in mountain view", "jobs in r&d in boston", "sql dba jobs in tampa, fl"
↪ **Mfg/Transp**	719,000	3	"van driver job in santa clara ca", "schoolbus driver jobs in king county", "cdl jobs in philadelphia"
Total	121,014,000		

Table 1: Distributions and examples of migration queries. Number are rounded and content is very slightly altered for privacy reasons. Percentages for sub-type queries are normalized by all housing or all jobs queries accordingly.

both Incorporated Places and Census Designated Places. In total, we extracted over 20,000 such names.

When matching these place names to the query content, an additional challenge is the ambiguity problem. For example, there are over 30 cities named "Franklin" in the United States. To increase the precision, we took a two step approach. First, for the largest 50 cities in the U.S. we assume the city name refers to that city (e.g., "chicago" in the query "biotech jobs Chicago" refers to Chicago, IL). For smaller cities, we disambiguate with a state name or abbreviation (e.g., "biotech jobs Portland ME") if one is present in the query and adjacent to the city name. In the second step, queries containing names of smaller cities that lacked an accompanying state name or abbreviation were post-processed by Bing's own location disambiguation service. This disambiguation process breaks the query into n-grams, identifies location names, and then provides a ranked list of the most likely matching locations using features such as the popularity of the location and proximity to the origin of the query (as determined by the reverse-IP look up). Using this, we chose the query destination to be the the top ranked result returned by the disambiguator. Generally, this process conforms to how search engines interpret location queries, and how users behave after they understand search engines' interpretations. For instance, users typically know to specify the state of a city when that city is small or is not in their immediate locale. Finally, we compare the origin and destination on *state* level for the purpose of analyses (detailed later) and extract queries whose origin states are different from destination states as migration queries.

3.3 Evaluation and Filtering Results

We conducted a lightweight evaluation of our migration query filter before deploying it on all queries. We first developed a test set by collecting 500 housing and job queries as identified by Step 1.1 and Step 1.2 in Figure 1. We used this as our test set rather than a random sample from all queries because migration queries are only a small percent of all queries. Two researchers coded the 500 queries as either *migratory* or *non-migratory* according to the definition of migration queries. For samples with disagreement, the researchers discussed and reached consensus on a label. Coding results show 92 migration queries among these 500 housing and jobs queries.

Comparing these human labels to the results of our migration query filter indicates generally strong classification results. Our filter achieves high performance on all metrics, including precision (0.870), recall (0.891), F1 score (0.880) and accuracy (0.880). We note that our filter's performance is comparable to prior work that filtered search queries into job categories [13]. We applied this filter on a large sample of queries from 2014 to 2016, yielding just over 121 million migration queries in total (see Table 1). Among these, 83% are housing-related and 17% are job-related. Among housing migration queries, we observe a roughly equal amount of buy-specific and rent-specific queries. Among job migration queries, there are three times as many Manufacturing and Transportation related migration queries as there are Science and Technology related queries, which is consistent with prior work [13].

4 FINDINGS AND INSIGHTS

The data collection and filtering pipeline described above produced a corpus of more than 120 million migration queries from 2014, 2015 and 2016, each categorized with information about its origin state, destination state and specific types of migration intent. In this section, we detail our analyses and findings, organized into three parts. First, we validate our migration queries against external government statistics, showing that our data are highly correlated with core migration measures. Second, we prove that adding variables derived from these queries enhances the prediction of migration measurements over two robust baseline models from the migration literature. Third, we demonstrate that by extracting categorical descriptors of the type of query, such as whether it is about housing or jobs, we are able to shed light on the differential demands of migrants from varied demographic backgrounds and geographic interests.

We conduct all comparisons to government measures using data from the *American Community Survey* (ACS), focusing on migration between the 50 states, excluding the District of Columbia. ACS data is chosen for the following reasons. First, among all popular government migration data sources, only ACS provides migrants' detailed demographic information, which allows us to understand how migration-related search demands vary across different demographics. Second, despite being only a 1% sample of the total population, ACS has shown to be equally accurate to IRS migration data, which cover 87% of American households, on many important migration measures [48]. We focus on the state level because it is a popular aggregation unit used in the traditional migration literature (e.g. [12, 27, 53, 61, 64]) and because it bears smaller sampling errors compared to finer-grained units of aggregation.

Since state-level migration data are geographic data, we tested for the existence of spatial autocorrelation. Spatial autocorrelation describes a well-known phenomenon in spatial data that measurements taken at nearby locations tend to be correlated [43], which

	Inflow Correlations		
	Migration 14	**Migration 15**	**Migration 16**
Queries 14	0.72	0.78	0.75
Queries 15	0.67	0.73	0.73
Queries 16	0.65	0.71	0.73
	Outflow Correlations		
	Migration 14	**Migration 15**	**Migration 16**
Queries 14	0.32	0.59	0.60
Queries 15	0.26	0.53	0.52
Queries 16	0.21	0.46	0.44
	Netflow Correlations		
	Migration 14	**Migration 15**	**Migration 16**
Queries 14	0.11	0.55	0.58
Queries 15	0.06	0.45	0.59
Queries 16	0.13	0.42	0.61

Table 2: Correlations between migration rates and migration queries by year for inflow, outflow, and netflow respectively.

violates the independence assumption that underlies many statistical tools. We followed the state-of-the-art procedure for testing spatial autocorrelation in [21, 65], finding weak to no spatial autocorrelations on all variables used in our analyses (defined below), and thus we maintain use of conventional statistical approaches.

4.1 Correlations with migration statistics

In this section, we validate our query-based migration measures. To do so, we examine the relationship between the volume of migration queries and three core migration measures from government: (1) inflow migration rate, which is the number of people who move into a specific state in a year, normalized by the state population; (2) outflow migration rate, which is the number of people who move out of a specific state in a year, normalized by the state population; and (3) net migration rate, which is the difference between inflow and outflow migration rates. These measures are used widely in many social science studies [10, 12, 61] and are the primary indicators of the nation's overall migration status. Although they are estimated annually by different federal agencies (e.g. ACS and IRS), there is typically a two year lag time to publication. For the time periods considered in this paper, these measures typically were in the low single digit range per state. For example, in 2016, the net migration rate varied from -1.5% in Alaska to +1.2% in Arizona. Search volumes that correspond to these three measures are also normalized by state population.

Pearson's correlation coefficients between these three core migration measures and their corresponding search volumes (normalized by state population) are shown in Table 2. These results suggest two themes. First, we observe generally high correlations between the official migration measures and the volume of migration queries. Among the three migration variables, migration search queries are most accurate at measuring inflow migration, with a mean correlation coefficient of 0.72 and standard deviation of 0.039 ($\mu = 0.72$, $\sigma^2 = 0.039$). Figure 2 shows a scatterplot of inflow migration rate in 2015 and inflow migration queries in 2014, controlling for state

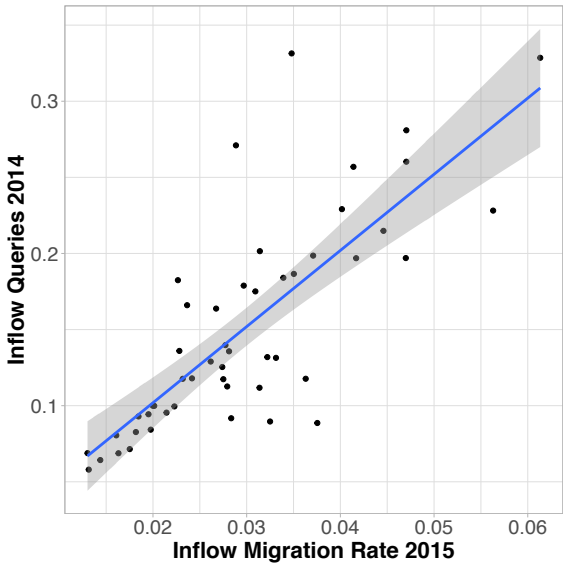

Figure 2: Incoming migration queries in 2014 and actual incoming migrants in 2015, both normalized by state population. Each point represents a U.S. state. Shaded area indicates 95% confidence interval of the linear regression.

population, with a strong linear relationship between migration queries and actual migrants. The correlation coefficients are lower for outflow ($\mu = 0.44$, $\sigma^2 = 0.14$, per Table 2) and net migrations ($\mu = 0.39$, $\sigma^2 = 0.22$, per Table 2). There are at least two possible explanations for these lower correlations. First, the origin states that are used to aggregate outflow migration are inferred by reverse-IP location, which might be less accurate than the destination states that are directly extracted from the query. Second, it is possible that the 2014 ACS outflow migration measure is an outlier, thus lowering the overall correlation. The outflow migration measure from ACS in 2014 have considerably lower autocorrelation with the same variables from 2015 ($r_{out14,out15} = 0.90$) and from 2016 ($r_{out14,out16} = 0.79$) compared to the equivalent autocorrelation for inflow migration ($r_{in14,in15} = 0.98$, $r_{in14,in16} = 0.96$). If only considering 2015 and 2016, our search queries present medium to strong correlations with the outflow migration ($\mu = 0.52$, $\sigma^2 = 0.06$) and with net migration ($\mu = 0.53$, $\sigma^2 = 0.08$).

The second theme from Table 2 is that search queries appear to have higher correlations with contemporaneous or future migration variables than with the past. Using inflow migration as an example, we group the correlation coefficients for inflow migrations in Table 2 by the number of years between the migration queries and the ACS statistics and compute the means for each group. Results in Figure 3 suggests that inflow search queries that precede the year of interest ("lead 2 years" and "lead 1 year") have higher correlations with the ACS inflow migration rates than the search queries that are contemporaneous ("same year") or follow the year of interest ("lag 1 year" and "lag 2 years"). We note that this leading effect of migration queries is consistent with previous findings on housing search queries, which demonstrates that web queries are usually good indicators of demand that will be eventually reflected in future consumer behavior [16, 68]. In the case of migration, it stands to reason that a typical prospective migrant would need to search

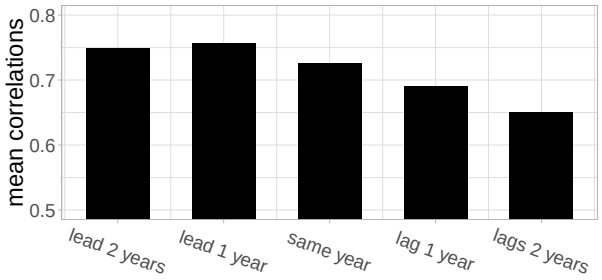

Figure 3: The leading effect of migration queries.

for a home or a job prior to actually moving. We provide further evidence for leading effect when demonstrating improvements to migration forecasting (see below).

Beyond the three primary migration measures, we also briefly highlight that the search query-based measures correlate strongly with secondary migration measures from government data. For example, ACS also collects data about the tenure of the migrants, which captures for each state the number of incoming migrants who currently live in owner occupied housing units and renter occupied housing units respectively. These tenure variables are very similar to the "Buy" and "Rent" variables we extracted (see Table 1). We thus compute the Pearson's correlation coefficients between the owner-renter ratio using ACS tenure data in 2016 and the buy-rent ratio using migration query data in 2015. Our result shows that these two variables indeed are strongly correlated ($\rho = 0.67$), further validating a query-based migration measurement.

4.2 Forecasting migrations statistics

The previous analyses demonstrated that migration queries alone can reasonably measure and even lead future migration variables. However, this doesn't necessarily indicate their incremental value in predicting future migration. In this section, we compare baseline migration prediction models with enhanced models that include search query measures, which is a typical methodology adopted by previous studies to demonstrate search queries' predictive power on economic indicators [3, 13, 16, 68]. Specifically, we follow these works to compare the goodness of fit (*adjusted* R^2) between the models with and without search query measures. We note that to be consistent with baseline models from the migration literature (e.g. [12, 61]), we construct models to predict *state level net migration*.

Our comparisons include two types of well-studied baseline models from migration literature. The first type of model is the autoregressive model. Because macroeconomics variables such as migration rates tend to be highly autocorrelated in time, simply forecasting future values from past data can provide good estimates. Traditionally known as the *Petersen-Greenwood hypothesis* in the migration literature [27, 53], this model treats current migration movement as a function of historical movement and has been shown to be effective in modeling state-to-state migration patterns [64]. We note that although more sophisticated nonlinear models are possible, we follow the practice common to these migration studies [27, 64] and use simple linear regression.

We first estimate the baseline model in Eq. 1 to predict 2016's ACS net migration rate using historical data from one year prior. This model is then compared with an enhanced model in Eq. 2 that adds search query variables from one year prior. Because domestic migration is a long decision making process, we hypothesize that adding query variables from multiple years might additionally enhance the prediction. As such, we also estimate an enhanced model in Eq. 3 that incorporates search query data from two years prior.

$$NetACS_{16} = \alpha + \beta_1 NetACS_{15} + \epsilon \tag{1}$$

$$NetACS_{16} = \alpha + \beta_1 NetACS_{15} + \beta_2 NetQueries_{15} + \epsilon \tag{2}$$

$$NetACS_{16} = \alpha + \beta_1 NetACS_{15} + \beta_2 NetQueries_{15} + \beta_3 NetQueries_{14} + \epsilon \tag{3}$$

We then estimate a stronger baseline model in Eq. 4 that includes the prior two years of ACS data. We note that we also explored models with longer histories of ACS migration data (e.g., an aggregate of the past five years) and the results were approximately the same or even worse in some cases. Similar to the previous comparison, we enhance this baseline by adding search variables of the prior one year (Eq. 5) and prior two years (Eq. 5) respectively.

$$NetACS_{16} = \alpha + \beta_1 NetACS_{15} + \beta_2 NetACS_{14} + \epsilon \tag{4}$$

$$NetACS_{16} = \alpha + \beta_1 NetACS_{15} + \beta_2 NetACS_{14} + \beta_3 NetQueries_{15} + \epsilon \tag{5}$$

$$NetACS_{16} = \alpha + \beta_1 NetACS_{15} + \beta_2 NetACS_{14} + \beta_3 NetQueries_{15} + \beta_4 NetQueries_{14} + \epsilon \tag{6}$$

The second type of baseline models we compare to is explanatory models that use socioeconomic factors to predict net migration. Among numerous such models (see comprehensive summaries in [11, 28]), we select the explanatory model proposed by Cebula and Alexander [12] as our baseline for the following reasons. First, it is designed and tested specifically to model state-level net migration rates. More importantly, it encompasses a comprehensive set of variables, including both traditional factors and novel "quality-of-life" factors [10], and has been shown to outperform models that include only economic factors [14, 56]. Lastly, as it was developed only a decade ago, the socioeconomic factors it considers should be the most pertinent to our context.

For model specification, we pick the best performing model from Cebular and Alexander [12] and include all the significant explanatory variables. We traced the source of these variables in the original model and found their most time-relevant counterparts [1]. Specifically, in Eq. 7, *MFI* is the median family income of each state; *COL* is the cost of living index for average four-person family; *EMPLGR* is the percent employment growth rate; *JANTEMP* is the daily maximum temperature in January; *HAZARD* is the percent distribution of hazardous waste sites of each state on the National Priority List; *TOXIC* is the toxic chemical releases per person; *EDPUP* is the government expenditures on elementary and secondary school, *STINCTAX* is the per capita state income tax burden. For brevity, we denote these socioeconomic variables with single notation *SOCIOECON* in ensuing model specifications and results interpretations. Readers should refer to the original paper [12] for detailed regression results for these variables. We enhance this baseline model by adding one year prior search variable (Eq. 8).

[1]We were unable find the exact counterpart data for a variable about the maximum January temperature, so we used the average winter temperature from NOAA.

	Dependent variable: $NetACS_{16}$

Table 3: Linear regression to predict 2016 net migration rate

$$NetACS_{16} = \alpha + \beta_1 MFI + \beta_2 COL + \beta_3 EMPLGR + \beta_4 WINTEMP + \beta_5 HAZARD + \beta_6 TOXIC + \beta_7 EDPUP + \beta_8 STINCTAX + \epsilon \quad (7)$$

$$NetACS_{16} = \alpha + \beta SOCIOECON + \beta_9 NetQueries_{15} + \epsilon \quad (8)$$

Finally, we estimate a third class of baseline model that combines the explanatory model and the autoregressive model, shown in Eq. 9. We compare this to an enhanced model Eq. 10 that adds one year prior search query variables.

$$NetACS_{16} = \alpha + \beta SOCIOECON + \beta_9 NetACS_{15} + \beta_{10} NetACS_{14} + \epsilon \quad (9)$$

$$NetACS_{16} = \alpha + \beta SOCIOECON + \beta_9 NetACS_{15} + \beta_{10} NetACS_{14} + \beta_{11} NetQueries_{15} + \epsilon \quad (10)$$

Results in Table 3 show consistent improvement when adding search query variables to various baseline models. For the simplest autoregressive baseline (Eq. 1), adding one year prior search queries (Eq. 2) increased the adjusted R^2 from 0.462 to 0.556, a 20% of improvement. Likewise, for the stronger autoregressive baseline that includes the prior two years of historical data (Eq. 4), adding one year prior search queries (Eq. 5) increased the goodness of fit from 0.521 to 0.656, or a 26% of increase. We highlight that these improvements are considerably larger than those found in similar work that also demonstrate the power of search query data to predict macroeconomic phenomena (e.g. [68]). Including an additional prior year of search queries (Eq. 3 and Eq. 6) does increase the adjusted R^2. However, the estimated coefficients of $NetQueries_{14}$ are non-significant and in fact slightly negative, indicating a multicollinearity issue. Indeed, the VIF for $NetQueries_{14}$ and $NetQueries_{15}$ in both models are greater than 5, confirming the existence of multicollinearity [58]. As such, with building parsimonious models in mind, we drop $NetQueries_{14}$ in later models. We also note that dropping $NetQueries_{15}$ from Eq. 3 and Eq. 6 still provides models better than the baseline (Eq. 1 and 4), indicating that two year ahead query variables can still contribute to migration prediction.

Similarly, we observe improvement in adding search query variables to the SOCIOECON explanatory model. Comparing the results for Eq. 7 and Eq. 8, we observe that the adjusted R^2 increases from 0.679 to 0.723. Finally, for the model that encompasses both socioeconomic variables and historical data (Eq. 9 and Eq. 10), adding search queries still provides 0.02 increase to the model's Adjusted R^2, again an improvement comparable to similar work demonstrating the predictive power of search query data in the macroeconomic domain (e.g. [68]). For all the above models, we emphasize that all estimated coefficients of $NetQueries_{15}$ are positive and significant, showing non-zero effects of the search query variable.

In addition to predicting *NetACS16*, we also estimated models predicting inflow migration rate and outflow migration rate. Although inflow or outflow alone are easier to predict compared to net migration, we observe consistent, though smaller, improvements even when the baseline models are already very accurate. For instance, for a baseline model that predicts 2016 inflow migration rate using previous two years' history data, adding search query measures enhances the adjusted R^2 from 0.871 to 0.893, again, an increase that is comparable to related work.

Finally, we note that we experimented with different specifications for these models. For example, we tried adding contemporaneous *NetQueries* variables to all models, e.g. using $NetACS_{15}$, $NetQueries_{15}$ and $NetQueries_{16}$ to predict $NetACS_{16}$. We observed little to even negative changes to the adjusted R^2, which offers additional support for our model specification and for the previous finding about the leading effect of search queries.

Overall, the analyses in this section demonstrate that that migration queries consistently improve the prediction of core migration outcomes across several strong, theory-based baseline models.

4.3 Understanding Migration Demand

One additional advantage of our approach is that out filter extracts detailed metadata for each migration query, indicating whether the search is housing-related related or job-related, even the sub-types for housing and jobs. We thus investigate how the intent to migrate varies on two important dimensions. First, we study how migration demand (indicating the sum of all expressed intent to migrate, even if this expression goes unrealized) varies *demographically* by age, income and educational attainment. These attributes have been shown in migration studies to have differential impacts on domestic migration [37, 39, 57]. Second, we demonstrate that the type of migration demand (e.g., driven by housing versus jobs)

	Housing	Jobs	Housing-Rent	Housing-Buy
Age 18-24	-0.40	0.40	-0.06	-0.19
Age 25-44	-0.19	0.19	0.41	-0.18
Age 45-64	0.48	-0.48	-0.40	0.30
Age > 65	0.53	-0.53	-0.50	0.31

(a)

Graduate	0.27	-0.43

(c)

Table 4: Correlation between migrants demographics and specific types of migration queries

varies *spatially*, even among states with similar net migration rates.

4.3.1 Migration Demand and Demographics. We hypothesize that the type of migration demand will differ based on varying demographics. Specifically, we focus on differential migration demand in relation to age, income, and education. These demographic attributes have previously been shown to affect related concepts, such as demand for employment, as measured by internet search queries (e.g. [13]). We obtained data for these demographic attributes from 2016 ACS provided through NHGIS [44]. Following our previous analyses, we compare these government data with search data from 2015, removing the District of Columbia. However, different from previous analyses which focused on net migration, here we study inflow migration for the following reasons. First, instead of prediction, this section focuses on explaining the relationship between where people are moving to and relevant demographics, and hence focusing on only one side of migration makes this relationship clearer. Second and more importantly, when segmenting total net migration into different groups, the margins of error of each group, as computed according to ACS's recommendation [25], can sometimes be larger than the net statistics, endangering the accuracy of our analysis. Furthermore, we chose to focus on inflow migration using traditional migration literature that studies the economic impact of international migration (e.g. [40, 42]) as guidance. We briefly discuss the outflow side at the end of the results, which present a generally similar trend.

First, we investigate how the types of migration demand, proxied by the types of migration queries, varies across age groups. To do so, we use ACS Table B07001 which captures for each state, the number of in-migrants for different age groups. Census publications uses a variety of age group breakdowns. To reduce the margins of error, we select the one with the fewest age groups, which is also used widely in decennial census publication (e.g. [31]). Motivated by the migration literature that argues that age plays an important role in housing-related migration (e.g. [33]), we study the relationship between age and housing-related migration searches, first in comparison to job related migration searches, and then within the buy versus rent housing query sub types. We normalize ACS age group data with the total number of inflow migrants, normalize housing and job queries by the total number of migration queries, and normalize rent and buy queries with the total number of housing queries, effectively turning every raw count into a proper percentage. We do so because we are most interested in understanding their relative relationships, rather than predicting their raw values.

Table 4 (a) presents the correlations between age groups and different types of migration demand. We note that because housing queries and jobs queries sum to 1 after our normalization, their correlation coefficients always have opposite signs and equal absolute values. Our results suggest that the percentage of older age migrants (e.g., age > 45) has positive correlations with the percentage of housing queries, whereas the percentage of younger migrants has positive correlations with the percentage of job queries to a state. In other words, states that attract a relatively large portion of housing queries in 2015, received large portion of older migrants in 2016 and states that drew job queries (or low housing queries) in 2015, pulled in more young migrants. These results are in line with prior migration theory which argues that young migrants are more motivated by employment and older migrants by housing [33]. To further unpack the relationships between age group and housing demand, the results in Table 4 (a) show that states that attract older age migrants in 2016 are positively associated with higher housing buy demand in 2015, whereas states that receive younger age group are positively associated with higher housing rent demand.

Next, we examine the relationship between income and migration demand. For income data, we again uses ACS Table B07010, that records the number of migrants for each income bracket. Similar to the previous analysis, we merge some income groups for ease of interpretation. Motivated by migration theories that demonstrate the interaction between migration, income and employment [17, 23], we investigated the relationship between income level and demand for employment related migration, with a particular focus on two job categories currently driving important economic disparities in the U.S.: science and technology versus manufacturing and transportation. We pre-process both ACS data and job related migration queries data with the same normalization procedure as in the above analysis on age.

Results in Table 4 (b) highlight two trends. First, as expected, our results indeed show that states with more higher income migrants are associated with more high tech job related inbound migration searches. Although the effect size is relatively small, these correlations shows distinctions when compared to the negative correlations between low income migrants and high tech job migration searches. For states that attract more low income migrants, our results did not suggest that they also attract large manufacturing and transportation jobs searches. Looking at this further, we did notice a trend that these same states saw increases in inflow job related migration searches in general, suggesting a possibility that

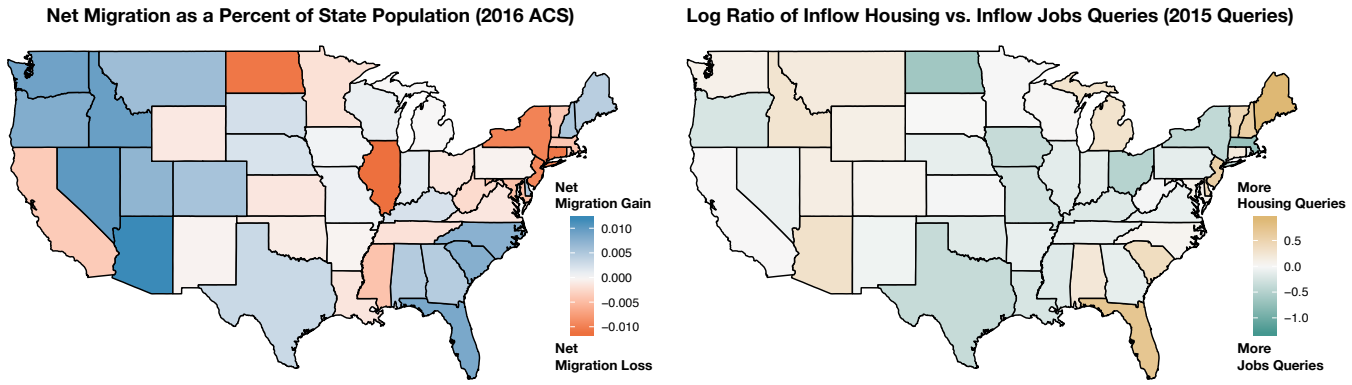

Figure 4: Left: Net domestic migration per state from the 2016 American Community Survey, shown as a percentage of state population. Right: the ratio of a state's 2015 inbound housing migration queries relative to its incoming jobs queries, normalized by that same ratio over all queries, shown here in log scale.

these lower income migrants might be looking for jobs that do not requires special skills. Non-specific job related migration may be a direction for future exploration.

Finally, we explore the relationship between education level and migration demand. ACS data record the number of migrants in five different education attainment groups ranging from "Below High School" to "Graduate". Like the previous analysis, we correlate these categories with science and technology versus manufacturing and transportation employment migration searches based on prior research that looks at employment searches and demographics [13]. We applied the same data pre-processing before conducting the correlation analyses. Results in Table 4 (c) indicate that states with greater inflow migration queries in science and technology see more migrants with bachelor and graduate degrees. By contrast, states with more inflow migration queries for manufacturing and transportation jobs attract more migrants with low education attainment. These results demonstrate that the relationships between employment demands and demographics that are shown in previous research [13] also ring true in the migration context.

As previously mentioned, we replicated the above analyses using outflow job queries and outflow migrants demographics. We generally observed similar trends, although some effect sizes are smaller. We hypothesize that this might be due to the fact that on the inflow side, certain states serve as the "magnets" that attract particular demographics, while such an effect is weaker on the outflow side.

4.3.2 Migration Demand and Geography. Domestic net migration is a core migration statistic that always draws extensive commentary and interpretation from columnists, policy makers and scholars upon its publication each year [1, 41, 63]. While much of this discussion centers around which states are growing and shrinking the fastest, raw migration statistics are not, on their own, able to contextualize the economic impact to local housing and job markets.

The left map in Figure 4 visualizes net domestic migration in the 48 contiguous United States using data from ACS 2016. In this figure, we see that states such as Florida (+0.83%), Texas (+0.31%), Arizona (+1.17%) and Nevada (+1.00%) are experiencing net population growth from domestic migration, while states such as New York (-0.96%), California (-0.36%), North Dakota (-1.06%), and Illinois (-1.11%) are losing more people than they are attracting.

Our data allow us to characterize the flow of migration queries into (or out of) a state as to whether the queries are disproportionately about housing or about jobs. Following the previous analysis, we focus only on an analysis of inflow; the analysis of outflow, which may help explain those states in deficit, follows analogously.

First, for each state s, we compute the proportion of incoming housing queries s receives relative to the housing queries in all other states:

$$\rho_{\text{in}}^{\text{housing}}(s) = \frac{\text{total inbound housing queries to } s}{\sum_{s'} (\text{total inbound housing queries to } s')}.$$

Similarly, we compute the proportion of incoming jobs queries:

$$\rho_{\text{in}}^{\text{jobs}}(s) = \frac{\text{total inbound jobs queries to } s}{\sum_{s'} (\text{total inbound jobs queries to } s')}.$$

All things equal, the ratio of job and housing related migration searches would be similar across states, however in practice, $\rho_{\text{in}}^{\text{housing}}(s)$ and $\rho_{\text{in}}^{\text{jobs}}(s)$ can be very different. The search behaviors that underlie each index are influenced by numerous factors, including the competitiveness of the local housing and job markets, and demographic differences among the migrants themselves, such as whether they are early in their career, or whether they are retired.

In the right side of Figure 4, we plot $\log\left(\rho_{\text{in}}^{\text{housing}}(s) \Big/ \rho_{\text{in}}^{\text{jobs}}(s)\right)$ for each state s using queries from 2015, highlighting which states attract a disproportionate fraction of housing migration searches relative to the proportion of job migration searches they attract, and vice versa. For example, while Florida (+0.83%) and Texas (+0.31%) are both net-positive in domestic migration, their inbound migration queries have very different profiles. Florida attracts disproportionately more housing searches (+0.70 in log ratio), indicating a stronger demand for its local housing market perhaps because of its status as a retirement destination, while Texas attracts more incoming job queries (-0.36 in log ratio), a possible reflection of a stronger demand for its labor market. Similarly, while neighboring states Nevada (+1.00%) and Arizona (+1.17%) are both domestic migration winners, Nevada attracts more job queries (-0.09 in log ratio) and Arizona attracts more housing queries (+0.30 in log ratio).

5 DISCUSSION

Forecasting and understanding large-scale migration patterns has long been a key problem of interest both for academics seeking to better understand the forces that shape society, and for government officials seeking to attract and retain more people to their regions. The impact of migration trends can be massive, with "winning" regions attracting a significant influx of skilled workers, and “losing" regions seeing their talent pool drift away to other shores.

In this work, we explore the use of internet search engine queries as a signal for predicting and understanding domestic migration trends that can augment and improve on government data-based models. The correlations with government data (Table 2, Figures 2, 3) indicate that the search query-based migration intent signals correlate with, and in fact even slightly lead current gold standard migration metrics. This leading relationship is most evident in the net migration flow correlations, in which the correlations between the search query metric and net migration jumps from about 0.10 when contemporaneous to 0.50 to 0.60 when leading official migration statistics. Thus, internet searching appears to be a precursor to migration, which is sensible given that people are likely to research possible migration destinations prior to moving.

The fact that queries tend to lead official metrics motivates our exploration of using search query data to *forecast* migration. Indeed we demonstrate that a migration query measure adds variance explained to regression models that predict future migration. Our model adds more than 10% variance explained over an autoregressive baseline to predictions of *net* migration, which is much harder to forecast than inflow or outflow migration alone. While the boost in variance explained in column 8 of Table 3 is more modest over the more robust baseline shown in column 7, bear in mind that this baseline incorporates many socioeconomic and environmental variables, such as median income and school expenditures, most of which are only available at annual timescales at best. The search query measure still adds variance explained over all of these individual measures, and is available in near real time. Indeed, since government migration data tend to be released two years after the period in question, the fact that search queries can provide a real-time, leading indicator of migration trends is testament to the potential of this method, which provides insights years in advance of any official government tally. Even once government data are released, combining such data with our data provides an even stronger model for predicting subsequent years' migration trends.

Beyond prediction, as shown in Table 4, we illustrate how migration queries shed light on some of the more important questions surrounding aggregated demand for migration. Perhaps the most fundamental question is whether people move for housing or for jobs. Using our migration query taxonomy, we aligned housing and job related migration queries with known demographics of migrants from the ACS, suggesting that younger people and people making the lowest income are more likely to migrate for employment reasons, while conversely older and wealthier people migrate for housing. Furthermore, among people who are searching for housing, older migrants are more likely to be looking to buy property, compared to their younger counterparts who are more likely to be renting. Similar relationships can be seen in looking at the data through he lens of geography. Figure 4 reveals that in states like Florida and Arizona, which attract a considerable number of retirees, incoming migrants are much more likely to be searching for housing than for jobs.

Regarding migration for employment, we highlight how query data can shed light on arguably the most pressing issue of employment today: high-tech versus manual labor jobs. We see a clear split between the less wealthy and less educated versus the wealthier and more highly educated. States attracting migrants in the lowest income bracket are the least likely to see job migration queries in the science and technology sector, while those with the higher income brackets are less likely to see migration queries in the manufacturing and transportation sectors. Education levels reveal a similar story, with science and technology migration queries aligning with high education states, and manufacturing and transportation migration queries aligning with lower education states.

These relationships demonstrate that search query data could be used to forecast the types of housing and employment incoming migrants to a state will seek, which could be extremely valuable for state and even city level planning. For instance, governments through permitting processes and developers could better plan for not only the overall increase or decrease in demand for housing, but whether that housing should be for rent or purchase. These forecasts simply are not feasible with government data, outside of autoregressive approaches that forecast based simply on past trends. Similarly, local governments and business leaders can benefit from forecasting incoming employees across industry sectors, again something not available as leading indicators in government data.

This then, indicates usage scenarios for government planning and policy agencies. At 10% of the population per year, churn in population for any given state is significant, and can drastically impact the social and economic development of a region. States will want to plan and draft housing and economic policies proactively in order to strategically encourage growth in desirable industries, to make housing stock as responsive to changes in demand, and so forth. Predictive policy and economic growth is far from trivial, but at the very least the relevant organizations could be using data that, like we have shown with these search query-based metrics, is at sufficient scale, is leading, and is nuanced in explanation.

6 CONCLUSION

In this paper, we proposed a novel approach that utilizes search query data to forecast and understand domestic migration trends in the United States. We developed a fast and robust migration query filter that achieves 0.88 F1 score. Our migration search data were validated against government data and showed high correlations. More importantly, we demonstrated that adding our migration search data could enhance two types of migration prediction models. Details of our search queries also offer nuanced explanations to how migrants' demands differ demographically and spatially. Overall, our approach will significantly benefit computational social scientists, migration researchers and local policy makers.

ABSTRACT

Relation extraction is an important task in structuring content of text data, and becomes especially challenging when learning with weak supervision—where only a limited number of labeled sentences are given and a large number of unlabeled sentences are available. Most existing work exploits unlabeled data based on the ideas of self-training (i.e., bootstrapping a model) and self-ensembling (e.g., ensembling multiple model variants). However, these methods either suffer from the issue of semantic drift, or do not fully capture the problem characteristics of relation extraction. In this paper, we leverage a key insight that *retrieving sentences expressing a relation* is a dual task of *predicting the relation label for a given sentence*—two tasks are complementary to each other and can be optimized jointly for mutual enhancement. To model this intuition, we propose DualRE, a principled framework that introduces a retrieval module which is jointly trained with the original relation prediction module. In this way, high-quality samples selected by the retrieval module from unlabeled data can be used to improve the prediction module, and vice versa. Experimental results[1] on two public datasets as well as case studies demonstrate the effectiveness of the DualRE approach.

1 INTRODUCTION

Relation extraction (RE) plays a key role in turning massive, unstructured text corpora into structures of factual knowledge, and has a wide range of downstream applications in many domains [19, 28, 34]. Given two entities in a sentence, the goal of (sentence-level) relation extraction is to predict the relation expressed between two entities based on their sentence context. For example, in Fig. 1, we aim to classify each sentence into several relation labels, such as "org:founded_by", "per:parents", and "no_relation". While many works have been done on developing supervised relation extraction models [4, 24, 36, 38, 39], they typically require a large amount of human-annotated data (i.e., sentences that are manually assigned with the appropriate relation labels) for model training. Despite its wide applications, the process of manually annotating a large training set with many relation labels is too expensive and error-prone. The rapid emergence of large, domain-specific text corpora (e.g., social media content, customer reviews, scientific publications) calls for methods that can automatically extract entity relationships from text with *less human supervision*.

Sentence	Relation
Steve Jobs and Wozniak co-founded **Apple** in 1976.	org:founded_by
He was on Safari in South Africa with his mother, **Trudy**.	per:parents
Trump believes the **United States** has incredible potential.	no_relation

Figure 1: Sentence-level Relation Extraction Task. This task concerns about predicting the relation of two entities mentioned in a sentence. Tokens in orange and blue are subject and object entities in correspondence.

In recent years there has been a surge of interest in applying *distant supervision* to relation extraction [19, 22, 37, 38]. The general idea is to leverage facts stored in external knowledge bases (KBs) to annotate sentences in an unlabeled corpus as training data—two entities co-occurring in a sentence will be labeled with their KB relations regardless of the specific context. Although distant supervision automates the process of labeling sentences, it suffers from two major limitations. First, not all sentences where two entities co-occur are expressing their KB relations (i.e., context-agnostic label noise). Second, in some application domains the target relations may not be found in existing knowledge bases (e.g., WikiData), making it hard to apply distant supervision for label generation. It is thus desirable to develop methods that can rely on less human-annotated data for training relation extraction models. This motivates the study of *semi-supervised relation extraction* methods [1, 3, 31], which seek to leverage a limited number of labeled

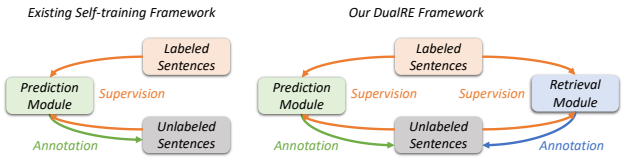

Figure 2: Illustration of the differences between the proposed DualRE framework and existing Self-training framework. Left: Self-training framework uses a single prediction module to annotate unlabeled sentences for generating additional labeled data. Right: DualRE framework leverages a prediction module and a retrieval modules for generating labeled data, where the newly labeled sentences are used to improve both modules. Two modules are jointly optimized and mutually enhance each other.

sentences and a large unlabeled (background) corpus for model training. Such setting has broad use cases, including cold-start knowledge base construction[2] and question answering [11].

In this paper, we study the problem of semi-supervised relation extraction. Towards this goal, there are broadly two kinds of methods, i.e., *self-ensembling* methods, and *self-training* methods. The main idea behind self-ensembling methods [12, 23, 27, 33] is to impose the assumption of "consistency under perturbation"—the prediction on the unlabeled instances should remain unchanged under small perturbations either on the data, or on the model parameters. In contrast, self-training methods [25, 29] aim to incrementally promote high-confidence predictions over unlabeled instances into the labeled training set, and improve the model by re-training with the updated labeled set. However, these methods suffer from the limitations as follows. (1) *Insufficient Supervision*: The process of enforcing prediction consistency between model variants in self-ensembling methods does not involve promoting new labeled instances from the unlabeled set. This makes it hard to improve models when "consistency-based" supervision is relatively weak compared to that from actual instances. (2) *Semantic Drift* [9]: While the self-training methods annotates unlabeled sentences as extra training data, the incremental promotion process can be biased (i.e., provides incorrect predictions), and may accumulate errors (i.e., including falsely-labeled instances into the training set). To overcome aforementioned challenges, we aim to design an approach that can generate high-quality labeled instances (as additional supervision) from the unlabeled corpus in an effective manner.

Intuitively, *retrieving sentences for a given relation* can be seen as a dual problem of *predicting the relation expressed in a sentence* (see the right-hand side of Fig. 2 for illustration). Models for the retrieval problem can help obtain more relevant sentences to a given relation from an auxiliary unlabeled corpus, for improving models for the prediction problem; while models for the prediction problem can predict the relation labels of the unlabeled sentences, and therefore help determine the quality of relevant sentences to collect (under each relation) for benefiting retrieval models. Such an observation of "problem duality" motivates us to solve the primal and dual problems jointly, and leverage the duality to overcome the aforementioned challenges. Specifically, as the prediction and retrieval models annotate/retrieve unlabeled sentences from the auxiliary corpus, both models provide additional training data to each other and thus help resolve the insufficient supervision issue. Meanwhile, during the joint learning process, both models provide feedback to correct the output of each other, helping generate high-quality labeled data and resolve semantic drift issue.

To model the above ideas, we propose a novel framework, called **DualRE**, for semi-supervised relation extraction. DualRE consists of a prediction module and a retrieval module (see Fig. 3 for illustration of the model design). Given a sentence x, the prediction module aims to determine its relation label y with a neural relation extraction model by approximating $p(y|x)$ (e.g., position-aware LSTM [39]). Meanwhile, the retrieval module employs a neural learning-to-rank model to approximate $p(x|y)$ (e.g., using pointwise or pairwise loss) to facilitate ranking sentences $\{x\}$ to identify relevant ones for a query relation y. During training, the two modules are jointly optimized to provide feedback for each other, by alternating between two processes as follows. In the first process, we fix the prediction module, and use additional training data promoted by both modules to update the retrieval module. Similarly, in the second process, the retrieval module is fixed, and we generate extra training data using both modules and update the prediction module. By doing so, the retrieval module can consistently provide additional supervision to improve the prediction module. As the two modules are jointly leveraged to promote new training data (via referencing the label distribution), it enables the prediction and retrieval module to mutually correct each other and generate high-quality annotation.

We conduct extensive experiments on two public relation extraction datasets to evaluate DualRE[3]. Experimental results show that DualRE consistently outperforms several state-of-the-art methods under different data settings (by varying the size of labeled data and unlabeled data). Detailed case study demonstrates that DualRE is able to select quality instances to guide the model training.

In summary, in this paper we make the following contributions:

- We propose a novel framework for semi-supervised relation extraction, which encourages the (primal) prediction task and the (dual) retrieval task to mutually benefit each other by generating additional training instances from an unlabeled corpus.
- We develop a joint learning algorithm to alternatively optimize the prediction and retrieval modules, such that they can collaborate with each other and improve the quality of annotations.
- We conduct extensive experiments on two public datasets. Experimental results and case studies validate the effectiveness of the proposed framework.

2 BACKGROUND AND PROBLEM

In this section, we introduce the relevant concepts and notations, and formally define semi-supervised relation extraction task.

Entity Mention. An entity mention e is a token span (or word sequence) that refers to a real-world entity. In Fig. 1, the word "Apple" is an entity mention that maps to the company *Apple Inc.*.

[2]https://tac.nist.gov/2017/KBP/ColdStart/index.html

[3]Source code: https://github.com/INK-USC/DualRE

Relation Mention and Label. A relation mention consists of two entity mentions and the sentence x they co-occur in (i.e., the two entity mentions are sub-strings of the sentence). Here we consider entity relations as directional connections between two entities. Therefore, we denote the left entity as subject entity $e_s = (x_{s_1}, ..., x_{s_p})$ and the right entity as object entity $e_o = (x_{o_1}, ..., x_{o_q})$, where s_i and o_j are the token indexes of subject and object entities in the sentence, respectively. A relation mention (x, e_s, e_o) can be assigned with a relation label $r \in \mathcal{R}$ (i.e., e_s and e_o express relation r in the sentence x). We use $\mathcal{R}$ to denote the pre-defined set of relations of interests in the downstream application. In particular, undefined or irrelevant relations are assigned with a special label "no_relation".

Problem Definition. In this paper, our goal is to learn a model to effectively predict the relation label between two entities e_s and e_o for a relation mention (x, e_s, e_o). Fig. 1 presents some examples for the task. Each row demonstrates a relation mention with two entities highlighted in blue (subject entity) and red (object entity). For relation mentions that are not expressing target relations of interests (or do not express any relation) like the third example, we assign "no_relation" as a special label in the relation label set. Moreover, the third example also demonstrates the difference between *sentence-level* and *instance-level* relation extraction. Despite the well-known fact that *Donald Trump* is the president of *United States*, which can be extracted from multiple sentences in the corpus, we cannot infer such relation from this specific sentence and thus should return a label that is the most appropriate for the given sentence. Formally, we define the task of sentence-level relation extraction as follows.

Definition 2.1. **(Sentence-level Relation Extraction)** Given a sentence $x = (x_1, x_2, ..., x_n)$, a subject entity e_s and an object entity e_o in the sentence, the task of sentence-level relation extraction is to predict the relation label $r \in \mathcal{R}$ given the sentence and two entities, where $\mathcal{R}$ is a pre-defined set of relations including "no_relation".

Under the semi-supervised learning setting, we aim to learn the relation extraction model using both *labeled relation mentions* (which are manually annotated) and *unlabeled relation mentions* (of which entity mentions are identified by some existing named entity recognition tools). Formally, let $\mathbf{x} = (x, e_s, e_o)$ denote a relation mention and y denote its corresponding relation label r from the set $\mathcal{R}$. We define the task of semi-supervised relation extraction as follows.

Definition 2.2. **(Semi-supervised Relation Extraction)** Given a set of labeled relation mentions $L = \{(\mathbf{x}_i, y_i)\}_{i=1}^{N_L}$ and a set of unlabeled relation mentions $U = \{\mathbf{x}_j\}_{j=1}^{N_U}$, semi-supervised relation extraction task aims to learn a multi-class classification model f that (1) fits the labeled training data L; and (2) captures the information in the unlabeled data U, at the same time.

In the following sections, we stick with the denotation of $\mathbf{x}$ and y when referring to the relation mention (x, e_o, e_s) and relation r.

Our Focus. In this work, we assume entity mentions have been recognized from text using existing tools. In our experiments, the entity mentions are provided by the public datasets [15, 39]. Similarly, the set of relations $\mathcal{R}$ is also given by the datasets. In particular, we focus on the cases that the labeled instances are manually annotated with reliable labels, as compared to the noisy labels obtained via distant supervision [22]. Here we do not consider applying distant supervision to generate pseudo labels over the unlabeled relation mentions, and leave this as future work.

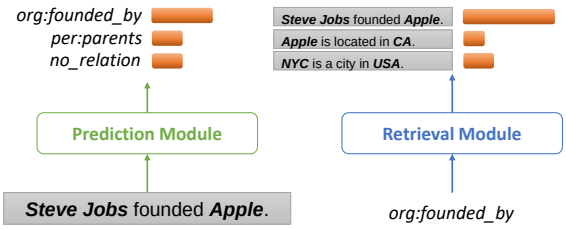

Figure 3: Illustration of the Two Modules in DualRE. Left: The prediction module focuses on the primal task, that is, predicting the relation label y of a sentence x. Right: The retrieval module focuses on the dual task, which aims at retrieving relevant sentences x for a query relation y.

3 THE DUALRE FRAMEWORK

Framework Overview. This section introduces our dual learning approach to semi-supervised relation extraction. Given that *retrieving sentences expressing a relation* can be seen as a dual task of *predicting the relation expressed in a sentence*, we propose DualRE to take advantage of the dual property of two tasks and overcome the challenges mentioned in the introduction. At a high level, DualRE trains a module for the prediction task and a module for the retrieval task jointly. The retrieval module helps obtain relevant sentences for each relation from an auxiliary unlabeled corpus, which are then used as additional training data for the prediction module. Meanwhile, the prediction module predicts the relation labels for the unlabeled sentences, and determines the relation labels for retrieved sentences, which then serve as training data to improve the retrieval module. Two modules are jointly optimized to mutually enhance each other, generating additional, high-quality labeled data to address the problems of insufficient supervision and semantic drift.

Formally, our framework consists of a prediction module $\mathcal{P}_\theta$ and a retrieval module $\mathcal{Q}_\phi$, where θ and ϕ are their model parameters. The prediction module focuses on the primal task, i.e., predicting the relation label for a given relation mention. Therefore, for a mention-label pair $(\mathbf{x}, y)$, it models the conditional probability $p_\theta(y|\mathbf{x})$. By contrast, the retrieval module solves the dual task, i.e., retrieving relevant sentences expressing a specific relation, and hence it defines the probability $q_\phi(\mathbf{x}|y)$ for a mention-label pair $(\mathbf{x}, y)$. In practice, since $q_\phi(\mathbf{x}|y) \propto q_\phi(\mathbf{x}, y)$ when given a specific relation y, the retrieval module will focus on estimating $q_\phi(\mathbf{x}, y)$ instead. The overall objective function is given below:

$$\mathbf{O} = \mathbf{O}_P + \mathbf{O}_R + \mathbf{O}_U \tag{1}$$

There are three terms in total. In $\mathbf{O}_P$ and $\mathbf{O}_R$, we use the given labeled sentences to train the prediction module and the retrieval module, respectively. In the unsupervised part $\mathbf{O}_U$, we promote the collaboration of the two modules to annotate unlabeled sentences as additional training data. In the rest of this section, we will introduce the details of each key component in DualRE.

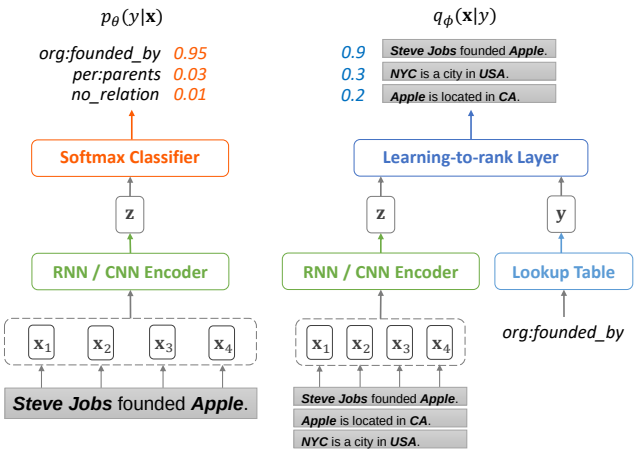

Figure 4: Model Design of the Two Modules in DualRE. Left: The prediction module encodes the relation mention and outputs a probability distribution over all relations. Right: The retrieval module ranks the relation mentions given a query by predicting a relevance score $q_\phi(\mathbf{x}, y)$. Retrieving instances given a relation is essentially taking the top instances from the ranking list. Note that this figure does not illustrate how two modules mutually enhance each other using unlabeled data.

3.1 Relation Prediction Module

In the DualRE framework, the prediction module $\mathcal{P}_\theta$ focuses on the primal task, that is, predicting the relation expressed in a relation mention, as shown in Fig. 4. We build the prediction module by first leveraging an encoder to encode the relation mention, and then adopting a softmax classifier to perform relation classification.

Relation Mention Encoder. The goal of relation mention encoders is to encode relation mentions into latent vectors, which can serve as features for prediction. A variety of encoders have been proposed for relation mention encoding, such as Long Short-Term Memory (LSTM) encoders [17], Piecewise Convolutional Neural Network (PCNN) encoders [37], and Position-aware Recurrent Neural Network (PRNN) encoders [39]. Among them, PRNN outperforms all other encoders on relation extraction, and therefore we use PRNN as our default encoder, but our framework can also adopt other encoders.

Formally, given a relation mention, PRNN considers the POS tagging, NER tagging, the position of each token (with regard to object and subject entities) as features. Then an LSTM cell is leveraged to learn the hidden representation of each word. Finally, the attention mechanism is utilized to weighted aggregate different hidden representations as the final encoding of the relation mention.

Objective Function. After encoding a relation mention, we feed it into a softmax classifier to predict the relation label of the mention. The prediction module can be trained using the given labeled data, in which we leverage the cross-entropy objective function, which is given below:

$$\mathbf{O}_P = \mathbb{E}_{(\mathbf{x}, y)\in L}[\log p_\theta(y|\mathbf{x})] \tag{2}$$

Given a relation mention $\mathbf{x}$ and its relation label y, the prediction module seeks to maximize the probability of y for the mention $\mathbf{x}$.

3.2 Sentence Retrieval Module

The intended behavior of retrieval module Q_ϕ is to select a set of relevant mentions given specific relations. In information retrieval domain, this is similar to the problem of retrieving a set of documents given a query. In our case, "document" and "query" correspond to relation mention and relation, respectively.

Learning-to-rank [20] is a type of model that aims to rank the documents according to its relevance to a query, thus we can select the top-ranking ones as retrieved documents. Learning-to-rank formulates such problems using joint probability $q_\phi(\mathbf{x}, y)$, which is in proportion to $q_\phi(\mathbf{x}|y)$ when the probability of observing query $q(y)$ is fixed. Similar to the prediction module, we can train the retrieval module by leveraging the labeled data and optimizing the following objective function:

$$\mathbf{O}_R = \mathbb{E}_{(\mathbf{x}, y)\in L}[\log q_\phi(\mathbf{x}, y)] \tag{3}$$

However, directly optimizing $q_\phi(\mathbf{x}, y)$ is intractable, since we have to ensure $\sum_{(\mathbf{x}, y)} q_\phi(\mathbf{x}, y) = 1$, which requires traversing over all possible pairs of $(\mathbf{x}, y)$ to calculate the partition function. Therefore, following existing learning-to-rank models, we seek not to enforce $q_\phi(\mathbf{x}, y)$ as a valid distribution. Instead, we let $q_\phi(\mathbf{x}, y)$ output a score to estimate the degree of *relevance* of the pair $(\mathbf{x}, y)$. In literature, there are mainly two types of approaches to train such retrieval models, i.e., the pointwise approach [8, 18] and the pairwise approach [5, 6], and we tried both in our experiment. Next, we introduce these approaches respectively.

Pointwise Approach. Pointwise learning-to-rank models assume that each query-document pair is assigned a score that reflects their degree of relevance, which can be used to determine the rank for each document given a query.

In the task of retrieving relation mentions, for each relation mention $\mathbf{x}$, we have a label y to indicate which relation it belongs to. Alternatively, we can regard such supervision signal as a binary score (0 or 1) that indicates whether a relation mention $\mathbf{x}$ is relevant to a specific relation $y \in \mathcal{R}$. In other words, each relation mention in the labeled dataset is paired up with all relations, with a binary label to indicate if they are relevant.

The model design for the learning-to-rank retrieval module is illustrated in Fig. 4. Given a relation y and a set of relation mentions $\{\mathbf{x}\}$ to be retrieved, we first encode each relation mention $\mathbf{x}$ as a vector $\mathbf{z}$. Each relation y is mapped to its relation embedding $\mathbf{y}$ according to a relation embedding matrix R, which has the same dimension as $\mathbf{z}$. In the learning-to-rank layer, pointwise approach takes the inner product $q_\phi(\mathbf{x}|y) = \sigma(\mathbf{z}^\top \mathbf{y})$ as the relevance score, where $\sigma(\cdot)$ denotes the sigmoid activation function.

$$\mathbb{E}_{(\mathbf{x}, y)\in L}[\log \sigma(\mathbf{z}^\top \mathbf{y})] + \mathbb{E}_{(\mathbf{x}, y')\notin L}[\log(1 - \sigma(\mathbf{z}^\top \mathbf{y}'))], \tag{4}$$

where $(\mathbf{x}, y)$ is a pair in the labeled dataset L, $(\mathbf{x}, y')$ pairs up the relation mention $\mathbf{x}$ with incorrect relation y', $\mathbf{z}$ is the mention encoding for $\mathbf{x}$, $\mathbf{y}$ and $\mathbf{y}'$ are embeddings of relation y and y'.

Pairwise Approach. Pairwise learning-to-rank models assume that a relative order can be determined between the retrieved documents. For a set of documents, we can compare any pair of them

and predict their relative order. We expect the model predictions (i.e. the set of relative orders) are consistent (no conflicting results such as $a > b, b > c$ but $c < a$), and thus the absolute order of each document in the ranked list can be derived.

The core part of pairwise learning-to-rank models is the design of objective function that can characterize the relative order of paired documents. We adopt the approach in RankNet [5], which proposes an objective function to minimize the number of inversions in ranking. An inversion happens when we rank a lower rated document above a higher rated one in a ranked list.

In the task of retrieving relation mentions, given a relation, we aim to rank all relevant mentions higher than the irrelevant ones. Similar to the design of pointwise learning-to-rank, we also encode each relation mention $\mathbf{x}$ and relation y into vector representation $\mathbf{z}$ and $\mathbf{y}$ respectively. The only difference is how the objective function in the learning-to-rank layer (as shown in Fig. 4) is calculated. We approximate O_R in Eq. 3 using the following term:

$$\mathbb{E}_{(\mathbf{x},y),(\mathbf{x}',y')\in L\times L}[r(\mathbf{x},\mathbf{x}',y)\log\sigma(\mathbf{z}^T\mathbf{y}-\mathbf{z}'^T\mathbf{y})], \tag{5}$$

where the order score $r(\mathbf{x},\mathbf{x}',y)$ expresses the relative order of two relation mentions, given the relation y. Consider $\mathbf{x}$ as a positive instance for relation y, the order score will return 1 if $\mathbf{x}'$ is a negative instance. During optimization process, this indicates that we attribute $\mathbf{z}^T y$ a higher score than $\mathbf{z}'^T y$. If $\mathbf{x}'$ happens to be another positive instance, we cannot make assertion about their relative order, then the order score returns 1/2. During the optimization process, this indicates that we assume the score $\mathbf{z}^T y$ and $\mathbf{z}'^T y$ are close.

3.3 Interaction Between the Two Modules

So far, we only introduced the formulation of prediction and retrieval modules and how they can be trained in a supervised way (by maximizing O_P and O_R). In the semi-supervised setting, we try to incorporate unlabeled data, which leads to the introduction of O_U in overall objective function. In DualRE, the formulation of this unsupervised objective function involves both prediction and retrieval modules. Intuitively, we hope to leverage the unlabeled data under the collaboration between both modules.

Formally, in $\mathbf{O}_U$, we seek to maximize the log-likelihood function of the unlabeled relation mentions:

$$\begin{aligned}\mathbf{O}_U &= \mathbb{E}_{\mathbf{x}\in U}[\log q_\phi(\mathbf{x})] \\ &\geq \mathbb{E}_{\mathbf{x}\in U, y\sim p_\theta(y|\mathbf{x})}[\log\frac{q_\phi(\mathbf{x},y)}{p_\theta(y|\mathbf{x})}]\end{aligned} \tag{6}$$

The above inequality is derived from the EM algorithm [10]. The two sides are equal when $p_\theta(y|\mathbf{x}) = q_\phi(y|\mathbf{x})$. By maximizing the lower bound of O_U, we incorporate both modules in the optimization process. As we will see in Sec. 4, we approach the optimization process by sampling from unlabeled data and accepting the instances that both modules agree on. These newly retrieved instances are regarded as pseudo-labeled data and enhance the training of both modules. Such process effectively leverages the selection quality of retrieved instances and boosts the overall model performance.

4 JOINT LEARNING OF PREDICTION AND RETRIEVAL MODULES

In Sec. 3, we introduce the formulation for three components (O_P, O_R and O_U) of the overall objective function. This section will present the details on how we approach the optimization of the overall objective function O, and the learning algorithm.

4.1 The EM-based Joint Optimization

To optimize the objective function O, we follow the EM algorithm to alternatively optimize the prediction and retrieval modules.

E Step. In this step, we update the prediction module $\mathcal{P}_\theta$ by fixing the retrieval module $\mathcal{Q}_\phi$. This corresponds to the minimization of KL divergence $KL(p_\theta(y|\mathbf{x})||q_\phi(y|\mathbf{x}))$. Directly minimizing this objective function is difficult, thus we follow the wake-sleep algorithm [16] to minimize the reversed KL divergence $KL(q_\phi(y|\mathbf{x})||p_\theta(y|\mathbf{x}))$, which yields the same optimal solution, i.e., $p_\theta(y|\mathbf{x}) = q_\phi(y|\mathbf{x})$. By integrating Eq. 2 and Eq. 6 as the overall objective function, and taking derivative with respect to θ, the gradient for θ is calculated as:

$$\begin{aligned}\nabla_\theta\mathbf{O} &= \mathbb{E}_{(\mathbf{x},y)\in L}[\nabla_\theta\log p_\theta(y|\mathbf{x})] \\ &\quad+\mathbb{E}_{\mathbf{x}\in U, y\sim q_\phi(y|\mathbf{x})}[\nabla_\theta\log p_\theta(y|\mathbf{x})],\end{aligned} \tag{7}$$

where the gradient is calculated from both the labeled data and additional data annotated by the retrieval module $\mathcal{Q}_\phi$. However, only leveraging the retrieval module for annotation can be biased, so we may expect both modules to mutually correct each other. Towards this goal, we notice that $\mathbb{E}_{p_\theta(y|\mathbf{x})}[\nabla_\theta\log p_\theta(y|\mathbf{x})] = 0$ [4], and therefore the gradient can be modified as:

$$\begin{aligned}\nabla_\theta\mathbf{O} &= \mathbb{E}_{(\mathbf{x},y)\in L}[\nabla_\theta\log p_\theta(y|\mathbf{x})] \\ &\quad+\mathbb{E}_{\mathbf{x}\in U, y\sim(q_\phi(y|\mathbf{x})+p_\theta(y|\mathbf{x}))}[\nabla_\theta\log p_\theta(y|\mathbf{x})]\end{aligned} \tag{8}$$

Although the gradient remains the same as in Eq. 7, the new gradient enables us to leverage both modules to collect additional labeled sentences, which usually has lower noise, and therefore leads to better performance.

M Step. In this step, we update the retrieval module $\mathcal{Q}_\phi$ by fixing the prediction module $\mathcal{P}_\theta$. The gradient with respect to ϕ can be similarly calculated as:

$$\begin{aligned}\nabla_\phi\mathbf{O} &= \mathbb{E}_{(\mathbf{x},y)\in L}[\nabla_\phi\log q_\phi(\mathbf{x},y)] \\ &\quad+\mathbb{E}_{(\mathbf{x},y)\sim(p_\theta(\mathbf{x},y)+q_\phi(\mathbf{x},y))}[\nabla_\phi\log q_\phi(\mathbf{x},y)]\end{aligned} \tag{9}$$

Again, directly calculating $\log q_\phi(\mathbf{x},y)$ is infeasible, and therefore in practice we use the pointwise term (Eq. 4) or the pairwise objective function (Eq. 5) to replace $\log q_\phi(\mathbf{x},y)$.

To summarize, the model alternates between optimizing the objective function with regard to ϕ and θ, which is referred to as E and M step. During each step, we incorporate both labeled and unlabeled data. Both E and M step require sampling annotated instances from unlabeled data. Noticing that samples from distribution $\mathbf{x}\in U, y\sim(q_\phi(y|\mathbf{x})+p_\theta(y|\mathbf{x}))$ is equivalent to sampling from distribution $(\mathbf{x},y)\sim(p_\theta(\mathbf{x},y)+q_\phi(\mathbf{x},y))$, we can keep a single version of sampled instances and apply to both steps.

[4] $\mathbb{E}_{p_\theta(y|\mathbf{x})}[\nabla_\theta\log p_\theta(y|\mathbf{x})] = \mathbb{E}_{p_\theta(y|\mathbf{x})}[\frac{\nabla_\theta p_\theta(y|\mathbf{x})}{p_\theta(y|\mathbf{x})}] = \sum\nabla_\theta p_\theta(y|\mathbf{x}) = \nabla_\theta\sum p_\theta(y|\mathbf{x}) = \nabla_\theta 1 = 0$

Next, we introduce an empirical sampling method that effectively generates high-quality training relation mentions (as additional supervision) to improve the performance.

4.2 Instance Selection

Empirically, sampling from distribution $p_\theta(\mathbf{x}, y) + q_\phi(\mathbf{x}, y)$ can be approximated by taking the intersection set of predicted results from both modules.

In prediction module $\mathcal{P}_\theta$, we first select new instances from distribution $p_\theta(\mathbf{x}, y)$. If we assume a uniform distribution for relation mentions $p(\mathbf{x})$, we are essentially sampling from distribution $p_\theta(y|\mathbf{x}) \propto p_\theta(\mathbf{x}, y)$. Given the unlabeled instance $\mathbf{x}$ and its predicted relation y, we rank these instances according to the probability of predicting y (i.e., $p(y|\mathbf{x})$) and take top-k instances from the ranked list. This is similar to what we do in self-training models.

In retrieval module $\mathcal{Q}_\phi$, we sample k instances from distribution $q_\phi(\mathbf{x}, y) = q_\phi(\mathbf{x}|y)q(y)$. The first term $q_\phi(\mathbf{x}|y)$ aligns with the intended behavior for the retrieval module: given a relation y, the retrieval module traverses through each unlabeled instance $\mathbf{x}$ and gives out a relevance score $q_\phi(\mathbf{x}, y) \propto q_\phi(\mathbf{x}|y)$. Therefore we can construct a ranked list for each relation y, in which top-k_y instances are retrieved for this relation. We aggregate the instances from each relation to construct the retrieved set. The second term $q(y)$ can be regarded as prior knowledge that constrains the relation distribution for retrieved instances. Given that we retrieved k instances which follows the reference relation distribution $q(y)$, we can determine the number of instances retrieved for each relation $k_y = kq(y)$.

Both modules collect a set of training instances, and the intersection of them are regarded as the final set. Intuitively, this is similar to majority voting or ensembling that considers multiple models when doing prediction.

4.3 Instance Promotion

To further eliminate the influence of incorrect annotations in retrieved instances, we experiment with two strategies to incorporate these instances in the training phase.

Equal promotion. Equal promotion treats the retrieved instances and original training data equally when calculating the loss function. This is the typical strategy for self-training models. The objective functions derived in Eq. 8 and 9 reflect this strategy.

Weighted promotion. In this strategy, each instance is assigned a weight π reflecting the confidence of its annotation, which is intended to be low when it's wrongly labeled. The weights are incorporated in training phase when promoting different instances. Considering Eq. 7 when training the prediction module, the first term is intended for promoting instances in the labeled set, which is assigned a weight of 1 and the formula remains unchanged. The second term is modified as follows:

$$\mathbb{E}_{(\mathbf{x},y)\sim(p_\theta(\mathbf{x},y)+q_\phi(\mathbf{x},y))}[\pi^p_{\mathbf{x}} \nabla_\phi \log q_\phi(\mathbf{x}, y)], \tag{10}$$

where $\pi^p_{\mathbf{x}}$ is the weight for pseudo-labeled instance ($\mathbf{x}$, y). Similarly, we introduce the weight $\pi^q_{\mathbf{x}}$ in objective function O_R for the retrieval module. In our experiment, we parameterize the weights as $\pi^p_{\mathbf{x}} = p_\theta(y|\mathbf{x})^\alpha$ and $\pi^q_{\mathbf{x}} = q_\phi(\mathbf{x}, y)^\beta$, in which α and β are hyperparmeters to tune in our model.

Algorithm 1: DualRE Learning Algorithm.

Input: Labeled data $L = \{(\mathbf{x}_i, y_i)\}_{i=1}^{N_L}$, unlabeled data $U = \{\mathbf{x}_j\}_{j=1}^{N_U}$, the amount of data to retrieve each in each iteration k.

Initialize: $L_U \leftarrow \emptyset$.

$P_\theta, Q_\phi \leftarrow$ Pretrain prediction and retrieval module using L.

while $U \neq \emptyset$ ***and*** *not converge* **do**

  $L' \leftarrow$ Retrieve k annotated instances $(\mathbf{x}, y)$ from U (Sec. 4.2).

  Remove instances L' from U and add them to L_U.

  // Update prediction module:

  Optimize P_θ using data from both L and L_U (Eq. 8).

  // Update retrieval module:

  Optimize Q_ϕ using data from both L and L_U (Eq. 9).

end

Table 1: Statistics for SemEval and TACRED dataset. We present the number of relation mentions in the train/dev/test sets. In particular, % Neg. implies the percentage of "negative" relation mentions (i.e., relation mentions that are labeled as "no_relation").

Dataset	# Train	# Dev	# Test	# Relations	% Neg.
SemEval [15]	7,199	800	1,864	19	17.40
TACRED [39]	75,049	25,763	18,659	42	78.68

4.4 The Joint Learning Algorithm

We summarize the training algorithm for DualRE in Algo. 1. The algorithm is basically an approximation of EM algorithm as described in Sec. 4.1. The whole process works in an iterative manner. In each iteration, we retrieve a new set of annotated instances using both prediction and retrieval modules. According to Sec. 4.2, this is an empirical practice to sample from distribution $p_\theta(\mathbf{x}, y) + q_\phi(\mathbf{x}, y)$. The retrieved instances, along with previous training data can be used for updating the prediction and retrieval module, which correspond to the E step and M step in the EM algorithm. The iterative process stops when our model converges or the unlabeled data is exhausted.

5 EXPERIMENTS

This section first introduces datasets and experimental settings, and then presents performance comparison results with baseline methods as well as case studies of various model components in order to validate different design choices in DualRE.

5.1 Dataset

We choose two public relation extraction datasets with different characteristics to validate the effectiveness of our proposed method. (1) **SemEval** [15]. SemEval 2010 Task 8 provides a standard benchmark dataset which is widely adopted for evaluating relation extraction systems. It has around 10,000 relation mentions in total (where entity mentions are given), with 19 relations (including "no_relation"). (2) **TACRED** [39]. The TAC Relation Extraction Dataset is a large-scale crowd-sourced relation extraction dataset

Table 2: Performance comparison on SemEval [15] with various amounts of labeled data and 50% unlabeled data. We report the mean and standard deviation of the evaluation metrics by conducting 5 runs of training and testing using different random seeds. DualRE outperforms all the baseline methods.

Methods / % Labeled Data	5%			10%			30%		
	Precision	Recall	F_1	Precision	Recall	F_1	Precision	Recall	F_1
LSTM [17]	25.31 ± 2.16	20.72 ± 3.91	22.71 ± 3.31	36.91 ± 6.10	29.85 ± 7.25	32.92 ± 6.71	64.83 ± 0.69	63.03 ± 0.67	63.91 ± 0.66
PCNN [37]	42.95 ± 4.69	40.79 ± 4.59	41.84 ± 4.63	53.78 ± 1.51	49.11 ± 2.22	51.32 ± 1.74	64.54 ± 0.58	62.98 ± 0.48	63.75 ± 0.33
PRNN [39]	56.16 ± 1.32	54.87 ± 1.49	55.49 ± 0.90	61.70 ± 1.16	63.61 ± 2.07	62.63 ± 1.42	69.66 ± 2.19	68.76 ± 2.60	69.14 ± 1.02
Mean-Teacher (PRNN) [33]	53.71 ± 4.43	49.54 ± 3.29	51.51 ± 3.58	62.43 ± 1.28	60.34 ± 0.62	61.36 ± 0.75	68.65 ± 0.64	69.84 ± 0.65	69.24 ± 0.56
Self-Training (PRNN) [29]	56.47 ± 1.11	56.14 ± 1.33	56.30 ± 0.96	64.27 ± 2.37	63.48 ± 2.02	63.79 ± 0.28	68.95 ± 0.68	72.63 ± 0.82	70.74 ± 0.58
RE-Ensemble (PRNN)	58.77 ± 0.58	58.50 ± 0.97	58.63 ± 0.62	65.10 ± 0.84	64.57 ± 0.54	64.83 ± 0.61	70.26 ± 0.92	73.20 ± 1.22	71.69 ± 0.47
DualRE-Pairwise (PRNN)	59.76 ± 0.47	63.36 ± 0.77	**61.51 ± 0.56**	64.39 ± 0.75	67.70 ± 0.80	66.00 ± 0.48	70.05 ± 0.53	74.83 ± 0.88	72.36 ± 0.60
DualRE-Pointwise (PRNN)	58.73 ± 1.50	62.23 ± 1.93	60.43 ± 1.67	64.50 ± 1.14	67.67 ± 1.66	**66.03 ± 1.00**	70.03 ± 0.74	74.87 ± 0.75	**72.36 ± 0.35**
RE-Gold (PRNN w. gold labels)*	72.57 ± 1.47	74.65 ± 1.98	73.56 ± 0.31	71.40 ± 1.42	76.72 ± 0.64	73.95 ± 0.50	72.98 ± 0.96	78.86 ± 0.76	75.80 ± 0.24

following the TAC KBP relation schema[5]. The corpora are collected from all the prior TAC KBP shared tasks. It has more than 100,000 relation mentions with relations categorized into 42 classes (including "no_relation").

Table 1 shows the overall statistics for these two datasets, which are significantly different in terms of dataset size, number of relations, and percentage of negative instances. As one can observe from the table, TACRED is far more complicated than SemEval, since it has more types of relations and more skewed distribution between positive and negative instances. We conduct experiments on both datasets so as to validate the effectiveness of our DualRE model learned with datasets of different characteristics.

5.2 Compared Methods

As the proposed DualRE framework is general and can be integrated with various supervised "base" model of relation extraction, we first compare several widely used supervised models, then adopt the best performing one as the base model and compare DualRE with other representative semi-supervised methods. All models mentioned below are re-implemented and integrated into a unified interface for efficient experiment conducting.

For base models proposed for supervised relation extraction, we select the following models and train them only on the labeled dataset (i.e., set L): (1) **LSTM** [17]: The Long Short-Term Memory (LSTM) network is a variant of basic Recurrent Neural Network (RNN). We can simply adopt LSTM without attention mechanism to encode the word sequence and classify it into predefined relation categories based on the sentence representation. (2) **PCNN** [37]: Different from the encoding part of LSTM RE model, Piecewise Convolutional Neural Network (PCNN) uses CNN with piecewise max pooling to encode the word sequence. Position embeddings are used to provide the model with the positions of subject and object entities in the sentence. (3) **PRNN** [39]: Integrating position-aware attention mechanism, the Position-aware Recurrent Neural Network (PRNN) is proposed specifically for supervised relation extraction and has achieved state-of-the-art performance on TACRED dataset. Details of PRNN model are described in Sec. 3.1.

As PRNN has achieved state-of-the-art performance in prior work, we construct our DualRE model based on PRNN, and compare with other semi-supervised classification methods which also adopt PRNN as the base model for fair evaluation. For semi-supervised baselines, we select several representative methods from different categories of semi-supervised learning approaches (See Sec. 6 for details), shown as follows. (4) **Self-Training** [29]: Self-Training is a semi-supervised method that uses a single model's predictions on unlabeled data to iteratively re-train and improve the model itself. In each iteration, the model is first used to label the unlabeled instances, then the most confident pseudo-labeled instances are added to the labeled set, which are further used to re-train the model in the next iteration. The iterative training procedure stops when the unlabeled data is exhausted. (5) **Mean-Teacher** [33]: Mean-Teacher belongs to the category of self-ensembling methods. It is first proposed for semi-supervised image classification task. The main idea is to encourage different variants of the model to make consistent predictions over similar inputs. A perturbation-based loss, and the original training loss, are jointly optimized to utilize the information provided by unlabeled data. In our implementation, the dropout strategy [13, 30] is applied to generate the perturbed input.

In addition to the existing semi-supervised methods introduced above, we propose a variant of DualRE model as another baseline model, to further validate the effectiveness of adopting a dual retrieval model in contrast to ensembling two prediction models with identical configuration, i.e., both modules use PRNN as the same base model but with different model parameters. (6) **RE-Ensemble**: By replacing the retrieval module in the proposed DualRE framework with the same prediction module (with a new set of model parameters), we design the RE-Ensemble model that selects the promoted instances based on the agreement of two prediction modules in each iteration. The structure and size of these two models are exactly the same, but they are independently initialized at random to make sure they are not identical.

For our proposed DualRE method, we focus on studying the performance of two model variants based on different learning-to-rank objectives in the retrieval module. The models are trained on both the labeled data and the unlabeled data, as detailed below: (1) **DualRE-Pointwise**: A DualRE model that uses pointwise learning-to-rank loss [7] in the retrieval module. (2) **DualRE-Pairwise**: A DualRE model that uses pairwise learning-to-rank loss [5] in the retrieval module.

Finally, we present another model to demonstrate the upper bound of the performance for all the semi-supervised methods. This model is learned using both the labeled dataset and the "unlabeled"

[5]https://tac.nist.gov/2017/KBP

dataset. **RE-Gold**: It trains the PRNN base model using both the labeled relation mentions and the gold labels of relation mentions from the unlabeled set. This represents the setting that labels over all unlabeled instances can be perfectly predicted, which gives an upper bound performance.

5.3 Experimental Settings

Data Preparation. To study the performance of semi-supervised relation extraction models with various labeled and unlabeled dataset sizes, we sample from the original training set and construct various sizes of labeled and unlabeled set. More specifically, for SemEval dataset, we sample 5%, 10% and 30% training data as labeled sets, the ratios amounts to 3%, 10% and 15% in TACRED. In both datasets, we sample 50% training data as unlabeled set, whose ground-truth labels are unavailable to models. We perform stratified sampling to ensure the label distribution remains unchanged. Duplication in labeled and unlabeled set is avoided as well. Note that since SemEval does not have official development set, we sample 10% of the training set as the development set, before the above data preparation process.

Data Processing. Since the SemEval dataset does not contain named entity (NE) tags for each relation mention, which is essential for our PRNN base model, we apply the Stanford CoreNLP toolkit [21] to extract the needed information.

Hyperparameter Tuning. For base models (LSTM, PCNN, PRNN), we follow the default hyperparameter settings used in previous works [37, 39]. For fair comparison, both DualRE and other baseline methods are built on top of the same base models. For Mean-Teacher, we perform grid search for weight of consistency loss (select from $\{0.1, 1, 10\}$) and number of labeled instances in a mini-batch with size 50 (select from $\{1, 3, 5\}$). For DualRE, we perform greedy search for retrieval module dropout (select from $\{0.1, 0.3, 0.5, 0.7, 0.9\}$), score weight α, β (select from $\{0.5, 1, 2\}$) and label distribution (select from top-k to top-7k distribution and true distribution). The best hyperparameters are chosen according to model performance on the development set.

For semi-supervised models that promote instances in an iterative manner (Self-Training, RE-Ensemble and DualRE), we fix the number of retrieved instances per iteration k for fair comparison. Since DualRE model takes the joint selection of prediction and retrieval modules, retrieving a fixed amount of instances k is not guaranteed. To solve this problem, we starts with a retrieval upper bound $k' = k$ for both modules to select instances. We iteratively increase the upper bound ($k' = 1.25k'$) until we can sample k unique instances from the joint set. In our experiments, k is set to 10% of the number of original unlabeled instances, which means that the unlabeled data is exhausted after 10 iterations.

Evaluation Metric. Following previous work in relation extraction [19, 39], we consider F_1 score as the main metric while precision and recall serve as auxiliary metrics. Note that the correct prediction for no_relation is ignored during the calculation.

5.4 Experiments and Performance Study

Table 2 and 3 show the model performance on both SemEval and TACRED dataset when 50% unlabeled data and various labeled data are available. We conduct several runs of training and testing using different random seeds and report the mean and standard deviation of the results.

Comparing DualRE with Different Methods and Its Variants. Comparing the performance of different models in Table 2 and 3, the first conclusion we draw is that PRNN outperforms other base models in almost all the data points, which demonstrates the effectiveness of the position-aware encoder with the attention mechanism. This justifies the reason for choosing PRNN as the base model for all semi-supervised models.

Secondly, moving on to semi-supervised baseline models, we observe a consistent performance gain when comparing RE-Ensemble with Self-Training. This is a strong evidence that ensemble of single models can boost the performance. However, Mean-Teacher as another self-ensembling method, does not have consistent gain over other models: It shows a clear win in TACRED dataset with 3% labeled data, but falls far behind in all other data points. The reason behind such phenomenon is still under investigation, but Mean-Teacher is clearly not as stable and strong as other semi-supervised baseline models.

Thirdly, our DualRE-Pointwise model outperforms all the baseline models except on TACRED with 3% labeled data. Its overall performance shows the effectiveness of DualRE framework. From the results, we attribute the performance gain to two design choices: (1) Ensemble method. Both DualRE-Pointwise and RE-Ensemble apply such strategy. By adding another prediction module, RE-Ensemble can already outperform its counterpart (Self-Training). (2) Introduction of dual task. Instead of replicating another prediction module as in RE-Ensemble, DualRE-Pointwise introduces the dual retrieval module. Two modules are jointly trained and complement each other. Thus we observe a consistent performance gain of DualRE-Pointwise over RE-Ensemble.

Lastly, speaking of the variant of DualRE, DualRE-Pairwise has comparable or even better performance as DualRE-Pointwise on the SemEval dataset but not on TACRED. Since DualRE-Pointwise generally performs better than DualRE-Pairwise, we use "DualRE" to refer to DualRE-Pointwise model in the following sections.

Performance on Different Datasets. One can clearly observe that the advantage of DualRE-Pairwise model over other baseline models becomes smaller on the TACRED dataset, comparing to SemEval. Considering the complexity and imbalance distribution in TACRED dataset over SemEval, it is more difficult to learn a strong retrieval module, especially for those rare relations. Thus DualRE models are not significantly better than other models.

Performance on Different Amounts of Labeled Data. From Table 2 and 3, when we fix the amount of unlabeled data to 50% of the original training set, we can observe that increasing the amount of labeled data effectively improves the model performance. Therefore, adding more labeled data (if accessible) is an efficient approach to boost the performance.

Performance on Different Amounts of Unlabeled Data. In specific domains where human-annotated training instances are expensive to obtain, we aim to leverage a large amount of unlabeled data to boost the performance of our model given limited amount of labeled data. Therefore, for semi-supervised learning, we may wonder whether more unlabeled data will always help. To investigate such a problem, we fix the amount of labeled data and compare

Table 3: Performance comparison on TACRED [39] with various amounts of labeled data and 50% unlabeled data. We report the mean and standard deviation of the evaluation metrics by conducting 3 runs of training and testing using different random seeds. DualRE outperforms all the baseline methods except Mean-Teacher at one data point.

Methods / % Labeled Data	3%			10%			15%

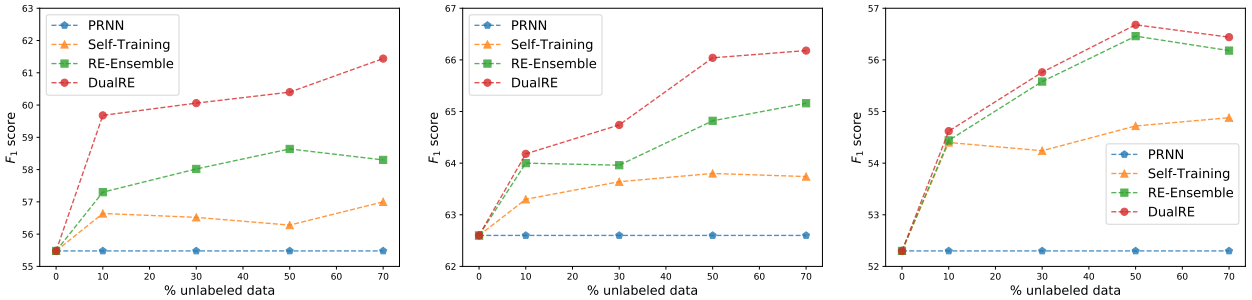

Figure 5: Performance w.r.t. the amount of unlabeled data. Left: 5% labeled data on SemEval; Middle: 10% labeled data on SemEval; Right: 10% labeled data on TACRED. In most cases, increasing unlabeled data results in better performance, but too much unlabeled data may hurt the performance.

Table 4: Comparison of Different Weighing Methods for Instance Promotion. We test with 10% labeled data and 50% unlabeled data on the SemEval dataset. Weighted promotion leads to significant improvement as compared with equal promotion.

Instance Weight	F_1 (Dev)	F_1 (Test)
α=0, β=0 (Equal Promotion)	62.40 ± 0.52	64.42 ± 0.82
α=1, β=1	63.84 ± 0.23	65.98 ± 0.46
α=1, β=2	64.22 ± 0.26	66.02 ± 0.15
α=0.5, β=2	**64.28 ± 0.46**	**66.04 ± 1.00**

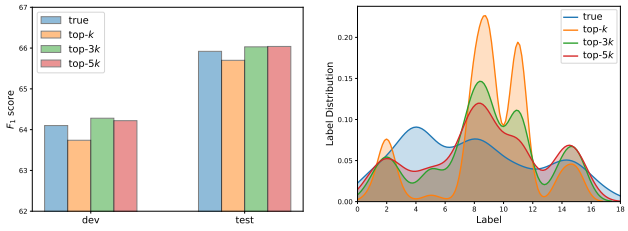

Figure 6: Case Study on Retrieval Module in DualRE. Left: Comparison of using different label distributions as the retrieval query; Right: A visualization of different label distributions in the first iteration. Both are evaluated with 10% labeled data and 50% unlabeled data on the SemEval dataset.

the performance under different amounts of unlabeled data. More specifically, we investigate the model performance in SemEval and TACRED dataset, with 5% or 10% labeled data presented. In our experiment, 10%, 30%, 50% and 70% unlabeled data are available.

We summarize the results of DualRE and other methods in Fig. 5. One can observe that most models benefit from larger amount of unlabeled data in the range of 10% to 50%. However, increasing unlabeled data to 70% doesn't result in further improvement for all models. Half of them perform even worse with more unlabeled data. Therefore, it is not necessarily beneficial for semi-supervised models to take in as much unlabeled data as possible.

5.5 Case Study

Effectiveness of Weighted Promotion. We experiment with two different ways of assigning weights to pseudo-labeled instances while training DualRE model. Specifically, different combinations of α and β are explored, according to Section 4.3 . Assigning α=0 and β=0, for instance, is to promote all instances equally in training. Results in Table 4 indicate that by using weighted promotion, we can get better results than equal promotion.

Choice of Reference Relation Distribution. In DualRE, when selecting instances to promote, the retrieval module takes in a reference relation distribution $q(y)$ as described in Sec. 4.2. Practically, we assign $q(y)$ with label distribution from available dataset. Two options are explored: (1) **true**: Use the label distribution from the labeled set L. (2) **top-nk**: Use the label distribution from the most confident $n \times k$ instances given by the prediction module.

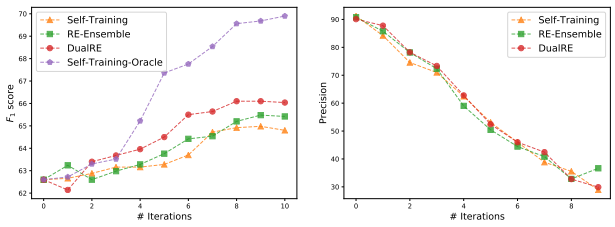

Figure 7: Analysis on Quality of Retrieved Instances. Left: Convergence curve of test F_1 score for different methods; Right: Precision of the relation mentions selected in each iteration. Both are evaluated with 10% labeled data and 50% unlabeled data on the SemEval dataset.

According to Fig. 6, it can be concluded that the best performance is achieved at top-3k, whose distribution lies between true and top-k. Intuitively, the retrieved instances work better if they follow the true distribution. Due to the unbalanced distribution, however, the long-tail relations usually have fewer instances and are harder to learn. The true relation distribution forces the model to attend to these relations and selection quality goes down. On the other hand, top-k distribution is too biased towards frequent relations. Retrieving more of these instances does not add much information for models to learn. Therefore, Top-3k distribution can be regarded as a combination of above two strategies and works better.

Quality of Retrieved Instances. To investigate the underlying reason for performance gain in DualRE, we hypothesize that the quality (i.e. precision) of retrieved instances is higher in DualRE. In the study, we utilize the ground-truth labels of the "unlabeled data" to evaluate the precision of retrieved instances.

In our study, we evaluate the self training methods (Self-Training, RE-Ensemble and DualRE) using test set F_1 score in each iteration together with the precision of its promoted pseudo-labeled instances. Additionally, we construct an oracle model "Self-Training-Oracle" to identify the upper bound of self-training methods. Similar to Self-Training, we rank the instances by their probability of predicted label and select new instances in each iteration. But here we assume that the model can perfectly select those correctly pseudo-labeled instances and add them to the training set in each iteration.

Experimental results are shown in Fig. 7. Comparing results on DualRE and other semi-supervised models, the precision for retrieved instances in each iteration are generally higher in DualRE, which indicates that DualRE can select instances with better quality. This directly contributes to the performance gain in F_1 score in each iteration. To measure the upper bound of semi-supervised models that fall in the self-training category, the performance of Self-Training-Oracle indicates that the potential for such models are high enough to be comparable with RE-Gold (refer to Table 2). But this upper bound is extremely hard to approach because the model does not have additional supervision to guide the instance selection process.

6 RELATED WORK

Relation extraction. Our work is related to sentence-level relation extraction, which aims at predicting the relation label between two entities in a sentence. Traditional relation extraction methods [1, 26] seek to find discriminative textual pattern s with some labeled sentences, and further leverage these patterns for relation extraction. Nevertheless, the learned patterns may have difficulties matching with unseen sentences, as patterns are composed of discrete words. Recent studies leverage deep neural networks such as Long Short-Term Memory Networks (LSTM) [17] and Convolutional Neural Networks (CNN) [37] for relation extraction, achieving much better performance. However, all these methods are fully-supervised, which require a large amount of labeled data to train effective models. By contrast, our proposed approach is semi-supervised, which requires much fewer labeled sentences during training.

Semi-supervised learning. In the literature of semi-supervised learning, there are some methods which can be applied to our problem. One major category is the self-ensembling method [12], which assumes that the predicted labels of the unlabeled instances should remain unchanged under small perturbations on the instances or the model parameters. In this way, they guarantee the local consistency of the prediction and hence improve the performance. However, when applied to our problem, such a training framework relies solely on local consistency as supervision signal, which is weak compared to labeled data, therefore the improvement is marginal. Another category is the self-training method [29], which iteratively promotes instances from unlabeled data. Self-training methods impose a stronger supervision signal and generally achieve better performance. However, it suffers from semantic drift [9], which accumulates systematic errors from prediction model in each iteration. Co-training [2] is an attempt to eliminate this problem. It promotes unlabeled data using two models that are trained on different views of data, which essentially relies on the assumptions that two different sets of features are independent and sufficient for prediction. This assumption is not easy to follow in the relation extraction task, in which relation mention is the only source of input. Our DualRE model, instead, introduces a dual retrieval module to correct the bias from prediction module. Therefore we are able to collect extra training data with higher quality to avoid semantic drifting.

Dual learning. Our work is also related to dual learning [14, 32, 35], which can be generalized to the concept of jointly learning the primal and dual models to boost the performance of each other. For example, English-French translation and French-English translation [14], image classification and image generation [35], question answering and question generation [32] can be treated together to leverage the duality of two tasks. Different from their supervised settings, we apply the concept of dual model in semi-supervised settings and propose an algorithm that effectively utilize the unlabeled data. We are also the first to perform dual model learning in the relation extraction task.

7 CONCLUSION

In this paper, we studied the problem of relation extraction in the semi-supervised setting, where a few labeled sentences and an auxiliary unlabeled corpus are provided. We proposed a principled framework consisting of a prediction module and a retrieval module, which focus on the primal prediction task and the dual retrieval task respectively. During training, we encouraged them to mutually

enhance each other through annotating unlabeled sentences as additional training data. A joint optimization method was proposed for optimizing our framework, which alternates between updating the prediction module and updating the retrieval module. Experimental results on two public datasets proved the effectiveness of our proposed framework. Interesting future work directions include switching the retrieval module to text generative models, extending our framework to deal with various text classification tasks, and studying its connection to the variational auto-encoder method.

Distributed Algorithms for Fully Personalized PageRank on Large Graphs

Wenqing Lin
Interactive Entertainment Group, Tencent Inc.
edwlin@tencent.com

ABSTRACT

Personalized PageRank (PPR) has enormous applications, such as link prediction and recommendation systems for social networks, which often require the fully PPR to be known. Besides, most of real-life graphs are edge-weighted, e.g., the interaction between users on the Facebook network. However, it is computationally difficult to compute the fully PPR, especially on large graphs, not to mention that most existing approaches do not consider the weights of edges. In particular, the existing approach cannot handle graphs with billion edges on a moderate-size cluster. To address this problem, this paper presents a novel study on the computation of fully edge-weighted PPR on large graphs using the distributed computing framework. Specifically, we employ the Monte Carlo approximation that performs a large number of random walks from each node of the graph, and exploits the parallel pipeline framework to reduce the overall running time of the fully PPR. Based on that, we develop several optimization techniques which (i) alleviate the issue of large nodes that could explode the memory space, (ii) pre-compute short walks for small nodes that largely speedup the computation of random walks, and (iii) optimize the amount of random walks to compute in each pipeline that significantly reduces the overhead. With extensive experiments on a variety of real-life graph datasets, we demonstrate that our solution is several orders of magnitude faster than the state-of-the-arts, and meanwhile, largely outperforms the baseline algorithms in terms of accuracy.

1 INTRODUCTION

Given a graph $G = (V, E, w)$, and two nodes $u, v \in V$, the personalized PageRank (PPR) of v with respect to u, denoted by $\pi(u, v)$, is defined as the probability of a random walk starting from u and ending at v. Compared to PageRank (PR), which is a global metric of nodes, PPR depicts the asymmetric perspective of each node to all the other nodes, i.e., $\pi(u, v)$ is not necessarily equal to $\pi(v, u)$. There are a plethora of applications that utilize PPR to measure the proximity of two nodes in the graph, such as recommendation system [5, 19, 21] and natural language processing [1]. In these applications, the fully PPR, i.e., the PPRs of all pairs of nodes, are often required. In other words, for all node v in the graph, the PPR of all the other nodes u with respect to v should be known.

However, most of previous work [9, 11, 16] focus on the computation of single-pair or single-source PPR, rendering them unsuitable for solving the problem of fully PPR. For example, FORA [27] is the recent algorithm for single-source PPR, and needs 103 seconds to answer a single-source query on a Twitter graph of 41.7 millions of nodes, which would require about 137 years to compute the single-source PPRs for all nodes. In addition, it is highly difficult to compute the fully PPR, especially on large graphs. In particular, the probability of a random walk is usually computed by the Power Iteration method [8] or approximated by the Monte Carlo method [7], which might require a large number of iterations of computation to obtain a converged results. Besides, most of existing methods are tailored for the setting of a single machine [7], which renders them unable to handle graphs that cannot fit in memory, not to mention that the space complexity of the fully PPR could be $O(n^2)$ where n is the number of nodes in the graph. What's more, most real-world graphs are weighted, which can be directly generated from the interactions between nodes. For instance, the weight of the edge from a user u to another user v in the Facebook network could be the number of comments from u to the posts of v. Nevertheless, most existing methods do not consider the weights on graph, making their algorithms unsuitable.

To address these issues, we devise a distributed share-nothing solution that employs the Monte Carlo approximation to perform a large number of random walks from all nodes of the graph in parallel. As such, for each node $u \in V$, we maintain only the PPR $\pi(u, v)$ where $v \in V$ is the node incurred in at least one random walk. Besides, we exploit the parallel pipeline framework [13] where (i) a subset of random walks is computed simultaneously in a pipeline and (ii) the new pipeline can remedy the deficiency of the old pipeline, as it is rare to generate long random walks due to the termination probability. Hence, it reduces the number of iterations of computation that significantly accelerates the process.

In order to optimize the above solution, we first address the issue of large nodes that would lead to the skewness of data. Specifically, we recursively divide each large node into small ones, which are then organized as the *alias tree* in a hierarchical manner.

In addition, to address the issue of under-utilization of small nodes, we pre-compute for each small node a set of *short* walks to facilitate the acceleration of random walk generation on small nodes. Finally, since it would significantly degrade the performance of a pipeline which deals with very few or too many random walks at a time, we develop a method that optimizes the number of random walks in each pipeline so as to reduce the overhead of pipelining.

In summary, our contributions are the followings.

- We devise the distributed algorithms based on the parallel pipeline framework that fully utilizes the parallelism to efficiently generate a large number of random walks simultaneously for all nodes of the graph.
- We design the hierarchical sampling algorithm that avoids the skewness on large nodes and also allows the algorithm to select a node from the set of neighbors following the distribution of weights on edges in constant time.
- We develop an efficient algorithm to deal with small nodes by pre-computing short walks so that some random walks can be stopped earlier, which saves lots of costs.
- We devise an effective method to optimize the number of random walks in each pipeline which largely increases the throughput of the algorithm that greatly improves its performance on large graphs.
- In the extensive experiments, we demonstrate that our solution outperforms the state-of-the-art solutions by up to 21% on accuracy and by up to 2 orders of magnitude on the running time.

Paper organization. Section 2 illustrates the definitions and notations used in the paper. An overview of our solution is depicted in Section 3. After that, the details of the algorithm are explained in Section 4. Section 5 demonstrates the superior performance of our algorithm compared with several baseline methods over many graphs. Section 6 discusses the related work of this paper. Finally, we conclude the paper in Section 7.

2 PRELIMINARIES

In this section, we present the concepts and frequently used notations in this paper, as listed in Table 1.

2.1 Personalized PageRank

Consider an edge-weighted graph $G = (V, E, w)$, where V is the set of nodes, E is the set of edges, and w is the weighting function that maps each edge $e \in E$ to a positive number $w(e)$, i.e., $w(e) > 0$. For each node $s \in V$, we say that t is an *out-neighbor* (resp. *in-neighbor*) of s, if there exists an edge $\langle s, t\rangle$ (resp. $\langle t, s\rangle$) such that $\langle s, t\rangle \in E$ (resp. $\langle t, s\rangle \in E$). Denote $N_{out}(s)$ (resp. $N_{in}(s)$) as the set of out-neighbors (resp. in-neighbors) of s.

Given an out-neighbor $t \in N_{out}(s)$ of a node $s \in V$, we refer to the *routing probability* of t with respect to s as $r(s,t) = w(\langle s,t\rangle)/\sum_{v \in N_{out}(s)} w(\langle s,v\rangle)$. As such, we have $r(s,t) \in (0,1]$.

Given a graph $G = (V, E, w)$, a *walk* or *path* P of G is a sequence of nodes, denoted by $\langle v_1, v_2, \cdots, v_k\rangle$, such that (i) $v_i \in V$ for each $i \in [1,k]$ and (ii) $\langle v_i, v_{i+1}\rangle \in E$ for each $i \in [1, k-1]$. The *length* of P, denoted by $\ell(P)$, is the number of edges in P, i.e., $\ell(P) = k - 1$.

A *random walk* $P_r = \langle v_1, v_2, \cdots, v_k\rangle$ of G is a path that is generated in a random manner following the distribution of routing probability. Specifically, for each node v_i where $i \in [1, k-1]$, we have $v_{i+1} \in N_{out}(v_i)$ and v_{i+1} is chosen with the routing probability $r(v_i, v_{i+1})$. Furthermore, at each step of the random walk P_r, there is a *termination probability* $\alpha \in (0,1)$, which is a user-defined number, that determines whether the path will be terminated or not. In other words, after choosing v_{i+1}, P_r will stop at v_{i+1} with the termination probability α. Hence, the expected length of a random walk is $1/\alpha$. In case that $N_{out}(v_i)$ is empty, following the previous work [27], we restart P_r from its head, i.e., v_1.

Example 2.1. Figure 1 shows a graph G which has 8 nodes and 12 weighted edges. The weights of edges incident to each node are normalized such that the routing probability of each edge equals its weight. Consider node v_0 and $\alpha = 0.5$. We have $N_{out}(v_0) = \{v_1, v_2, v_3, v_4, v_5, v_6\}$ and $N_{in}(v_0) = \{v_5\}$. The path $\langle v_0, v_3, v_4\rangle$ is walk starting from v_0 and ending at v_4, which can be generated by (i) first selecting v_3 from $N_{out}(v_0)$ with the probability 0.15, (ii) and then with the probability of $(1-\alpha) = 0.5$ continuing to select v_4 from $N_{out}(v_3)$ with the probability 1, (iii) finally stopping at v_4 with the termination probability $\alpha = 0.5$. Besides, there exist the other paths that start from v_0 and end at v_4, such as $\langle v_0, v_4\rangle$ and $\langle v_0, v_2, v_3, v_4\rangle$. □

Given a graph $G = (V, E, w)$ and two nodes $u, v \in V$, the *personalized PageRank* (PPR) of v with respect to u, denoted by $\pi(u, v)$, is the probability of a random walk which starts from u and ends at v.

To address this problem, there are roughly two kinds of solutions: One is the matrix based solution that utilizes the adjacency matrix of the graph and the matrix of fully PPR, the other one is based on the Monte Carlo (MC) method that estimates the probability by simulating a large number of random walks on the graph. However, the matrix-based solution incurs a space complexity of $O(n^2)$ where n is the number of nodes in the graph, which is extremely huge, especially for large graph. As such, we adopt the MC based solution in our proposed approach.

Specifically, for each node $s \in V$, the MC method generates a number ω of random walks starting from s to estimate $\pi(s,t)$ for every other node $t \in V$. If there are ω' random walks terminating at t, then we have an unbiased estimate of $\pi(s,t)$ as $\hat{\pi}(s,t) = \omega'/\omega$. It is easy to see that a larger ω leads to a more accurate estimate of $\pi(s,t)$, and also a much more expensive computational cost. To strike a good trade-off, we follow the theorem in the work [7] by setting $\omega = \Omega(\frac{\log(1/p_f)}{\epsilon^2\delta})$ to obtain an ϵ-approximate PPR for any $\pi(s,t) \geq \delta$ with a probability $1 - p_f$, where $s, t \in V$, which is formally defined as follows.

Definition 2.2 (Fully Approximate PPR (FAPPR)). Given an edge-weighted graph $G = (V, E, w)$, a threshold δ, an error bound ϵ, and a failure probability p_f, the fully approximate PPR returns an estimated PPR $\hat{\pi}(s,t)$ for all pairs (s,t) of nodes where $s, t \in V$, such that for all $\pi(s,t) \geq \delta$,

$$|\pi(s,t) - \hat{\pi}(s,t)| \leq \epsilon \cdot \pi(s,t) \tag{1}$$

holds with a probability at least $1 - p_f$. □

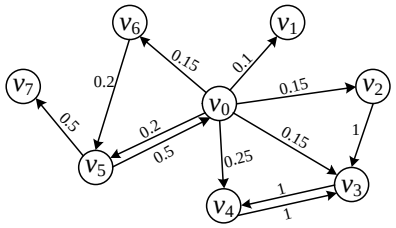

Figure 1: A toy graph with 8 nodes and 12 weighed edges.

Goal. In the present work, we are to devise efficient distributed algorithms for the computation of fully approximate PPR on large graphs.

2.2 The Alias Method

One of the key operations in random walk is to select one node t from s's out-neighbors, where $s \in V$, according to the routing probability. In other words, given a set S of elements, as well as the routing probability $r(e)$ for each $e \in S$, where $\sum_{e \in S} r(e) = 1$, we are to select an element e from S with the probability $r(e)$.

In a naive approach, similar to [4], we can identify an element e from S which has the largest $z^{1/r(e)}$, where $z \in [0, 1]$ is a random number. Consequently, this approach needs to inspect each element in S on the fly, whose time complexity is $O(|S|)$. However, it might lead to the workload imbalance in the distributed computing algorithm on the graph, as the sets of out-neighbors could be of different sizes.

We present *the alias method* [25], which pre-computes a *switch probability* $p(e) \in [0, 1]$ and an *alias* $a(e) \in S$ for each element $e \in S$. As such, an element e can be selected from S with constant time complexity by exploiting $p(e)$ and $a(e)$.

Algorithm 1 illustrates the pre-computing step of the alias method that takes as input the routing probability r and the set S of elements, i.e., edges. Initially, for each edge $e \in S$, its alias $a(e)$ is set as e, and its switch probability $p(e)$ is computed as $|S| \cdot r(e)$ (Line 1). Thus, we have $\sum_{e \in S} p(e) = |S|$ at the beginning of the algorithm. Denote S^l (resp. S^s) as the set of elements e where $p(e) > 1$ (resp. $p(e) < 1$) (Line 2). Then, we choose an element x from S^s and an element y from S^l respectively. After that, we update the alias of x as $a(x) = y$, and decrease the probability of y by $(1 - p(x))$, referred to as $p'(y) = p(y) - (1 - p(x))$. As x is processed, we remove x from S_s. Besides, If $p'(y) \leq 1$, then we remove y from S^l. Furthermore, if $p'(y) < 1$, then we add y into S^s. We iteratively process the elements in S^l, until S^l is empty (Line 3-9). Finally, we have $p(e)$ and $a(e)$ for all $e \in S$ as the results. Since each element in S is inspected only once, the time complexity of this pre-computing step is $O(|S|)$.

Example 2.3. Consider the set $S_1 = \{e_1, e_2, e_3\}$ in Fig. 3. Consider the edges e in S_1. The routing probability of e_1 is computed as $r(e_1) = w(e_1)/\sum_{e \in S_1} w(e) = 0.25$. Similarly, we have $r(e_2) = r(e_3) = 0.375$. At the beginning, the switch probability of e_1 is computed as $p(e_1) = |S_1| \cdot r(e_1)/\sum_{e \in S_1} r(e) = 0.75$. Similarly, we have $p(e_2) = p(e_3) = 1.125$. Besides, we have $a(e_i) = e_i$ where $1 \leq i \leq 3$. As such, we construct $S_1^l = \{e_2, e_3\}$ since $p(e_2) > 1$ and $p(e_3) > 1$, and $S_1^s = \{e_1\}$ since $p(e_1) < 1$. Assume that $e_1 \in S_1^s$ and $e_2 \in S_1^l$ are selected. Then, we update $a(e_1)$ as e_2, remove e_1 from S_1^s, and decrease $p(e_2)$ by $(1 - p(e_1))$, resulting in $p(e_2) = 0.875$. Since $p(e_2) < 1$, we remove e_2 from S_1^l and add e_2 into S_1^s. Then, we have $S_1^s = \{e_2\}$ and $S_1^l = \{e_3\}$. In the same way, we can compute that $a(e_2) = e_3$ and $p(e_3) = 1$, which forms the aliases and switch probabilities of S_1, as shown in Fig. 3. □

Algorithm 1: Alias(S, r)

Input: The set S of elements and the routing probability r
Output: The switch probability $p(e)$ and the alias $a(e)$ for all $e \in S$

1 Let $p(e) = |S| \cdot r(e)$ and $a(e) = e$;
2 Let $S^l = \{e \in S | p(e) > 1\}$ and $S^s = \{e \in S | p(e) < 1\}$;
3 **while** S^l is not empty **do**
4 Select any elements $x \in S^s$ and $y \in S^l$;
5 Let $a(x) = y$ and remove x from S^s;
6 Decrease $p(y)$ by $(1 - p(x))$;
7 **if** $p(y) \leq 1$ **then**
8 Remove y from S^l;
9 If $p(y) < 1$, then add y into S^s;
10 **return** $p(e)$ and $a(e)$ for all $e \in S$.

To select an element e from S with the switch probability $p(e)$ and the alias $a(e)$, we first identify an element e' with the probability $1/|S|$. Then, a probability threshold $p_t \in [0, 1]$ is generated by random. If $p_t \leq p(e')$, then we have $e = e'$; Otherwise, let e be the alias of e', i.e., $e = a(e')$. Therefore, the probability of selecting e from S is $\frac{1}{|S|} \cdot p(e) + \sum_{e' \in S \wedge a(e') = e} \frac{1}{|S|} \cdot (1 - p(e')) = r(e)$. Apparently, the time complexity of selecting by the alias method is $O(1)$.

2.3 Distributed Computing

However, it is impractical to compute FAPPR on a single machine, since (i) the graph could be massive that cannot fit in the memory of a single machine, and (ii) there could be an extremely large amount of computational cost due to lots of graph traversals, especially when the graph is sufficiently large, which also results in a large number of random walks (see Section 2.1).

As such, we utilize the distributed computing to generate the large number of random walks for all nodes of the graph among massive machines in parallel. In particular, we adopt Spark [30], whose fundamental computing unit is MapReduce [3, 23]. Note that, it is easy to extend to the other parallel computing framework, such as Pregel [20]. In a MapReduce job, there are mainly two consequent phases: The first one is the Map phase that takes as input the data and emits key-value pairs by the map function; After that, it is the Reduce phase that aggregates the key-value pairs by the key and then applies the reduce function on the aggregated data, which outputs the new key-value pairs.

To facilitate the processing of graphs on Spark, we store the graph as key-value pairs, such that, for each node $v \in V$, we a key-value pair $\langle v, N_{out}(v) \rangle$ where the key is v and the value is the set of v's out-neighbors, i.e., $N_{out}(v)$. Denote the set of key-value pairs of G as $KV(G) = \{\langle v, N_{out}(v) \rangle | v \in V\}$. Besides, to present a path $P = \langle v_h, \cdots, v_t \rangle$, we use a key-value pair $\langle v_t, v_h \rangle$ consisting

Table 1: Frequently used notations.

Notation	Description
$G = (V, E, w)$	an edge-weighted and directed graph, where V is the set of nodes, E is the set of edges, and w is the weighting function that maps each edge in E to a positive number.
r	the routing probability of an edge (see Section 2.1).
ω	the number of random walks for each node (see Definition 2.2).
γ	the number of random walks in each pipeline (see Definition 2.2).
α	the termination probability of a random walk (see Definition 2.2).
ϵ	the relative accuracy guarantee (see Definition 2.2).
δ	the PPR value threshold (see Definition 2.2).
p	the switch probability of an edge in the alias tree.
a	the alias of an edge in the alias tree.
d	the degree threshold in Algorithm 3 and Algorithm 4.

of the tail v_t of P as the key and the head v_h of P as the value. This is because (i) only the head and tail of a random walk can contribute to the calculation of PPR, and (ii) the extension of a path happens at its tail.

Based on that, given a set $\mathcal{P}$ of paths, we can make a further *move* or *step* for all paths $P \in \mathcal{P}$ by one *round* of computation on Spark that utilizes a MapReduce job: First, the Map phase takes as input both the key-value pairs $\langle v_h, v_t \rangle$ of all paths $P \in \mathcal{P}$ and the key-value pairs $\langle v, N_{out}(v) \rangle \in KV(G)$ of the graph G, and emits the key-value pairs as what they are; Then, in the Reduce phase, we aggregates the key-value pairs by the key, resulting in that each aggregated data has one $\langle v_h, N_{out}(v_h) \rangle$ and several other key-value pairs $\langle v_h, u \rangle$ that represent the paths starting from u and currently visiting v_h. For each $\langle v_h, u \rangle$, we select a node v'_h from $N_{out}(v_h)$ with the routing probability $r(v_h, v'_h)$, and output a new key-value pair $\langle v'_h, u \rangle$, which represents the extended path of $\langle v_h, u \rangle$.

Note that, one can implement the above algorithm by exploiting the *join* operation on Spark. As such, it can be optimized by a careful designed data partitioning scheme [31], which can avoid the cost of transferring between machines the set $KV(G)$ of key-value pairs of G.

3 SOLUTION OVERVIEW

In this section, we present an overview of our distributed algorithm for the computation of the fully approximate edge-weighted PPR (see Definition 2.2). As the major cost of FAPPR resides in the computation of random walks, in the sequel, we will concentrate our discussions on the algorithms for generating random walks.

Given a graph $G = (V, E, w)$, to generate ω random walks for each node $v \in V$ in the distributed computing framework, one straightforward solution could run in ω iterations, each of which computes one random walk for each node. In particular, one random walk P ending with the node v can be extended by one more step in one round of the distributed computing, where we append P with one node randomly chosen from $N(v)$. However, as the expected length of a random walk is $1/\alpha$, this approach results in ω/α number of rounds of computation, which is highly expensive. Alternatively, one might propose to generate all ω random walks for each node $v \in V$ using one iteration with only $1/\alpha$ rounds, where ω number of paths for each node are computed simultaneously. However, this approach would incur significant overhead in the management of memory, as ω could be sufficiently large.

Algorithm 2: Distributed-FAPPR(G, ϵ, p_f, δ, α)

Input: Graph $G = (V, E, w)$, relative accuracy guarantee ϵ, failure probability p_f, threshold δ, termination probability α
Output: The estimated PPR $\hat{\pi}(s, t)$, for all $s, t \in V$

```
Let R_t = ∅ be the collection of terminated random walks;
Let R_a = ∅ be the collection of active random walks;
Let ω = Ω((log(1/p_f))/(ε²δ)) be the number of random walks to be computed for each node v ∈ V;
while S ≠ ∅ or ω > 0 do
    if ω > 0 then
        for each node v ∈ V in parallel do
            Add into R_a min(γ, ω) number of paths consisting of a single node v, i.e., ⟨v, v⟩;
        Update ω as ω − γ;
    for each path P ∈ R_a in parallel do
        Let s and u be the head and tail of P respectively;
        Select a node t ∈ N_out(u);
        Append t to the end of P;
        Generate a random number q ∈ [0, 1];
        if q ≤ α then
            Mark P as terminated;
    Remove from R_a the terminated paths, which are then added into R_t;
Let R_t(s, t) be the set of paths P ∈ R_t where s and t are the head and tail of P respectively;
Compute π̂(s, t) = Σ_{P∈R_t(s,t)} 1/ω in parallel;
return π̂(s, t) for all s, t ∈ V.
```

To remedy the aforementioned issues, we exploit the parallel pipeline framework, as depicted in Figure 2, where (i) each pipeline generates at most $\gamma \in [1, \omega]$ random walks for each node $v \in V$, and (ii) the pipelines begin sequentially, such that one pipeline L starts only when the pipeline L', prior to L, completes one round of computation, i.e., the paths in L' are extended with one step. Therefore, there are $\lceil \omega/\gamma \rceil$ pipelines, and the expected number of rounds in each pipeline is $1/\alpha$. That is, the parallel pipeline framework is expected to employ $(\lceil \omega/\gamma \rceil + 1/\alpha - 1)$ number of rounds of computation, which is much smaller than the one of previous approaches. Besides, as each random walk could be terminated with the probability α, the workload of each pipeline becomes fewer and fewer as the number of iterations increases. Therefore, we can avoid the under-utilization of computing for long pipelines, and make sure that the pipeline L would receive few affections from the pipelines that are far from L.

Algorithm 2 depicts an overview of the proposed algorithm that takes as input the graph $G = (V, E, w)$, the relative accuracy guarantee ϵ, failure probability p_f, threshold δ, and termination

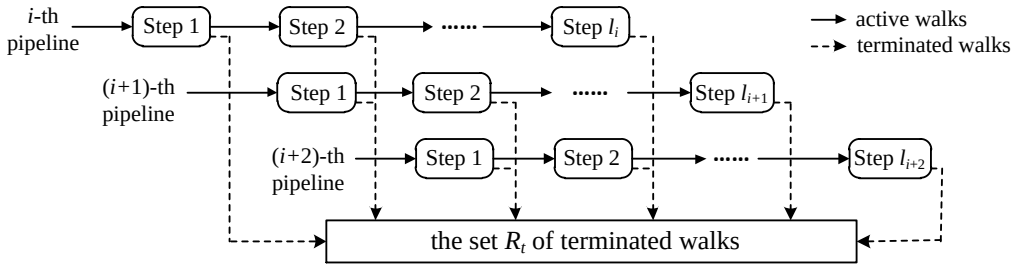

Figure 2: This is an illustration of the parallel pipeline framework. In this framework, there are $\lceil \omega/\gamma \rceil$ pipelines, each of which generates at most γ random walks by several steps. For each $i \in [1, \lceil \omega/\gamma \rceil]$, the $(i+1)$-th pipeline starts, only when the random walks in the i-th pipeline have completed the first step. All terminated walks in the pipelines are maintained in the set R_t, which are the final output of the computation of random walks.

probability α. Initially, we have the empty collections of terminated and active random walks, referred to as R_t and R_a respectively (Lines 1-2). Besides, the number ω of random walks is calculated as $\Omega(\frac{\log(1/p_f)}{\epsilon^2 \delta})$. Then, we generate the random walks by several iterations (Lines 4-16). Each iteration consists of three phases, as follows. In the first phase, for each node $v \in V$, if $\omega > 0$, then we create $\min(\gamma, \omega)$ number of paths $\langle v, v \rangle$ consisting of a single node v, and decrease ω by γ (Lines 5-8). In the second phase, for each path $P \in R_a$, we extend P with one step by selecting a node t the set of out-neighbors of the tail u of P according to the routing probability $r(u, t)$. After that, we append t to the end of P and mark P as terminated if α is not smaller than a random number generated on the fly (Lines 12-15). Finally, we remove from R_a the terminated paths, which are then added into R_t (Line 16). At the end of the algorithm, to compute $\hat{\pi}(s, t)$ for all $s, t \in V$, we calculate the number of paths P in R_t such that the head and tail of P are s and t respectively.

4 OPTIMIZATION TECHNIQUES

In this section, we develop several efficient techniques that significantly improve the performance of Algorithm 2.

4.1 Handling Large Nodes: The Alias Tree

As explained previously, we adopt the alias method which allows us to select one node t from s's out-neighbors, where $s \in V$, according to the routing probability with constant time and linear space complexity. However, when the degree of a node $u \in V$ is sufficiently large, due to that the size of $N_{out}(u)$ could be too large to fit in memory. To avoid this deficiency, we devise a hierarchical approach that recursively divides $N_{out}(u)$ into several subsets, each of which has a size not bigger than d, that can fit in memory, where d is a user-defined parameter and can be estimated according to the amount of available memory. Then, we denote each subset $S' \subseteq S$ as a new item with a weight equal to $\sum_{e \in S'} r(e)$. As such, we construct a new set $\mathcal{S}$ of items, whose alias and switch probability can be computed by the alias method on subsets of S. We build the *alias tree* by letting the alias and switch probability of S' be a child of $\mathcal{S}$ for each item $S' \in \mathcal{S}$. Apparently, the alias tree is multi-way tree, where each node has a similar number of children. If the size of the set $\mathcal{S}$ of the subsets exceeds the size of memory, we recursively divide $\mathcal{S}$ in the same way.

Algorithm 3: Construct-Alias-Tree(S, r, d)

Input: The set S of elements, the routing probability r, and the degree threshold d
Output: The alias tree $T(S)$ of S

1 **if** $|S| \leq d$ **then**
2 Let $T(S)$ be the output of the alias method on S;
3 **else**
4 Let $b = \lceil |S|/d \rceil$;
5 Split S into b disjoint subsets by random, referred to as $\mathcal{S} = \{S_1, S_2, \cdots, S_b\}$;
6 Let $w'(S_i) = \sum_{e \in S_i} r(e)$ for each $i \in [1, b]$;
7 Let $r'(S_i) = \frac{w'(S_i)}{\sum_{S' \in \mathcal{S}} w'(S')}$ for each $i \in [1, b]$;
8 Let $r_i(e) = \frac{r(e)}{\sum_{e' \in S_i} r(e')}$ for each $e \in S_i$ and $i \in [1, b]$;
9 For each $i \in [1, b]$, compute $f(S_i)$ by the alias method, which is treated as a child of $\mathcal{S}$;
10 Build $T(S)$ with Construct-Alias-Tree($\mathcal{S}$, r', d);
11 **return** $T(S)$.

Algorithm 3 provides the pseudo-code of the construction of an alias tree on a given set S of items. The algorithm first inspects the size of S. If its size is not bigger than d, then the algorithm returns the alias directly computed on S by the alias method, which forms a single node of the alias tree (Line 2). Otherwise, we randomly split S into b disjoint subsets (Line 5). Denote the set of subsets by $\mathcal{S} = \{S_1, S_2, \cdots, S_b\}$. Hence, we have $\cup_{S' \in \mathcal{S}} S' = S$ and $\cap_{S' \in \mathcal{S}} S' = \emptyset$. Then, we compute the weight of $S' \in \mathcal{S}$, which is the sum of routing probability of items in S', referred to as $w'(S') = \sum_{e \in S'} r(e)$. Then, for each subset S_i where $1 \leq i \leq b$, the routing probability of S_i with respect to $\mathcal{S}$ is computed as $r'(S_i) = \frac{w'(S_i)}{\sum_{S' \in \mathcal{S}} w'(S')}$ (Line 7). Besides, to compute the alias of each item e in each subset S_i, the routing probability of e with respect to S_i is updated as $r'(S_i) = \frac{w'(S_i)}{\sum_{S' \in S} w'(S')}$ (Line 8). As a result, the child $f(S_i)$ of $\mathcal{S}$ is created by performing the alias method on the updated routing probability of items in S_i

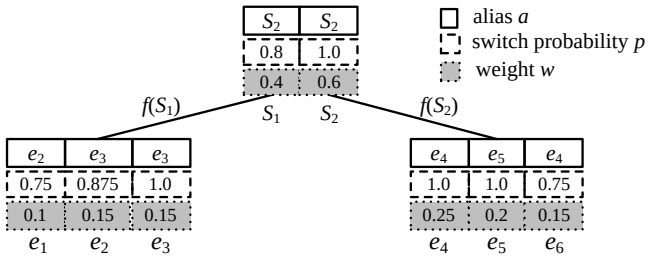

Figure 3: An example of the alias tree.

(Line 9). Finally, we recursively construct the alias tree on $\mathcal{S}$, until the size of $\mathcal{S}$ fits in memory, i.e., not bigger than d (Line 10).

Example 4.1. Consider the 6 out-going edges of v_0 in Figure 1, denoted by $e_1, e_2, \cdots, e_6$ respectively. As shown, in Figure 3, the alias tree stores the 6 edges by treating them as 6 items in a set S. Assume that the degree threshold is $d = 3$. As the size of S is larger than d, we randomly divide S into two sets, e.g., $S_1 = \{e_1, e_2, e_3\}$ and $S_1 = \{e_4, e_5, e_6\}$. Hence, we have $w'(S_1) = r(e_1)+r(e_2)+r(e_3) = 0.4$. Similarly, we have $w'(S_2) = 0.6$. As such, to obtain the routing probabilities, we can normalize the weights of elements in S_1, S_2, and $\mathcal{S}$ respectively. Then, by utilizing the alias method, we construct the aliases and switch probabilities of S_1 and S_2, which form the children of $\mathcal{S}$. After that, we recursively construct the alias of $\mathcal{S}$, which is returned as shown in Figure 3, since the size of $\mathcal{S}$ is less than 3. □

To select an item, we traverse the alias tree $T(S)$ recursively by starting from the root T of $T(S)$. To explain, we first select an item e from T with a probability $1/|T|$, which can be achieved in $O(1)$ time. Then, a random number $r \in [0, 1]$ is generated. If $r \leq p(e)$, then we select e, otherwise $a(e)$. Afterwards, if $f(e)$ is not empty, i.e., e has children, we recursively inspect the items in $f(e)$; otherwise, we return e as the result. Apparently, The running time of the selection process is determined by the height of the alias tree, i.e., $O(\log(|S|)/\log(d))$, where d is the degree threshold. Lemma 1 provides the correctness of random item generation based on the alias tree.

Example 4.2. Consider the alias tree in Example 2.3. To select an element, it consists of two steps: First, we select an element S' from $\mathcal{S}$; Then, an element e is selected from S'. In the first step, assume that S_1 is selected with the probability $1/|\mathcal{S}| = 0.5$. After that, we generate a random number $r \in [0, 1]$. If $r \leq p(S_1)$, we select S_1, otherwise select $a(S_1) = S_2$. As a result, the probability of selecting S_1 is $0.5 \cdot p(S_1) = 0.4$, which equals the normalized weight of S_1, i.e., the routing probability of S_1. Assume that S_1 is selected in the first step. We recursively select an element from S_1 in the same way, which leads to the final selection. □

Lemma 1. *Given a set S of edges, as well as the alias tree T constructed on S, the selection an element $e \in S$ from T has the probability equal to $r(e)$.*

Proof. Let $\langle S_1, S_2, \cdots, S_i \rangle$ be the path from the root of T to a leaf of T, where e resides. Consider a node S_j, where $1 \leq j \leq i$. As shown previously, each item x in S_j is selected with the probability $w(x)/\sum_{y \in S_j} w(y)$. Besides, the weight of S_j is the sum of weights of items in S_j, i.e., $w(S_j) = \sum_{y \in S_j} w(y)$. Note that, $w(S_1) = \sum_{e \in S} r(e) = 1$, since S_1 represents all items in S. Therefore, the probability of selecting e is

$$\frac{w(S_2)}{w(S_1)} \cdot \frac{w(S_3)}{w(S_2)} \cdot \cdots \cdot \frac{w(e)}{w(S_i)} = \frac{r(e)}{w(S_1)} = r(e).$$

□

Algorithm 4: Pre-compute-Big-Moves(G, V_s, d, α)

Input: The graph $G = (V, E, w)$, the set $V_s \subseteq V$ of small nodes, the degree threshold d, and the termination probability α

Output: The big moves for all $v \in V_s$

1 Let $prevBSize = 0$;
2 Let $F(v) = \{\langle u, p(v, u)\rangle \mid u \in N_{out}(v)\}$ for each $v \in V_s$;
3 Let $B(v) = F(v)$ for each $v \in V_s$;
4 **while** $|B(v)| + |F(v)| < d$ and $prevBSize < |B(v)|$ **do**
5 Update $prevBSize$ as $prevBSize = |B(v)|$;
6 Let $F'(v)$ be an empty collection for each $v \in V_s$;
7 **for** each node $\langle u, p(v, u)\rangle \in F(v)$ **in parallel do**
8 **for** each node $t \in N_{out}(u)$ **in parallel do**
9 Add $\langle t, p(v, u) \cdot (1 - \alpha) \cdot p(u, t)\rangle$ into $F'(v)$;
10 Update $B(v)$ as the aggregation result on the pairs $\langle t, p\rangle$ in $F'(v) \cup B(v)$ by t;
11 Replace $F(v)$ with $F'(v)$;
12 Let the set of terminated big moves be $P_t^b(v) = \{\langle t, 0, p \cdot \alpha\rangle \mid \langle t, p\rangle \in B(v)\}$ for $v \in V_s$;
13 Let the set of active big moves be $P_a^b(v) = \{\langle t, 1, p \cdot (1 - \alpha)\rangle \mid \langle t, p\rangle \in F(v)\}$ for $v \in V_s$;
14 **return** $P_t^b(v) \cup P_a^b(v)$ for all $v \in V_s$.

4.2 Handling Small Nodes: Make Big Moves

Most real-life graphs follow the power law [6], whose implication is that the majority of nodes in the graph have a very small set of neighbors (see Table 2). To speed up the random walks among the small-degree nodes, we devise a pre-computing method that generates the *big moves* for each small-degree node, such that each big move represents a random walk of several steps. To facilitate the computation with big moves, we maintain each big move P^b with the similar structure as the normal random walk with a difference in that we add a mark, denoted by $M(P^b)$, to represent whether P^b is terminated or not. If $M(P^b) = 0$, then P^b is a terminated path; otherwise, if $M(P^b) = 1$, then P^b is an active path. As a result, we can denote a big move of v by $\langle u, t_m, p\rangle$ which are the walks ending at u with the termination mark t_m and the probability p. In other words, compared with the set of out-neighbors, the big moves consists of the event of termination, which expands the probability space.

Algorithm 4 describes the generation of big moves for each node v in the set V_s of small nodes. Initially, for each $v \in V_s$, we have the set $F(v)$ of active walks be the set of out-neighbors u of v with the

accumulated probability equal to $p(v,u)$, i.e., $F(v) = \{\langle u, p(v,u)\rangle \mid u \in N_{out}(v)\}$. Besides, we let the set $B(v)$ of the terminated walks be initialized as $F(v)$, and we denote the size of $B(v)$ before updating (Line 10) by *prevBSize*, which is initialized as 0. Note that, the initial sizes of $F(v)$ and $B(v)$ equal the size of $N_{out}(v)$. In what follows, the algorithm runs in several iterations. In each iteration, we extend each walk in $F(v)$ with one more step by adding each node $u \in N_{out}(v)$, resulting in a set $F'(v)$ of new walks. Then, we compute the accumulated paths in both $B(v)$ and $F'(v)$, and also update $F(v)$ with new walks (Lines 5-11). These processes are repeated in iterations, until (i) the number of terminated and active walks exceeds d, i.e., $|B(v)| + |F(v)| \geq d$, or (ii) the walks can not reach any new nodes, i.e., the size of $B(v)$ does not change any more, namely $prevBSize = |B(v)|$. Finally, we integrate the walks in $B(v)$ and $F(v)$ by multiplying the probability in $B(v)$ and $F(v)$ with α and $1-\alpha$ respectively, and adding the termination mark 0 and 1 respectively, which leads to resulting set $BM(v)$ of big moves of v.

Example 4.3. Consider the graph $G = (V, E, w)$ in Figure 1. Assume that the degree threshold $d = 4$ and the termination probability $\alpha = 0.5$. Then, all the nodes $v \in V$, except v_0, need to compute their big moves, since $|N_{out}(v)| < d$. Consider node v_2, which has one out-neighbor v_3. To compute the big move of v_2, we first initialize the set $F(v_2)$ as $\{\langle v_3, 1\rangle\}$ and the set $B(v_2) = F(v_2)$. Since $|F(v_2)|+|B(v_2)| = 2 < d$, we extend each walk in $F(v_2)$ by one step, and obtain the set $F'(v_2) = \{\langle v_4, 1 \times 0.5 \times 1 = 0.5\rangle\}$ as v_3 has only one neighbor, i.e., v_4. Then, we update $prevBSize = |B(v_2)| = 1$, and update $B(v_2)$ as the aggregation of items in $B(v_2)$ and $F'(v_2)$, resulting in the set $\{\langle v_3, 1\rangle, \langle v_4, 0.5\rangle\}$. In addition, $F(v_2)$ is updated as $F'(v_2)$, i.e., $F(v_2) = \{\langle v_4, 0.5\rangle\}$. Afterwards, we continue to extend the walks in $F(v_2)$, since $|F(v_2)| + |B(v_2)| = 3 < d$, and we have $F'(v_2) = \{\langle v_3, 0.5 \times 0.5 \times 1 = 0.25\rangle\}$. Now, we update $prevBSize = |B(v_2)| = 2$, update $F(v_2) = F'(v_2)$, and update $B(v_2)$ as the aggregation of items in $F'(v_2)$ and $B(v_2)$, leading to the set $\{\langle v_3, 1.25\rangle, \langle v_4, 0.5\rangle\}$. Because $prevBSize = |B(v_2)|$, i.e., the size of $B(v_2)$ does not change any more, we stop the iteration, and compute the set $P_t^b(v_2)$ of terminated big moves as $\{\langle v_3, 0, 1.25 \times 0.5 = 0.625\rangle, \langle v_4, 0, 0.5 \times 0.5 = 0.25\rangle\}$ and the set $P_a^b(v_2)$ of active big moves as $\{\langle v_3, 1, 0.25{\times}0.5 = 0.125\rangle\}$. As a result, we have the big moves of v_2 as the set $BM(v_2) = P_t^b(v_2) \cup P_a^b(v_2) = \{\langle v_3, 0, 0.625\rangle, \langle v_4, 0, 0.25\rangle, \langle v_3, 1, 0.125\rangle\}$. □

We show the correctness of Algorithm 4 by Lemma 2.

Lemma 2. *Given a set $BM(v)$ of big moves of v, then $BM(v)$ consists of all random walks starting from v within k steps, where k is the longest length of walks in $BM(v)$.*

Proof. It is sufficient to show that (i) if there exists a path of length at most k that starts from v and ends at u, then u must be in $BM(v)$; and (ii) $\sum_{\langle v, t_m, p\rangle \in BM(v)} p = 1$.

In the first case, we are to show that all paths, whose lengths are not larger than k, are in $BM(v)$. Let $P(v, u_t) = \langle v, u_1, u_2, \cdots, u_t\rangle$ be a path of length $t \leq k$ that starting from v. In the first round, we have u_1 selected, as u_1 is an out-neighbor of v, i.e., $u_1 \in N_{out}(v)$. By induction, u_{i+1} is an out-neighbor of u_i, where $1 \leq i < t$. As such, the sequence $\langle v, u_1, u_2, \cdots, u_t\rangle$ is a path of G.

In the second case, we need to demonstrate that the probability space of $BM(v)$ is completed. Let p_t be the probability that a random walk $P = \langle v, u_1, u_2, \cdots u_t\rangle$ is of length t. Hence, we have

$$\begin{aligned} p_t &= \sum_{\ell(P)=t} p(\langle v, u_1\rangle) p(\langle u_1, u_2\rangle) \cdots p(\langle u_{t-1}, u_t\rangle)(1-\alpha)^{t-1} \\ &= (1-\alpha)^{t-1}. \end{aligned}$$

Consider the probability p' of the event that a random walk $P \in BM(v)$ is a terminated path, which means that P is of length $t \leq k$. As $BM(v)$ contains all paths of length not bigger than k, we have

$$p' = \alpha \cdot \sum_{1 \leq t \leq k} p_t = \alpha \cdot \sum_{1 \leq t \leq k} (1-\alpha)^{t-1} = 1 - (1-\alpha)^k.$$

Besides, consider the probability p'' of the event that a random walk $P \in BM(v)$ is an active path, which indicates that P is of length k. Therefore, we have $p'' = (1-\alpha) \cdot p_k = (1-\alpha)^k$. To sum up, we obtain $\sum_{\langle v, t_m, p\rangle \in BM(v)} p = p' + p'' = 1$, which completes the proof.

□

To continue the generation of the random walk ending with the node v, which is a small node with the set $BM(v)$ of big moves, we randomly select a path $P^b = \langle v, t_m, p\rangle \in BM(v)$ following the distribution of probabilities of paths in $BM(v)$. Note that, the selection can be accomplished in constant time with the alias method. If $t_m = 0$, then P^b is a terminated path, and we add P^b into the set R_t. Otherwise, we continue the walk along the path P^b until the termination.

4.3 Optimizing γ

Our previous discussion has focused on the generation of random walks in the graph G. When the number ω of random walks is considerably large, it could be highly inefficient to generate all random walks for all nodes of G at a time, as discussed in the previous sections. To remedy this deficiency, we proposed the parallel pipeline framework that processes the ω number of random walks by several iterations, each of which generates at most γ random walks for each node of G. That is, there will be $\lceil \omega/\gamma \rceil$ number of pipelines.

One crucial question remains: how do we decide the number γ of random walks in each pipeline? A straightforward approach is to set $\gamma = 1$, i.e., we generate one random walk for each node $v \in V$ in each pipeline. Although this can avoid the memory issues as aforementioned, it brings up the other deficiencies where (i) the probability to having a long walk is low, which leads to the under-utilization of computing resources, and (ii) the number of pipelines would be a lot, which increases the running time. To tackle these issues, we devise a heuristic method to choose γ, as follows. First, in our implementation, we maintain a path P by keeping the head s and the tail t of P, i.e., $\langle s, t\rangle$. As such, it is a constant space cost c for a path P. Second, in the parallel pipeline framework, we start the pipelines sequentially such that one latter pipeline L is started only upon that the pipeline L', prior to L, completes the extension of random walks in L' by one step. Specifically, let s_i be the total number of active random walks that are generated by the first i pipelines. After the extension of one step at the i-th round, the number of remaining random walks is expected to be $(1-\alpha) \cdot s_i$.

Table 2: Datasets.

Name	$\|V\|$	$\|E\|$	d_{avg}	d_{max}	$\|V_s\|/\|V\|$	$\|V_l\|/\|V\|$
GrQc	5,241	28,968	5.5	81	78.3%	15.9%

DBLP	317,080	1,049,866	5.6	306	46.9%	4.2%
Stanford	281,903	2,312,497	8.2	255	75.5%	14.7%
Google	875,713	5,105,039	6.9	456	53.6%	1.9%
Skitter	1,696,415	11,095,298	11.5	35,387	51.0%	0.3%
Patents	3,774,768	16,518,947	7.9	770	38.5%	1.5%
Pokec	1,632,803	30,622,564	21.4	8,763	61.0%	2.6%
LiveJournal	4,846,609	68,475,391	15.9	20,292	66.5%	1.0%
Orkut	3,072,441	117,185,083	43.0	33,007	65.7%	3.3%
Twitter	41,652,230	1,468,364,884	36.6	2,997,469	87.9%	0.2%
Friendster	68,349,466	2,586,147,869	46.1	5,214	65.5%	12.8%

In the $(i+1)$-th pipeline, we start another $n \cdot \gamma$ number of new random walks in total, where n is the number of nodes of G. To sum up, the total expected number of random walks to be processed at the $(i+1)$-th round is $s_{i+1} = n \cdot \gamma + (1-\alpha) \cdot s_i$. Note that, at the beginning, we have $s_1 = n \cdot \gamma$. By solving these formulas, we have

$$s_i = n \cdot \gamma \cdot \sum_{1 \le j \le i} (1-\alpha)^{j-1} = n \cdot \gamma \cdot \frac{1-(1-\alpha)^i}{\alpha} < \frac{n \cdot \gamma}{\alpha}.$$

As such, if the size of available memory on a machine is M, then we have $c \cdot n \cdot \gamma/\alpha \le M$. That is, we obtain $\gamma \le \alpha \cdot M/(n \cdot c)$. Therefore, we can set γ to the maximum integer such that the total size of processed random walks does not exceed the size of available memory, which helps the full utilization of the cluster. By experiments as shown later, we demonstrate that our choice of γ results in good performance of the proposed algorithm.

5 EXPERIMENTS

This section presents the thorough experimental studies on the performance of the proposed algorithm, compared with the state-of-the-art approach, on several real-life datasets.

5.1 Experimental Settings

We implement our distributed algorithm for the computation of FAPPR (dubbed as *DistPPR*) in Scala on Spark 2.0[1], and compare it against two state-of-the-art distributed algorithms: *Doubling* [2] and the PPR library in GraphX[2] (denoted as *GXPPR*). Note that, (i) *Doubling* is a MapReduce algorithm, which can be easily implemented on Spark, and (ii) *GXPPR* is a matrix-based method that iteratively computes with the adjacency matrix of the graph until the convergence of PPR. All of our experiments are conducted on an in-house cluster consisting of up to 201 machines, each of which runs CentOS, and has 16GB memory and 12 Intel Xeon Processor E5-2670 CPU cores. By default, we exploit 51 machines to run the algorithms, where we have one machine as the master and the others as the workers in Spark.

We use 13 real-life networks in our experiments, as shown in Table 2. These data are obtained from the SNAP collection[3], and are intensively evaluated in the literatures [27, 28]. Besides, these data are from various categories: *GrQc* and *CondMat* are collaboration networks; *Enron* is a communication network; *Standford* and *Google* are the web graphs; *Skitter* is a internet topology network; *Patents* and *DBLP* are the citation networks; *Pokec*, *LiveJournal*, *Orkut*, *Twitter*, and *Friendster* are social networks. Furthermore, these data have different sizes, ranged from thousands of edges to billions of edges. Their average out-degrees (denoted by d_{avg}) are relatively small, though their maximum out-degrees (denoted by d_{max}) could be significantly large that are more than 2 million. Let V_s be the set of *small* nodes whose out-degrees are less than d_{avg}, and let V_l be the set of *large* nodes whose out-degrees are more than $\sqrt{d_{max}}$. As shown in Table 2, the small nodes are the majorities in the graph, while the large nodes take only a small portion. Following previous work [29], we adopt the linear parameterization to assign each edge a positive weight for each graph.

In addition, according to previous work [7, 27], we set the failure probability p_f to $1/n$ where n is the number of nodes in the graph, and set the default value of the relative accuracy guarantee ϵ, the threshold δ, and the termination probability α to 0.5. Besides, if the algorithm does not terminate within 24 hours, we omit it from the experiments. We repeat each experiment 3 times and report the average reading of each approach.

5.2 Comparisons with Previous Work

In the first set of experiments, we demonstrate the superiority of our proposed algorithm by evaluating the running time of all the algorithms on all datasets. Note that, the running time of *DistPPR* includes both the time of the optimization techniques, i.e., we compare the running time of all algorithms with the same input data. Figure 5(a) shows the results of *DistPPR*, *Doubling*, and *GXPPR* on the datasets in Table 2. *DistPPR* outperforms all the other methods by up to 2 orders of magnitude on all datasets. This is because *DistPPR* addresses the issues of both large and small nodes and is able to leverage the massive parallelism of the distributed computing. However, *Doubling* spends lots of efforts on combining the short walks that results in a huge combinational space, and *GXPPR* incurs significant overhead in the operations of matrix which could be highly sparse. Besides, *GXPPR* is able to process only two small datasets, which again demonstrates that the matrix-based methods are difficult to handle large graphs that require huge memory space. Furthermore, the results of *Doubling* on the datasets, *LiveJournal*, *Orkut*, *Twitter*, and *Friendster*, are omitted, since the running time of *Doubling* on those datasets exceeds 24 hours. On the contrary, *DistPPR* is able to handle all datasets with a relatively short running time. What's more, compared to *Doubling* and *GXPPR*, the performance of *DistPPR* is less sensitive to the number of edges in the graph.

Besides, to evaluate the accuracy of the approximate solutions, we generate the ground-truth by the exact PPR algorithm [29] that is able to process the graphs with less than ten millions edges on a machine with 48GB memory. Based on that, we evaluate the accuracy of *DistPPR* and *Doubling* on 6 datasets by NDCG and MAP, which are widely used to evaluate the results of ranking[4]. In particular, given the graph $G = (V, E, w)$, for each node $v \in V$,

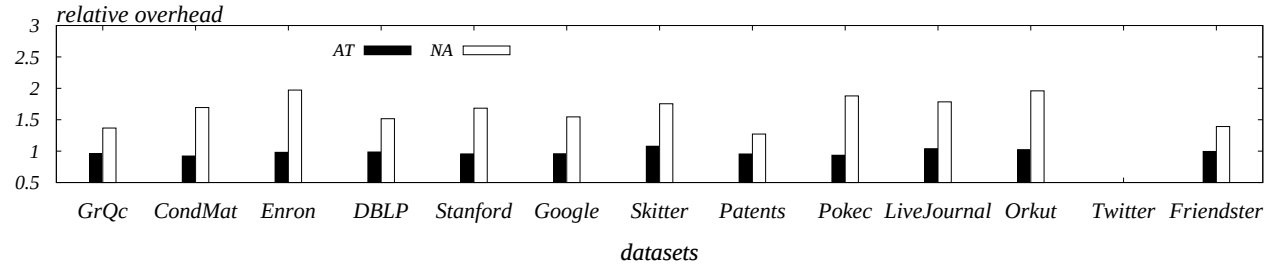

Figure 5: Effects of optimizations.

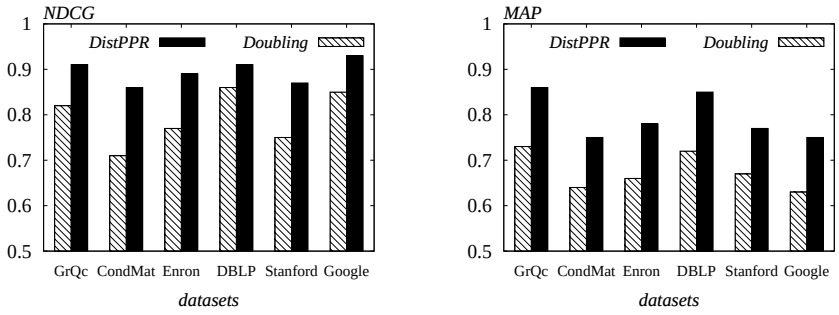
we rank the nodes $u \in V$ by the value $\pi(v, u)$. We take the first 1000 nodes from each ranking for evaluation. Figure 6 shows the results of NDCG and MAP on several datasets for both *DistPPR* and *Doubling* respectively. On all datasets, the NDCG of *DistPPR* outperforms the one of *Doubling* by up to 21%, and the MAP of *DistPPR* is also better than the one of *Doubling* by up to 19%. This is because *Doubling* does not guarantee the accuracy of results, whereas *DistPPR* has a strong accuracy guarantee according to Definition 2.2.

5.3 Effects of Optimizations

In this section of experiments, we study the effects of the three proposed optimization techniques: the alias tree (AT) method for handling large nodes, the big move (BM) technique for accelerating the walks on small nodes, and the technique that auto-tunes γ.

We first evaluate the techniques of AT and BM. We consider two versions of algorithms modified from *DistPPR*: *DistPPR* but with the two optimizations disabled (denoted as *NA*), and *DistPPR* but with only the AT enabled (denoted as *AT*). We define the *relative overhead* of each modified version of *DistPPR* on a dataset D as its running time of D divided by the running time of *DistPPR* with all optimizations enabled. Figure 5(b) shows the relative overheads of *AT* and *NA* on each dataset. Note that, the results on *Twitter* are not shown, as both *AT* and *NA* fail to process *Twitter* whose node degree is highly skew. The relative overheads of *AT* are around 1 in all cases, which indicates that the AT technique allows the algorithm avoiding the issues of large nodes and brings very few overheads in the running time. Meanwhile, the relative overhead of *NA* is around 1.5 on all datasets, implying that the BM technique improves the efficiency of *DistPPR* by a factor of 1.5.

Then, we evaluate the performance of the technique that automatically tunes γ. Recall that $\gamma \leq \omega$ is the parameter in the parallel pipeline framework that decides the number of random walks to generate in a pipeline. To evaluate our choice of γ, we measure the running time of *DistPPR* on the largest dataset *Friendster* by varying γ from 30 to 480, and compare with our autotune technique. We plot the results in Figure 7(a). Observe that the optimal value for γ is around 120, and our automatic choice of γ leads to a performance identical to the optimum. On the contrary, compared to the optimum, when $\gamma \leq 120$, it leads to longer running time, since the number of pipelines increases. Note that, the number of pipelines is $\lceil \omega/\gamma \rceil$. On the other hand, when $\gamma \geq 240$, it overloads the cluster with an excessive number of random walks to process simultaneously, which degrades the performance of *DistPPR*.



In summary, the three optimization techniques improve the efficiency of *DistPPR* by up to 2 times, and help scale *DistPPR* to large graphs whose node degrees could be highly skew.

5.4 Varying Other Parameters

In the last set of experiments, we study the sensitive of *DistPPR* to the other parameters, i.e., the number of workers on Spark and the termination probability α. Note that, we omit the studies on the threshold δ, as δ has the same effect as α to the number ω of random walks. We adopt the largest dataset *Friendster* in all subsequent experiments.

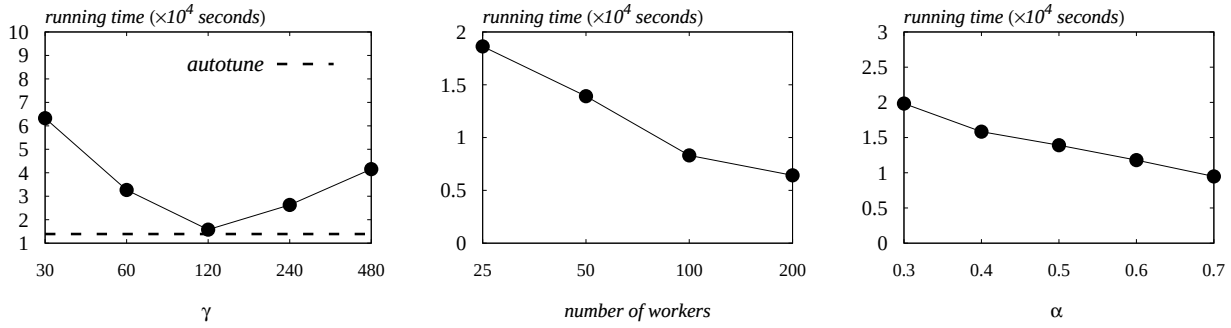


Figure 7(b) reports the running time of *DistPPR* on *Friendster* dataset by varying the number of workers on Spark. When we increase the number of workers, the running time of *DistPPR* decreases accordingly. However, when the number of workers ranges from 100 to 200, the decrease rate of *DistPPR*'s running time becomes low, since the cost of communication between workers increases.

Figure 7(c) shows the performance of *DistPPR* by varying the termination probability α. When α increases, it increases the

(a) NDCG. (b) MAP.

probability of a random walk to be terminated at a certain step, leading to the decrease of the total amount of computation.

6 RELATED WORK

There exist some work [2, 22] that exploit the distributed computing techniques to accelerate the computation of the fully PPR or PR on large graphs based on the Monte Carlo approximation. They first generate some random walks of relatively short length, and then combine the short walks to obtain the random walks of long length. In particular, given two short walks $P_1 = \langle v_{h1} \cdots v_{t1} \rangle$ and $P_2 = \langle v_{h2} \cdots v_{t2} \rangle$, we can combine P_1 and P_2 if and only if the tail v_{t1} of P_1 equals the head v_{h2} of P_2, i.e., $v_{t1} = v_{h2}$, which results in a path $P = \langle v_{h1}, \cdots, v_{t1}, \cdots, v_{t2} \rangle$ of length $\ell(P_1) + \ell(P_2) - 1$. To make the combined paths sufficiently random, however, the number of short walks could be extremely large, especially for the large-degree nodes, rendering these approaches inefficient. Besides, there is no guarantee on the accuracy of the results produced by these approaches [2, 22].

Besides, some distributed algorithms are proposed to answer the queries of single-pair PPR [16] or single-source PPR [9, 11, 16], which differ from the problem of this paper that focuses on the computation of fully PPR. Additionally, there are some distributed and parallel algorithms for graph data [10, 14, 15], but they do not aim for the problem of fully PPR computation.

On the other hand, Fogaras et al. [7] developed an approach on a single machine for the fully PPR by the Monte Carlo approximation. In particular, to facilitate the traversal on the graph, their approach relies on an indexing structure of the graph that is required by the computation of random walks for all nodes, which renders this approach difficult to be implemented as a distributed algorithm. Moreover, there also exist a plethora of techniques for processing the queries of single-pair PPR [17, 18, 26], single-source PPR [12, 24, 27], and top-k PPR [28] on a single machine, all of which have a different problem setting against the fully PPR. Besides, these techniques often require a preprocessing step, which are sequential algorithms, rendering them difficult to be translated in parallel.

Finally, Xie et al. [29] addressed an important issue that edge-weighted graphs widely exist in various applications, which is ignored by previous studies. However, their approach requires to compute based on the adjacency matrix of the graph, which could be prohibitively large.

7 CONCLUSIONS

This paper studies the problem of the fully Personalized PageRank, which has enormous applications in link prediction and recommendation systems for social networks. We approach this problem by devising an efficient distributed algorithm to accelerate the Monte Carlo approximation, which requires to generate a large number of random walks for each node of the graph. We exploit the parallel pipeline framework to achieve the superiority of cluster parallelism. To optimize the proposed algorithm, we develop three techniques that significantly improve the performance of the proposed algorithm in terms of efficiency and scalability. With extensive experiments on various real-life networks, we demonstrate that our proposed solution is up to 2 orders of magnitude faster than the start-of-the-art solutions,

and also outperforms the baseline solutions on the evaluation of accuracy.

ABSTRACT

The task of fashion recommendation includes two main challenges: *visual understanding* and *visual matching*. Visual understanding aims to extract effective visual features. Visual matching aims to model a human notion of compatibility to compute a match between fashion items. Most previous studies rely on recommendation loss alone to guide visual understanding and matching. Although the features captured by these methods describe basic characteristics (e.g., color, texture, shape) of the input items, they are not directly related to the visual signals of the output items (to be recommended). This is problematic because the aesthetic characteristics (e.g., style, design), based on which we can directly infer the output items, are lacking. Features are learned under the recommendation loss alone, where the supervision signal is simply whether the given two items are matched or not.

To address this problem, we propose a neural co-supervision learning framework, called the FAshion Recommendation Machine (FARM). FARM improves visual understanding by incorporating the supervision of generation loss, which we hypothesize to be able to better encode aesthetic information. FARM enhances visual matching by introducing a novel layer-to-layer matching mechanism to fuse aesthetic information more effectively, and meanwhile avoiding paying too much attention to the generation quality and ignoring the recommendation performance.

Extensive experiments on two publicly available datasets show that FARM outperforms state-of-the-art models on outfit recommendation, in terms of AUC and MRR. Detailed analyses of generated and recommended items demonstrate that FARM can encode better features and generate high quality images as references to improve recommendation performance.

CCS CONCEPTS

• **Information systems → Recommender systems**.

1 INTRODUCTION

Fashion recommendation has attracted increasing attention [14, 18, 20] for its potentially wide applications in fashion-oriented online communities such as, e.g., Polyvore[1] and Chictopia.[2] By recommending fashionable items that people may be interested in, fashion recommendation can promote the development of online retail by stimulating people's interests and participation in online shopping. In this paper, we target *outfit recommendation*, that is, given a top (i.e., upper garment), we need to recommend a list of bottoms (e.g., trousers or skirts) from a large collection that best match the top, and vice versa. Specifically, we allow users to provide some descriptions as conditions that the recommended items should accord with as much as possible.

Unlike conventional recommendation tasks, outfit recommendation faces two main challenges: *visual understanding* and *visual matching*. Visual understanding aims to extract effective features by building a deep understanding of fashion item images. Visual matching requires modeling a human notion of the compatibility between fashion items [41], which involves matching features such as color and shape etc. Early studies into outfit recommendation rely on feature engineering for visual understanding and traditional machine learning for visual matching [16]. For example, Iwata et al. [15] define three types of feature, i.e., color, texture and local descriptors such as Scale Invariant Feature Transform (SIFT) (for visual understanding), and propose a recommendation model based on Graphical Models (GM) (for visual matching). Liu et al. [29] define five types of feature including Histograms of Oriented Gradient (HOG) [9], Local Binary Pattern (LBP) [1], color moment, color histogram and skin descriptor [5] (for visual understanding), and propose a latent Support Vector Machine (SVM) based recommendation model (for visual matching).

Recently, neural networks have been applied to address the challenges of fashion recommendation: Song et al. [41] use a pre-trained Convolutional Neural Network (CNN) (on ImageNet) to extract visual features (for visual understanding). Then, they employ a separate Bayesian Personalized Ranking (BPR) [35] method to exploit pairwise preferences between tops and bottoms (for visual matching). Lin et al. [28] propose to train feature extraction (for visual understanding) and preference prediction (for visual matching) in a single back-propagation scheme. They introduce a mutual attention mechanism into CNN to improve feature extraction. The visual features captured by these methods only describe basic characteristics (e.g., color, texture, shape) of the input items, which lack aesthetic characteristics (e.g., style, design) to describe the output items (to be recommended). Visual understanding and matching are conducted based on recommendation loss alone, where the supervision signal is just whether two given items are matched or not and no supervision is available to directly connect the visual signals of the fashion items. Recently, some studies have realized the importance of modeling aesthetic information. For example, Ma et al. [30] build a universal taxonomy to quantitatively describe aesthetic characteristics of clothing. Yu et al. [46] propose to encode aesthetic information by pre-training models on aesthetic assessment datasets. However, none of them is for outfit recommendation and none improves visual understanding and matching like we do.

In this paper, we address the challenges of outfit recommendation from a novel perspective by proposing a neural co-supervision learning framework, called *FAshion Recommendation Machine* (FARM). FARM enhances visual understanding and visual matching with the *joint supervision* of generation and recommendation learning. Let us explain. By incorporating the generation process as a supervision signal, FARM is able to encode more aesthetic characteristics, based on which we can directly generate the output items. FARM enhances visual matching by incorporating a novel layer-to-layer matching mechanism to evaluate the matching score of generated and candidate items at different neural layers; in this manner FARM fuses the generation features from different visual levels to improve the recommendation performance. This layer-to-layer matching mechanism also ensures that FARM avoids paying too much attention to the generation quality and ignoring the recommendation performance. To the best of our knowledge, FARM is the first end-to-end learning framework that improves outfit recommendation with joint modeling of fashion generation.

Extensive experimental results conducted on two publicly available datasets show that FARM outperforms state-of-the-art models on outfit recommendation, in terms of AUC and MRR. To further demonstrate the advantages of FARM, we conduct several analyses and case studies.

To sum up, our contributions can be summarized as follows:

- We propose a neural co-supervision learning framework, FARM, for outfit recommendation that simultaneously yields recommendation and generation.
- We propose a layer-to-layer matching mechanism that acts as a bridge between generation and recommendation, and improves recommendation by leveraging generation features.
- Our proposed approach is shown to be effective in experiments on two large-scale datasets.

2 RELATED WORK

We survey related work on fashion recommendation by focusing on the two main challenges in the area: visual understanding and visual matching.

2.1 Visual understanding

One branch of studies aims at extracting better features to improve the visual understanding of fashion items.

For instance, Iwata et al. [15] propose a recommender system for clothing coordinates using full-body photographs from fashion magazines. They extract visual features, such as color, texture and local descriptors such as SIFT, and use a probabilistic topic model for visual understanding of coordinates from these features. Liu et al. [29] target occasion-oriented clothing recommendation. Given a user-input event, e.g., wedding, shopping or dating, their model recommends the most suitable clothing from the user's own clothing photo album. They adopt clothing attributes (e.g., clothing category, color, pattern) for better visual understanding. Jagadeesh et al. [16] describe a visual recommendation system for street fashion images. They mainly focus on color modeling in terms of visual understanding.

The studies listed above achieve visual understanding mostly based on feature engineering and conventional machine learning techniques. With the availability of large scale fashion recommendation datasets and the rapid development of deep learning models, several recent publications turn to neural networks for fashion recommendation. CNNs are certainly widely employed [26, 31]. Ma et al. [30] build a taxonomy based on a theory of aesthetics to describe aesthetic features of fashion items quantitatively and universally. Then they capture the internal correlation in clothing collocations by a novel fashion-oriented multi-modal deep learning based model. Song et al. [41] use a pre-trained CNN on ImageNet to extract visual features. Then, to improve visual understanding with contextual information (such as titles and categories), they propose to use multi-modal auto-encoders to exploit the latent compatibility of visual and contextual features. Han et al. [11] enrich visual understanding by incorporating sequential information by using a Bidirectional Long Short-Term Memory Network (Bi-LSTM) to predict the next item conditioned on previous ones. They further inject attribute and category information as a kind of regularization to learn a visual-semantic space by regressing visual features to their semantic representations. Kang et al. [20] use a CNN-F [7] to learn image representations and train a personalized fashion recommendation system jointly. Besides, they devise a personalized fashion design system based on the learned CNN-F and user representations. Yu et al. [46] propose to introduce aesthetic information into fashion recommendation. To achieve this, they extract aesthetic features using a pre-trained brain-inspired deep structure on the aesthetic assessment task. Lin et al. [28] enhance visual understanding by jointly modeling fashion recommendation and user comment generation, where the visual features learned with a CNN are enriched because they are related to the generation of user comments.

Even though there is a growing number of studies on better visual understanding for fashion recommendation, none of them takes fashion generation into account like we do in this paper.

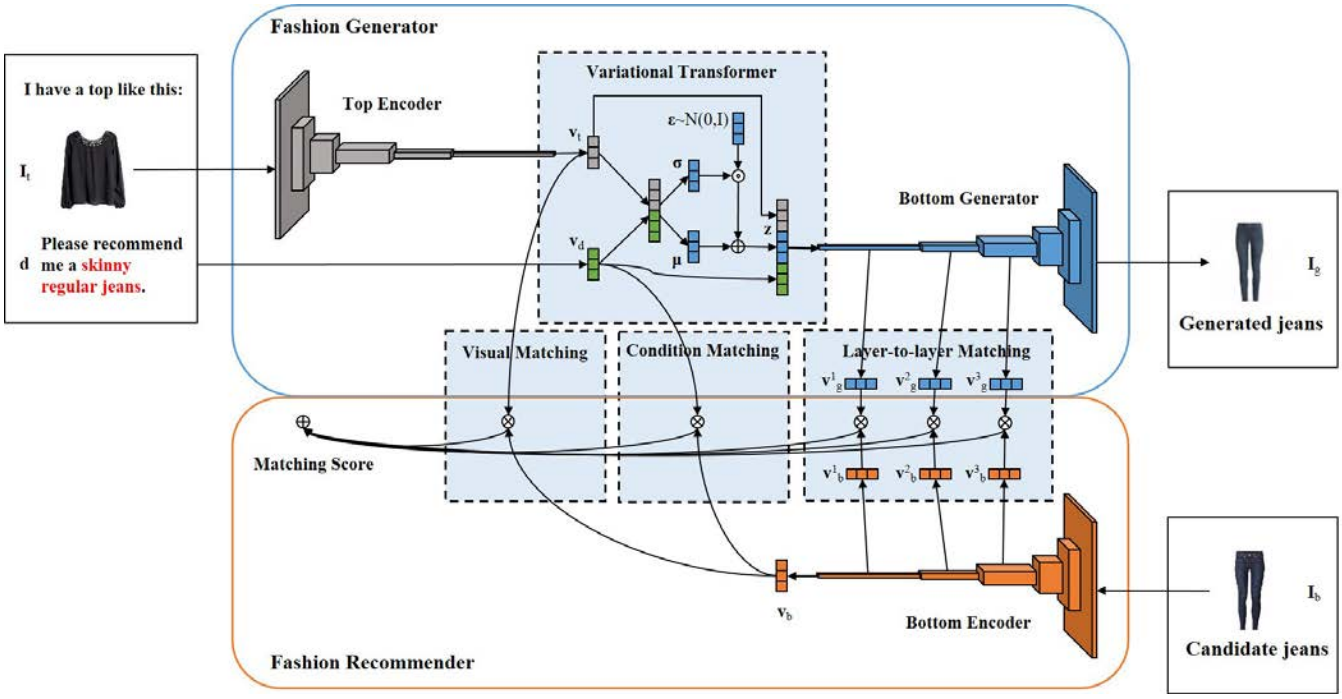

Figure 1: Overview of FARM. The fashion generator (top) uses a variational transformer to learn a special Gaussian distribution for a given top image $\mathbf{I}_t$ and a given bottom description d. It then generates a bottom image $\mathbf{I}_g$ to match $\mathbf{I}_t$ and d. The fashion recommender (bottom) evaluates the matching score between the recommended bottom image $\mathbf{I}_b$ and $(\mathbf{I}_t, \mathbf{d})$ pair from three angles, i.e., visual matching, description matching, and layer-to-layer matching.

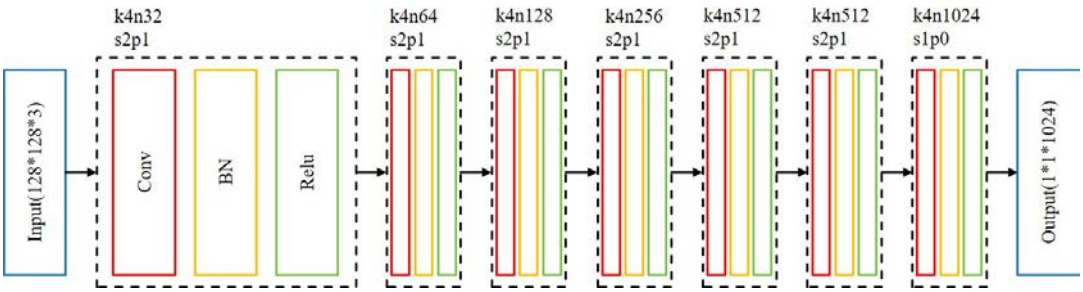
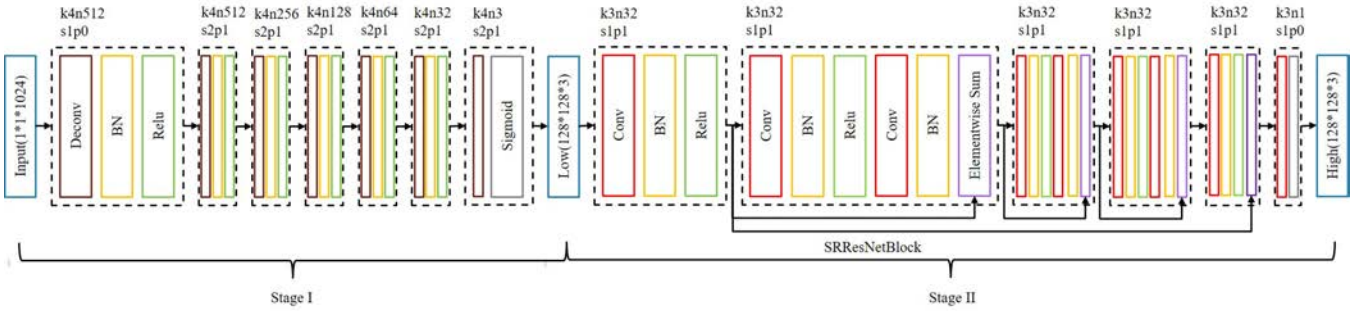
2.2 Visual matching

Early studies into visual matching are based on conventional machine learning methods. Iwata et al. [15] use a topic model to learn the relation between photographs and recommend a bottom that has the closest topic proportions to those of the given top. Liu et al. [29] employ an SVM for recommendation, which has a term describing the relationship between visual features and attributes of tops and bottoms. Simo-Serra et al. [38] predict the popularity of an outfit to implicitly learn its compatibility by a Conditional Random Field (CRF) model. McAuley et al. [31] measure the compatibility between clothes by learning a distance metric with pretrained CNN features. Hu et al. [14] propose a functional pairwise interaction tensor factorization method to model the interactions between fashion items of different categories. Hsiao and Grauman [13] develop a submodular objective function to capture the key ingredients of visual compatibility in outfits. They propose a topic model namely Correlated Topic Models (CTM) to generate compatible outfits learned from unlabeled images of people wearing outfits.



Recently, deep learning methods have been used widely in the fashion recommendation community. Veit et al. [43] train an end-to-end Siamese CNN network to learn a feature transformation from images to a latent compatibility space. Oramas and Tuytelaars [33] mine mid-level elements from CNNs to model the compatibility of clothes. Li et al. [26] use a Recurrent Neural Network (RNN) to predict whether an outfit is popular, which also implicitly learns the compatibility relation between fashion items. Han et al. [11] further train a Bi-LSTM to sequentially predict the next item conditioned on the previous ones for learning their compatibility relationship. Song et al. [41] employ a dual auto-encoder network to learn the latent compatibility space where they use the BPR model to jointly model the relation between visual and contextual modalities and implicit preferences among fashion items. Song et al. [40] consider the knowledge about clothing matching and follow a teacher-student scheme to encode the fashion domain knowledge in a traditional neural network. And they introduce an attentive scheme to the knowledge distillation procedure to flexibly assign rule confidence. Nakamura and Goto [32] present an architecture containing three subnetworks, i.e., VSE (Visual-Semantic Embedding), Bi-LSTM and SE (Style Embedding) modules, to model the matching relation between different items to generate outfits. Lin et al. [28] propose a mutual attention mechanism into CNNs to model the compatibility between different parts of images of fashion items.

Although there are many studies on improving visual matching, none of them considers connecting it with fashion generation.



3 NEURAL FASHION RECOMMENDATION

3.1 Overview

Given a top t from a pool $\mathcal{T} = \{t_1, t_2, \ldots, t_{N_t}\}$ and a user's description d for the target bottom, the *bottom recommendation task* is to recommend a list of bottoms from a candidate pool $\mathcal{B}$ =

(a) Encoder

(b) Generator

Figure 2: Details of the encoder and the generator in FARM, where k represents kernel size, n represents the number of channels, s represents strides and p represents padding.

$\{b_1, b_2, \ldots, b_{N_b}\}$. Similarly, the *top recommendation task* is to recommend a ranked list of tops for a given bottom and top description pair. Here, we use bottom recommendation as the setup to introduce our framework FARM.

As shown in Figure 1, FARM consists of two parts, i.e., a fashion generator (for visual understanding) and a fashion recommender (for visual matching), where the fashion generator is actually an auxiliary module for recommendation. For the fashion generator, we use a CNN as the top encoder to extract the visual features from a given top image $\mathbf{I}_t$. We learn the semantic representation for the bag-of-words vector $\mathbf{d}$ of a given bottom description. Then we use a variational transformer to learn the mapping from the bottom distribution to a specific Gaussian distribution that is based on the visual features of $\mathbf{I}_t$ and the semantic representation of $\mathbf{d}$. Finally, we sample a random vector from the Gaussian distribution and input it to a DeConvolutional Neural Network (DCNN) [48] (as bottom generator) to generate a bottom image $\mathbf{I}_g$ that matches $\mathbf{I}_t$ and $\mathbf{d}$, which explicitly forces the top encoder to encode more aesthetic matching information into the visual features. For the fashion recommender, we also employ a CNN as the bottom encoder to extract the visual features from a candidate bottom image $\mathbf{I}_b$. Then we evaluate the matching score between $\mathbf{I}_b$ and $(\mathbf{I}_t, \mathbf{d})$ pair from three angles, namely the visual matching between $\mathbf{I}_b$ and $\mathbf{I}_t$, the description matching between $\mathbf{I}_b$ and $\mathbf{d}$, and the layer-to-layer matching between $\mathbf{I}_b$ and $\mathbf{I}_g$ which leverages the generation information to improve the recommendation. FARM jointly trains the fashion generator and fashion recommender. Next we will detail each of these two main parts.

3.2 Fashion generator

Given an image $\mathbf{I}_t$ of a top t and the bag-of-words vector $\mathbf{d}$ of a bottom description d, the fashion generator needs to generate a bottom image $\mathbf{I}_g$ that not only matches $\mathbf{I}_t$, but also meets $\mathbf{d}$ as much as possible. We enforce the extracted visual features from $\mathbf{I}_t$ to contain the information about its matching bottom by using the generator as a supervision signal. The generated image can be seen as a reference for recommendation.

Specifically, for a generated bottom image $\mathbf{I}_g$ that matches $\mathbf{I}_t$ and $\mathbf{d}$, the aim of the fashion generator is to maximize Eq. 1:

$$p(\mathbf{I}_g|\mathbf{I}_t, \mathbf{d}) = \int_{\mathbf{z}} p(\mathbf{I}_g|\mathbf{z}, \mathbf{I}_t, \mathbf{d}) p(\mathbf{z}|\mathbf{I}_t, \mathbf{d}) \mathrm{d}\mathbf{z}, \tag{1}$$

where $p(\mathbf{z}|\mathbf{I}_t, \mathbf{d})$ is the top encoder, $p(\mathbf{I}_g|\mathbf{z}, \mathbf{I}_t, \mathbf{d})$ is the bottom generator, and $\mathbf{z}$ is the latent variable. Because the integral of the marginal likelihood shown in Eq. 1 is intractable, inspired by variational inference [4], we first find the Evidence Lower BOund (ELBO) of $p(\mathbf{I}_g|\mathbf{I}_t, \mathbf{d})$, as shown in Eq. 2:

$$\begin{aligned} \mathrm{ELBO} = \mathbb{E}_{\mathbf{z}\sim q(\mathbf{z}|\mathbf{I}_t, \mathbf{d})}[\log p(\mathbf{I}_g|\mathbf{z}, \mathbf{I}_t, \mathbf{d})] \\ -\mathrm{KL}[q(\mathbf{z}|\mathbf{I}_t, \mathbf{d}) \| p(\mathbf{z}|\mathbf{I}_t, \mathbf{d})], \end{aligned} \tag{2}$$

where $q(\mathbf{z}|\mathbf{I}_t, \mathbf{d})$ is the approximation of the intractable true posterior $p(\mathbf{z}|\mathbf{I}_g, \mathbf{I}_t, \mathbf{d})$. The following inequality holds for the ELBO:

$$\log p(\mathbf{I}_g|\mathbf{I}_t, \mathbf{d}) \geqslant \mathrm{ELBO}. \tag{3}$$

Hence, we can maximize the ELBO so as to maximize $\log p(\mathbf{I}_g|\mathbf{I}_t, \mathbf{d})$. The ELBO contains three components: $q(\mathbf{z}|\mathbf{I}_t, \mathbf{d})$, $p(\mathbf{z}|\mathbf{I}_t, \mathbf{d})$ and $p(\mathbf{I}_g|\mathbf{z}, \mathbf{I}_t, \mathbf{d})$. Below we explain each component in detail.

3.2.1 $q(\mathbf{z}|\boldsymbol{I}_t, \boldsymbol{d})$ *and* $p(\mathbf{z}|\boldsymbol{I}_t, \boldsymbol{d})$. We propose a variational transformer (as shown in Figure 1) to model these two components, which transforms $\mathbf{I}_t, \mathbf{d}$ into a latent variable $\mathbf{z}$. As with previous work [23, 37], we assume that $q(\mathbf{z}|\mathbf{I}_t, \mathbf{d})$ and $p(\mathbf{z}|\mathbf{I}_t, \mathbf{d})$ are Gaussian distributions, i.e.,

$$q(\mathbf{z}|\mathbf{I}_t, \mathbf{d}) \sim \mathcal{N}(\mathbf{z}; \boldsymbol{\mu}, \boldsymbol{\sigma}^2), \quad p(\mathbf{z}|\mathbf{I}_t, \mathbf{d}) \sim \mathcal{N}(0, 1), \tag{4}$$

where $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ denote the variational mean and standard deviation respectively, which are calculated with our top encoder and variational transformer as follows.

Specifically, for a top image $\mathbf{I}_t$ of size 128×128 with 3 channels, we first use a CNN, i.e., *the top encoder* (as shown in Figure 2(a)) to extract visual features $\mathbf{F}_t$:

$$\mathbf{F}_t = \mathbf{CNN}(\mathbf{I}_t), \tag{5}$$

where $\mathbf{F}_t \in \mathbb{R}^{W \times H \times D}$, W and H are the width and height of the output feature maps, respectively, and D is the number of output feature maps. And we flatten $\mathbf{F}_t$ into a vector $\mathbf{f}_t \in \mathbb{R}^N$, where $N = W \times H \times D$, and project $\mathbf{f}_t$ to the visual representation $\mathbf{v}_t$:

$$\mathbf{v}_t = \text{sigmoid}(\mathbf{W}_{vt}\mathbf{f}_t + \mathbf{b}_{vt}), \tag{6}$$

where $\mathbf{W}_{vt} \in \mathbb{R}^{e \times N}$, $\mathbf{v}_t$ and $\mathbf{b}_{vt} \in \mathbb{R}^e$, and e is the size of the representation.

Besides the top image, FARM also allows users to give a natural language description $\mathbf{d}$, which describes the ideal bottom they want. In order to take into account the description $\mathbf{d}$, we follow Eq. 7 to get the semantic representation $\mathbf{v}_d$:

$$\mathbf{v}_d = \text{sigmoid}(\mathbf{W}_d\mathbf{d}), \tag{7}$$

where $\mathbf{v}_d \in \mathbb{R}^e$, $\mathbf{d} \in \mathbb{R}^{D_d}$, D_d is the vocabulary size, and $\mathbf{W}_d \in \mathbb{R}^{e \times D_d}$ is the visual semantic word embedding matrix [32], which transforms words from the textual space to the visual space. Specially, when d is an empty description, $\mathbf{v}_d$ is a zero vector.

Then *the variational transformer* uses the visual representation $\mathbf{v}_t$ and the semantic representation $\mathbf{v}_d$ to calculate the mean $\boldsymbol{\mu}$ and standard deviation $\boldsymbol{\sigma}$ for $q(\mathbf{z}|\mathbf{I}_t, \mathbf{d})$:

$$\begin{aligned} \boldsymbol{\mu} &= \mathbf{W}_{\mu t}\mathbf{v}_t + \mathbf{W}_{\mu d}\mathbf{v}_d + \mathbf{b}_\mu \\ \log \boldsymbol{\sigma}^2 &= \mathbf{W}_{\sigma t}\mathbf{v}_t + \mathbf{W}_{\sigma d}\mathbf{v}_d + \mathbf{b}_\sigma, \end{aligned} \tag{8}$$

where $\mathbf{W}_{\mu t}$, $\mathbf{W}_{\mu d}$, $\mathbf{W}_{\sigma t}$ and $\mathbf{W}_{\sigma d} \in \mathbb{R}^{k \times e}$, $\boldsymbol{\mu}$, $\boldsymbol{\sigma}$, $\mathbf{b}_\mu$ and $\mathbf{b}_\sigma \in \mathbb{R}^k$, and k is the size of latent variable $\mathbf{z}$. The latent variable $\mathbf{z}$ can be calculated by the reparameterization trick [23, 37]:

$$\boldsymbol{\epsilon} \sim \mathcal{N}(0, 1), \quad \mathbf{z} = \boldsymbol{\mu} + \boldsymbol{\sigma} \otimes \boldsymbol{\epsilon}, \tag{9}$$

where $\boldsymbol{\epsilon}$ and $\mathbf{z} \in \mathbb{R}^k$, and $\boldsymbol{\epsilon}$ is the auxiliary noise variable. By the reparameterization trick, we make sure $\mathbf{z}$ is a random vector sampled from $\mathcal{N}(\mathbf{z}; \boldsymbol{\mu}, \boldsymbol{\sigma}^2)$.

3.2.2 $p(\boldsymbol{I}_g|\mathbf{z}, \boldsymbol{I}_t, \boldsymbol{d})$. We use the bottom generator (as shown in Figure 2(b)) to generate $\mathbf{I}_g$ from the variable $\mathbf{z}$. We also assume $p(\mathbf{I}_g|\mathbf{z}, \mathbf{I}_t, \mathbf{d})$ is a Gaussian distribution [23, 37], i.e.,

$$p(\mathbf{I}_g|\mathbf{z}, \mathbf{I}_t, \mathbf{d}) \sim \mathcal{N}(g(\mathbf{z}, \mathbf{I}_t, \mathbf{d}), \boldsymbol{\sigma}^2), \tag{10}$$

where g is the bottom generator.

Specifically, we first follow Eq. 11 to obtain the basic visual feature vector $\mathbf{f}_g$:

$$\mathbf{f}_g = \text{relu}(\mathbf{W}_{gz}\mathbf{z} + \mathbf{W}_{gt}\mathbf{v}_t + \mathbf{W}_{gd}\mathbf{v}_d + \mathbf{b}_g), \tag{11}$$

where $\mathbf{f}_g$ and $\mathbf{b}_g \in \mathbb{R}^N$, $\mathbf{W}_{gz}\mathbb{R}^{N \times k}$, $\mathbf{W}_{gt}$ and $\mathbf{W}_{gd} \in \mathbb{R}^{N \times e}$. Then we reshape $\mathbf{f}_g$ into a 3-D tensor $\mathbf{F}_g \in \mathbb{R}^{W \times H \times D}$, which is the reverse operation to what we do for $\mathbf{F}_t$. Finally, we use a DCNN, i.e., *the bottom generator* to generate the bottom image $\mathbf{I}_g$:

$$\mathbf{I}_g = \mathbf{DCNN}(\mathbf{F}_g), \tag{12}$$

where $\mathbf{I}_g \in \mathbb{R}^{128 \times 128 \times 3}$. To avoid generating blurry images [3], we divide the process of image generation into two stages [6, 49]. The first stage is an ordinary deconvolutional neural network that generates low-resolution images. The second stage is similar to the super-resolution residual network (SRResNet) [24], which accepts the images from the first stage and refines them to generate high quality ones. The DCNN is meant to capture high-level aesthetic features of the bottoms to be recommended [47, 48]. Besides, in order to generate the bottom, the generation process also forces the top encoder to capture more aesthetic information.

During training, we first sample a z from $q(\mathbf{z}|\mathbf{I}_t, \mathbf{d})$. Then we generate $\mathbf{I}_g$ with $g(\mathbf{z}, \mathbf{I}_t, \mathbf{d})$. During testing, in order to avoid the randomness introduced by $\boldsymbol{\epsilon}$, we directly generate $\mathbf{I}_g$ by $g(\mathbf{z} = \boldsymbol{\mu}, \mathbf{I}_t, \mathbf{d})$.

3.3 Fashion recommender

Given the image $\mathbf{I}_b$ of a bottom b, the fashion recommender needs to evaluate the matching score between $\mathbf{I}_b$ and the pair $(\mathbf{I}_t, \mathbf{d})$. Specifically, we first use the *bottom encoder* (as shown in Figure 2(a)), which has the same structure as the top encoder (parameters not shared), to extract visual features $\mathbf{F}_b \in \mathbb{R}^{W \times H \times D}$ from $\mathbf{I}_b$. Then we flatten $\mathbf{F}_b$ into a vector $\mathbf{f}_b \in \mathbb{R}^N$ and project $\mathbf{f}_b$ to the visual representation $\mathbf{v}_b$. Next, we calculate the matching score between $\mathbf{I}_b$ and the pair $(\mathbf{I}_t, \mathbf{d})$ in three ways.

3.3.1 Visual matching. We propose visual matching to evaluate the compatibility between $\mathbf{I}_b$ and $\mathbf{I}_t$ based on their visual features. Specifically, we calculate the visual matching score s_v between $\mathbf{I}_b$ and $\mathbf{I}_t$ by Eq. 13:

$$s_v = \mathbf{v}_b^T\mathbf{v}_t. \tag{13}$$

3.3.2 Description matching. For evaluating the matching degree between $\mathbf{I}_b$ and $\mathbf{d}$, we propose to match descriptions. The description matching score s_d between $\mathbf{I}_b$ and $\mathbf{d}$ is calculated by Eq. 14:

$$s_d = \mathbf{v}_b^T\mathbf{v}_d. \tag{14}$$

Note that if d does not contain any word, s_d equals 0.

3.3.3 Layer-to-layer matching. As we will demonstrate in our experiments in Section 6.2, a simple combination of generation and recommendation is not able to improve the recommendation performance. The reason is that there is no direct connection between generation and recommendation, which results in two issues. First, the aesthetic information from the generation process cannot be used effectively. Second, the generation process might introduce features that are only helpful for generation while unhelpful for recommendation. To overcome these issues, we propose a layer-to-layer matching mechanism. Specifically, we denote the visual features of the l-th CNN layer in the bottom encoder as $\mathbf{F}_b^l \in \mathbb{R}^{W^l \times H^l \times D^l}$. And we denote the visual features of the corresponding DCNN layer, which has the same size as $\mathbf{F}_b^l$, in the bottom generator as

$\mathbf{F}_g^l \in \mathbb{R}^{W^l \times H^l \times D^l}$. Then, we reshape $\mathbf{F}_b^l = [\mathbf{f}_{b,1}^l, \ldots, \mathbf{f}_{b,S}^l]$ by flattening the width and height of the original $\mathbf{F}_b^l$, where $S = W^l \times H^l$ and $\mathbf{f}_{b,i}^l \in \mathbb{R}^{D^l}$. And we can consider $\mathbf{f}_{b,i}^l$ as the visual features of the i-th location of $\mathbf{I}_b$. We perform global-average-pooling in $\mathbf{F}_b^l$ to get the global visual features $\mathbf{f}_b^l \in \mathbb{R}^{D^l}$:

$$\mathbf{f}_b^l = \frac{1}{S} \sum_{i=1}^{S} \mathbf{f}_{b,i}^l. \tag{15}$$

We project $\mathbf{f}_b^l$ to the visual representation $\mathbf{v}_b^l \in \mathbb{R}^e$:

$$\mathbf{v}_b^l = \text{sigmoid}(\mathbf{W}_{vb}^l \mathbf{f}_b^l + \mathbf{b}_{vb}^l), \tag{16}$$

where $\mathbf{W}_{vb}^l \in \mathbb{R}^{e \times D^l}$ and $\mathbf{b}_{vb}^l \in \mathbb{R}^e$. The same operations apply to $\mathbf{F}_g^l$ to get $\mathbf{v}_g^l$. Then we calculate the dot product between $\mathbf{v}_b^l$ and $\mathbf{v}_g^l$, which represents the matching degree s_g^l between $\mathbf{I}_b$ and $\mathbf{I}_g$ in the l-th visual level:

$$s_g^l = {\mathbf{v}_b^l}^T \mathbf{v}_g^l. \tag{17}$$

For different visual levels, we sum all s_g^l to get the matching score s_g between $\mathbf{I}_b$ and $\mathbf{I}_g$:

$$s_g = \sum_{l \in L} s_g^l, \tag{18}$$

where L is the selected CNN layer set for layer-to-layer matching.

Finally, the total matching score s between $\mathbf{I}_b$ and the pair $(\mathbf{I}_t, \mathbf{d})$ is defined as follows:

$$s = s_v + s_d + s_g. \tag{19}$$

3.4 Co-supervision learning framework

For FARM, we train the fashion generator and the fashion recommender jointly with a co-supervision learning framework.

Specifically, for the generation part, we regard the image $\mathbf{I}_p$ of a positive bottom p, which not only matches the given top $\mathbf{I}_t$ but also meets the given description $\mathbf{d}$, as the generation target. And we denote the generated bottom image in the first stage as $\mathbf{I}_g^1$, and denote the generated bottom image in the second stage as $\mathbf{I}_g^2$. Then, the first loss is to maximize the first term in ELBO, which is Eq. 20:

$$\mathcal{L}_{gen}(t, d, p) = \frac{1}{2} \|\mathbf{I}_g^1 - \mathbf{I}_p\|_2^2 + \|\mathbf{I}_g^2 - \mathbf{I}_p\|. \tag{20}$$

The second loss is to minimize the second term in ELBO, which is Eq. 21:

$$\mathcal{L}_{kl}(t, d, p) = \frac{1}{2} \sum_{i=1}^{k} (1 + \log \boldsymbol{\sigma}_i^2 - \boldsymbol{\mu}_i^2 - \boldsymbol{\sigma}_i^2), \tag{21}$$

where $\boldsymbol{\mu}_i$ and $\boldsymbol{\sigma}_i$ are the i-th elements in $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ respectively.

For the recommendation part, we employ BPR [35] as the loss:

$$\mathcal{L}_{bpr}(t, d, p, n) = -\log(\text{sigmoid}(s_p - s_n)), \tag{22}$$

where s_p and s_n are the matching scores of a positive bottom $\mathbf{I}_p$ and a negative bottom $\mathbf{I}_n$, respectively (calculated with Eq. 19). $\mathbf{I}_n$ (image of bottom n) is randomly sampled.

The total loss function can be defined as follows:

$$\mathcal{L} = \sum_{(t,d,p,n) \in \mathcal{D}} \mathcal{L}_{gen}(t, d, p) + \mathcal{L}_{kl}(t, d, p) + \mathcal{L}_{bpr}(t, d, p, n), \tag{23}$$

where $\mathcal{D} = \{(t, d, p, n) | t \in \mathcal{T}, d \in \mathcal{D}_b, p \in \mathcal{B}_{t,d}, n \in \mathcal{B} \setminus \mathcal{B}_{t,d}\}$, $\mathcal{D}_b$ is the bottom description set, $\mathcal{B}_{t,d}$ is the positive bottom set for the pair $(\mathbf{I}_t, \mathbf{d})$ and $\mathcal{B} \setminus \mathcal{B}_{t,d}$ is the negative bottom set for the pair $(\mathbf{I}_t, \mathbf{d})$. The whole framework can be efficiently trained using back-propagation in an end-to-end paradigm.

For top recommendation, we follow the same way to build and train the model, but exchange the roles of tops and bottoms.

4 EXPERIMENTAL SETUP

We set up a series of experiments to evaluate the recommendation performance of FARM. Details of our experimental settings are listed below. All code and data used to run the experiments in this paper are available at https://bitbucket.org/Jay_Ren/www2019_fashionrecommendation_yujie/src/master/farm/.

4.1 Datasets

Existing fashion datasets include *WoW* [29], *Exact Street2Shop* [21], *Fashion-136K* [16], *FashionVC* [41] and *ExpFashion* [28]. *WoW*, *Exact Street2Shop*, and *Fashion-136K* have been collected from street photos[3] on the web and involve (visual) parsing of clothing, which still remains a great challenge in the computer vision domain [41, 44, 45] and which is beyond the scope of this paper. *FashionVC* and *ExpFashion* have been collected from the fashion-oriented online community Polyvore[4] and contain both images and texts. The images are of good quality and the texts include descriptions like names and categories. For our experiments, we choose *FashionVC* and *ExpFashion*. The statistics of the two datasets are given in Table 1. We preprocess *FashionVC* or *ExpFashion* with the following steps, taking bottom recommendation as an example. For each tuple (*top*, *top description*, *bottom*, *bottom description*), we regard (*top*, *bottom description*) as input and the *bottom* as the ground truth output. We follow existing studies [41] and randomly select bottoms to generate 100 candidates along with the ground truth bottoms in the validation and test set. Similar processing steps are used for top recommendation.

Table 1: Dataset statistics.

Dataset	Tops	Bottoms	Outfits
FashionVC [41]	14,871	13,663	20,726
ExpFashion [28]	168,682	117,668	853,991

4.2 Implementation details

The parameters W, H, D and N of the encoder and the generator are set to 1, 1, 1024 and 1024, respectively. The size e of the visual semantic word embedding, the semantic representation and the visual representation is set to 100. And the latent variable size k is set to 100 too. The 7th, the 6th and the 5th layers of the encoder CNN are adopted to compute the layer-to-layer matching with the input, the 1st and the 2nd layers of the generator DCNN. To build descriptions, we first filter out words whose frequency is less than 100. Then, we manually go through the rest to only keep words that can describe tops or bottoms. Finally, the remaining vocabulary

[3] http://www.tamaraberg.com/street2shop/
[4] http://www.polyvore.com/

size D_d is 547. During training, we initialize model parameters randomly with the Xavier method [10]. We choose Adam [22] as our optimization algorithm. For the hyper-parameters of the Adam optimizer, we set the learning rate $\alpha = 0.001$, two momentum parameters $\beta 1 = 0.9$ and $\beta 2 = 0.999$, and $\epsilon = 10^{-8}$. We apply dropout [42] to the output of our encoder and set the rate to 0.5. We also apply gradient clipping [34] with range $[-5, 5]$ during training. We use a mini-batch size 64 by grid search to both speed up the training and converge quickly. We test the model performance on the validation set for every epoch. Our framework is implemented with MXNet [8]. All experiments are conducted on a single Titan X GPU.

4.3 Methods used for comparison

We choose the following methods for comparison.

- *LR*: Logistic Regression (LR) is a standard machine learning method [17]. We use it to predict whether a candidate bottom matches a given (*top*, *bottom description*) pair or not. Specifically, we employ a pre-trained CNN to extract visual features from images. Then we follow Eq. 24 to calculate the matching probability p:

$$p = \text{sigmoid}(\mathbf{w}_t^T \mathbf{v}_t + \mathbf{w}_b^T \mathbf{v}_b + \mathbf{w}_d^T \mathbf{d}), \tag{24}$$

  where $\mathbf{v}_t$ and $\mathbf{v}_b \in \mathbb{R}^{D_v}$ are the visual features of the top and the bottom respectively, $\mathbf{w}_t$ and $\mathbf{w}_b \in \mathbb{R}^{D_v}$, and $\mathbf{w}_d \in \mathbb{R}^{D_d}$. D_v is set to 4096 in our experiments.
- *IBR$_d$*: IBR [31] learns a visual style space in which related objects are close and unrelated objects are far. In order to consider the given descriptions at the same time, we modify IBR by projecting descriptions to the visual style space. As a result, we can evaluate the matching degree between objects and descriptions by their distance in the space. Specifically, the distance function between the candidate bottom b and the given (*top*, *bottom description*) pair (t, d) is as follows:

$$m_{tdb} = \|\mathbf{W}_v \mathbf{v}_t - \mathbf{W}_v \mathbf{v}_b\|_2^2 + \|\mathbf{W}_d \mathbf{v}_d - \mathbf{W}_v \mathbf{d}\|_2^2, \tag{25}$$

  where $\mathbf{W}_v \in \mathbb{R}^{K \times D_v}$, $\mathbf{W}_d \in \mathbb{R}^{K \times D_d}$, $\mathbf{v}_t$ and $\mathbf{v}_b \in \mathbb{R}^{D_v}$ are the visual features extracted by a pre-trained CNN, and K is the dimension of the visual style space. D_v is 4096, and K is 100 in our experiments. We refer to the modified version as IBR$_d$.
- *BPR-DAE$_d$*: BPR-DAE [41] can jointly model the implicit matching preference between items in visual and textual modalities and the coherence relation between different modalities of items. In our task, we do not have other text information except descriptions, so we first remove the part of BPR-DAE that is related to text information. Then, for evaluating the matching score between the given description and the candidate item, we project the description representation and the item representation to the same latent space:

$$\mathbf{v}'_d = \text{sigmoid}(\mathbf{W}_d \mathbf{d}), \quad \mathbf{v}'_i = \text{sigmoid}(\mathbf{W}_v \mathbf{v}_i), \tag{26}$$

  where $\mathbf{W}_d \in \mathbb{R}^{K \times D_d}$, $\mathbf{W}_v \in \mathbb{R}^{K \times D_v}$, and $\mathbf{v}_i \in \mathbb{R}^{D_v}$ is the latent representation of item i learned by BPR-DAE. Finally, we follow Eq. 27 to evaluate the compatibility between a candidate bottom b and a given (*top*, *bottom description*) pair (t, d):

$$m_{tdb} = \mathbf{v}_t^T \mathbf{v}_b + \mathbf{v}'^T_d \mathbf{v}'_b. \tag{27}$$

  We set $D_v = 512$, and $K = 100$ in experiments. We refer to the modified version as BPR-DAE$_d$.
- *DVBPR$_d$*: DVBPR [20] learns the image representations and trains the recommender system jointly to recommend fashion items for users. We adopt DVBPR to our task and refer to it as DVBPR$_d$. Specifically, we first follow DVBPR to use a CNN-F to learn image representations of tops and bottoms. Then we calculate the matching score between a bottom and the given (*top*, *bottom description*) pair by Eq. 28:

$$m_{tdb} = \mathbf{v}_t^T \mathbf{v}_b + \mathbf{v}_d^T \mathbf{v}_b, \tag{28}$$

  where $\mathbf{v}_t$ and $\mathbf{v}_b \in \mathbb{R}^K$ are the image representations of the top and bottom respectively, $\mathbf{v}_d \in \mathbb{R}^K$ is the description representation learned in the same way as FARM, and K is set to 100 in experiments.

4.4 Evaluation metrics

We employ *Mean Reciprocal Rank* (MRR) and *Area Under the ROC Curve* (AUC) to evaluate the recommendation performance, which are widely used in recommender systems [25, 36, 50].

In the case of bottom recommendations, for example, MRR and AUC are calculated as follows:

$$\text{MRR} = \frac{1}{|Q^{td}|} \sum_{i=1}^{|Q^{td}|} \frac{1}{rank_i}, \tag{29}$$

where Q^{td} is the (*top*, *bottom description*) collection as queries, and $rank_i$ refers to the rank position of the first positive bottom for the i-th (*top*, *bottom description*) pair. Furthermore,

$$\text{AUC} = \frac{1}{|Q^{td}|} \sum_{(t,d) \in Q^{td}} \frac{1}{|E(t,d)|} \sum_{(p,n) \in E(t,d)} \delta(s_p > s_n), \tag{30}$$

where $E(t, d)$ is the set of all positive and negative candidate bottoms for the given top t and the given bottom description d, s_p is the matching score of a positive bottom p, s_n is the matching score of a negative bottom n, and $\delta(\alpha)$ is an indicator function that equals 1 if α is true and 0 otherwise.

5 RESULTS

The recommendation results on the FashionVC and ExpFashion datasets of FARM and the methods used for comparison are shown in Table 2. We can see that FARM consistently outperforms all baselines in terms of AUC and MRR on both datasets. We have five main observations from Table 2.

(1) FARM significantly outperforms all baselines and achieves the best results on all metrics. There are three main reasons. First, FARM contains a fashion generator as an auxiliary module for recommendation. With its co-supervision learning framework, FARM can encode more aesthetic characteristics and use this extra information to improve recommendation performance; see Section 6.1 for further analysis. Second, we propose a layer-to-layer matching scheme to make sure that FARM can effectively use the aesthetic features in the fashion generator to improve recommendation results; see Section 6.2 for a further analysis. Third, LR, IBR$_d$ and BPR-DAE$_d$ employ pre-trained CNNs (all

Table 2: Recommendation results on the FashionVC and ExpFashion datasets (%).

Method	FashionVC			
	Top		Bottom	
	AUC	MRR	AUC	MRR
LR	48.7	4.5	46.4	4.4
IBR_d	52.8	6.1	62.9	10.3
BPR-DAE_d	62.9	8.6	70.2	10.9
$DVBPR_d$	64.6	9.1	76.9	13.0
FARM	**71.2***	**12.6***	**77.8**	**15.3***
Method	**ExpFashion**			
	Top		Bottom	
	AUC	MRR	AUC	MRR
LR	50.5	5.4	48.4	4.4
IBR_d	56.1	7.1	68.9	12.0
BPR-DAE_d	73.0	12.3	79.9	14.7
$DVBPR_d$	82.4	18.5	83.7	15.4
FARM	**85.2***	**25.1***	**88.4***	**24.3***

The superscript * indicates that FARM significantly outperforms $DVBPR_d$, using a paired t-test with $p < 0.05$.

AlexNet [19] trained on ImageNet[5]) to extract visual features from images, but they do not fine-tune the CNNs during experiments. However, in FARM, we jointly train the top encoder, the bottom encoder and the top/bottom generator, which can extract better visual features.

(2) $DVBPR_d$ performs better than other baseline methods. The reason is that $DVBPR_d$ employs a CNN-F to jointly learn image representations during recommendation. Hence, it can extract more effective visual features to improve recommendation performance.

(3) Although BPR-DAE_d, IBR_d and LR all use visual features extracted by a pre-trained CNN as input, BPR-DAE_d performs much better than the other two. This is because BPR-DAE_d learns a more sophisticated latent space using an auto-encoder neural network to represent the fashion items. However, IBR_d only applies a linear transformation to inputs, which restricts the expressive ability of the visual style space. And LR directly uses the visual features and the bag-of-words vectors as inputs, making it hard to learn an effective matching relation.

(4) The performance of all methods on the ExpFashion dataset is better than on the FashionVC dataset. The most important reason is that the average length of the descriptions in the ExpFashion dataset is 5.6 words, however, it is only 3.7 words in the FashionVC dataset. That means that the descriptions in the ExpFashion dataset contain more details that can provide more information for recommendation and generation, which boosts the recommendation performance.

(5) The bottom recommendation performance is better than the top recommendation performance for most methods. The number of tops is larger than the number of bottoms and the styles of tops are also richer than those of bottoms on both datasets. That makes bottom recommendation and bottom generation easier.

[5]http://www.image-net.org/

Table 3: Analysis of co-supervision learning. Recommendation results on the FashionVC and ExpFashion datasets (%).

Method	FashionVC			
	Top		Bottom	
	AUC	MRR	AUC	MRR
FARM-G	54.8	8.4	60.9	9.8
FARM-R	68.0	9.8	77.2	12.8
FARM	**71.2***	**12.6***	**77.8**	**15.3***
Method	**ExpFashion**			
	Top		Bottom	
	AUC	MRR	AUC	MRR
FARM-G	64.4	14.2	72.4	21.3
FARM-R	82.3	18.9	84.2	15.2
FARM	**85.2***	**25.1***	**88.4***	**24.3***

The superscript * indicates that FARM significantly outperforms FARM-R, using a paired t-test with $p < 0.05$.

In summary, FARM significantly outperforms state-of-the-art methods on both datasets. The improvements mainly come from the co-supervision of generation and the layer-to-layer mechanism, which we will demonstrate in the next section.

6 ANALYSIS

We provide two types of analyses (concerning co-supervision learning and layer-to-layer matching) and two cases studies (recommendation and generation).

6.1 Co-supervision learning

To demonstrate the superiority of incorporating the extra supervision of the generator, we compare FARM with FARM-G and FARM-R, where FARM-G is FARM without the recommendation part and FARM-R is FARM without the generation part. The results are shown in Table 3. To be able to apply FARM-G to the recommendation task, we first use FARM-G to generate a bottom image for a given (*top*, *bottom description*) pair. Then, similar to [2, 27], we use a pre-trained AlexNet to get the representations of the generated bottom and the candidate bottoms. Finally, we compute the similarity between the generated bottom and a candidate bottom based on their representations.

From Table 3, we can see that FARM achieves significant improvements over FARM-R. On the FashionVC dataset, for top recommendation, AUC increases by 3.2%, MRR increases by 2.8%, and for bottom recommendation, AUC increases by 0.6%, MRR increases by 2.5%. On the ExpFashion dataset, for top recommendation, AUC increases by 2.9%, MRR increases by 6.2%, and for bottom recommendation, AUC increases by 4.2%, MRR increases by 9.1%. Thus, FARM is able to improve recommendation performance by using the generator as a supervision signal.

Comparing FARM-G with all baselines, we notice that FARM-G achieves better performance, and especially it performs better than IBR_d in most settings. Hence, the images generated by FARM-G and FARM reflect some key factors of the items to be recommended, which is why the generator can help improve recommendation.

Table 4: Analysis of layer-to-layer matching. Recommendation results on the FashionVC and ExpFashion datasets (%).

Method	FashionVC			
	Top		Bottom	
	AUC	MRR	AUC	MRR
FARM-WL	59.8	7.6	67.8	8.2
FARM	**71.2***	**12.6***	**77.8***	**15.3***
Method	ExpFashion			
	Top		Bottom	
	AUC	MRR	AUC	MRR
FARM-WL	68.6	9.9	74.3	10.3
FARM	**85.2***	**25.1***	**88.4***	**24.3***

The superscript * indicates that FARM significantly outperforms FARM-WL, using a paired t-test with $p < 0.05$.

Additionally, we find that FARM-R outperforms LR, IBR$_d$ and BPR-DAE$_d$. And it achieves comparable performance with DVBPR$_d$, whose difference against FARM-R is mainly in the CNN part. If FARM employs more powerful CNN architectures such as VGG [39] or ResNet [12], it should perform even better.

6.2 Layer-to-layer matching

To analyze the effect of the layer-to-layer matching scheme, we compare FARM with FARM-WL which only uses the visual matching and the description matching to evaluate the matching degree. We can see from Table 4 that FARM performs significantly better than FARM-WL according to all metrics on both datasets, which confirms that layer-to-layer matching does indeed improve the performance of recommendation.

To help understand the effect of layer-to-layer matching, we list some real and generated images in Figure 3. FARM generates good quality images that are similar to real images. This means that the generated images can tell us what kind of bottoms can match the given (*top*, *bottom description*) pair from the perspective of generation, so layer-to-layer matching can direct the recommender by evaluating the matching degree between the candidate images and the generated images. That is why layer-to-layer matching is able to improve the performance of recommendation.

Additionally, we notice that FARM-WL performs worse than FARM-R, which means that a simple combination of recommendation and generation is not able to improve recommendation performance significantly. This may be because, without layer-to-layer matching, FARM-WL pays too much attention to the generation quality and ignores recommendation performance. We are able to improve this situation with layer-to-layer matching. Layer-to-layer matching builds a connection between the bottom generator and the bottom encoder in different layers. As a result, the bottom encoder pushes the bottom generator to learn useful matching information for improving recommendation performance.

6.3 Recommendation case studies

We list some recommendation produced by FARM in Figure 4. For each input, we list the top-10 recommended items. We highlight

(a) Top generation.

(b) Bottom generation.

Figure 3: Comparison between real and generated images.

the positive items with red boxes. We can see that most recommended items not only match the given items, but also meet the given descriptions. For example, in the second case of the top recommendation, the given top description is "sleeve black blazer outerwear jackets,"so most recommended tops are jackets, and especially almost all recommended tops are black. Also in the first case of the bottom recommendation, the given bottom description is "distressed straight leg jean," so the recommended bottoms are all jeans, most of which are straight leg and some are distressed. By comparing the generated items with the recommended items, such as in the first case of the top recommendation and the second case of the bottom recommendation, we can see that the generated images are able to provide good guidance for the recommendation.

We also notice that not all recommended items meet the given description, mostly because FARM recommends items not only based on the given description, but also based on the given item. For example, in the third case of the bottom recommendation, the sixth recommended bottom is a denim jeans instead of a daydress. The given top is a denim coat, which makes FARM believe that recommending a denim jeans is also reasonable. Besides, not all positive items are ranked in the first position. See, e.g., the third case of the top recommendation., where the top recommended item and the given bottom have the same color green, which looks more compatible. In these failure cases, the quality of the generated images is poor so they are likely less helpful for recommendation.

6.4 Generation case studies

Although this paper focuses on improving recommendation by incorporating generation, we also list some generation cases in Figure 5. Overall, the generated items are able to match the given input.

(a) Top recommendation.

(b) Bottom recommendation.

Figure 4: Case studies of recommendation. The items highlighted in the red boxes are the positive ones.

For example, in the sixth case of the top generation, the generated navy blouse with the yellow keen length skirt looks beautiful and elegant. Although there are many kinds of navy blouses like sailor suits, the style of the generated top seems to be more suitable for the given bottom. And in the eighth case of the bottom generation, the given description does not give the specific pattern of the generated bottom.

But the generated bottom has a flame-like pattern, which makes it more compatible with the bright yellow camisole. From these samples we can see that FARM is able to generate fashion items based on the relation between the visual features of different fashion items.

(a) Top generation.

(b) Bottom generation.

Figure 5: Case studies of generation. Each case is in the form: "given description + given item = generated item".

The generated items can accord with the given descriptions no matter what they are about. For example, in the second case of the top generation, the description is "grey wool coats," so the generated top is a grey coat which also looks like wool. And in the fourth case, the description is "gold fur trim puffer jackets", so the generated jacket has fur in its collar and cuff. In the bottom generation, we also observe that FARM is able to distinguish between skinny jeans and bootcut jeans from the first and the second cases. Another example is the sixth case, where the description contains "floral print." FARM generates a black long pencil skirt with flower pattern. In short, FARM is able to build a cross-modal connection between text and images in order to generate fashion items.

Generation is a challenging process, which means that powerful features are needed in order to generate a matching item. We can see from the examples provided that FARM is able to generate aesthetically matching outfits. FARM is able to improve recommendation performance through jointly modeling generation.

7 CONCLUSION

In this paper, we have studied the task of outfit recommendation, which has two main challenges: visual understanding and visual matching. To tackle these challenges, we propose a co-supervision learning framework, namely FARM. For visual understanding, FARM captures aesthetic characteristics with the supervision of generation learning. For visual matching, FARM incorporates a layer-to-layer matching mechanism to evaluate the matching score at different neural layers.

We have conducted experiments to confirm the effectiveness of FARM. It achieves significant improvements over state-of-the-art baselines in terms of AUC and MRR. We also show that the proposed layer-to-layer matching mechanism can make effective use of generation information to improve recommendation performance. We further exhibit some cases to analyze the performance of FARM.

Our results can be used to improve users' experience in fashion-oriented online communities by providing better recommendation and to promote the research into fashion generation by demonstrating a novel application in outfit recommendation.

A limitation of FARM is that its recommendation performance is affected by the quality of the generated images. If the quality of the generated images is not high, the generation part cannot provide effective guidance for the recommendation part.

As to future work, we plan to improve the recommendation and the generation of FARM when the descriptions are lacking. And we want to extend FARM to recommend and generate whole outfits that not only contain tops and bottoms but also include shoes and hats, etc. We will also try more powerful CNN and DCNN architectures for recommendation and generation.

ABSTRACT

Automatic question generation is an important technique that can improve the training of question answering, help chatbots to start or continue a conversation with humans, and provide assessment materials for educational purposes. Existing neural question generation models are not sufficient mainly due to their inability to properly model the process of how each word in the question is selected, i.e., whether repeating the given passage or being generated from a vocabulary. In this paper, we propose our Clue Guided Copy Network for Question Generation (CGC-QG), which is a sequence-to-sequence generative model with copying mechanism, yet employing a variety of novel components and techniques to boost the performance of question generation. In CGC-QG, we design a multi-task labeling strategy to identify whether a question word should be copied from the input passage or be generated instead, guiding the model to learn the accurate boundaries between copying and generation. Furthermore, our input passage encoder takes as input, among a diverse range of other features, the prediction made by a clue word predictor, which helps identify whether each word in the input passage is a potential clue to be copied into the target question. The clue word predictor is designed based on a novel application of Graph Convolutional Networks onto a syntactic dependency tree representation of each passage, thus being able to predict clue words only based on their context in the passage and their relative positions to the answer in the tree. We jointly train the clue prediction as well as question generation with multi-task learning and a number of practical strategies to reduce the complexity. Extensive evaluations show that our model significantly improves the performance of question generation and out-performs all previous state-of-the-art neural question generation models by a substantial margin.

1 INTRODUCTION

Asking questions plays a vital role for both the growth of human beings and the improvement of artificial intelligent systems. As a dual task of question answering, question generation based on a text passage and a given answer has attracted much attention in recent years. One of the key applications of question generation is to automatically produce question-answer pairs to enhance machine reading comprehension systems [8, 34, 35, 38]. Another application is generating practice exercises and assessments for educational purposes [4, 12, 13]. Besides, question generation is also important in conversational systems and chatbots such as Siri, Cortana, Alexa and Google Assistant, helping them to kick-start and continue a conversation with human users [25].

Conventional methods for question generation rely on heuristic rules to perform syntactic transformations of a sentence to factual questions [2, 12], following grammatical and lexical analysis. However, such methods require specifically crafted transformation and generation rules, with low

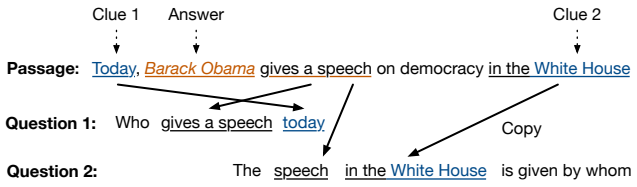

Figure 1: Questions are often asked by repeating some text chunks in the input passage, while there is great flexibility as to which chunks are repeated.

generalizability. Recently, various neural network models have been proposed for question generation [8, 9, 14, 16, 42]. These models formulate the question generation task as a sequence-to-sequence (Seq2Seq) neural learning problem, where different types of encoders and decoders have been designed. Like many other text generation tasks, the copying or pointer mechanism [11] is also widely adopted in question generation to handle the copy phenomenon between input passages and output questions, e.g., [16, 31, 32, 38, 42]. However, we point out that a common limitation that hurdles question generation models mainly use copying mechanisms to handle out-of-vocabulary (OOV) issues, and fail to mark a clear boundary between the set of question words that should be directly copied from the input text and those that should be generated instead.

In this paper, we generate questions by learning to identify where each word in the question should come from, i.e., whether generated from a vocabulary or copied from the input text, and given the answer and its context, what words can potentially be copied from the input passage. People usually repeat text chunks in an input passage when asking questions about it, and generate remaining words from their own language to form a complete question. For example, in Fig. 1, given an input passage "Today, Barack Obama gives a speech on democracy in the White House" and an answer "Barack Obama", we can ask a question "The speech in the White House is given by whom?" Here the text chunks "speech" and "in the White House" are copied from the input passage. However, in the situation that a vocabulary word is an overlap word between a passage and a question, existing models do not clearly identify the underlying reason about the overlapping. In other words, whether this word is copied from the input or generated from vocabulary is not properly labeled. For example, some approaches [42] only take out-of-vocabulary (OOV) words that are shared by both the input passage and target question as copied words, and adopt a copying mechanism to learn to copy these OOV words into questions. In our work, given a passage and a question in a training dataset, we label a word as copied word if it is a nonstop word shared by both the passage and the question, and its word frequency rank in the vocabulary is lower than a threshold. We further aggressively shortlist the output vocabulary based on frequency analysis of the non-copied question words (according to our labeling criteria). Combining this labeling strategy with target vocabulary reduction, during the process of question generation, our model can make better decisions about when to copy or generate, and predict what to generate more accurately.

After applying the above strategies, a remaining problem is which word we should choose to copy. For example, in Fig. 1, we can either ask the question "Who gives a speech today?" or the question "The speech in the White House is given by whom?", where the two questions are related to two different copied text chunks "today" and "White House". We can see that asking a question about a passage and a given answer is actually a "one-to-many" mapping problem: we can ask questions in different ways based on which subset of words we choose to copy from input. Therefore, how to enable a neural model to learn what to copy is a critical problem. To solve this issue, we propose to predict the potential clue words in input passages. A word is considered as a "clue word" if it is helpful to reduce the uncertainty of the model about how to ask a question or what to copy, such as "White House" in question 2 of Fig. 1. In our model, we directly use our previously mentioned copy word labeling strategy to assign a binary label to each input word to indicate whether it is a clue word or not.

To predict the potential clue words in input, we have designed a novel clue prediction model that combines the syntactic dependency tree of an input with Graph Convolutional Networks. The intuition underlying our model design is that: the words copied from an input sentence to an output question are usually closely related to the answer chunk, and the patterns of the dependency paths between the copied words and answer chunks can be captured via Graph Convolutional Networks. Combining the graphical representation of input sentences with GCN enables us to incorporate both word features, such as word vector representation, Named Entity (NE) tags, Part-of-Speech (POS) tags and so on, and the syntactic structure of sentences for clue words prediction.

To generate questions given an answer chunk and the predicted clue words distribution in an input sentence, we apply the Seq2Seq framework which contains our feature-rich sentence encoder and a decoder with attention and copy mechanism. The clue word prediction results are incorporated into the encoder by a binary feature embedding. Based on our multi-task labeling strategy, i.e., labeling for both clue prediction and question generation, we jointly learn different components of our model in a supervised manner.

We performed extensive evaluation on two large question answering datasets: the SQuAD dataset v1.1 [29] and the NewsQA dataset [36]. For each dataset, we use the answer chunk and the sentence that contains the answer chunk as input, and try to predict the question as output. We compared our model with a variety of existing rule-based and neural network based models. Our approach achieves significant improvement by jointly learning the potential clue words distribution for copy and the encoder-decoder framework for generation, and out-performs state-of-the-art approaches.

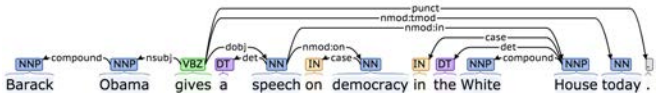

Figure 2: An example to show the syntactic structure of an input sentence. Clue words "White House" and "today" are close to the answer chunk "Barack Obama" with respect to the graph distance, though they are not close to each other in terms of the word order distance.

2 PROBLEM DEFINITION AND MOTIVATION

In this section, we formally introduce the problem of question generation, and illustrate the motivation behind our work.

2.1 Answer-aware Question Generation

Let us denote a passage by P, a question related to this passage by Q, and the answer of that question by A. A passage can be either an input sentence or a paragraph, based on different datasets. A passage consists of a sequence of words $P = \{p_t\}_{t=1}^{|P|}$ where $|P|$ denotes the length of P. A question $Q = \{q_t\}_{t=1}^{|Q|}$ contains words from either a predefined vocabulary V or from the input text P. The task is finding the most probable question $\hat{Q}$ given an input passage and an answer:

$$\hat{Q} = \arg\max_{Q} prob(Q|P, A). \quad (1)$$

Fig. 3 shows an example of the dataset used in our paper. Note that the answer A of the question Q is limited to sub spans of the input passage. However, our work can be easily adapted to the cases where the answer is not a sub span of the input passage by adding an extra answer encoder.

2.2 What to Ask: Clue Word Prediction

Even given the answer of a desired question, the task of question generation is still not a one-to-one mapping, as there are potentially multiple aspects related to the given answer. For example, in Fig. 2, given the answer chunk "Barack Obama", the questions "The speech in the White House is given by whom?", "Who gives a speech on democracy?", and "Today who gives a speech?" are all valid questions. As we can see, although these questions share the same answer, they can be asked in different ways based on which word or phrase we choose to copy (e.g., "White House", "democracy", or "today").

To resolve this issue, we propose to predict the potential "clue words" in the input passage. A "clue word" is defined as a word or phrase that is helpful to guide the way we ask a question, such as "White House", "democracy", and "today" in Fig. 2. We design a clue prediction module based on the syntactical dependency tree representation of passages and Graph Convolutional Networks. Graph Convolutional Networks generalize Convolutional Neural Networks to graph-structured data, and have been successfully applied to natural language processing tasks, including semantic role labeling [23], document matching [20, 39], relation extraction [40], and so on. The intuition underlying our model design is that clue words will be more closely connected to the answer in dependency trees, and the syntactical connection patterns can be learned via graph convolutional networks. For example, in Fig. 2, the graph path distances between answer "Barack Obama" to "democracy", "White House", and "today" are 3, 3, and 2, while the corresponding word order distances between them are 5, 8, and 10, respectively.

Passage:
The Soviet Union and *the People's Republic of China* supported post–World War II communist movements in foreign nations and colonies to advance their own interests, but were not always successful.

Question:
Who along with Russia supported post WW-II communist movements?

Answer:
the People's Republic of China

Figure 3: An example from the SQuAD dataset. Our task is to generate questions given an input passage and an answer. In SQuAD dataset, answers are sub spans of the passages.

2.3 How to Ask: Copy or Generate

Another important problem of question generation is when to choose a word from the target vocabulary and when to copy a word from the input passage during the generation process. People tend to repeat or paraphrase some text pieces in a given passage when they ask a question about it. For instance, in Fig. 3, the question "Who along with Russia supported post WW-II communist movements", the text pieces "supported", "post", and "communist movements" are repeating the input passage, while "Russia" and "WW-II" are synonymous replacements of input phrases "The Soviet Union" and "World War II". Therefore, the copied words in questions should not be restricted to out-of-vocabulary words. Although this phenomenon is well-known by existing approaches, they do not properly and explicitly distinguish whether a word is from copy or from generate.

In our model, we consider the non-stop words that are shared by both an input passage and the output question as clue words, and encourage the model to copy clue words from input. After labeling clue words, we train a GCN-based clue predictor to learn whether each word in source text can be copied to the target question. The predicted clue words are further fed into a Seq2Seq model with attention and copy mechanism to help with question generation. Besides, different from existing approaches that share a vocabulary between source passages and target questions, we reduce the size of the target vocabulary of questions to be smaller than source passages and only include words with word frequency higher than a threshold. The idea is that the low-frequency words in questions are usually copied from source text rather

than generated from a vocabulary. By combining the above strategies, our model is able to learn when to generate or copy a word, as well as which words to copy or generate during the progress of question generation. We will describe our operations in more detail in the next section.

3 MODEL DESCRIPTION

In this section, we introduce our proposed framework in detail. Similar to [8, 30, 42], our question generator is based on an encoder-decoder framework, with attention and copying mechanisms incorporated. Fig. 4 illustrates the overall architecture and detailed components in our model. Our model consists of three components: the clue word predictor, passage encoder and question decoder.

The clue word predictor predicts potential clue words that may appear a target question, based on the specific context of the input passage (without knowing the target question). It utilizes a syntactic dependency tree to reveal the relationship of answer tokens relative to other tokens in a sentence. Based on the tree representation of the input passage, we predict the distribution of clue words by a GCN-based encoder applied on the tree and a Straight-Through (ST) Gumbel-Softmax estimator [15] for clue word sampling. The outputs of the clue word predictor are fed to the passage encoder to advise the encoder about what words may potentially be copied to the target question.

The passage encoder incorporates both the predicted clue word distribution and a variety of other feature embeddings of the input words, such as lexical features, answer position indicators, etc. Combined with a proposed low-frequency masking strategy (a shortlist strategy to reduce complexity on tuning input word embeddings), our encoder learns to better capture the useful input information with fewer trainable parameters.

Finally, the decoder jointly learns the probabilities of generating a word from vocabulary and copying a word from the input passage. At the decoder side, we introduce a multi-task learning strategy to intentionally encourage the copying behavior in question generation. This is achieved by explicitly labeling the copy gate with a binary variable when a (non-stop) word in the question also appears in the input passage in the training set. Other multi-task labels are also incorporated to accurately learn when and what to copy. We further shortlist the target vocabulary based on the frequency distribution of non-overlap words. These strategies, assisted by the encoded features, help our model to clearly learn which word in the passage is indeed a clue word to be copied into the target question, while generating other non-clue words accurately.

The entire model is trained end-to-end via multitask learning, i.e., by minimizing a weighted sum of losses associated with different labels. In the following, we first introduce the encoder and decoder, followed by a description of the clue word predictor.

3.1 The Passage Encoder with Masks

Our encoder is based on bidirectional Gated Recurrent Unit (BiGRU) [3], taking word embeddings, answer position indicators, lexical and frequency features of words, as well as the output of the clue word predictor as the input. Specifically, for each word p_i in input passage P, we concatenate the following features to form a concatenated representation w_i to be input into the encoder:

- **Word Vector**. We initialize each word vector by Glove embedding [28]. If a word is not covered by Glove, we initialize its word vector randomly.
- **Lexical Features**. We perform Named Entity Recognition (NER), Part-of-Speech (POS) tagging and Dependency Parsing (DEP) on input passages using spaCy [24], and concatenate the lexical feature embedding vectors.
- **Binary Features**. We check whether each word is lowercase or not, whether it is a digit or like a number (such as word "three"), and embed these features by vectors.
- **Answer Position**. Similar to [42], we utilize the B/I/O tagging scheme to label the position of a given answer, where a word at the beginning of an answer is marked with **B**, **I** denotes the continuation of the answer, while words not contained in an answer are marked with **O**.
- **Word Frequency Feature**. We derive the word vocabulary from passages and questions in the training dataset. We then rank all the words in a descending order in terms of word frequencies, such that the first word is the most frequent word. The top r_h words are labeled as frequent words. Words ranked between r_h and r_l are labeled as intermediate words. The remaining with rank lower than r_l are labeled as rare words, where r_h and r_l are two predefined thresholds. In this way, each word will be assigned a frequency tag **L** (low frequency), **H** (highly frequent) or **M** (medium frequency).
- **Clue Indicator Feature**. In our model, the clue predictor (which we will introduce in more detail in Sec. 3.3) assigns a binary value to each word to indicate whether it is a potential clue word or not.

Denote an input passage by $P = (w_1, w_2, \cdots, w_{|P|})$. The BiGRU encoder reads the input sequence $w_1, w_2, \cdots, w_{|P|}$ and produces a sequence of hidden states $h_1, h_2, \cdots, h_{|P|}$ to represent the passage P. Each hidden state is a concatenation of a forward representation and a backward representation:

$$h_i = [\overrightarrow{h}_i; \overleftarrow{h}_i], \tag{2}$$

$$\overrightarrow{h}_i = \mathbf{BiGRU}(w_i, \overrightarrow{h}_{i-1}), \tag{3}$$

$$\overleftarrow{h}_i = \mathbf{BiGRU}(w_i, \overleftarrow{h}_{i+1}), \tag{4}$$

where $\overrightarrow{h}_i$ and $\overleftarrow{h}_i$ are the forward and backward hidden states of the i-th token in P, respectively.

Furthermore, rather than learning the full representation w_i for every word in the vocabulary, we use a masking strategy to replace the word embeddings of low-frequency words

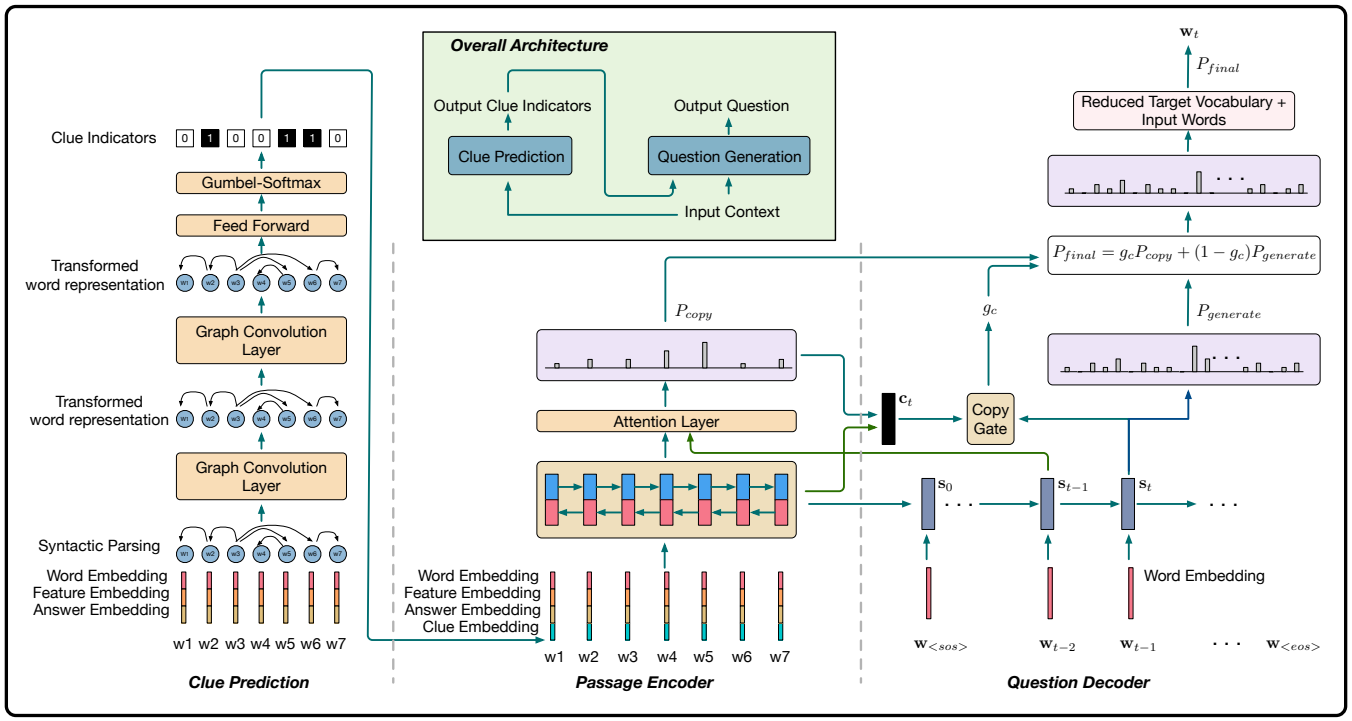

Figure 4: Illustration of the overall architecture of our proposed model. It contains a GCN-based clue word predictor, a masked feature-rich encoder for input passages, and an attention-and-copy-based decoder for generating questions.

with a special ¡l¿ token, such that the information of low-frequency words is only represented by its answer/clue indicators and other augmented feature embeddings, except the word vectors. This strategy can improve performance due to two reasons. First, the augmented tagging features of a low-frequency word tend to be more influential than the word meaning in question generation. For example, given a sentence "¡PERSON¿ likes playing football.", a question that can be generated is "What does ¡PERSON¿ like to play?"—what the token "¡PERSON¿" exactly is does not matter. This way, the masking strategy helps the model to omit the fine details that are not necessary for question generation. Second, the number of parameters that need be learned, especially the number of word embeddings that need be tuned, is largely reduced. Therefore, masking out unnecessary word embeddings while only keeping the corresponding augmented features and indicators does not hurt the performance of question generation. It actually improves training by reducing the model complexity.

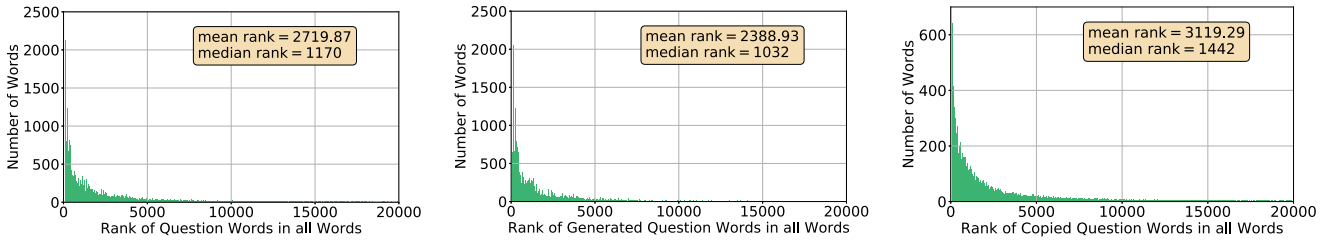
3.2 The Question Decoder with Aggressive Copying

In the decoding stage, we utilize another GRU with copying mechanism to generate question words sequentially based on the encoded input passage representation and previously decoded words. We first initialize the hidden state of the decoder GRU by passing the last backward encoder hidden state $\overleftarrow{h}_1$ to a linear layer:

$$s_0 = tanh(\mathbf{W}_0 \overleftarrow{h}_1 + b). \tag{5}$$

For each decoding time step t, the GRU reads the embedding of the previous word w_{t-1}, previous attentional context vector c_{t-1}, and its previous hidden state s_{t-1} to calculate its current hidden state:

$$s_t = \mathbf{GRU}([w_{t-1}; c_{t-1}], s_{t-1}). \tag{6}$$



The context vector c_t for time step t is generated through the concatenated attention mechanism [21]. Attention mechanism calculates a semantic match between encoder hidden states and the decoder hidden state. The attention weights indicate how the model spreads out the amount it cares about different encoder hidden states during decoding. At time step t, the attention weights and the context vector are calculated as:

$$e_{t,i} = v^\intercal tanh(\mathbf{W}_s s_t + \mathbf{W}_h h_i), \tag{7}$$

$$\alpha_{t,i} = \frac{\exp(e_{t,i})}{\sum_{j=1}^{|P|} \exp(e_{t,j})}, \tag{8}$$

$$c_t = \sum_{i=1}^{|P|} \alpha_{t,i} h_i. \tag{9}$$

Combining the previous word embedding w_{t-1}, the current decoder state s_t and the current context vector c_t, we can calculate a readout state r_t by an MLP maxout layer with dropouts [10]. Then the readout state is passed to a linear

(a) Rank Distribution of All Question Words (b) Rank Distribution of Generated Question Words (c) Rank Distribution of Copied Question Words

Figure 5: Comparing the rank distributions of all question words, words from generation, and words from copy.

layer and a softmax layer to predict the probabilities of the next word over the decoder vocabulary:

$$r_t = \mathbf{W}_{rw} w_{t-1} + \mathbf{W}_{rc} c_t + \mathbf{W}_{rs} s_t \tag{10}$$

$$m_t = [\max\{r_{t,2j-1}, r_{t,2j}\}]_{j=1,\ldots,d}^{\intercal} \tag{11}$$

$$p(y_t|y1, \cdots, y_{t-1}) = \text{softmax}(\mathbf{W}_o m_t), \tag{12}$$

where r_t is a 2-D vector.

The above module generates question words from a given vocabulary. Another important method to generate words is copying from source text. Copy or point mechanism [11] was introduced into sequence-to-sequence models to allow the copying of unknown words from the input text, which solves the out-of-vocabulary (OOV) problem. When decoding at time step t, the probability of copying is given by:

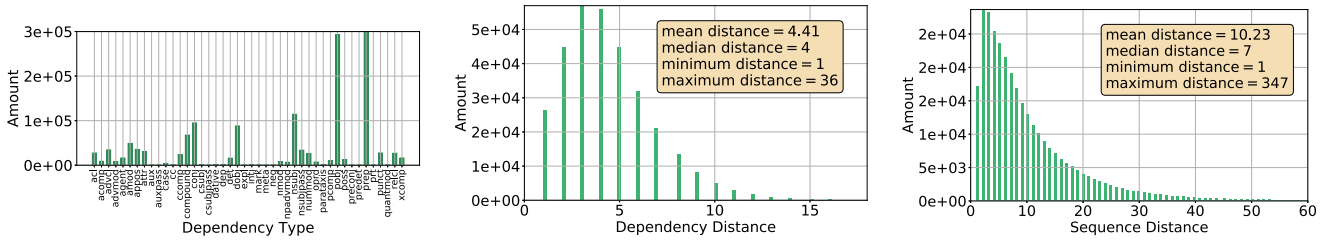
$$g_c = \sigma(\mathbf{W}_{cs} s_t + \mathbf{W}_{cc} c_t + b), \tag{13}$$

where σ is the Sigmoid function, and g_c is the probability of copying. For the copy probability of each input word, we reuse the attention weights given by Equation (8).

Copying mechanism has also been used in question generation [14, 31, 42], however, mainly to solve the OOV issue. Here we leverage the copying mechanism to enable the copying of potential clue words, instead of being limited to OOV words, from input. Different from existing methods, we take a more aggressive approach to train the copying mechanism via multitask learning based on different labels. That is, when preparing the training dataset, we explicitly label a word in a target question as a word copied from the source passage text if it satisfies all the following criteria:

i) it appears in both source text and target question;
ii) it is not a stop word;
iii) its frequency rank in the vocabulary is lower than a threshold r_h.

The remaining words in the question are considered as being generated from the vocabulary. Such a binary label (copy or not copy), together with which input word the question word is copied from, as well as the target question, are fed into different parts of the decoder as labels for multi-task model training. This is to intentionally encourage the copying of potential clue words into the target question rather than generating them from a vocabulary.



The intuition behind such an aggressive copying mechanism can be understood by checking the frequency distributions of both generated words and copied words (as defined above) in the training dataset of SQuAD. Fig. 5 shows the frequency distributions of all question words, and then of generated question words and copied question words. The mean and median rank of generated words are 2389 and 1032, respectively. While for copied words, they are 3119 and 1442. Comparing Fig. 5(b) with Fig. 5(c), we can see that question words generated from the vocabulary tends to be clustered toward high ranked (or frequent) words. On the other hand, the fraction of low ranked (or infrequent) words in copied words are much greater than that in generated words. This means the generated words are mostly from frequent words, while the majority of low-frequency words in the long tail are copied from the input, rather than generated.

This phenomenon matches our intuition: when people ask a question about a given passage, the generated words tend to be commonly used words, while the repeated text chunks from source passage may contain relatively rare words such as names and dates. Based on this observation, we further propose to reduce the vocabulary at the decoder for target question generation to be top N frequently generated words, where N is a predefined threshold that varies according to datasets.

3.3 A GCN-Based Clue Word Predictor

Given a passage and some answer positions, our clue word predictor aims to identify the clue words in the passage that can help to ask a question and are also potential candidates for copying, by understanding the semantic context of the input passage. Again, in the training dataset, the non-stop words that are shared by both an input passage and an output question are aggressively labeled as *clue words*.

We note that clue words are, in fact, more closely connected to the answer chunk in the form of syntactic dependency trees than in word sequences. Fig. 6 shows our observation on the SQuAD dataset. For each training example, we get the nonstop words that appear in both the input passage and the output question. For each clue word in the training set, we find its shortest undirected path to the answer chunk based on the dependency parsing tree of the passage. For each jump

(a) Distribution of Syntactic Dependency Types between Copied Words and the Answer

(b) Distribution of Syntactic Dependency Distances between Copied Words and theAnswer

(c) Distribution of Sequential Word Distances between Copied Words and the Answer

Figure 6: Comparing the distributions of syntactic dependency distances and sequential word distances between copied words and the answer in each training sample.

on the shortest path, we record the dependency type. We also calculate the distance between each clue word and the answer in terms of the number of words between them. As shown in Fig. 6(a), *prep*, *pobj*, and *nsubj* appear frequently on these shortest paths. Comparing Fig. 6(b) with Fig. 6(c), we can see that the distances in terms of dependency trees are much smaller than those in terms of sequential word orders. The average and median distances on the dependency trees are 4.41 and 4, while those values are 10.23 and 7 for sequential word distances.

In order to predict the positions of clue words based on their dependencies on the answer chunk (without knowing the question which is yet to be generated), we use a Graph Convolutional Network (GCN) to convolve over the word features on the dependency tree of each passage, as shown in Fig. 4. The predictor consists of four layers:

Embedding layer. This layer shares the same features with the passage encoder, except that it does not include the clue indicators. Therefore, each word is represented by its word embedding, lexical features, binary features, the word frequency feature, and an answer position indicator.

Syntactic dependency parsing layer. We obtain the syntactic dependency parsing tree of each passage by spaCy [24], where the dependency edges between words are directed. In our model, we use the syntactic structure to represent the structure of passage words.

Encoding layer. The objective of the encoding layer is to encode the context information into each word based on the dependency tree. We utilize a multi-layered GCN to incorporate the information of neighboring word features into each vertex, which is a word. After L GCN layers, the hidden vector representation of each word will incorporate the information of its neighboring words that are no more than L hops away in the dependency tree.

Output layer. After obtaining the context-aware representation of each word in the passage, we calculate the probability of each word being a clue word. A linear layer is utilized to calculate the unnormalized probabilities. We subsequently sample the binary clue indicator for each word through a Gumbel-Softmax layer, given the unnormalized probabilities. A sampled value of 1 indicates that the word is predicated as a clue word.

3.3.1 GCN Operations on Dependency Trees. We now introduce the operations performed in each GCN layer [18, 40]. GCNs generalize the CNN from low-dimensional regular grids to high-dimensional irregular graph domains. In general, the input to a GCN is a graph $G = (\mathcal{V}, E)$ with N vertices $v_i \in \mathcal{V}$, and edges $e_{ij} = (v_i, v_j) \in E$. The edges can be weighted with weights w_{ij}, or unweighted. The input also contains a vertex feature matrix denoted by $X = \{\mathbf{x}_i\}_{i=1}^{N}$, where $\mathbf{x}_i$ is the *feature vector* of vertex v_i.

Since a dependency tree is also a graph, we can perform the graph convolution operations on dependency trees by representing each tree into its corresponding adjacency matrix form. Now let us briefly introduce the GCN propagation layers used in our model [40]. The weighted adjacency matrix of the graph is denoted as $A \in \mathbb{R}^{N \times N}$ where $A_{ij} = w_{ij}$. For unweighted graphs, the weights are either 1 or 0. In an L-layer GCN, let $h_i^{(l-1)}$ denotes the input vector and $h_i^{(l)}$ denotes the output vector of node i at the l-th layer. We will utilize a multi-layer GCN with the following layer-wise propagation rule [40]:

$$h_i^{(l)} = \sigma(\sum_{j=1}^{N} \tilde{\mathbf{A}}_{ij} \mathbf{W}^{(l)} h_j^{(l-1)} / d_i + b^{(l)}), \tag{14}$$

where σ is a nonlinear function (e.g., ReLU), and $W^{(l)}$ is a linear transformation. $\tilde{\mathbf{A}} = \mathbf{A} + \mathbf{I}_N$ where $\mathbf{I}_N$ is an $n \times n$ identity matrix. $d_i = \sum_{j=1}^{N} \tilde{\mathbf{A}}_{ij}$ is the degree of node (or word in our case) i in the graph (or dependency tree).

In our experiments, we treat the dependency trees as undirected, i.e., $\forall i, j, \mathbf{A}_{ij} = \mathbf{A}_{ji}$. Besides, as we already included the dependency type information in the embedding vectors of each word, we do not need to incorporate the edge type information in the adjacency matrix.

Stacking this operation by L layers gives us a deep GCN network. The input to the nodes in the first layer of the GCN are the feature vectors of words in the passage. After L layers of transformations, we can obtain a context-aware representation of each word. We then feed them into a linear layer to get the unnormalized probability of each word being a clue word. After that, the unnormalized probabilities are fed to a Straight-Through (ST) Gumbel-Softmax estimator

to sample an N-dimensional binary vector indicating whether each of the N words is a clue word or not.

3.3.2 Gumbel-Softmax. Gumbel-Softmax [15] is a method of sampling discrete random variables in neural networks. It approximates one-hot vectors sampled from a categorical distribution by making them continuous, therefore the gradients of model parameters can be calculated using the reparameterization trick and the standard backpropagation. Gumbel-Softmax distribution is motivated by Gumbel-Max trick [22], an algorithm for sampling from a categorical distribution. Let $(p_1, ..., p_k)$ denotes a k-dimensional categorical distribution where the probability p_i of class i is defined as:

$$p_i = \frac{\exp(\log(\pi_i))}{\sum_{j=1}^{k} \exp(\log(\pi_j))}, \tag{15}$$

where π_i is the unnormalized log probability of class i. We can easily draw a one-hot sample $\mathbf{z} = (z_1, \cdots, z_k) \in \mathbb{R}^k$ from the distribution by the following equations:

$$z_i = \begin{cases} 1, & i = \arg\max_j (log(\pi_j) + g_j) \\ 0, & \text{otherwise} \end{cases} \tag{16}$$

$$g_i = -\log(-\log(u_i)), \tag{17}$$

$$u_i \sim \text{Uniform}(0, 1) \tag{18}$$

where g_i is Gumbel noise used to perturb each $\log(\pi_i)$. In this way, taking arg max is equivalent to drawing a sample using probabilities $(p_1, \cdots, p_k)$.

Gumbel-Softmax distribution replaces the arg max function by differentiable softmax function. Therefore, a sample $\mathbf{y} = (y_1, \cdots, y_k)$ drawn from Gumbel-Softmax distribution is given by:

$$y_i = \frac{\exp((\log(\pi_i) + g_i)/\tau)}{\sum_{j=1}^{k} \exp((\log(\pi_j) + g_j)/\tau)}, \tag{19}$$

where τ is a temperature parameter. The Gumbel-Softmax distribution resembles the one-hot sample when τ diminishes to zero.

Straight-Through (ST) Gumbel-Softmax estimator [15] is a discrete version of the continuous Gumbel-Softmax estimator. It takes different paths in the forward and backward propagation. In the forward pass, it discretizes a continuous probability vector $\mathbf{y}$ sampled from the Gumbel-Softmax distribution into a one-hot vector $\mathbf{y}^{ST} = (y_1^{ST}, \cdots, y_k^{ST})$ by:

$$y_i^{ST} = \begin{cases} 1, & i = \arg\max_j y_j, \\ 0, & \text{otherwise.} \end{cases} \tag{20}$$

In the backward pass, it uses the continuous $\mathbf{y}$, so that the error signal can still backpropagate.

Using the ST Gumbel-Softmax estimator, our model is able to sample a binary clue indicator vector for an input passage. Then the clue indicator vector is fed into the passage encoder for question generations, as shown in Fig. 4.

4 EVALUATION

In this section, we evaluate the performance of our proposed models on the SQuAD dataset and the NewsQA dataset, and compare them with state-of-the-art question generation models.

Table 1: Description of evaluation datasets.

Dataset	Train	Dev	Test	P-Length*	Q-Length*	A-Length*
SQuAD	86,635	8,965	8,964	32.72	11.31	3.19
NewsQA	77,538	4,341	4,383	28.14	7.82	4.60

* P-Length: average number of tokens of passages.

* Q-Length: average number of tokens of questions.

* A-Length: average number of tokens of answers.

4.1 Datasets, Metrics and Baselines

The SQuAD dataset is a reading comprehension dataset, consisting of questions posed by crowd-workers on a set of Wikipedia articles, where the answer to every question is a segment of text from the corresponding reading passage. SQuAD 1.1 is used in our experiment containing 536 Wikipedia articles and more than 100K question-answer pairs. When processing a sample from dataset, instead of using the entire document, we take the sentence that contains the answer as the input. Since the test set is not publicly available, we use the data split proposed by [42] where the original dev set is randomly split into a dev test and a test set of equal size.

In the NewsQA dataset, there are 120K questions and their corresponding answers as well as the documents that are CNN news articles. Questions are written by questioners in natural language with only the headlines and highlights of the articles available to them. With the information of the questions and the full articles, answerers select related sub-spans from the passages of the source text and mark them as answers. Multiple answers may be provided to a same question by different answerers and they are ranked by validators based on the quality of the answers. In our experiment, we picked a subset of NewsQA where answers are top-ranked and are composed of a contiguous sequence of words within the input sentence of the document.

Table 1 shows the number of samples in each set and the average number of tokens of the input sentences, questions, and answers listed in columns P-Length, Q-Length, and A-Length respectively.

We report the evaluation results with following metrics.

- **BLEU** [26]. BLEU measures precision by how much the words in prediction sentences appear in reference sentences at the corpus level. BLEU-1, BLEU-2, BLEU-3, and BLEU-4, use 1-gram to 4-gram for calculation, respectively.
- **ROUGE-L** [19]. ROUGE-L measures recall by how much the words in reference sentences appear in prediction sentences using Longest Common Subsequence (LCS) based statistics.

- **METEOR** [6]. METEOR is based on the harmonic mean of unigram precision and recall, with recall weighted higher than precision.

In the experiments, we have eight baseline models for comparison. Results reported on PCFG-Trans, MPQG, and NQG++ are from experiments we conducted using published code on GitHub. For other baseline models, we directly copy the reported performance given in their papers. We report all the results on the SQuAD dataset, and for the NewsQA dataset, we can only report the baselines with open source code available.

- **PCFG-Trans** [12] is a rule-based system that generates a question based on a given answer word span.
- **MPQG** [31] proposed a Seq2Seq model that matches the answer with the passage before generating the question.
- **SeqCopyNet** [43] proposed a method to improve the copying mechanism in Seq2Seq models by copying not only a single word but a sequence of words from the input sentence.
- **seq2seq+z+c+GAN** [37] proposed a model employed in GAN framework using the latent variable to capture the diversity and learning disentangled representation using the observed variable.
- **NQG++** [42] proposed a Seq2Seq model with a feature-rich encoder to encode answer position, POS and NER tag information.
- **Answer-focused Position-aware model** [33] incorporates the answer embedding to help generate an interrogative word matching the answer type. And it models the relative distance between the context words and the answer for the model to be aware of the position of the context words when generating a question.
- **s2sa-at-mp-gsa** [41] proposed a model which contains a gated attention encoder and a maxout pointer decoder to address the challenges of processing long text inputs. This model has a paragraph-level version and a sentence-level version. For the purpose of fair comparison, we report the results of the sentence-level model to match with our settings.
- **ASs2s** [16] proposed an answer-separated Seq2Seq to identify which interrogative word should be used by replacing the target answer in the original passage with a special token.

For our models, we evaluate the following versions:

- **CGC-QG (no feature-rich embedding)**. We name our model as Clue Guided Copy for Question Generation (CGC-QG). In this variant, we only keep the embedding of words, answer position indicators, and clue indicators for each token, and remove the embedding vectors of other features.
- **CGC-QG (no target reduction)**. This model variant does not contain target vocabulary reduction operation.
- **CGC-QG (no clue prediction)**. The clue predictor and clue embedding are removed in model variant.
- **CGC-QG**. This is the complete version of our proposed model.

4.2 Experiment Settings

We implement our models in PyTorch 0.4.1 [27] and train the model with a single Tesla P40. We utilize spaCy [24] to perform dependency parsing and extract lexical features for tokens. As to the vocabulary, we collect it from the training dataset and keep the top 20K most frequent words for both datasets.

We set the threshold $r_h = 100$ and $r_l = 2000$. For target vocabulary reduction, we set $N = 2000$. The embedding dimension of word vector is set to be 300 and initialized by GloVe. The word vectors of words that are not contained in GloVe are initialized randomly. The word frequency features are embedded to 32-dimensional vectors, and other features and indicators are embedded to 16-dimensional vectors. All embedding vectors are trainable in the model. We use a single layer BiGRU with hidden size 512 for the encoder, and a single layer undirected GRU with hidden size 512 for the decoder. The dropout rate $p = 0.1$ is applied to the encoder, decoder, and the attention module.

During training, we optimize the Cross-Entropy loss function for clue prediction, question generation, and question copying, and perform gradient descent by the Adam [17] optimizer with an initial learning rate $l_r = 0.001$, two momentum parameters are $\beta_1 = 0.8$ and $\beta_2 = 0.999$ respectively, and $\epsilon = 10^{-8}$. The mini-batch size for each update is set to 32 and model is trained for up to 10 epochs (as we found that usually the models derive the best performance after 6 or 7 epochs). We apply gradient clipping with range $[-5, 5]$ for Adam. Besides, exponential moving average is applied on all trainable variables with a decay rate 0.9999. When testing, beam search is conducted with beam width 20. The decoding process stops when a token *¡EOS¿* that represents end of sentence is generated.

4.3 Main Results

Table. 2 and Table. 3 compare the performance of our model with existing question generation models on SQuAD and NewsQA in terms of different evaluation metrics. For the SQuAD dataset, we compare our model with all the baseline methods we have listed. As to the NewsQA dataset, since only a part of the baseline methods made their code public, we compare our model with approaches that have open source code. We can see that our model achieves the best performance on both datasets and significantly outperforms state-of-the-art algorithms. On the SQuAD dataset, given an input sentence and an answer, the BLEU-4, ROUGE-L, and METEOR of our result are 17.55, 44.53, and 21.24 respectively, while corresponding previous state-of-the-art results are 16.17, 44.24, and 19.67 from different approaches. Similarly, our method also gives a significantly better performance on NewsQA compared with the baselines in Table 3.

Table 2: Evaluation results of different models on SQuAD dataset.

Model	BLEU-1	BLEU-2	BLEU-3	BLEU-4	ROUGE-L	METEOR

The reason is that we combine different strategies in our model to make it learn when to generate or copy a word, and what to generate or copy. First, our model learns to predict clue words through a GCN-based clue predictor. Second, our encoder incorporates a variety of embeddings of different features and clue indicators. Combining with the masking strategy, our model can better discover the relationship between input patterns and output patterns. Third, the reduced target vocabulary also helps our model to better capture when to copy or generate, and the generator is easier to train with a reduced vocabulary size. And most importantly, our new criteria of marking a question word as copied word (as described in Sec.3.3) helps the model to make better decisions on which path to go, i.e., to copy or to generate, during question generation. By incorporating part of these new strategies and modules into our model, we can achieve performance better than state-of-the-art models on SQuAD and NewsQA. With all these designs implemented, our model gives the best performance on both datasets.

There is a significant gap between the performance on SQuAD and on NewsQA due to the different characteristics of the datasets. The average answer length of NewsQA is 44.2% larger than it of SQuAD according to the statistics shown in Table 1. Long answers usually hold more information and are more difficult to generate questions. Furthermore, reference questions in NewQA tend to have less strict grammars and more diverse phrasings. To give a typical example, "Iran criticizes who?" is a reference question in NewsQA which does not start with an interrogative word but ends with one. These characteristics make the performance on NewsQA not as good as on SQuAD. However, our approach is still significantly better than the compared approaches on NewsQA dataset. It demonstrates that copy from the input is a general phenomenon across different datasets. Our model better captures what copied words are and what generated words are in a question based on our new criteria of labeling a question word as copied word or not.

4.4 Analysis

We evaluate the impact of different modules in our model by ablation tests. Table 2 and Table 3 list the performance of our model variants with different sub-components removed.

When we remove the extra feature embeddings in our model, i.e., the embeddings of POS, NER, Dependency Types,

word frequency levels (low-frequent, median-frequent, high-frequent), and binary features (whether it is lowercase, digit), the performance drops significantly. This is because the tags and feature embeddings represent each token in different aspects. The number of different tags is much smaller than the number of different words. Therefore, the patterns which can be learned from these tags and features are more obvious than what we can learn from word embeddings. Even though a well-trained word vector may contain the information of other features such as POS or NER, explicitly concatenating these feature embedding vectors helps the model to capture the patterns to ask a question more easily.

Removing the operation of target vocabulary reduction also hurts the performance of our model. As we discussed earlier, the non-overlap question words (or generated words) are mostly covered by the high frequency words. Reducing the target vocabulary size helps our model to better learn the probabilities of generating these words. On the other hand, it also encourages the model to better capture what they can copy from input text.

Finally, without the clue prediction module, the performance also drops on both datasets. This is because when given an answer span in a passage, asking a question about it is still a one-to-many mapping problem. Our clue prediction module learns how people select the related clue words to further reduce the uncertainty of how to ask a question by learning from a large training dataset. With predicted clue indicators incorporated into the encoder of generator, our model can fit the way how people ask questions in the dataset.

5 RELATED WORK

In this section, we review related works on question generation and graph convolutional networks.

Existing approaches for question generation can be mainly classified into two classes: heuristic rule-based approaches and neural network-based approaches. The rule-based approaches rely on well-designed rules or templates manually created by human to transform a piece of given text to questions [2, 12, 13]. However, they require creating rules and templates by experts which is extremely expensive. Also, rules and templates have a lack of diversity and are hard to generalize to different domains.

Compared with rule-based approaches, neural network-based models are trained end-to-end and do not rely on hand-crafted rules or templates. Most of the neural question generation models consider the task as Seq2Seq and take advantage of the encoder-decoder framework with attention mechanism. [30] utilizes an encoder-decoder framework with attention mechanism to generate factoid questions from FreeBase. [8] generates questions from SQuAD passages based on a sequence-to-sequence model with attention mechanism.

However, given an input sentence, generating questions is a one-to-many mapping, as we can ask different questions from different aspects. Purely relying on Seq2Seq model may not be able to learn such a one-to-many mapping [9]. To resolve this issue, recent works assume the aspect is known when generating a question [16, 31, 32, 38, 42] or can be detected by a third-party pipeline [7]. [42] enriches the sequence-to-sequence model with answer position indicator to indicate if the current word is an answer word or not, and further incorporates copy mechanism to copy words from the context when generating a question. [14, 31] fuse the answer information into input sentence first, and apply a Seq2Seq model with attention and copy mechanism to generate answer-aware questions. [9] takes question difficulty into account by a difficulty estimator, and generate questions on different difficulty levels. [33] enriches the model with both answer embedding and the relative distance between the context words and the answer. [34, 35] model question answering and question generation as dual tasks. They found that jointly training the two tasks helped to generate better questions.

We argue that even with an answer indicator, the problem of question generation is still a one-to-many mapping. To solve this problem, we enrich the model with a "clue word" predictor, where a clue word means a word that is related to the aspect of the targeting output question and usually copied to the question. We represent an input sentence by its syntactic dependency tree and represent each word using feature-rich embeddings, and let the model learn to predict whether each word in context can be a clue word or not. Combining the clue prediction module with a Seq2Seq model with attention and copy mechanism, our model learns when to generate a word from a target vocabulary and when to copy a word from the input context.

Graph Convolutional Networks generalize Convolutional Neural Networks to graph-structured data, and have been developed and grown rapidly in scope and popularity in recent years [1, 5, 18, 20, 23]. Here we focus on the applications of GCNs on natural language. [23] applies GCNs over syntactic dependency trees as sentence encoders, and produces latent feature representations of words in a sentence for semantic role labeling. [20] matches long document pairs using graph structures, and classify the relationships of two documents by GCN. [40] proposes an extension of graph convolutional networks that is tailored for relation extraction. It pools information over dependency trees efficiently in parallel. In our paper, we apply GCN over the dependency tree of an input sentence, and predict the potential clue words in the sentence together with a Gumbel-Softmax estimator.

6 CONCLUSION

In this paper, we demonstrate the effectiveness of teaching the model to make decisions during the question generation process on which words to generate and to copy. We label the nonstop and overlap words between input passages and questions as copy targets and use such labels to train our model. Besides, we further observe that the distribution of generated question words are mostly common words with relative high frequency. Based on this observation, we reduce the vocabulary size for generating question words. To help the model better capture how to ask a question and alleviate

the issue of one-to-many mapping when asking a question, we propose a GCN-based clue prediction module to predict which part of words can be a clue word to ask a question given an answer. It utilizes the syntactic dependency tree representation of a passage to encode the information of each token in the passage, and sample a clue indicator for each token using a Straight-Through (ST) Gumbel-Softmax estimator. Our simulation results on the SQuAD dataset and NewsQA dataset show that our model outperforms a range of existing state-of-the-art approaches significantly.

ABSTRACT

Click-Through Rate prediction is an important task in recommender systems, which aims to estimate the probability of a user to click on a given item. Recently, many deep models have been proposed to learn low-order and high-order feature interactions from original features. However, since useful interactions are always sparse, it is difficult for DNN to learn them effectively under a large number of parameters. In real scenarios, artificial features are able to improve the performance of deep models (such as Wide & Deep Learning), but feature engineering is expensive and requires domain knowledge, making it impractical in different scenarios. Therefore, it is necessary to augment feature space automatically.In this paper, We propose a novel Feature Generation by Convolutional Neural Network (FGCNN) model with two components: *Feature Generation* and *Deep Classifier*. *Feature Generation* leverages the strength of CNN to generate local patterns and recombine them to generate new features. *Deep Classifier* adopts the structure of IPNN to learn interactions from the augmented feature space. Experimental results on three large-scale datasets show that FGCNN significantly outperforms nine state-of-the-art models. Moreover, when applying some state-of-the-art models as *Deep Classifier*, better performance is always achieved, showing the great compatibility of our FGCNN model. This work explores a novel direction for CTR predictions: it is quite useful to reduce the learning difficulties of DNN by automatically identifying important features.

1 INTRODUCTION

Click-Through Rate (CTR) is a crucial task for recommender systems, which estimates the probability of a user to click on a given item [9, 23]. In an online advertising application, which is a billion-dollar scenario, the ranking strategy of candidate advertisements is by CTR×bid where "bid" is the profit that the system receives once the advertisement is clicked on. In such applications, the performance of CTR prediction models [9, 23, 40] is one of the core factors determining system's revenue.

The key challenge for CTR prediction tasks is to effectively model feature interactions. Generalized linear models, such as FTRL [21], perform well in practice, but these models lack the ability to learn feature interactions. To overcome the limitation, Factorization Machine [26] and its variants [16] are proposed to model pairwise feature interactions as the inner product of latent vectors and show promising results. Recently, deep neural networks (DNN) have achieved remarkable progress in computer vision [11, 32] and natural language processing [1, 33]. And some deep learning models have been proposed for CTR predictions, such as PIN [23], xDeepFM [19] and etc. Such models feed raw features to a deep neural network to learn feature interactions explicitly or implicitly. Theoretically, DNN is able to learn arbitrary feature interactions from the raw features. However, due to that useful interactions are ususally sparse compared with the combination space of raw features, it is of great difficulties to learn them effectively from a large number of parameters [23, 29].

Observing such difficulties, Wide & Deep Learning [7] leverages feature engineering in the *wide* component to help the learning of *deep* component. With the help of artificial features, the performance of deep component is improved significantly (0.6% improvement on offline AUC and 1% improvement on online CTR). However, feature engineering can be expensive and requires domain knowledge. If we can generate sophisticated feature interactions automatically by machine learning models, it will be more practical and robust.

Therefore, as shown in Figure 1, we propose a general framework for automatical feature generation. Raw features are input into a machine learning model (represented by the red box in Figure 1) to identify and generate new features [1]. After that, the raw features and the generated new features are combined and fed into a deep neural network. The generated features are able to reduce the learning difficulties of deep models by capturing the sparse but important feature interactions in advance.

The most straightforward way for automatical feature generation is to perform Multi-Layer Perceptron (MLP[2]) and use the hidden neurons as the generated features. However, as mentioned above, due to that useful feature interactions are usually sparse [23], it is rather difficult for MLP to learn such interactions from a huge parameter space. For example, suppose we have four user features: *Name*, *Age*, *Height*, *Gender* to predict whether a user will download an online game. Assume that the feature interaction between *Age* and *Gender* is the only signal that matters, so that an optimal model should identify this and only this feature interaction. When performing MLP with only one hidden layer, the optimal weights associated to the embeddings of *Name* and *Height* should be all 0's, which is fairly difficult to achieve.

As an advanced neural network structure, Convolutional Neural Network (CNN) has achieved great success in the area of computer vision [14] and natural language processing [1]. In CNN, the design of shared weights and pooling mechanism greatly reduces the number of parameters needed to find important local patterns and it will alleviate the optimization difficulties of later MLP structures. Therefore, CNN provides a potentially good solution to realize our idea (identify the sparse but important feature interactions). However, applying CNN directly could result in unsatisfactory performance. In CTR prediction, different arrange orders of original features do not have different meanings. For example, whether the arrangement order of features being *(Name, Age, Height, Gender)* or *(Age, Name, Height, Gender)* does not make any difference to describe the semantics of a sample, which is completely different from the case of images and sentences. If we only use the neighbor patterns extracted by CNN, many useful global feature interactions will be lost. This is also why CNN models do not perform well for CTR prediction task. To overcome this limitation, we perform CNN and MLP, which complement each other, to learn global-local feature interactions for feature generation.

In this paper, we propose a new model for CTR prediction task, namely Feature Generation by Convolutional Neural Network (FGCNN), which consists of two components: *Feature Generation* and *Deep Classifier*. In *Feature Generation*, a CNN+MLP structure is designed to identify and generate new important features from raw features. More specifically, CNN is performed to learn neighbor feature interactions, while MLP is applied to recombine them to extract global feature interactions. After *Feature Generation*, the feature space can be augmented by combining raw features and new features. In *Deep Classifier*, almost all state-of-the-art network structures (such as PIN [23], xDeepFM [19], DeepFM [9]) can be adopted. Therefore, our model has good compatibility with the state-of-the-art models in recommender systems. For the ease of illustration, we will adopt IPNN model [22, 23] as *Deep Classifier* in FGCNN, due to its good trade-off between model complexity and accuracy. Experimental results in three large-scale datasets show that FGCNN significantly outperforms nine state-of-the-art models, demonstrating the effectiveness of FGCNN. While adopting other models in *Deep Classifier*, better performance is always achieved, which shows the usefulness of the generated features. Step-by-step analyses show that each component in FGCNN contributes to the final performance. Compared with traditional CNN structure, our CNN+MLP structure performs better and more stable when the order of raw features changes, which demonstrates the robustness of FGCNN.

To summarize, the main contributions of this paper can be highlighted as follows:

- An important direction is identified for CTR prediction: it is both necessary and useful to reduce the optimization difficulties of deep learning models by automatically generating important features in advance.
- We propose a new model-FGCNN for automatical feature generation and classification, which consists of two components: *Feature Generation* and *Deep Classifier*. *Feature Generation* leverages CNN and MLP, which complement each other, to identify the important but sparse features. Moreover, almost all other CTR models can be applied in *Deep Classifier* to learn and predict based on the generated and raw features.
- Experiments on three large-scale datasets demonstrate the overall effectiveness of FGCNN model. When the generated features are used in other models, better performance is always achieved, which shows the great compatibility and robustness of our FGCNN model.

The rest of this paper is organized as follows: Section 2 presents the proposed FGCNN model in detail. Experimental results will be shown and discussed in Section 3. Related works will be introduced in Section 4. Section 5 concludes the paper.

2 FEATURE GENERATION BY CONVOLUTIONAL NEURAL NETWORK MODEL

2.1 Overview

In this section, we will describe the proposed Feature Generation by Convolutional Neural Network (FGCNN) model in detail. The used notations are summarized in Table 1.

As shown in Figure 2, FGCNN model consists of two components: *Feature Generation* and *Deep Classifier*. More specifically, *Feature Generation* focuses on identifying useful local and global patterns to generate new features as a complement to raw features, while *Deep Classifier* learns and predicts based on the augmented feature

[1]Here, new features are the feature interactions of the raw features. In the rest of this paper, we may use the term "new features" for the ease of presentation.
[2]MLP is a neural network with several fully connected layers.

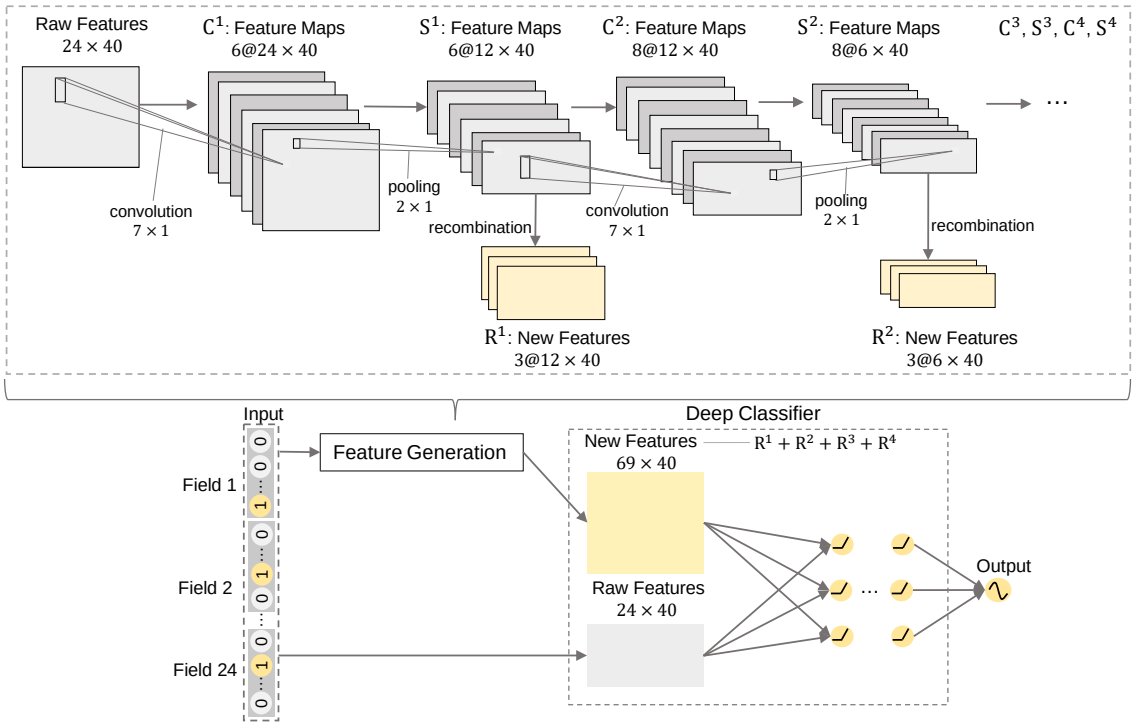

Figure 2: An overview of Feature Generation by Convolutional Neural Network Model (The hyper-parameters in the figure are the best setting of FGCNN on Avazu Dataset)

space through a deep learning model. Besides the two components, we will also formalize *Feature Embedding* of our model. The details of these components are presented in the following subsections.

2.2 Feature Embedding

In most CTR prediction tasks, data is collected in a multi-field categorical form[3] [30, 38], so that each data instance is normally transformed into a high-dimensional sparse (binary) vector via one-hot encoding [13]. For example, (Gender=Male, Height=175, Age=18, Name=Bob) can be represented as:

$$\underbrace{(0,1)}_{\text{Gender=Male}}\ \underbrace{(0,...,1,0,0)}_{\text{Height=175}}\ \underbrace{(0,1,...,0,0)}_{\text{Age=18}}\ \underbrace{(1,0,0,..,0)}_{\text{Name=Bob}} \quad (1)$$

An embedding layer is applied upon the raw features' input to compress them to low-dimensional vectors. In our model, if a field is univalent (e.g., "Gender=Male"), its embedding is the feature embedding of the field; if a field is multivalent (e.g., "Interest=Football, Basketball"), the embedding of the field takes the sum of features' embeddings [8].

More formally, in an instance, each field i ($1 \le i \le n_f$) is represented as a low-dimensional vector $e_i \in R^{1\times k}$, where n_f is the number of fields and k is embedding size. Therefore, each instance can be represented as an embedding matrix $E = (e_1^T, e_2^T, ..., e_{n_f}^T)^T$, where $E \in R^{n_f \times k}$. In FGCNN model, the embedding matrix E can be utilized in both *Feature Generation* and *Deep Classifier*. To avoid the inconsistency of gradient direction when updating parameters, we will introduce another embedding matrix $E' \in R^{n_f \times k}$ for *Deep Classifier* while E is used in *Feature Generation*.

[3]Features in numerical form are usually transformed into categorical form by bucketing.

Table 1: Notations

Parameter	Meaning
k	embedding size
t_f	the total number of one-hot features
n_f	the number of fields
n_c	the number of convolutional layers
n_h	the number of hidden layers
h^i	the height of convolutional kernel in the i-th convolutional layer
h_p	pooling height (width=1) of pooling layers
e_i	the embedding vector for i-th field
E^i	the input of the i-th convolutional layer
m_c^i	the number of feature maps in the i-th convolutional layer
m_r^i	the number of new features' map in the i-th recombination layer
N_i	the number of generated features in the i-th recombination layer ($=n_f/h_p^i m_r^i$)
$C_{:,:,j}^i$	the j-th output feature map of the i-th convolutional layer
$\mathbb{WC}_{:,:,j}^i$	weights for the j-th output feature map of i-th convolutional layer
$S_{:,:,j}^i$	the j-th output feature map of the i-th pooling layer
$\mathbb{WR}^i$	weights for the i-th recombination layer
$\mathbb{BR}^i$	bias for the i-th recombination layer
$R_{:,:,j}^i$	the j-th output map of new features in the i-th recombination layer
W^i	weights for the i-th hidden layer
B^i	biases for the i-th hidden layer
H_i	number of hidden neorons in the i-th hidden layer

2.3 Feature Generation

As stated in Section 1, generating new features from raw features helps improve the performance of deep learning models (as demonstrated by Wide & Deep Learning [7]). To achieve this goal, *Feature Generation* designs a proper neural network structure to identify useful feature interactions then generate new features automatically. As argued in Section 1, using MLP or CNN alone is not able to generate effective feature interactions from raw features, due to the following reasons: *Firstly*, useful feature interactions are always

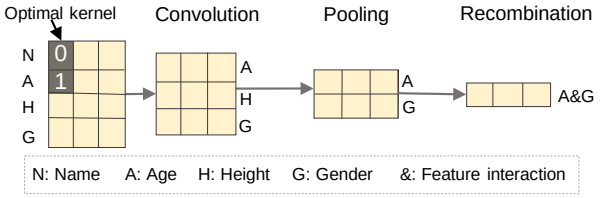

Figure 3: CNN+Recombination structure is able to capture global non-neighbor feature interactions to generate new features. CNN consists of convolutional layer and pooling layer, while Recombination consists of a fully connected layer.

sparse in the combination space of raw features. Therefore, it is difficult for MLP to learn them from a large amount of parameters. *Secondly*, although CNN can alleviates optimization difficulties of MLP by reducing the number of paramters, it only generates neighbor feature interactions which can lose many useful global feature interactions.

In order to overcome the weakness of applying MLP or CNN alone, as shown in the upper part of Figure 2, we perform CNN and MLP [4] as a complement to each other for feature generation. Figure 3 shows an example of CNN+Recombination structure to capture global feature interactions. As can be observed, CNN learns useful neighbor feature patterns with a limited number of parameters, while recombination layer (which is a fully connected layer) generates global feature interactions based on the neighbor patterns provided by CNN. Therefore, important features can be generated effectively via this neural network structure, which has fewer parameters than directly applying MLP for feature generation.

In the following parts, we detail the CNN+Recombination structure of *Feature Generation*, namely, *Convolutional Layer*, *Pooling layer* and *Recombination layer*.

2.3.1 Convolutional Layer. Each instance is represented as an embedding matrix $E \in R^{n_f \times k}$ via feature embedding, where n_f is the number of fields and k is embedding size. For convenience, reshape the embedding matrix as $E^1 \in R^{n_f \times k \times 1}$ as the input matrix of the first convolutional layer. To capture the neighbor feature interactions, a convolutional layer is obtained by convolving a matrix $\mathbb{WC}^1 \in R^{h^1 \times 1 \times 1 \times m_c^1}$ with non-linear activation functions (where h^1 is the height of the first convolutional weight matrix and m_c^1 is the number of feature maps in the first convolutional layer). Suppose the output of the first convolutional layer is denoted as $C^1 \in R^{n_f \times k \times m_c^1}$, we can formulate the convolutional layer as follows:

$$C^1_{p,q,i} = tanh(\sum_{m=1}^{1} \sum_{j=1}^{h^1} E^1_{p+j-1,q,m} \mathbb{WC}^1_{j,1,1,i}) \tag{2}$$

$$tanh(x) = \frac{exp(x) - exp(-x)}{exp(x) + exp(-x)} \tag{3}$$

where $C^1_{:,:,i}$ denotes the i-th feature map in the first convolutional layer and p, q are the row and column index of the i-th feature map. Notice that the above equation excludes padding which is performed in practice.

[4] According to its function, we will call MLP with one hidden layer as recombination layer later.

2.3.2 Pooling Layer. After the first convolutional layer, a max-pooling layer is applied to seize the most important feature interactions and reduce the number of parameters. We refer h_p as the height of pooling layers (width=1). The output in the first pooling layer is $S^1 \in R^{(n_f/h_p) \times k \times m_c^1}$:

$$S^1_{p,q,i} = max(C^1_{p \cdot h_p,q,i}, \ \dots, C^1_{p \cdot h_p + h_p - 1,q,i}) \tag{4}$$

The pooling result of the i-th pooling layer will be the input for the $(i+1)$-th convolutional layer: $E^{i+1} = S^i$.

2.3.3 Recombination Layer. After the first convolutional layer and pooling layer, $S^1 \in R^{(n_f/h_p) \times k \times m_c^1}$ contains the patterns of neighbor features. Due to the nature of CNN, global non-neighbor feature interactions will be ignored if S^1 is regarded as the generated new features. Therefore, we introduce a fully connected layer to recombine the local neighbor feature patterns and generate important new features. We denote the weight matrix as $\mathbb{WR}^1 \in R^{(n_f/h_p k m_c^1) \times (n_f/h_p k m_r^1)}$ and the bias as $\mathbb{BR}^1 \in R^{(n_f/h_p k m_r^1)}$, where m_c^1 is the number of feature maps in the first convolutional layer and m_r^1 is the number of new features' map in the first recombination Layer. Therefore, in the i-th recombination layer, $n_f/h_p^i m_r^i$ features are generated:

$$R^1 = tanh(S^1 \cdot \mathbb{WR}^1 + \mathbb{BR}^1) \tag{5}$$

2.3.4 Concatenation. New features can be generated by performing CNN+Recombination multiple times. Assume there are n_c convolutional layers, pooling layers and recombination layers and $N_i = n_f/h_p^i m_r^i$ fields of features are generated by i-th round denoted as R^i. The overall new features $\mathcal{R} \in R^{N \times k}$ (where $N = \sum_{i=1}^{n_c} N_i$) generated by *Feature Generation* are formalized as:

$$\mathcal{R} = (R^1, R^2, ..., R^{n_c}) \tag{6}$$

Then, raw features and new features are concatenated as

$$\mathbb{E} = (E'^T, \mathcal{R}^T)^T \tag{7}$$

where E' is the embedding matrix of raw features for *Deep Classifier* (see Section 2.2). Both the raw features and new features are utilized for CTR prediction in *Deep Classifier*, which will be elaborated in the next subsection.

2.4 Deep Classifier

As mentioned above, raw features and new features are concatenated as an augmented embedding matrix $\mathbb{E} \in R^{(N+n_f) \times k}$, where N and n_f are the number of fields of new features and raw features respectively. $\mathbb{E}$ is input into *Deep Classifier*, which aims to learn further interactions between the raw features and new generated features. In this subsection, for the ease of presentation, we adopt IPNN model [23] as the network structure in *Deep Classifier*, due to its good trade-off between model complexity and accuracy. In fact, any advanced network structure can be adopted, which shows the compatibility of FGCNN with the existing works. The compatibility of FGCNN model will be verified empirically in Section 3.

2.4.1 Network Structure. IPNN model [23] combines the learning ability of FM [27] and MLP. It utilizes an FM layer to extract pairwise feature interactions from embedding vectors by inner product operations. After that, the embeddings of input features and the results of FM layer are concatenated and fed to MLP for learning. As evaluated in [23], the performance of IPNN is slightly worse

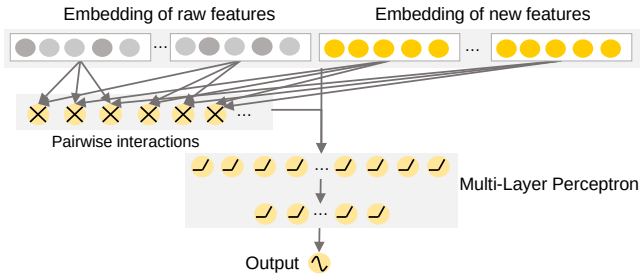

Figure 4: Structure of IPNN Model

than PIN (the best model in [23]), but IPNN is much more efficient. We will illustrate the network structure of IPNN model.

As shown in Figure 4, the pariwise feature interactions of augmented embedding matrix $\mathbb{E} \in R^{(N+n_f)\times k}$ are modeled by an FM layer, as follows:

$$R_{fm} = (< \mathbb{E}_1, \mathbb{E}_2 >, ..., < \mathbb{E}_{N+n_f-1}, \mathbb{E}_{N+n_f} >) \tag{8}$$

where $\mathbb{E}_i$ is the embedding of the i-th field, $< a, b >$ means the inner product of a and b. The number of pairwise feature interactions in the FM layer is $\frac{(N+n_f)(N+n_f-1)}{2}$.

After the FM layer, R_{fm} is concatenated with the augmented embedding matrix $\mathbb{E}$, which are fed into MLP with n_h hidden layers to learn implicit feature interactions. We refer the input for the i-th hidden layer as I_i and the output for the i-th hidden layer as O_i. The MLP is formulated as:

$$I_1 = (R_{fm}, flatten(\mathbb{E})) \tag{9}$$

$$O_i = relu(I_i W^i + B^i) \tag{10}$$

$$I_{i+1} = O_i \tag{11}$$

where W^i and B^i are the weight matrix and bias of the i-th hidden layer in MLP. For the last hidden layer (the n_h-th layer), we will make final predictions:

$$\hat{y} = sigmoid(O_{n_h} W^{n_h+1} + b^{n_h+1}) \tag{12}$$

2.4.2 Batch Normalization. Batch Normalization (BN) is proposed in [15] to solve covariant shift and accelerate DNN training. It normalizes activations $w^T x$ using statistics within a mini-batch, as follows:

$$BN(w^T x) = \frac{w^T x - avg_i(w^T x)}{std_i(w^T x)} g + b \tag{13}$$

where g and b scale and shift the normalized values.

In the FGCNN model, Batch Normalization is applied before each activation function to accelerate model training.

2.4.3 Objective Function. The objective function in the FGCNN model is to minimize cross entropy of predicted values and the labels, which is defined as:

$$\mathcal{L}(y, \hat{y}) = -ylog\hat{y} - (1-y)log(1-\hat{y}) \tag{14}$$

where $y \in \{0, 1\}$ is the label and $\hat{y} \in (0, 1)$ is the predicted probability of $y = 1$.

2.5 Complexity Analysis

In this section, we analyse the space and time complexity of FGCNN model. Notations in Table 1 will be reused.

2.5.1 Space Complexity. The space complexity of FGCNN model consists of three parts, namely *Feature Embedding*, *Feature Generation* and *Deep Classifier*. In feature embedding, since there are two matrices (one for *Feature Generation* and one for *Deep Classifier* (as discussed in Section 2.2)), there are $s_0 = 2t_f k$ parameters, where t_f is the total number of one-hot raw features.

In *Feature Generation*, there are $h^i m_c^{i-1} m_c^i$ parameters for convolutional matrix in i-th convolutional layer and $n_f/h_p^i k m_c^i$ neurons in the output of i-th pooling layer. In addition, the number of parameters in i-th recombination layer is $n_f^2/h_p^{2i} k^2 m_c^i m_r^i$, which will generate $N_i = n_f/h_p^i m_r^i$ fields of new features ($n_f/h_p^i = N_i/m_r^i$). Therefore, the total parameters of *Feature Generation* is:

$$\sum_{i=1}^{n_c} h^i m_c^{i-1} m_c^i + n_f^2/h_p^{2i} k^2 m_c^i m_r^i = \tag{15}$$

$$\sum_{i=1}^{n_c} h^i m_c^{i-1} m_c^i + N_i^2 k^2 m_c^i / m_r^i \tag{16}$$

After the *Feature Generation* process, we can get $T = n_f + \sum_{i=1}^{n_c} N_i$ feature embeddings in total. Normally, m_r^i is usually set as $1, 2, 3, 4$ and $m_r^i = m_r^{i-1}$. Meanwhile, h_p is usually set to 2 so that $N_i = N_1/2^{i-1}$. Furthermore, $N_i^2 k^2 >> h_i m_c^{i-1}$ and $\sum_{i=1}^{n_c} m_c^i / m_r^i 2^{2(i-1)}$ is usually a small number. The space complexity s_1 of the feature generating process can be simplified as:

$$s_1 = O(\sum_{i=1}^{n_c} N_1^2/2^{2(i-1)} k^2 m_c^i/m_r^i) = O(N_1^2 k^2) \tag{17}$$

For the first hidden layer of *Deep Classifier*, the number of parameters in the weight matrix is $(T(T-1)/2 + Tk)H_1$ (recall that the input is the raw and new features' embedding and their pairwised product). In the i-th hidden layer, the number of parameters is $H_{i-1}H_i$. Therefore, the space complexity of *Deep Classifier* is:

$$s_2 = O(\frac{T(T-1) + 2Tk}{2} H_1 + \sum_{i=2}^{n_h} H_i H_{i-1}) \tag{18}$$

where Eq. (18) can be simplified as $O(T^2 H_1 + \sum_{i=2}^{n_h} H_i H_{i-1})$ since $Tk < T(T-1)$ usually.

In summary, the overall space complexity of FGCNN is $s_0 + s_1 + s_2 = O(t_f k + N_1^2 k^2 + T^2 H_1 + \sum_{i=1}^{q} H_i H_{i-1})$, which is dominated by the number of one-hot features, the number of generated features, the number of hidden neurons and the embedding size.

2.5.2 Time Complexity. We first analyze the time complexity in *Feature Generation*. In the i-th convolutional layer, the output dimension is $n_f/h_p^{i-1} k m_c^i = N_i h_p / m_r^i k m_c^i$ (recall that $N_i = n_f/h_p^i m_r^i$) and each point is calculated from $h^i m_c^{i-1}$ data points where h^i is the height of convolutional kernels in the i-th convolutional layer. Therefore, the time complexity of the i-th convolutional layer is $N_i h_p k m_c^i h^i m_c^{i-1}/m_r^i$. In the pooling layer, the time complexity of the i-th pooling layer is $n_f/h_p^{i-1} k m_c^i = N_i h_p k m_c^i/m_r^i$. In the i-th recombination layer, the time complexity is $n/h_p^i k m_c^i \cdot N_i k = N_i^2 k^2 m_c^i/m_r^i$ (recall $h_p = 2$ and $N_i = N_1/2^{i-1}$). Therefore, total

Table 2: Dataset Statistics

Dataset	#instances	#features	#fields	pos ratio
Criteo	1×10^8	1×10^6	39	0.5
Avazu	4×10^7	6×10^5	24	0.17
Huawei App Store	2.3×10^8	1.6×10^5	29	0.05

time complexity of the *Feature Generation* is

$$\begin{aligned} t_1 &= \sum_{i=1}^{n_c} N_i h_p k m_c^i h^i m_c^{i-1}/m_r^i + N_i h_p k m_c^i/m_r^i + N_i^2 k^2 m_c^i/m_r^i \\ &= \sum_{i=1}^{n_c} N_1 k m_c^i/(m_r^i 2^{i-1})(2h^i m_c^{i-1} + 2 + N_1/2^{i-1}k) \\ &= O(N_1 k \sum_{i=1}^{n_c} m_c^{i-1} h^i + N_1^2 k^2) \end{aligned}$$

(Notice: $m_c^i/(m_r^i 2^i)$ is usually a small number ranging from 2 to 10)

Then, we analyze the time complexity of *Deep Classifier* (taking IPNN as an example). In the FM layer, the time complexity to calculate pairwise inner product is $\frac{T(T-1)k}{2}$. The number of neurons, that are input to the first hidden layer is $T(T-1)/2 + Tk$. Therefore, the time complexity of the first hidden layer is $O((T(T-1)/2 + Tk)H_1) = O(T^2 H_1)$. For the other hidden layers, the time complexity is $O(H_i H_{i-1})$. Therefore, the total time complexity in *Deep Classifier* is

$$t_2 = O(T^2 H_1) + \sum_{i=2}^{n_h} O(H_i H_{i-1}) \tag{19}$$

In summary, the overall time complexity for FGCNN model is $t_1 + t_2 = O(N_1 k \sum_{i=1}^{n_c} m_c^{i-1} h^i + N_1^2 k^2 + T^2 H_1 + \sum_{i=2}^{q} H_i H_{i-1})$ which is dominated by the number of generated features, the number of neurons in the hidden layers, embedding size and convolutional parameters.

3 EXPERIMENTS

In this section, we conduct extensive experiments to answer the following questions.

- **(Q1)** How does FGCNN perform, compared to the state-of-the-art models for CTR prediction task?
- **(Q2)** Can FGCNN improve the performance of other state-of-the-art models by using their structures in *Deep Classifier*?
- **(Q3)** How does each key structure in FGCNN boost the performance of FGCNN?
- **(Q4)** How do the key hyper-parameters of FGCNN (i.e., size of convolutional kernels,number of convolutional layers, number of generated features) impact its performance?
- **(Q5)** How does *Feature Generation* perform when the order of raw features are randomly shuffled?

Note that when studying questions other than **Q2**, we adpot IPNN as the *Deep Classifier* in FGCNN.

3.1 Experimental Setup

3.1.1 Datasets. Experiments are conducted in the following three datasets:

Table 3: Parameter Settings

Param	Criteo	Avazu	Huawei App Store

Note: bs=batch size, opt=optimizer, lr=learning rate, l2=l2 regularization on Embedding Layer, k=embedding size, conv=shape of convolutional kernels, kernel=number of convolutional kernels, pool=max-pooling shape, net=MLP structure, sub-net=micro metwork, drop=dropout rate, LN=layer normalization, BN= batch normalization{T=True}, new=number of kernels for new features.

Criteo: Criteo[5] contains one month of click logs with billions of data samples. A small subset of Criteo was published in Criteo Display Advertising Challenge 2013 and FFM was the winning solution [16, 23]. We select "day 6-12" as training set while select "day 13" for evaluation. Due to the enormous data volume and serious class imbalance (i.e., only 3% samples are positive), negative sampling is applied to keep the positive and negative ratio close to 1:1. We convert 13 numerical fields into one-hot features through bucketing, where the features in a certain field appearing less than 20 times are set as a dummy feature "other".

Avazu: Avazu[6] was published in the contest of Avazu Click-Through Rate Prediction, 2014. The public dataset is randomly splitted into training and test sets at 4:1. Meanwhile, we remove the features appearing less than 20 times to reduce dimensionality.

Huawei App Store: In order to evaluate the performance in industrial CTR prediction problems, we conduct experiments on Huawei App Store Dataset. We collect users' click logs from Huawei App Store while logs from 20180617 to 20180623 are used for training and logs of 20180624 are used for test. Negative sampling is applied to reduce data amount and to adjust the ratio of positive class and negative class. The dataset contains app features (e.g., identification, category), user features (e.g., user's behavior history) and context features (e.g., operation time).

In addition, the statistics of the three datasets are summarized in Table 2.

3.1.2 Baselines. We compare nine baseline models in our experiments, including LR [17], GBDT [6], FM [26], FFM [16], CCPM [20], DeepFM [9], xDeepFM [19], IPNN and PIN [23]. Wide & Deep is not compared here because some state-of-the-art models (such as xDeepFM, DeepFM, PIN) have shown better performance in their publications. We use XGBoost [6] and libFFM[7] as the implementation of GBDT and libFFM, respectively. In our experiments, the other baseline models are implemented with Tensorflow[8].

3.1.3 Evaluation Metrics. The evaluation metrics are **AUC** (Area Under ROC) and **log loss** (cross entropy).

3.1.4 Parameter Settings. Table 3 summerizes the hyper-parameters of each model. For *Criteo* and *Avazu* Datasets, the hyper-parameters of baseline models are set to be the same as in [23]. Notice that when conducting experiments on Criteo and Avazu, we observed that FGCNN uses more parameters in *Deep Classifier* than other models. To make fair comparisons, we also conduct experiments to increase the parameters in MLPs of other deep models. However, all these models cannot achieve better performance than the original settings[9]. The reason could be the overfitting problem where such models simply use embedding of raw features for training but use a complex structure. On the other hand, since our model augments the feature space and enriches the input, more parameters in *Deep Classifier* can boost the performance of our model.

In FGCNN model, *new* is the number of kernels when generating new features. The number of generated features can be calculated as $\sum_{i=1}^{n_c} \#fields/2^i * new_i$.

3.1.5 Significance Test. We repeat the experiments 10 times by changing the random seed for FGCNN and the best baseline model. The two-tailed pairwise t-test is performed to detect significant differences between FGCNN and the best baseline model.

3.2 Overall Performance (Q1)

In this subsection, we compare the performance of different models on the test set. Table 4 summarizes the overall performance of all the compared models on the three datasets, where the underlined numbers are the best results of the baseline models and bold numbers are the best results of all models. We have the following observations:

Firstly, in majority of the cases, non-neural network models perform worse than neural network models. The reason is that deep neural network can learn complex feature interactions much better than the models where no feature interaction is modeled (i.e., LR), or feature interactions are modeled by simple inner product operations (i.e., FM and FFM).

Secondly, FGCNN achieves the best performance among all the models on the three evaluated datasets. It is significantly better than the best baseline models with 0.05%, 0.14% and 0.13% improvements in AUC (0.09%, 0.24% and 0.79% in log loss) on Criteo, Avazu and Huawei App Store datasets, which demonstrates the effectiveness of FGCNN. In fact, a small improvement in offline AUC is likely to lead to a significant increase in online CTR. As reported in [7], compared with LR, Wide & Deep improves offline AUC by 0.275% and the improvement of online CTR is 3.9%. The daily turnover of Huawei App Store is millions of dollars. Therefore, even a few lifts in CTR brings extra millions of dollars each year.

Thirdly, with the help of the generated new features, FGCNN outperforms IPNN by 0.11%, 0.19% and 0.13% in terms of AUC (0.2%, 0.29% and 0.79% in terms of log loss) on Criteo, Avazu and Huawei App Store datasets. It demonstrates that the generated features are very useful and they can effectively reduce the optimization difficulties of traditional DNNs thus leading to better performance.

Fourthly, CCPM, which applies CNN directly, achieves the worst performance among neural network models. Moreover, CCPM performs worse than FFM on Criteo and Avazu datasets. It shows that directly using traditional CNN for CTR prediction task is inadvisable, as CNN is designed to generate neighbor patterns while the arrangement order of feature is usually no meaning in recommendation scenarios. However, in FGCNN, we leverage the strength of CNN to extract local patterns while complementing it with Recombination Layer to extract global feature interactions and generate new features. Therefore, better performance is achieved.

[7] https://github.com/guestwalk/libffm
[8] https://www.tensorflow.org/
[9] Due to the limited pages, we do not show the experimental result in the paper.

[11] According to the experimental recordings, the results of PIN in [23] uses the trick of adaptive embedding size. Here, we use fixed embedding size for all the deep models.

Table 5: Compatibility Study of FGCNN

	Criteo		Avazu		Huawei App Store	
	AUC	Log Loss	AUC	Log Loss	AUC	Log Loss
FM	79.09%	0.5500	77.93%	0.3805	93.26%	0.1191

3.3 Compatibility of FGCNN with Different Models (Q2)

As stated in Section 2.4, *Feature Generation* can augment the original feature space and *Deep Classifier* of FGCNN can adopt any advanced deep neural networks. Therefore, we select several models as *Deep Classifeir* to verify the utility of *Feature Generation*, including non-deep models (FM), deep learning models (DNN, DeepFM, IPNN).

Table 5 summarizes the performance. We have the following observations: Firstly, with the help of the generated new features, the performance of all models are improved, which demonstrates the effectiveness of the generated features and shows the compatibility of FGCNN. Secondly, we observe that when only using raw features, DeepFM always outperforms DNN. But when using the augmented features, FGCNN+DNN outperforms FGCNN+DeepFM. The possible reason is that DeepFM sums up the inner product of input features to the last MLP layer which may cause contradictory gradient updates (compared with MLP) on embeddings.This could be one of the reasons why IPNN (feeding the product into MLP) outperforms DeepFM in all datasets.

In a word, the results show that our FGCNN model can be viewed as a general framework to enhance the existing neural networks by generating new features automatically.

3.4 Effectiveness of FGCNN Variants(Q3)

We conduct experiments to study how each component in FGCNN contributes to the final performance. Each variant is generated by removing or replacing some components in FGCNN, which is described as follows:

- **Removing Raw Features**: In this variant, raw features are not input into *Deep Classifier* and only the generated new features are fed to *Deep Classifier*.
- **Removing New Features**: This variant removes *Feature Generation*. Actually, it is equivalent to IPNN.
- **Applying MLP for *Feature Generation***: *Feature Generation* is replaced by MLP which takes the neurons in each layer as new features. This variant uses the same hidden layers and generates the same number of features in each layer as FGCNN.
- **Removing Recombination Layer**: This variant is to evaluate how *Recombination Layer* complements CNN to capture global feature interactions. The *Recombination Layer* is removed from *Feature Generation* so that the output of pooling layer serves as new features directly. The number of generated new features in each layer keeps the same as FGCNN.

As shown in Table 6, removing any component in FGCNN leads to a drop in performance. We have the following observations:

Firstly, FGCNN with raw features alone or with new generated features alone performs worse than the FGCNN with both of them. This result demonstrates that the generated features are good supplementaries to the original features, which are both crucial.

Secondly, the performance decrease of *Appling MLP for Feature Generation*, compared to FGCNN, shows the ineffectiveness of MLP to identify the sparse but important feature combinations from a large number of parameters. CNN simplifies the learning difficulties by using the shared convolutional kernels, which has much fewer parameters to get the desired combinations. Moreover, MLP recombines the neighbor feature interactions, which is extracted by CNN, to generate global feature interactions.

Thirdly, removing the Recombination Layer will limit the generated features as neighbor feature interactions. Since the arrangement order of raw features has no actual meanings in the CTR prediction task, the restriction can lead to losing important non-neighbor feature interactions thus resulting in worse performance.

3.5 Hyper-parameter Investigation (Q4)

Our FGCNN model has several key hyper-parameters, i.e., the height of convolutional kernels, number of convolutional kernels, number of convolutional layers, and the number of kernels for generating new features. In this subsection, to study the impact of these hyper-parameters, we investigate how FGCNN model works by changing one hyper-parameter while fixing the others on Criteo and Huawei App Store datasets.

3.5.1 Height of Convolutional Kernels. The height of convolutional kernels controls the perception range of convolutional layers. The larger the height is, the more features are involved in the neighbor patterns, but more parameters need to be optimized. To investigate its impact, we increase the height from 2 to the number of fields of a dataset. As shown in the top of Figure 5, the performance generally ascends first and then descends as the height of convolutional kernels increases[10].

The results show that as more features are involved in the convolutional kernels, higher-order feature interactions can be learned

[10]Due to that *Feature Generation* and *Deep Classifier* interrelate with each other, the curve has some fluctuations.

Table 6: Performance of Different FGCNN Variants

	Criteo		Avazu		Huawei App Store	
Method	AUC	Log Loss	AUC	Log Loss	AUC	Log Loss
FGCNN	**80.22%**	**0.5388**	**78.83%**	**0.3746**	**94.07%**	**0.1134**
Removing Raw Features	80.21%	0.5390	78.66%	0.3757	94.01%	0.1138
Removing New Features	80.13%	0.5399	78.68%	0.3757	93.95%	0.1143
Applying MLP for Feature Generation	80.12%	0.5402	78.58%	0.3761	94.04%	0.1135
Removing Recombination Layer	80.11%	0.5403	78.74%	0.3753	94.04%	0.1135

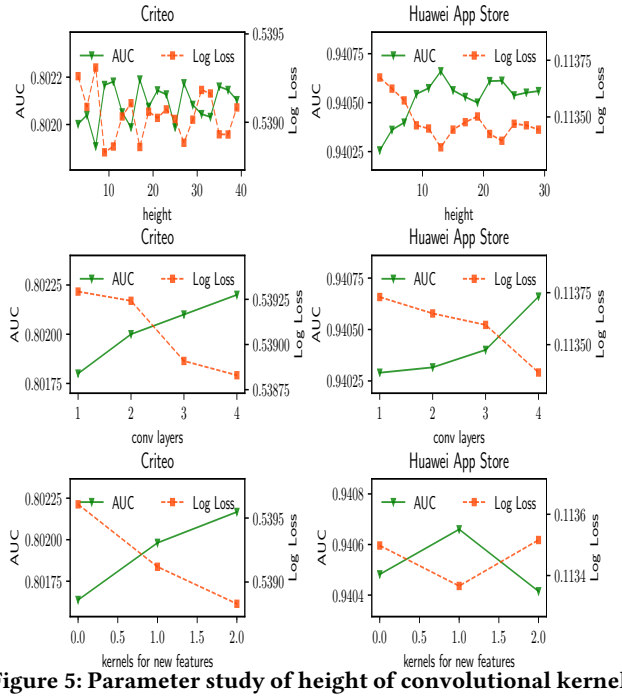

Figure 5: Parameter study of height of convolutional kernel, number of convolutional layers and number of kernels for new features (from top to bottom)

so that the performance increases. However, due to that useful feature interactions are usually sparse, larger heights can cause more difficulties to learn them effectively, leading to a decrease in performance. This observation is consistent with the finding in Section 3.4, i.e., the performance decreases in Appling MLP for Feature Generation.

3.5.2 Number of Convolutional Layers. As shown in the middle of Figure 5, as the number of convolutional layers increases, the performance of FGCNN is improved. Notice that more layers usually lead to higher-order feature interactions. Therefore, the result also shows the effectiveness of high-order feature interactions.

3.5.3 Number of Kernels for Generating New Features. We study how the number of generated features affects the performance of FGCNN. We use the same number of kernels for new features in different *Recombination Layers*. As can be observed in the bottom of Figure 5, the performance is gradually improved with more features generated. The results verify our research idea that it is useful to identify the sparse but important feature interactions first, which can effectively reduce the learning difficulties of DNNs. However, the useful feature interactions can be sparse and limited. If too many features are generated, the extra new features are noisy which will increase the learning difficulties of MLP, leading to the decrease in the performance.

3.6 Effect of Shuffling Order of Raw Features (Q5)

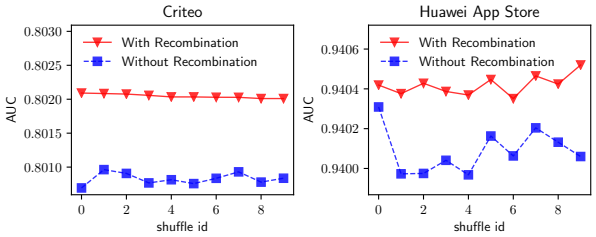

Figure 6: Shuffling the order of raw features

As mentioned before, CNN is designed to capture local neighbor feature patterns so that it is sensitive to the arrangement order of raw features. In our FGCNN model, the design of Recombination Layer is to learn global feature interactions based on CNN's extracted local patterns. Intuitively, our model should have more stable performance than traditional CNN's structure if the order of raw features is shuffled. Therefore, to verify it, we compare the performance of two cases: with/without Recombination Layer. The arrangement order of raw features is shuffled many times at random where the two compared cases are performed for the same shuffled arrangement order.

As shown in Figure 6, the case with Recombination Layer achieves better and more stable performance than that of without Recombination Layer. It demonstrates that with the help of Recombination Layer, FGCNN can greatly reduce the side effects of changing the arrangement order of raw features, which also demonstrates the robustness of our model.

4 RELATED WORK

Click-Through Rate Prediction is normally formulated as a binary classification problem [5, 28]. In this section, we will introduce two important categories of models in Click-Through Rate predictions, namely **shallow models** and **deep learning models**.

4.1 Shallow Models for CTR Prediction

Due to the robustness and efficiency, Logistic Regression (LR) models [18, 25], such as FTRL [21] are widely used in CTR prediction. To learn feature interactions, a common practice is to manually design pairwise feature interactions in its feature space [10, 31]. Poly-2 [4] models all pairwise feature interactions to avoid feature engineering. Factorization Machine (FM) [26] introduces low-dimensional vectors for each feature and models feature interactions through

inner product of feature vectors. FM improves the ability of modelling feature interactions when data is sparse. FFM [16] enables each feature to have multiple latent vectors to perform interactions with features from different fields. LR, Poly-2 and FM variants are widely used in CTR prediction in industry.

4.2 Deep Learning for CTR Prediction

Deep learning has achieved great success in different areas, such as computer vision [11, 14, 32, 36], natural language processing [1, 2, 24, 33] etc. In order to leverage deep Learning for CTR prediction, several models are proposed [34, 37]. FNN [39] is proposed in [39], which uses FM to pre-train the embedding of raw features and then feeds the embeddings to several fully connected layers. Some models adopt DNN to improve FM, such as Attentional FM [35], Neural FM [12].

Wide & Deep Learning [7] jointly trains a wide model and a deep model where the wide model leverages the effectiveness of feature engineering and the deep model learns implicit feature interactions. Despite the usefulness of wide component, feature engineering is expensive and requires expertise. To avoid feature engineering, DeepFM [9] introduces FM layer (order-2 feature interaction) as a wide component and uses a deep component to learn implicit feature interactions. Different from DeepFM, IPNN [23] (also known as PNN in [22]) feeds both the result of FM layer and embeddings of raw features into MLP and results in comparable performance. Rather than using inner product to model pairwise feature interactions as DeepFM and IPNN, PIN [23] uses a Micro-Network to learn complex feature interaction for each feature pair. xDeepFM [19] proposes a novel Compressed Interaction Network (CIN) to explicitly generate feature interactions at the vector-wise level.

There are several models which use CNN for CTR Prediction. CCPM [20] applies multiple convolutional layers to explore neighbor feature dependencies. CCPM performs convolutions on the neighbor fields in a certain alignment. Due to that the order of features has no actual meaning in CTR predictions, CCPM can only learn limited feature interactions between neighbor features. In [3], it is shown that features' arrangement order has a great impact on the final performance of CNN based models. Therefore, the authors propose to generate a set of suitable feature sequences to provide different local information for convolutional layers. However, the key weakness of CNN is not solved.

In this paper, we propose FGCNN model, which splits the CTR prediction task into two stages: *Feature Generation* and *Deep Classifier*. *Feature Generation* augments the original feature space by generating new features while most state-of-the-art models can be adopted in *Deep Classifier* to learn and prediction based on the augmented feature space. Different from traditional CNN models for CTR Prediction [3, 20], FGCNN can leverage the strength of CNN to extract local information and it greatly alleviates the weakness of CNN by introducing the *Recombination Layer* to recombine information from different local patterns learned by CNN to generating new features.

5 CONCLUSION

In this paper, we propose a FGCNN model for CTR prediction which aims to reduce the learning difficulties of DNN models by identifying important features in advance. The model consists of two components: *Feature Generation* and *Deep Classifier*. *Feature Generation* leverages the strength of CNN to identify useful local patterns and it alleviates the weakness of CNN by introducing a *Recombination Layer* to generate global new features from the recombination of the local patterns. In *Deep Classifier*, most existing deep models can be applied on the augmented feature space. Extensive experiments are conducted on three large-scale datasets where the results show that FGCNN outperforms nine state-of-the-art models. Moreover, when applying other models in *Deep Classifier*, compared with the original model without *Feature Generation*, better performance is always achieved, which demonstrates the effectiveness of the generated features. Step-by-step experiments show that each component in FGCNN contributes to the final performance. Furthermore, compared with the traditional CNN structure, our CNN+Recombination structure in *Feature Generation* always performs better and more stable when shuffling the arrangement order of raw features. This work explores a novel direction for CTR prediction that it is effective to automatically generate important features first rather than feeding the raw embeddings to deep learning models directly.

ABSTRACT

The problem of computing (α, β)-core in a bipartite graph for given α and β is a fundamental problem in bipartite graph analysis and can be used in many applications such as online group recommendation, fraudsters detection, etc. Existing solution to computing (α, β)-core needs to traverse the entire bipartite graph once. Considering the real bipartite graph can be very large and the requests to compute (α, β)-core can be issued frequently in real applications, the existing solution is too expensive to compute the (α, β)-core. In this paper, we present an efficient algorithm based on a novel index such that the algorithm runs in linear time regarding the result size (thus, the algorithm is optimal since it needs at least linear time to output the result). We prove that the index only requires $O(m)$ space where m is the number of edges in the bipartite graph. Moreover, we devise an efficient algorithm with time complexity $O(\delta \cdot m)$ for index construction where δ is bounded by $\sqrt{m}$ and is much smaller than $\sqrt{m}$ in practice. We also discuss efficient algorithms to maintain the index when the bipartite graph is dynamically updated and parallel implementation of the index construction algorithm. The experimental results on real and synthetic graphs (more than 1 billion edges) demonstrate that our algorithms achieve up to 5 orders of magnitude speedup for computing (α, β)-core and up to 3 orders of magnitude speedup for index construction, respectively, compared with existing techniques.

1 INTRODUCTION

Many real-world relationships across various entities can be modelled as bipartite graphs, such as customer-product networks [40], user-page networks [8], gene co-expression networks [21], collaboration networks [24], etc. With the proliferation of bipartite graph applications, research efforts have been devoted to many fundamental problems in managing and analyzing bipartite graph data. Among them, the problem of computing (α, β)-core of a bipartite graph for given α and β has been recently studied in [10, 11]. Formally, a bipartite graph $G = (U, V, E)$ is a graph with the nodes divided into two separate sets, U and V, such that every edge connects one node in U to another node in V. Given $G = (U, V, E)$ and two integers α and β, the (α, β)-core of G consists of two node sets $U' \subseteq U(G)$ and $V' \subseteq V(G)$ such that the subgraph induced by $U' \cup V'$ is the maximal subgraph of G in which all the nodes in U' have degree at least α and all the nodes in V' have degree at least β

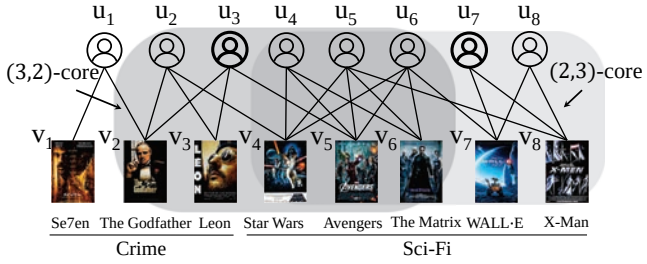

Figure 1: Part of a customer-movie network

Applications. Computing (α, β)-cores has many real applications.

(1) Online group recommendation. Group recommendation aims at recommending products to a group of users who may or may not share similar tastes, e.g., recommending movies for friends to watch together [4, 9, 15, 49]. Fault-tolerant group recommendation is proposed to deal with missing values in incomplete data and has shown its effectiveness in group recommendation [18, 31, 33]. A key step in fault-tolerant group recommendation is to compute fault-tolerant subspace clusters for each user in the group. For a given user u_q, a subspace cluster is a set of u_q's similar users, which is exploited by collaborative filtering [30] to compute the relevance of products to u_q. Recently, to accelerate the computation of fault-tolerant subspace clustering, [11] has shown that (α, β)-core is an efficient way of computing fault-tolerant subspace clustering. For a user u_q and user-specific parameters α and β, all the users in the (α, β)-core are treated as u_q's fault-tolerant subspace cluster. Since the α and β values can vary greatly based on users' preference and

the degree of tolerance for missing values [11], efficiently computing (α, β)-core is a critical procedure for online fault-tolerant group recommendation.

Example 1.1: Figure 1 shows part of the customer-movie network in the IMDB (https://www.imdb.com/) where each node in U represents a user, each node in V represents a movie and each edge indicates the customer has a preference for the movie. Assume that u_3 and u_7 are given as a group and the user-specific α and β for u_3 and u_7 are $(3, 2)$ and $(2, 3)$, respectively. Fault-tolerant group recommendation method first computes $(3, 2)$-core and $(2, 3)$-core, and uses $\{u_2, u_3, u_4, u_5, u_6\}$ and $\{u_4, u_5, u_6, u_7, u_8\}$ as fault-tolerant subspace clusters for u_3 and u_7, respectively. Then it conducts collaborative filtering based on the subspace clusters to calculate movie preference. In this case, Sci-Fi movies would be recommended to the group as both u_3 and u_7 have preference for Sci-Fi movies. □

(2) Fraudsters detection. In social networks, such as Facebook and Twitter, users and pages form a user-page bipartite graph in which the edge indicates a user likes a page. To promote certain pages, fraudsters use a larger number of fake accounts to inflate the *Like* counts for these pages; this results in a large number (β) of users liking a few (α) pages. (α, β)-core with small α and large β can facilitate the detection of such fraudsters [2, 8]. Similar fraud scenario also occurs in E-Commence/Online-Shopping, for example, fraudsters may improve the ranking of certain items by adding items to fake accounts' shopping lists.

(3) A key step to other problems in bipartite graphs. Computing (α, β)-core can also serve as a key step to solve other important graph problems, such as biclique computation [23, 52] and quasi-biclique computation [25, 28].

Motivations. In the literature, an online algorithm [11] is proposed for the computation of (α, β)-core. However, it has to traverse the entire graph to compute the (α, β)-core for given α and β. This makes it impractical to real scenarios, especially while taking into consideration that real bipartite graphs nowadays can be very large and the requests for computing (α, β)-core can be issued frequently. For example, the consumer-product networks of Amazon or Alibaba often reach billion-scale [27, 41]; in the application of online group recommendation, there can be millions of groups issuing recommendation requests at the peak time [12, 27, 49]. To recommend products to these groups, we need to compute (α, β)-core with different α and β for each user in every group. Therefore, numerous underlying computations of (α, β)-cores with different combinations of α and β have to be processed in realtime (typically within half a second [27]). However, it is shown in our experiments that, even in Orkut dataset with 327 million edges, existing method spends 236 seconds to compute (α, β)-core for a group of ten users. For fraud detection case, we also need to do lots of (α, β)-core computations to union results together because fraudsters may hide behind different combinations of α and β values [2, 8] and we don't want to miss out the suspicious people. Motivated by this, in this paper, we aim to devise an index-based optimal algorithm (linear time with respect to the result size) to compute the (α, β)-core for given α and β.

Challenges. To achieve our goal, we adopt an index-based approach. Straightforwardly, if we store the (α, β)-cores for all possible α and β combination, we can obtain the (α, β)-core in optimal time for given α and β. Nevertheless, this approach will take $O(n^3)$ space to store all results where n is the number of nodes in a bipartite graph. Obviously, this is prohibitive for a very large graph. Below, we present the challenges to be overcome in this paper.

- *Challenge 1: Optimal (α, β)-core computation vs Space Efficiency.* Considering that even one particular (α, β)-core for a given (α, β) may have $O(n)$ size and there could be $O(n^2)$ different combinations of α and β values, it is a challenge to develop a compact index such that we can compute (α, β)-core for given α and β in optimal time.
- *Challenge 2: Efficient index construction.* The proposed index is built upon the results of core decomposition on bipartite graphs. Note that core decomposition on unipartite (general) graphs [7] requires $O(m)$ time, simply extending this strategy to bipartite graphs with two disjoint node sets will lead to $O(\mathsf{dmax} \cdot m)$ time (details in Section 4.1), where dmax is the maximum degree of nodes and m is the number of edges in G. dmax could be very large in real graphs (e.g., dmax>10^7 in Web Trackers dataset), such method is impractical for large graphs. Hence, it is a challenge to devise an efficient algorithm to construct the index.

Contributions. In this paper, we overcome the above challenges and make the following contributions:

(1) The first space-efficient index-based work to compute (α, β)-core . In this paper, we propose a non-trivial space-efficient index structure, BiCore-Index, with the size bounded by $O(m)$. To the best of our knowledge, this is the first linear space index structure to support the optimal computation of (α, β)-core in bipartite graphs.

(2) Efficient algorithms to construct the index. We carefully consider the computation sharing between two node sets of the bipartite graph when conducting the core decomposition and devise an efficient algorithm to construct the BiCore-Index. We show that the time complexity of our proposed algorithm is $O(\delta \cdot m)$, where δ is the maximum value such that the (δ, δ)-core in G is nonempty and is bounded by $\sqrt{m}$. In our experiments, it is shown that δ is much smaller than $\sqrt{m}$ in practice.

(3) Efficient incremental maintenance algorithm for dynamic graphs and parallel implementation of index construction algorithm. In many applications, graphs are frequently updated. Therefore, we develop an efficient incremental algorithm to maintain BiCore-Index for dynamic graphs by reducing unnecessary recomputation in the procedure of updating BiCore-Index. Moreover, we also discuss the parallel implementation of our index construction algorithm.

(4) Extensive performance studies on real datasets from various domains. We conduct extensive performance studies on ten real graphs and two synthetic graphs. The experimental results demonstrate the efficiency of our proposed algorithms.

Outline. Section 2 gives the problem definition and the existing solution. Section 3 introduces our proposed index, BiCore-Index, and the optimal algorithm to compute (α, β)-core for arbitrary α and β. Section 4 presents algorithms to construct BiCore-Index. Section 5 presents an efficient algorithm to maintain BiCore-Index

in dynamic graphs and discusses parallel implementation of the index construction algorithm. Section 6 evaluates our algorithms using extensive experiments. Section 7 reviews the related work and Section 8 concludes the paper.

2 PRELIMINARIES

A bipartite graph $G = (U, V, E)$ is a graph consisting of two disjoint sets of nodes U and V such that every edge from $E \subseteq U \times V$ connects one node of U and one node of V. We use $U(G)$ and $V(G)$ to denote the two disjoint node sets of G and $E(G)$ to represent the edge set of G. We denote the number of nodes in $U(G)$ and $V(G)$ as n_U and n_V, the total number of nodes as n and the number of edges in $E(G)$ as m. The degree of a node $u \in U(G) \cup V(G)$, denoted by $\deg(u, G)$, is the number of neighbors of u in G. We also use $\mathsf{dmax}_U(G)$ ($\mathsf{dmax}_V(G)$) to denote the maximum degree among all the nodes in $U(G)$ ($V(G)$), i.e., $\mathsf{dmax}_U(G) = \max\{\deg(u, G) | u \in U(G)\}$ ($\mathsf{dmax}_V(G) = \max\{\deg(v, G) | v \in V(G)\}$). For simplicity, we omit G in the notations if the context is self-evident. For a bipartite graph G and two node sets $U' \subseteq U(G)$ and $V' \subseteq V(G)$, the bipartite subgraph induced by U' and V' is the subgraph G' of G such that $U(G') = U'$, $V(G') = V'$ and $E(G') = E(G) \cap (U' \times V')$.

Definition 2.1: ((α, β)-core) Given a bipartite graph G and two integers α and β, the (α, β)-core of G, denoted by $C_{\alpha,\beta}$, consists of two node sets $\mathcal{U} \subseteq U(G)$ and $\mathcal{V} \subseteq V(G)$ such that the bipartite subgraph g induced by $\mathcal{U} \cup \mathcal{V}$ is the maximal subgraph of G in which all the nodes in $\mathcal{U}$ have degree at least α and all the nodes in $\mathcal{V}$ have degree at least β, i.e., $\forall u \in \mathcal{U}, \deg(u, \mathrm{g}) \geq \alpha \wedge \forall v \in \mathcal{V}, \deg(v, \mathrm{g}) \geq \beta$. □

Problem Statement. In this paper, we study the problem of efficient computation of (α, β)-core for given α and β. For ease of presentation, we refer a request of computing the (α, β)-core for given α and β as an *(α, β)-core query* and denote it as $Q_{\alpha,\beta}$. Our object is to design a time-optimal algorithm for processing (α, β)-core queries on large bipartite graphs.

Existing Solution. Given an (α, β)-core query $Q_{\alpha,\beta}$, the state-of-the-art algorithm to compute $C_{\alpha,\beta}$ is proposed in [11]. Intuitively, it computes $C_{\alpha,\beta}$ by iteratively removing nodes in $U(G)$ with degree less than α and nodes in $V(G)$ with degree less than β until no more nodes can be removed. The above algorithm adopts an online paradigm to process (α, β)-core queries. For a query $Q_{\alpha,\beta}$, its time complexity to compute $C_{\alpha,\beta}$ is $O(m)$ in the worst case. Nevertheless, the graphs are typically very large in real applications (e.g., there are 327 million edges in Orkut dataset). Therefore, this algorithm cannot satisfy the real-time requirements for (α, β)-core queries since it needs to traverse the whole graph for a $Q_{\alpha,\beta}$.

3 SPACE-EFFICIENT INDEX AND TIME-OPTIMAL QUERY PROCESSING

In this section, we organize all the (α, β)-cores into a linear space index structure, through which an (α, β)-core query can be answered in optimal time. We first introduce a naive index structure. After analyzing the problems in the naive index structure, we present our linear space index structure, BiCore-Index. Based on BiCore-Index, we propose an optimal query processing algorithm. At last, we analyze the space complexity of BiCore-Index.

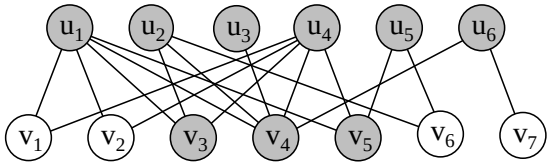

Figure 2: A bipartite graph G

3.1 BiCore-Index

A Naive Index Structure. To support optimal (α, β)-core query processing, a naive index is as follows: we pre-compute (α, β)-cores for all the possible α and β and store them in the index. Then, for all possible combination of α and β, we record the location of the corresponding (α, β)-core in the index through two level pointer tables. Given a query $Q_{\alpha,\beta}$, we can compute $C_{\alpha,\beta}$ in optimal time by visiting the nodes stored in the location referred by the (α, β) value. We show the naive index in the following example.

Example 3.1: Considering the graph G in Figure 2, the naive index of G is shown in Figure 3. For ease of presentation, we only show the nodes in $U(G)$ in Figure 3 and the nodes in $V(G)$ can be indexed similarly. In the index, all the pre-computed (α, β)-cores are stored and shown in the bottom bucket of Figure 3. For instance, $(1, 3)$-core is $\{\{u_1, \ldots u_6\}, \{v_3, v_4, v_5\}\}$, thus, $u_1, \ldots, u_6$ are stored in the grey bucket in Figure 3. Since both the maximum possible α value (dmax_U) and β value (dmax_V) of G are 5, the first-level pointer table (FPT) contains 5 pointers and each sub-table contains 5 pointers. Suppose the given query is $Q_{1,3}$, we can compute $C_{1,3}$ by following bold arrows and obtain $C_{1,3}.\mathcal{U} = \{u_1, \ldots, u_6\}$. □

This naive index can achieve optimal query processing time, however, it requires $O(n^3)$ space. Clearly, it is prohibitive for large graphs. In order to make the index-based approach practical, we aim to further reduce the space of the index without sacrificing the optimal query processing property.

Observing the naive index in Figure 3, we can find the following two problems exist, which leads to its huge space consumption. The first one is that a node may be stored multiple time in the index. For example, when $\alpha = 1$, u_1 is stored five times in the index, namely, in $C_{1,1}$, $C_{1,2}$, $C_{1,3}$, $C_{1,4}$ and $C_{1,5}$. The same problem also exists on other nodes and other α values. The second one is that empty entries are also kept in the index. For example, there exist no $C_{5,3}$, $C_{5,4}$ and $C_{5,5}$ in G. These entries should be managed to be removed while not affecting the optimal time complexity.

BiCore-Index Structure. We aim to reduce the space consumption of the naive index by addressing the two problems discussed above. Given a bipartite graph G, the (α, β)-cores in G has the following monotonic containment relationship:

Lemma 3.1: *Given a bipartite graph G, $C_{\alpha,\beta}$ is contained in $C_{\alpha',\beta'}$ if $\beta' \leq \beta$ and $\alpha' \leq \alpha$.*

Based on Lemma 3.1, for a node $u \in U(G)$ and a specific α, if we know the (α, β)-core with maximum β value containing u, we can infer that u is also contained in any (α, β)-core of G where β' is smaller than the maximum β value. For example, when $\alpha = 1$, since

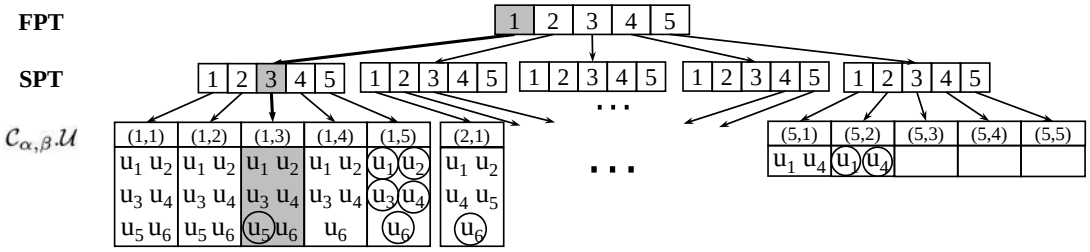

Figure 3: Naive Index

u_1 is contained in $C_{1,5}$, we know u_5 is also contained in $C_{1,1}$, $C_{1,2}$, $C_{1,3}$ and $C_{1,4}$. In other word, storing u_1 at $C_{1,1}$, $C_{1,2}$, $C_{1,3}$ and $C_{1,4}$ is redundant regarding (α, β)-core query processing and we only need to store it at $C_{1,5}$ (marked with circle in Figure 3). Therefore, to address the redundant nodes storage problem in the naive index, for a specific α, we remove the nodes $u \in U(G)$ from the (α, β)-cores that contain u but does not have the maximum β value.

For the empty entry problem, besides the existing empty entries in the index, the node removal procedure introduced above leads to new empty entries. For example, in Figure 3, after the node removal, $C_{1,1}.\mathcal{U}$ is empty. To address this problem, the naive index structure for nodes in $V(G)$.

Following the above idea, we give the formal definition of our index. Before that, to characterize the (α, β)-core with the maximum β (α) value that contains a node regarding a specific α (β), we define:

Definition 3.1:

(1) $\beta_{\max,\alpha}(u)$**.** Given a bipartite graph G and an integer α, for each node $u \in U(G) \cup V(G)$, $\beta_{\max,\alpha}(u)$ is the maximum value of β such that u is contained in the corresponding $C_{\alpha,\beta}$. If no such β, $\beta_{\max,\alpha}(u) = 0$.

(2) $\alpha_{\max,\beta}(u)$**.** Given a bipartite graph G and an integer β, for each node $u \in U(G) \cup V(G)$, $\alpha_{\max,\beta}(u)$ is the maximum value of α such that u is contained in the corresponding $C_{\alpha,\beta}$. If no such α, $\alpha_{\max,\beta}(u) = 0$. □

Our index, BiCore-Index, denoted by $\mathbb{I}$, is a three-level tree structure with two parts for nodes in $U(G)$ and $V(G)$, respectively, denoted by $\mathbb{I}^U$ and $\mathbb{I}^V$. As $\mathbb{I}^V$ is symmetrical to $\mathbb{I}^U$, we focus on $\mathbb{I}^U$ here.

- *Node Blocks* (NB). The third level of $\mathbb{I}^U$, named the node blocks, is a double linked list. Each block in the list is associated with a (α, β) value and contains the nodes $u \in U(G)$ with $\beta_{\max,\alpha}(u) = \beta$.
- *First-level Pointer Table* (FPT). The first level of $\mathbb{I}^U$ is an array with dmax_U elements. Each element contains a pointer to an array in the second level. We use $\mathbb{I}^U[\alpha]$ to represent the α-th element.
- *Second-level Pointer Table* (SPT). The second level of $\mathbb{I}^U$ consists of dmax_U arrays (sub-table). The α-th array is pointed by $\mathbb{I}^U[\alpha]$. The length of the α-th array equals to the maximum β value among the node blocks pointed by this array. We use $\mathbb{I}^U[\alpha][\beta]$ to denote the β-th element of the α-th array in SPT. The pointer in $\mathbb{I}^U[\alpha][\beta]$ points to the first node block associated with (α, β') where $\beta' \geq \beta$.

Example 3.2: Figure 4 shows the BiCore-Index of G. In NB, u_1 is in node block $(1, 5)$ since $\beta_{\max,1}(u_1) = 5$. In FPT, since $\mathsf{dmax}_U = 5$, the array of FPT contains 5 pointers pointing to the corresponding array in SPT. Different from the naive index, the length of the arrays is not unique. For example, the length of the second array is 3. This is because for $\alpha = 2$, the $(2, \beta)$ node block with maximum β value kept in NB is node block $(2, 3)$. The pointer in the 1st element of the 1st array in SPT points to node block $(1, 3)$ as node block $(1, 1)$ and $(1, 2)$ do not exist in NB. *A key point needed to note here is that a node block in $\mathbb{I}^U$ and a node block in $\mathbb{I}^V$ may share the same associated (α, β) value, but their meanings are different.* For example, v_1 is contained in node block $(1, 5)$ in $\mathbb{I}^V$ means v_1 is contained in $(5, 1)$-core while u_1 is contained in node block $(1, 5)$ in $\mathbb{I}^U$ means u_1 is contained in $(1, 5)$-core. □

Algorithm 1 QueryOPT

Input: $\mathbb{I}$ of G and $Q_{\alpha,\beta}$
Output: $C_{\alpha,\beta}$ of G

```
1:  C_{α,β} ← ∅;
2:  if 𝕀^U.FPT.size() < α or 𝕀^U[α].size() < β then
3:      return ∅;
4:  nb ← node block pointed by 𝕀^U[α][β];
5:  while the first element of the associated value of nb = α do
6:      for each u ∈ nb do
7:          C_{α,β}.𝒰 ← C_{α,β}.𝒰 ∪ u;
8:      nb ← next node block in 𝕀^U.NB;
9:  Compute C_{α,β}.𝒱 similarly
10: return C_{α,β} ;
```

3.2 Optimal Query Processing

With BiCore-Index, for a query $Q_{\alpha,\beta}$, we compute $C_{\alpha,\beta}$ by retrieving $C_{\alpha,\beta}.\mathcal{U}$ through $\mathbb{I}^U$ and $C_{\alpha,\beta}.\mathcal{V}$ through $\mathbb{I}^V$. The algorithm, QueryOPT, is shown in Algorithm 1.

Algorithm. For a given $Q_{\alpha,\beta}$, if the (α, β)-core is empty, QueryOPT immediately returns $\emptyset$ as the result since either $\mathbb{I}^U[\alpha]$ or $\mathbb{I}^U[\alpha][\beta]$ is empty (line 2-3). If the (α, β)-core is not empty, it first retrieves $C_{\alpha,\beta}.\mathcal{U}$ and computes the node block nb referred by the pointer in $\mathbb{I}^U[\alpha][\beta]$ (line 4). After that, it iteratively processes the node block in $\mathbb{I}^U$.NB until the first element of the associated value of nb is not the given α (line 5 and 8). All the nodes in visited nb are added into $C_{\alpha,\beta}.\mathcal{U}$ (line 6-7). The nodes in $C_{\alpha,\beta}.\mathcal{V}$ are retrieved similarly and $C_{\alpha,\beta}$ is returned at the end (line 9-10).

Example 3.3: Figure 4 illustrates the procedure of QueryOPT to compute $C_{1,3}$. Processing steps are shown in bold arrows and the visited elements are marked in grey. To compute $C_{1,3}.\mathcal{U}$, QueryOPT

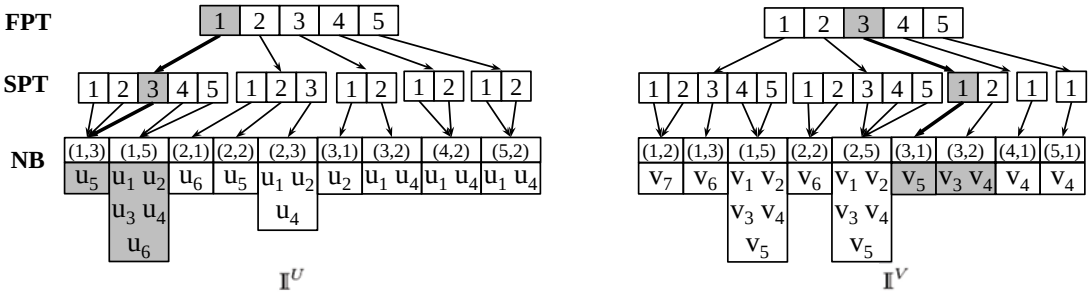

Figure 4: BiCore-Index **and procedure of** QueryOPT **for** $Q_{1,3}$

follows the pointer kept in the 1st element in $\mathbb{I}^U$.FPT and the 3rd element of the 1st array in $\mathbb{I}^U$.SPT and obtains u_5 in the node block $(1,3)$. It continues to visit node block $(1,5)$ and stops at node block $(2,1)$ since the first element of $(2,1)$ is larger than 1. Thus, $C_{1,3}.\mathcal{U} = \{u_1, u_2, u_3, u_4, u_5, u_6\}$. Similarly, QueryOPT follows the pointer kept in the 3rd element in $\mathbb{I}^V$.FPT and the 1st element of the 3rd array in $\mathbb{I}^V$.SPT and obtains $C_{1,3}.\mathcal{V} = \{v_3, v_4, v_5\}$. □

Theorem 3.1: *Given a $Q_{\alpha,\beta}$ posed on a bipartite graph G,* QueryOPT *computes $C_{\alpha,\beta}$ in $O(|C_{\alpha,\beta}.\mathcal{U}| + |C_{\alpha,\beta}.\mathcal{V}|)$.*

Proof: For a given α, each $u \in U(G)$ appears at most once in the node blocks pointed by the pointers in α-th array in SPT. Therefore, no duplicate node is added in $C_{\alpha,\beta}.\mathcal{U}$ in line 7. Similarly, no duplicate node is added in $C_{\alpha,\beta}.\mathcal{V}$ in line 9. Since all the nodes visited in QueryOPT are exactly the nodes we need to retrieve, QueryOPT computes $C_{\alpha,\beta}$ in $O(|C_{\alpha,\beta}.\mathcal{U}| + |C_{\alpha,\beta}.\mathcal{V}|)$ time. □

3.3 Space Complexity of BiCore-Index

In this section, we prove the linear space complexity of BiCore-Index. We first show that the size of SPT can be bounded by $O(m)$ in Lemma 3.2. Then, we prove that the space complexity of BiCore-Index is $O(m)$ in Theorem 3.2.

Lemma 3.2: *Given a bipartite graph G, the space of its* SPT *is bounded by $O(m)$.*

Proof: Let $u_1, u_2, u_3, \ldots, u_{n_U}$ be any given sequence of $u \in U(G)$. Starting from an empty graph with only $V(G)$, we add nodes in $U(G)$ with their incident edges to the graph one by one following the sequence until we finally get G. Suppose that u_i is just added to the graph. As u_i cannot be contained in any (α,β)-core whose $\alpha > \deg(u_i, G)$, u_i only influences the length of the k-th arrays in SPT with $1 \le k \le \deg(u_i, G)$. Because the length of the α-th array increases at most one after the insertion of u_i, the size of SPT increases at most $\deg(u_i, G)$. Thus, the space of SPT in $\mathbb{I}^U$ is bounded by $O(\sum_{u \in U(G)} \deg(u, G)) = O(m)$. Similarly, it can be shown that the space of SPT in $\mathbb{I}^V$ is also bounded by $O(m)$. Therefore, the space of SPT is bounded by $O(m)$. □

Theorem 3.2: *Given a bipartite graph G, the space of its* BiCore-Index *is bounded by $O(m)$.*

Proof: Since both $\mathsf{dmax}_U(G)$ and $\mathsf{dmax}_V(G)$ is smaller than m, the size of FPT can be bounded by $O(m)$. For each node $u \in U(G) \cup V(G)$, the number of node blocks containing u is $\deg(u)$. Hence, the space of NB is $O(\sum_{u \in U(G) \cup V(G)} \deg(u, G)) = O(m)$. Based on Lemma 3.2, the space of BiCore-Index can be bounded by $O(m)$. □

4 INDEX CONSTRUCTION ALGORITHM

In this section, we introduce how to construct BiCore-Index efficiently. Based on the structure of BiCore-Index, if we know $\beta_{\max,\alpha}(u)$ for each node $u \in U(G)$ regarding all possible α and $\alpha_{\max,\beta}(v)$ for each node $v \in V(G)$ regarding all possible β (in consistence with the literature on unipartite graphs, we call the procedure as core decomposition as well), the construction of BiCore-Index is straightforward and can be finished in $O(m)$ time as shown in Section 4.3. Therefore, we first present techniques to conduct the core decomposition.

4.1 A Basic Core Decomposition Algorithm

Inspired by the algorithm in [11], considering a node $u \in U(G)$ and a specific α, if $u \in C_{\alpha,\beta}.\mathcal{U}$ and $u \notin C_{\alpha,\beta+1}.\mathcal{U}$, we know $\beta_{\max,\alpha}(u) = \beta$. Moreover, for a specific α, $C_{\alpha,\beta+1}$ is contained in $C_{\alpha,\beta}$. Therefore, for a specific α, if we compute all the possible (α,β)-cores in increasing order of β by iteratively removing nodes in $U(G)$ with degree less than α and nodes in $V(G)$ with degree less than β, we can obtain $\beta_{\max,\alpha}(u)$ for all nodes $u \in U(G)$ regarding the specific α. Following this way, we can compute $\beta_{\max,\alpha}(u)$ for all $u \in U(G)$ by iterating all possible α values of G in a bottom-up manner. $\alpha_{\max,\beta}(v)$ can be computed similarly.

Algorithm. The basic algorithm, BasicDecom, is shown in Algorithm 2. BasicDecom first computes $\beta_{\max,\alpha}(u)$ for nodes in $u \in U(G)$. Since the maximum value of α for all nodes in $U(G)$ is dmax_U, it iterates α between 1 and dmax_U and computes $\beta_{\max,\alpha}(u)$ for $u \in U(G)$ regarding the specific α by invoking compute$\beta_{\max}$ (line 1-2). Similarly, $\alpha_{\max,\beta}(v)$ for $v \in V(G)$ are computed in line 3-4.

Procedure compute$\beta_{\max}$ computes $\beta_{\max,\alpha}(u)$ for all the nodes in $u \in U(G)$ for a given α. It first removes the nodes and their incident edges in G' whose degree is less than α (line 7-8). Then, it processes the nodes in $U(G)$ in increasing of β (line 10). Whenever a node v with $\deg(v, G') \le \beta$ is removed (line 11), if there exists a node u with $\deg(u, G') < \alpha$ in G', we know that $u \in C_{\alpha,\beta}$ but $u \notin C_{\alpha,\beta+1}$, which means $\beta_{\max,\alpha}(u)$ regarding α is β (line 14). Procedure compute$\alpha_{\max}$ follows a similar framework as compute$\beta_{\max}$ to compute $\alpha_{\max,\beta}(v)$ for $v \in V(G)$ regarding a given β (line 16-17).

Example 4.1: Considering the graph in Figure 2, Figure 5 shows the procedure of BasicDecom to conduct the core decomposition. Since

Algorithm 2 BasicDecom

11: **while** $\exists v \in V(G') : \deg(v, G') \leq \beta$ **do**
12: remove v and its incident edges from G';
13: **while** $\exists u \in U(G') : \deg(u, G') < \alpha$ **do**
14: $\beta_{\max,\alpha}(u) \leftarrow \beta$;
15: remove u and its incident edges from G';
16: **procedure** compute$\alpha_{\max}(G, \beta)$
17: line 6-15 by interchanging u with v, U with V, α with β;

Iteration	$\beta_{\max,\alpha}(u_1)$					$\alpha_{\max,\beta}(v_4)$				
	1	2	3	4	5	1	2	3	4	5
1 ($\alpha = 1$)	5	0	0	0	0	0	0	0	0	0
2 ($\alpha = 2$)	5	3	0	0	0	0	0	0	0	0
3 ($\alpha = 3$)	5	3	2	0	0	0	0	0	0	0
4 ($\alpha = 4$)	5	3	2	2	0	0	0	0	0	0
5 ($\alpha = 5$)	5	3	2	2	2	0	0	0	0	0
6 ($\beta = 1$)	5	3	2	2	2	5	0	0	0	0
7 ($\beta = 2$)	5	3	2	2	2	5	5	0	0	0
8 ($\beta = 3$)	5	3	2	2	2	5	5	2	0	0
9 ($\beta = 4$)	5	3	2	2	2	5	5	2	1	0
10($\beta = 5$)	5	3	2	2	2	5	5	2	1	1

Figure 5: Decomposition procedure of Algorithm 2

the decomposition involves all the nodes and large number of values, we only show the procedure for two representative nodes, u_1 and v_4, for brevity. In iteration 1, BasicDecom invokes compute$\beta_{\max}$ with $\alpha = 1$ and finds that u_1 is removed when $\beta = 5$. Thus, it updates $\beta_{\max,1}(u_1)$ as 5. BasicDecom finishes computation in 10 iterations as both dmax_U and dmax_V are 5. □

Theorem 4.1: *Given a bipartite graph G, Algorithm 2 runs in $O(\text{dmax} \cdot m)$ time, where $\text{dmax} = \max\{\text{dmax}_U, \text{dmax}_V\}$.*

Proof: The removal of node v in line 12 and node u in line 8 and 15 can be done in $O(\deg(v, G'))$ and $O(\deg(u, G'))$ time with the efficient data structure proposed in [22]. Since each node is removed once, the time complex of compute$\beta_{\max}$ is bounded by $O(m)$. Similarly, the running time compute$\alpha_{\max}$ is also $O(m)$. Thus, the time complexity of BasicDecom is $O(\text{dmax} \cdot m)$. □

4.2 A Computation-sharing Core Decomposition Algorithm

Algorithm 3 processes the nodes in $U(G)$ and $V(G)$ independently and has to conduct $O(\text{dmax})$ iterations to complete the core decomposition. However, dmax can be very large in real graphs [6], which makes Algorithm 2 impractical. In this section, we reduce the number of iterations to 2δ, where δ is the maximum value

Algorithm 3 ComShrDecom

7: line 6-8 of Algorithm 2;
8: **while** $G' \neq \emptyset$ **do**
9: $\beta \leftarrow \min_{v \in V(G')} \deg(v, G')$;
10: **while** $\exists v \in V(G') : \deg(v, G') \leq \beta$ **do**
11: remove v and its incident edges from G';
12: **for** $i = 1$ **to** β **do**
13: **if** $\alpha_{\max,i}(v) < \alpha$ **then**
14: $\alpha_{\max,i}(v) \leftarrow \alpha$;
15: **while** $\exists u \in U(G') : \deg(u, G') < \alpha$ **do**
16: $\beta_{\max,\alpha}(u) \leftarrow \beta$;
17: remove u and its incident edges from G';
18: **procedure** compute$\alpha^{+}_{\max}(G, \beta)$
19: line 8-19 by interchanging u with v, U with V, α with β;

such that $C_{\delta,\delta}$ is nonempty and is bounded by $\sqrt{m}$, by exploring computation-sharing opportunities during processing the nodes in $U(G)$ and $V(G)$.

In Algorithm 2, when finishing processing a specific α, we actually have computed all the $C_{\alpha',\beta}$ with $\alpha' \leq \alpha$ in G. Meanwhile, for a node $v \in V(G)$ and a given β, $\alpha_{\max,\beta}(v)$ is the maximum value of α such that v is contained in the corresponding $C_{\alpha,\beta}$. Therefore, we can also obtain $\alpha_{\max,\beta}(v) \leq \alpha$ for $v \in V(G)$ when finishing processing a specific α in Algorithm 2. Similarly, we can obtain $\beta_{\max,\alpha}(u) \leq \beta$ for $u \in U(G)$ after processing a specific β. Moreover, let δ be the maximum value such that the corresponding $C_{\delta,\delta}$ is nonempty, we have:

Lemma 4.1: *Given a bipartite graph G, $\alpha_{\max,\beta}(v) \leq \delta$, for all $\beta > \delta$ and $v \in V(G)$; $\beta_{\max,\alpha}(v) \leq \delta$, for all $\alpha > \delta$ and $u \in U(G)$.*

Proof: Suppose that there exists some $v \in V(G)$ and $\beta > \delta$ such that $\alpha_{\max,\beta}(v) > \delta$, based on the definition of $\alpha_{\max,\beta}(v)$, $C_{\delta+1,\delta+1}$ must be nonempty, which contradicts the definition of δ. Thus, $\alpha_{\max,\beta}(v) \leq \delta$, for all $\beta > \delta$ and $v \in V(G)$. Similarly, the second part is correct. □

Based on Lemma 4.1, if we iterate α from 1 to δ in Algorithm 2, besides computing $\beta_{\max,\alpha}(u)$ for each $\alpha \leq \delta$ and each $u \in U(G)$ in line 14, we can actually also obtain $\alpha_{\max,\beta}(v)$ for each $\beta > \delta$ and each $v \in V(G)$. Similarly, if we iterate β from 1 to δ, we can obtain not only $\alpha_{\max,\beta}(v)$ for each $\beta \leq \delta$ and each $v \in V(G)$ but also $\beta_{\max,\alpha}(u)$ for each $\alpha > \delta$ and each $u \in U(G)$.

Algorithm. Following above idea, our computation-sharing algorithm, ComShrDecom, is shown in Algorithm 3. In Algorithm 3, ComShrDecom first computes δ of G. δ can be achieved based on its definition by increasing δ step by step starting from 1 while iteratively removing nodes from G whose degree is less than δ. When G is empty, δ is obtained and it can be done in $O(m)$ time. Then, ComShrDecom iterates α and β from 1 to δ to compute

Iteration	$\beta_{\max,\alpha}(u_1)$					$\alpha_{\max,\beta}(v_4)$				
	1	2	3	4	5	1	2	3	4	5
1 ($\alpha=1$)	5	0	0	0	0	1	1	1	1	1
2 ($\alpha=2$)	5	3	0	0	0	2	2	2	1	1
3 ($\beta=1$)	5	3	1	1	1	5	2	2	1	1
4 ($\beta=2$)	5	3	2	2	2	5	5	2	1	1

Figure 6: Decomposition procedure of Algorithm 3

$\beta_{\max,\alpha}(u)$ for $u \in U(G)$ and $\alpha_{\max,\beta}(v)$ for $v \in V(G)$ by invoking compute$\beta^+_{\max}$ and compute$\alpha^+_{\max}$, respectively (line 2-5).

The main difference between procedure compute$\alpha^+_{\max}$ and procedure compute$\alpha_{\max}$ is that compute$\alpha_{\max}$ updates $\beta_{\max,\alpha}(u)$ and $\alpha_{\max,\beta}(v)$ simultaneously based on the computation result of previous iterations. More specifically, when compute$\beta^+_{\max}$ removes a node $v \in V(G)$ and its incident edges from G' (line 11), for each i from 1 to β, if $\alpha_{\max,i}(v) < \alpha$, it updates the corresponding $\alpha_{\max,i}(v)$ as α (line 13-14). This is because when v is removed, v is in a $C_{\alpha,\beta}$, thus $\alpha_{\max,i}(v)$ is at least α. After compute$\beta^+_{\max}$ finishes, the $\alpha_{\max,\beta}(v) \le \alpha$ for nodes $v \in V(G)$ are obtained. Procedure compute$\alpha^+_{\max}$ conducts the process symmetrically as compute$\beta^+_{\max}$.

Example 4.2: Figure 6 shows the procedure of ComShrDecom to compute $\beta_{\max,\alpha}(u_1)$ and $\alpha_{\max,\beta}(v_4)$. ComShrDecom first computes $\delta = 2$, thus it needs 4 iterations to finish the decomposition. Compared with BasicDecom, ComShrDecom updates both $\beta_{\max,\alpha}(u_1)$ and $\alpha_{\max,\beta}(v_4)$ simultaneously in a single iteration. In iteration 2, it invokes compute$\beta^+_{\max}$ with $\alpha = 2$ and finds that both u_1 and v_4 are removed when $\beta = 3$. Thus ComShrDecom updates $\beta_{\max,2}(u_1)$ to 3 and $\alpha_{\max,1}(v_4)$, $\alpha_{\max,2}(v_4)$, $\alpha_{\max,3}(v_4)$ to 2. □

Theorem 4.2: *Given a bipartite graph G, the time complexity of Algorithm 3 is $O(\delta \cdot m)$, where $\delta \le \lceil\sqrt{m}\rceil$.*

Proof: The difference between compute$\beta_{\max}$ and compute$\beta^+_{\max}$ lies in line 12-14. Since the maximum possible value of β in line 12 can be no larger than $\deg(v,G)$, the time complexity of line 12-14 is $O(\deg(v,G))$. Hence, compute$\beta^+_{\max}$ runs in $O(m)$ time. Similarly, compute$\alpha^+_{\max}$ runs in $O(m)$ time. Thus, Algorithm 3 also runs in $O(\delta \cdot m)$.

Let g denote the subgraph induced by $C_{\delta,\delta}$. Based on the definition of (α,β)-core , there are at least δ nodes in g and the degree of each node is at least δ. Thus, we have $\delta \cdot \delta \le E(g) \le m$. Therefore, $\delta \le \sqrt{m}$. □

Remark. In fact, the number of iterations in Algorithm 3, which equals to $2 \cdot \delta$, is within a constant factor of 2 to the optimal number of iterations we can achieve. This is because essentially during the decomposition process we need to compute each nonempty (α,β)-core at least once. Hence, we should at least iterate α from 1 to δ or iterate β from 1 to δ to compute all the (α,β)-cores whose $\alpha \le \delta \wedge \beta \le \delta$. In other words, the lower bound of the number of iterations required to conduct the decomposition is δ. Therefore, the number of iterations in Algorithm 3 is within a constant factor of 2 to the optimal number of iterations.

4.3 Index Construction Algorithm

After obtaining the core decomposition result, we can construct BiCore-Index based on its structure directly. For $\mathbb{I}^U$, we first constructs $\mathbb{I}^U$.NB based on $\beta_{\max,\alpha}(u)$ and sort all the node blocks with their associated (α,β) value. After that, we store the address of the first node block (α,β') such that $\beta' \ge \beta$ in $\mathbb{I}^U[\alpha][\beta]$ and the address of the α-th array in $\mathbb{I}^U[\alpha]$. $\mathbb{I}^V$is constructed similarly. For a given bipartite graph G and its core decomposition result, the index can be constructed in $O(m)$ time.

5 EXTENSIONS

Index Maintenance on Dynamic Graphs. When graphs are dynamically updated, a straightforward solution to maintain BiCore-Index is reconstructing it from scratch, which is inefficient for large graphs. In this section, we discuss the incremental algorithms for maintaining BiCore-Index on dynamic graphs. We mainly focus on edge insertion and deletion, because node insertion/deletion can be treated as a sequence of edge insertions/deletions. For brevity, we use G^+/G^- to represent the updated graph after (u,v) is inserted/removed. Since the computation of $\beta_{\max,\alpha}(u)$ and $\alpha_{\max,\beta}(v)$ is the most time-consuming part for maintaining BiCore-Index, we concentrate on computing these values here.

Edge Insertion. Suppose that an edge (u,v) is inserted, for an integer α, let $\tau_\alpha = \min\{\beta_{\max,\alpha}(u,G), \beta_{\max,\alpha}(v,G)\}$. Because both u and v have already been included in any $C_{\alpha,\beta}$ whose $\beta < \tau_\alpha$, these (α,β)-cores will not change after the insertion. Thus, we only need to consider those nodes u' whose $\beta_{\max,\alpha}(u',G) \ge \tau_\alpha$, i.e., nodes in C_{α,τ_α}. Similarly, for an integer β, let $\tau_\beta = \min\{\alpha_{\max,\beta}(u,G), \alpha_{\max,\beta}(v,G)\}$, all the nodes u' whose $\alpha_{\max,\beta}(u',G^+)$ value will change after the insertion of (u,v) are contained in $C_{\tau_\beta,\beta}$. Thus, we retrieve the induced subgraph of C_{α,τ_α} ($C_{\tau_\beta,\beta}$) through the BiCore-Index and compute $\beta_{\max,\alpha}(u',G^+)$ ($\alpha_{\max,\beta}(u',G^+)$) for those nodes by using compute$\beta^+_{\max}$ (compute$\alpha^+_{\max}$).

Edge Removal. Similarly to edge insertion case, for an integer α, all the nodes u' whose $\beta_{\max,\alpha}(u',G)$ will change after the removal of (u,v) must have $\beta_{\max,\alpha}(u',G) \le \tau_\alpha$. This is because edge (u,v) is not included in any induced subgraph of $C_{\alpha,\beta}$ where $\beta > \tau_\alpha$. Similarly, for an integer β, we know all the nodes u' whose $\alpha_{\max,\beta}(u',G)$ will change after the removal of (u,v) must have $\alpha_{\max,\beta}(u',G) \le \tau_\beta$. Thus, we retrieve C_{α,τ_α} ($C_{\tau_\beta,\beta}$) through the BiCore-Index and compute $\beta_{\max,\alpha}(u',G^-)$ ($\alpha_{\max,\beta}(u',G^-)$) for those nodes similarly as edge insertion case.

Batch Update. When a sequence of edges are inserted/removed, we first scan the sequence and remove all the operation pairs consisting of insertion then removal (removal then insertion) of the same edge as these operation pairs have no effect on the final result. After that we rearrange the order such that all the inserted edges come after removed edges. Thus, we can treat batch update as first removing a set of edges then inserting another set of edges. When a set of edges is inserted, our incremental algorithm can be easily extended to handle such situation. For an integer $\alpha(\beta)$, we set $\pi_\alpha(\pi_\beta)$ as the smallest $\beta_{\max,\alpha}(u,G)(\alpha_{\max,\beta}(u,G))$ where u is incident to at least one inserted edge. Then, we use the method in *Edge Insertion* to update BiCore-Index by replacing $\tau_\alpha(\tau_\beta)$ as $\pi_\alpha(\pi_\beta)$. Similarly, when a set of edges is removed, we set $\pi_\alpha(\pi_\beta)$ as the largest $\beta_{\max,\alpha}(u,G)(\alpha_{\max,\beta}(u,G))$ where u is incident to at least one removed edge. Then, we can use the method in *Edge Removal* by replacing $\tau_\alpha(\tau_\beta)$ as $\pi_\alpha(\pi_\beta)$.

Parallel Index Construction. Algorithm 3 can be easily extended to run in parallel. We first compute δ as line 1 in Algorithm 3. Then, we run compute$\beta^+_{\max}$ for each α from 1 to δ and compute$\alpha^+_{\max}$ for

each β from 1 to δ in parallel, i.e., each thread is in charge of a continuous subrange of possible values of α or β. To avoid race condition, we keep a copy of $\beta_{\max,\alpha}(u,G)$ and $\alpha_{\max,\beta}(v,G)$ for each thread. At last, we set $\beta_{\max,\alpha}(u,G)$ and $\alpha_{\max,\beta}(v,G)$ as the largest value among the results computed in all threads.

6 PERFORMANCE STUDIES

This section presents our experimental results. All experiments are performed under a Linux operating system on a machine with an Intel Xeon 3.4GHz CPU and 64GB RAM.

Dataset. We evaluate the algorithms on ten real graphs and two synthetic graphs. All the real graphs are downloaded from KONECT[1]. For the synthetic graphs, we generate a power-law graph (PL) in which edges are randomly added such that the degree distribution follows a power-law distribution and a uniform-degree graph (UD) in which all edges are added with the same probability. The details of these graphs are shown in Table 1. Note that we remove isolated nodes and duplicate edges in graphs and their sizes listed are based on the processed graphs.

Algorithms. We implement and compare following algorithms:

- Baseline: the state-of-the-art existing solution proposed in [11] (introduced in Section 2).
- QueryOPT: Our (α,β)-core query processing algorithm (Algorithm 1).
- BasicDecom: Our proposed index construction algorithm based on basic decomposition algorithm (Algorithm 2 + Index construction algorithm in Section 4.3).
- ComShrDecom: Our proposed index construction algorithm based on computation-sharing decomposition algorithm (Algorithm 3 + Index construction algorithm in Section 4.3).
- BiCore-Index-Ins: Our algorithm for handling edge insertion.
- BiCore-Index-Rem: Our algorithm for handling edge removal.
- BiCore-Index-Batch: Our algorithm for handling batch update.
- ParallelDecom: Our proposed algorithm for parallel index construction.

All algorithms are implemented in C++, using gcc compiler at -O3 optimization level. The time cost is measured as the amount of wall-clock time elapsed during the program's execution. All the experiments are repeated 5 times and we report the average time.

6.1 Performance of Querying Processing

In this section, we evaluate the performance of our proposed (α,β)-core query processing algorithm QueryOPT with the state-of-the-art algorithm Baseline. The running time we report is based on answering the query 10 times. We first test the algorithms on all the twelve datasets with the same query $Q_{10,10}$. Then, we report the performance of the algorithms to process $Q_{\alpha,\beta}$ when varying α (β) regarding fixed β (α).

Exp-1: Query performance on different datasets. Figure 7 shows the running time of two query processing algorithms to process $Q_{10,10}$. We only show the results on the six largest datasets due to the similar trends. Since QueryOPT is optimal, it is always the fastest algorithm in all cases. For example, on DUI, the running time of QueryOPT is 0.04s, which achieves three order of magnitude improvement compared with Baseline (86.8s).

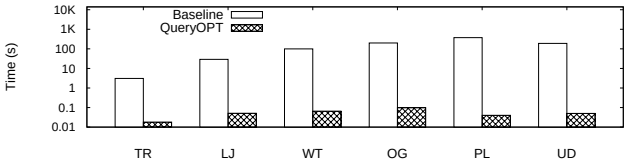

Figure 7: Query performance on different datasets

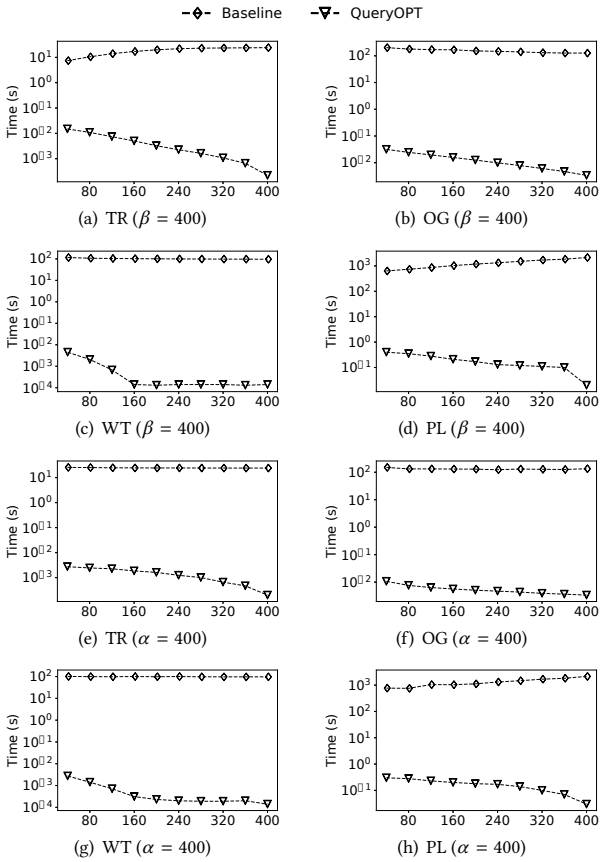

Figure 8: Query time for different α (β)

Exp-2: Varying α (β). The running time of Baseline and QueryOPT when varying α (β) is reported in Figure 8. We just show the results on four real graphs due to the similar trends. As shown in Figure 8, QueryOPT is far more efficient than Baseline on all datasets under every α (outperforms Baseline by 3-7 orders of magnitude). This is because QueryOPT is a time-optimal algorithm. As α grows, the time cost of Baseline is relatively stable since no matter what α is, Baseline needs to visit the entire graph. The gap between QueryOPT and Baseline increases as α grows. This is because as α grows, the size of $C_{\alpha,\beta}$ decreases and the running time of QueryOPT depends on the size of $C_{\alpha,\beta}$ while that of Baseline depends on the size of input graph. The results when varying β is similar to varying α.

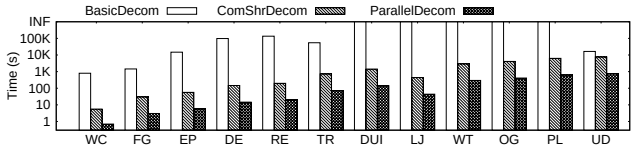

Figure 9: Index construction time for different datasets

6.2 Performance of Index Construction

In this section, we report the size of BiCore-Index for the datasets and evaluate the performance of two index algorithms BasicDecom and ComShrDecom. In this set of experiments, we set the maximum running time for each test as 48 hours. If a test does not stop within the time limit, we denote its processing time as INF.

Exp-3: Index size $|\mathbb{I}|$. The BiCore-Index size $|\mathbb{I}|$ of all the datasets is reported in Table 1. For ease of comparison, we also report the graph size in Table 1. As shown in Table 1, the size of BiCore-Index is linear to the size of its corresponding graph. For example, the size of OG is 2,644.93 MB while the size of its BiCore-Index is 2,645.46 MB. The results are consistent with our theoretical analysis in Section 3.3.

Exp-4: Index construction time for different datasets. In this experiment, we evaluate the time cost for constructing BiCore-Index on different datasets using BasicDecom and ComShrDecom. The results are reported in Figure 9. ComShrDecom is faster than BasicDecom on all datasets and on average achieves over 1000x improvement. For example, in EP, ComShrDecom spends 56 seconds while BasicDecom spends 14,818 seconds.

Exp-5: Comparison of dmax, $\sqrt{m}$ and δ. To better demonstrate the efficiency of BasicDecom and ComShrDecom, we report dmax, $\sqrt{m}$ and δ in Table 1 as these values directly relates to their running time. As shown in Table 1, δ is at least two order of magnitude smaller than dmax for all datasets, which explains the outstanding performance of ComShrDecom. Furthermore, δ is much smaller than $\sqrt{m}$ on real and power-law graphs, which means ComShrDecom hardly runs in worst case and is very efficient in practice. The results confirm our analysis in Section 4 and are consistent with the results in Exp-4.

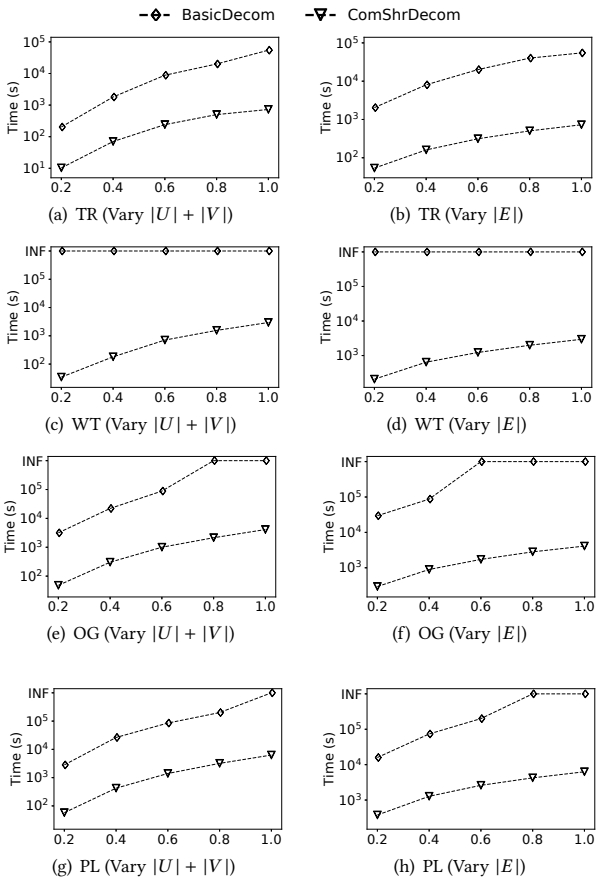

Figure 10: Scalability of index construction algorithms

Exp-6: Scalability of index construction. In this experiment, we evaluate the scalability of BasicDecom and ComShrDecom. To test the scalability, we vary the number of nodes and the number of edges by randomly sampling nodes and edges respectively from 20% to 100% and keeping the induced subgraphs as the input graphs. We only show the results on TR, WT, OG, and PL in Figure 10 since trends are similar on all other datasets. As shown in Figure 10, when varying the number of nodes, the running time for both algorithms

stably increases. ComShrDecom has better performance in all cases and outperforms BasicDecom over two orders of magnitude on average. For example, on WT, the running time of ComShrDecom increases from 35s to 2,953s while BasicDecom cannot terminate within 48 hours for all cases of WT. Varying the number of edges has a similar trend as varying the number of nodes. The results verify that ComShrDecom has a good scalability in practice.

6.3 Dynamic Maintenance and Parallel Construction

In this section, we test the performance of our index maintenance algorithms. We take the algorithm which invokes ComShrDecom to construct BiCore-Index from scratch for each update as the baseline solution. For the baseline solution, the running time is nearly the same for edge insertion and removal, therefore, we just show one result in the figures.

Exp-7: Index maintenance on different datasets. For BiCore-Index-Ins and BiCore-Index-Rem, we randomly remove 5000 distinct existing edges from the graph and report the average processing time for each edge removal. After that, we insert the removed edges back into the graph one by one and report the average processing time for each edge insertion. For BiCore-Index-Batch, we randomly generate 5000 edges and each edge is randomly chosen as insertion or removal. We report the processing time in Figure 11. Generally, the average processing time of our proposed algorithms is much smaller than the baseline solution. For example, on WT, our proposed algorithms BiCore-Index-Ins and BiCore-Index-Rem can handle edge insertion and removal in 31s and 35s respectively while the baseline solution ComShrDecom requires 2,953s. This is because our proposed algorithms are incremental algorithms and save lots of unnecessary computation. Moreover, BiCore-Index-Batch can handle batch update on WT and OG in 292s and 857s respectively.

Exp-8: Parallel index construction. In this experiment, we implement parallel index construction algorithm ParallelDecom using C++11 thread class and test it with 12 cores in default. The running time of ParallelDecom on all datasets is reported in Figure 9. ParallelDecom achieves one order magnitude improvement over BasicDecom. For, example, in WT, the running time of ParallelDecom is 317s while ComShrDecom costs 2953s. We also report performance of ParallelDecom on TR, WT, OG, and PL with different number of cores in Figure 12. The running time of ParallelDecom is almost inversely proportional to the number of cores, which shows that ParallelDecom is efficient in practice.

7 RELATED WORK

Dense Subgraphs in Bipartite Graphs. (α, β)-core is first introduced in [1]. [10] and [11] extend the linear k-core mining algorithm to compute (α, β)-core. [19, 23] generalizes the k-clique on unipartite graph to biclique on bipartite graphs. [32] proves that finding the maximum edge biclique is NP-complete. [53] proposes an efficient algorithm to enumerate all bicliques. [26, 39] relax the definition of biclique to introduce quasi-biclique on bipartite graphs and propose heuristic algorithms to enumerate all quasi-bicliques. [37] defines a framework of bipartite subgraphs based on the butterfly motif (2,2-biclique) to model the dense regions in a hierarchical structure. [34] proposes efficient algorithms for counting the butterfly motif.

Bipartite Graph Models. [16] shows that all complex networks can be decomposed into underlying bipartite structures sharing some important statistics. [17, 29] model bipartite graphs by assigning degree distribution to each node set separately. [20] uses a Markov chain rewiring algorithm to generate bipartite graphs. Preferential attachment process, which is popularly use in generating scale free networks, is studied on bipartite graphs by [17].

Cohesive Subgraph Detection in Unipartite Graphs. Seidman first introduces k-core in [38]. [7] gives an efficient linear-time algorithm for core decomposition. Core decomposition is also studied in weighted graphs [14] and directed graphs [13]. Algorithms for core number maintenance in dynamic graphs are proposed in [35, 36, 54]. Application of k-core can be found in social networks [14, 46], graph visualization[3, 51], protein interaction network analysis [5, 42] and so on. Other cohesive subgraph models are also studied recently, such as clique [43, 44, 48], k-edge connected component [45, 47], and k-mutual-friend subgraph model [50].

8 CONCLUSION

In this paper, we study the problem of efficient (α, β)-core computation. We devise a compact index BiCore-Index whose size can be bounded by $O(m)$. Based on BiCore-Index, we propose an optimal algorithm for (α, β)-core computation and investigate efficient algorithms to construct the index. Moreover, we also discuss about how to maintain the index in dynamic graphs and construct it with parallel algorithm. The experimental results demonstrate the efficiency of our proposed algorithms.

ABSTRACT

With the rapid development of the Internet, millions of documents, such as news and web pages, are generated everyday. Mining the topics and knowledge on them has attracted a lot of interest on both academic and industrial areas. As one of the prevalent unsupervised data mining tools, topic models are usually explored as probabilistic generative models for large collections of texts. Traditional probabilistic topic models tend to find a closed form solution of model parameters and approach the intractable posteriors via approximation methods, which usually lead to the inaccurate inference of parameters and low efficiency when it comes to a quite large volume of data. Recently, an emerging trend of neural variational inference can overcome the above issues, which offers a scalable and powerful deep generative framework for modeling latent topics via neural networks. Interestingly, a common assumption for the most neural variational topic models is that topics are independent and irrelevant to each other. However, this assumption is unreasonable in many practical scenarios. In this paper, we propose a novel Centralized Transformation Flow to capture the correlations among topics by reshaping topic distributions. Furthermore, we present the Transformation Flow Lower Bound to improve the performance of the proposed model. Extensive experiments on two standard benchmark datasets have well-validated the effectiveness of the proposed approach.

1 INTRODUCTION

Nowadays, the numerous texts, such as online news and reports, are generated by various kinds of daily web services. Mining and organizing large number of topics and knowledge from them has attracted much attention [2, 16, 28, 33, 35]. As one of the most prevalent unsupervised algorithms in data mining and natural language processing, topic model has become such a successful technique to discover topics from collections. The conventional topic models, such as Latent Dirichlet Allocation (LDA) [9], offer a practical and explainable probability generative process for modeling topics. In the LDA, topic distribution of a document is drawn as a multinomial with Dirichlet prior, and document words are drawn from their topical words distribution. Then many LDA-like probability topic models are proposed. However, since generative process is getting expressive as the data grows, the inference of topic models tends to be challenging and tricky due to the complicated intractable marginal likelihood.

Recent efforts in neural variational inference (NVI) [23] offers a powerful auto-encoding framework to handle with large amount of data, and it can also facilitate topic modeling. The advantage of the NVI is that it replaces the arduous works on inference of probabilistic models by applying flexible and powerful neural networks through stochastic back propagation [31]. In addition, the NVI can be automatically applied to a new model with a simple declarative specification of the generative process. Based on the NVI framework, several neural variational topic models are proposed, such as Neural Variational Document Model (NVDM) [23],

Neural Variation Latent Dirichlet Allocation (NVLDA) [34], and Gaussian Softmax Model (GSM) [22]. To reduce the computation complexity, their topics are always modeled as isotropic Gaussian distributions via inference network.

The covariance matrix of the isotropic Gaussian is a diagonal matrix for topical representations. It means that topics are solely independent to each other. Yet, in reality, topics in documents are usually correlated. For instance, the topics about "hardware" are probably related with topics about "software" and " company". Therefore, it is reasonable to expect the relationships among different topics can be modeled to expand the limitations of the classical neural variational topic models in which topics are generated by the isotropic Gaussian distribution. Intuitively, the isotropic Gaussian topic distribution can be replaced by a Gaussian distribution with full covariance matrix, so that the topic correlations can be captured.

Similar challenges also exist in the field of computer vision. Several efforts have been dedicated to solving this independent problem, such as Normalizing flow [30], Inverse auto regressive flow [18], and Householder flow [37]. These flow-based methods map an isotropic Gaussian samples into full covariance one by using several invertible transformations. Among them, the most efficient one is Householder Flow since it only involves linear transformations compared with the other flow-based methods [37]. However, Householder flow cannot be directly applied to the topic models designed for NLP tasks. Because Householder flow can only transform single stochastic Gaussian sample into non-isotropic one, which is obviously insufficient in computing loss function.

To tackle with the aforementioned problems, in this paper, we first propose a Centralized Transformation Flow (CTF) to make the inference network capable of modeling covariance matrix of latent distribution. Based on this, we further propose a Neural Variational Correlated Topic Model (NVCTM) that integrates the CTF with multinomial softmax generative process. The proposed NVCTM can enhance the capability of capturing the correlations among topics with the assistance of the new CTF process. In particular, inspired by involutory property of Householder matrix and linear property of Gaussian, the proposed CTF utilizes the product of several Householder transformations to get final transformation matrix. Then the isotropic Gaussian samples can be transformed into non-isotropic samples via the linear operator. Finally, the document is reconstructed by the multinomial softmax generative model given correlated topic vectors. Besides, to effectively infer with Centralized Transformation Flow, we also present the Transformation Flow Lower Bound (TFLB) to regulate KL divergence term of the objective function. The TFLB utilizes the linear property of Gaussian distribution and gives the closed form KL divergence between encoded non-isotropic Gaussian distribution and topic prior. To evaluate the proposed methods, we conduct experiments on two standard datasets. The experimental results indicate the effectiveness of the correlated topic modeling via the CTF and the TFLB is an appropriate lower bound for the inference of the NVCTM. In summary, this paper makes following contributions:

(1) We propose the CTF for inference network, which is capable of transforming isotropic Gaussian distribution samples into Gaussian samples with full covariance matrix.
(2) We propose the NVCTM model, which is able to capture the correlations among topics via the proposed CTF process.
(3) We design the new TFLB which gives an appropriate KL divergence term of the NVCTM and is capable to effectively facilitate the training of the NVCTM.

The rest of this paper is organized as follows. Section 2 focuses on the related works. In Section 3, we briefly introduce the background knowledge of neural variational topic models and Householder flow. In Section 4, we propose our NVCTM and present its inference process. In Section 5, we introduce the dataset, options of experiments, evaluating metric, results and analysis. Finally, the conclusion of this work is made in Section 6.

2 RELATED WORKS

2.1 Correlated Topic Models

Latent Dirichlet Allocation [9] is one of the most popular approaches to text analysis community. In LDA, the multinomial-based topic distribution cannot model correlations between topics. To solve this issue, a CTM [7] replaces the component-independent Dirichlet topic prior with the full covariance Gaussian to capture the correlations. Similarly, many approaches are continually proposed. The Gaussian Process Topic Model (GPTM) [1] captures the correlations among document collection and adds known similarities among documents via Gaussian process. The above CTM and GPTM models capture the topic correlations by reconstructing topic distributions. Another kind of approaches, such as Gaussian-LDA [11] and Correlated Gaussian Topic Model (CGTM) [38], leverage external resources to model the topic correlations, such as computing relations by embedding-based representations [24, 25]. Notably, for most of the correlation-based topic models, Gaussian distribution is often adopted. It means that it is flexible to model dependent distributions and easy to capture correlations among topics. Traditional topic models utilize directed probability graph to describe their generative processes. Their training methods often adopt sampling methods [3, 27] and variational inference [6, 15]. These training methods requires closed form solution of deviations for updating model parameters to approximate intractable posterior. However, as the expressiveness and structure of generative processes grows, the deviation of parameters tends to be tough and complicated, which also hinders the model's efficiency when it comes to a large scale.

2.2 Neural Variational Topic Models

In recent years, the advances in stochastic variational inference and neural networks brings about the idea of using neural networks for parameter inference. Neural variational inference (NVI) approach [23] makes variational auto- encoders (VAEs) [19] a powerful deep generative framework for topic modeling. In VAEs, the flexible neural network is served as a estimator of the target distribution, which eliminates those arduous and complicated mathematical deviations. Neural variational document model (NVDM) [23] is a typical neural variational topic model with VAEs-like architecture. The NVDM consists of two parts: an inference network to parameterize latent topic distributions and a multinomial softmax generative model to reconstruct the document based on the topic vectors from latent

topic distribution. Similarly, neural variational latent Dirichlet allocation (NVLDA) [34] implements an isotropic Gaussian topic distribution under the Laplace approximation [12]. Gaussian Softmax Model (GSM) [22] normalizes the topic representation of NVDM to get topic proportion of each document. These neural variational approaches share a same drawback: topic distribution is assumed to be an isotropic Gaussian, which makes them incapable of modeling topic correlations.

2.3 Flow-based Methods for VAEs

Recent efforts have been conducted to improve latent variable distribution for neural variational inference. For instance, the flow-based methods such as Normalizing flow [30], which implements a series of invertible functions to transform the original latent variables. Householder flow [37] further utilizes a series of Householder transformation to model the orthogonal matrix and transforms an isotropic Gaussian sample into a non-isotropic one. Additionally, several more complicated flow-based methods, i.e., Hamiltonian Variational Inference (HVI) [32], and linear Inverse Autoregressive Flow (IAF) [18], are also proposed. Among these flow-based methods, the Householder flow is the most efficient one that only involves several linear transformations.

In this paper, our model overcomes the drawbacks of above works and consider both neural variational network and correlations among topics. It is noteworthy that our work introduces neural variational correlated topic model by bringing a new concept of *centralized transformation flow* and enhances the flexibility and interpretations of topic models for text analysis.

3 PRELIMINARIES

In this section, we firstly introduce a most classical framework of neural variational topic mdoel, Neural Variational Document Model (NVDM). Then, we briefly introduce Householder flow. The notations and symbols frequently used in this paper are displayed in Table 1.

Table 1: Notations in our model.

Name	Description
$\mathbf{x}$	Bag-of-word document vector
$\mathbf{h}^{(0)}$	Latent isotropic Gaussian topic vector
k	Length of CTF
$\mathbf{h}^{(k)}$	Latent non-isotropic topic vector after k length of CTF
$\mathbf{H}_i$	$i-th$ Householder matrix in Householder flow
π	Output vector from MLP in Inference network
μ	Mean vector of isotropic Gaussian topic distribution
Σ	Diagonal covariance matrix of isotropic Gaussian topic distribution
$\mathbf{U}$	Transformation matrix of CTF
V	Length of vocabulary
θ	Parameter set of inference network
γ	Parameter set of generative model

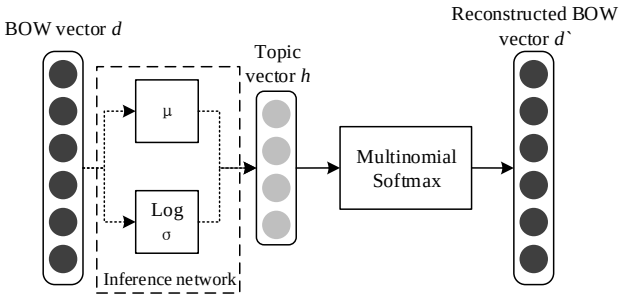

Figure 1: Schematic representation of NVDM.

3.1 Neural Variational Document Model

In traditional probability topic models, the inference of models often requires tricky and complicated math deviations for intractable posterior when the expressiveness of models' generative process grows. To fulfill efficient inference and learning in probabilistic topic models, neural variational inference (NVI) is introduced. In NVI, the inference of model parameters relies on neural networks to approximate the intractable posterior and only limited deviations of parameters are needed.

Neural Variational Document Model (NVDM) [23] is a typical NVI topic model. The schematic representation of NVDM is displayed in figure 1. Each input document is encoded into an isotropic Gaussian distribution via inference network. Then topic vectors are drawn from the Gaussian distributions and passed into a multinomial softmax generative model to reconstruct the input document. Specifically, let $\mathbf{d}$ indicate the bag-of-words document vector, which is the input of inference network; π denotes the output vector of multilayer perceptron (MLP) in inference network. The isotropic Gaussian topic distribution $\mathcal{N}(\mu, \Sigma)$ is parameterized by μ and σ. $\mathbf{l}_1(\cdot)$ and $\mathbf{l}_2(\cdot)$ are two linear neural networks.

$$\begin{aligned} \pi &= MLP(\mathbf{d}) \\ \mu &= \mathbf{l}_1(\pi) \\ \log \sigma &= \mathbf{l}_2(\pi) \\ \Sigma &= diag(\exp 2{\cdot}\mathbf{l}_2(\pi)) \end{aligned} \tag{1}$$

For M documents in corpus and N words in each document, the document generative process of NVDM then can be described as follows:

(1) Topic vector $\mathbf{h} \sim N(\mu, \Sigma)$.
(2) For each word in document $w_n \sim p(w_n|\mathbf{h})$. The definition of $p(w_n|\mathbf{h})$ is given by Equation 2.

$$p(w_n|\mathbf{h}) = \frac{exp\{-\mathbf{h}Wd_n - \mathbf{b}_{d_n}\}}{\sum_{j=1}^{|V|}\{\mathbf{h}Wd_j + \mathbf{b}_{d_i}\}} \tag{2}$$

The training objective of NVDM is to maximize the lower bound of marginal likelihood given in Equation 3.

$$L_{NVDM} = E_q[\log p(\mathbf{d}|\mathbf{h})] - KL[q(\mathbf{h}|\mathbf{d}) \parallel p(\mathbf{h})] \tag{3}$$

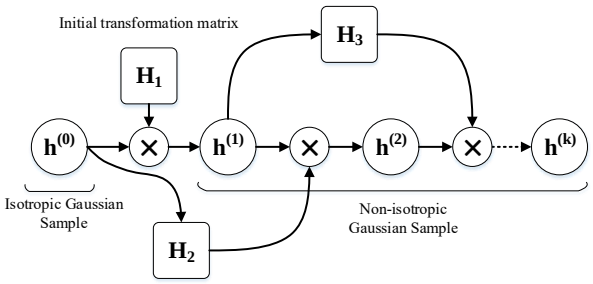

Figure 2: Schematic representation of Householder flow.

The objective function, which is also known as evidence lower bound (ELBO), has two components, i.e., the negative reconstruction term and the KL divergence term. The reconstruction term is mainly determined by generative model and KL divergence term denotes the measurement between the encoded isotropic Gaussian and its prior. The objective of training is equivalent to minimize reconstruction loss as well as KL divergence.

3.2 Householder flow

Previous work [37] introduces Household flow to break independent assumption in latent distributions.

Householder flow utilizes unitary and involutary properties of Householder matrix and establishes iterative invertible linear transformations to map an isotropic Gaussian sample into a non-isotropic one.

Intuitively, to transform an isotropic Gaussian sample into a full covariance one, an orthogonal matrix is needed. Generally, for any Gaussian sample $\mathbf{h}$ $N(\mu, \Sigma)$, it can be generated from a standard Gaussian distribution via $\mathbf{h} = \mu + \Sigma^{\frac{1}{2}} \cdot \epsilon, \epsilon \sim \mathcal{N}(0, I)$ where μ, Σ are parameters of Gaussian distribution. The Σ in isotropic Gaussian is a diagonal matrix. To model an orthogonal matrix, Householder flow can be represented as the product of k Householder transformation [5, 36]. Therefore, according to [37], the Householder matrix $\mathbf{H_i}$ is calculated as

$$\mathbf{H_t} = \begin{cases} \mathbf{I} - 2\dfrac{\pi \cdot (\pi)^{\mathbf{T}}}{\| \pi \|^2}, & t = 1 \\ \mathbf{I} - 2\dfrac{\mathbf{h^{(t-1)}} \cdot (\mathbf{h^{(t-1)}})^{\mathbf{T}}}{\| \mathbf{h^{(t-1)}} \|^2}, & t \geq 2 \end{cases} \tag{4}$$

where $\mathbf{h^{(1)}}$ is a random sample from isotropic Gaussian distribution. Householder matrix, mathematically, refers to an unitary, Hermitian and involutory matrix. Therefore, the product of Householder matrices can be simplified in terms of those useful properties. The vector π is the output vector of MLP in the inference network. We can iteratively get the transformed non-isotropic Gaussian sample via the following equation.

$$\mathbf{h^{(m)}} = \begin{cases} \mathbf{h^{(1)}} & , m = 1 \\ \mathbf{H_{m-1}} \quad \cdot \mathbf{h^{(m-1)}}, & m \geq 2 \end{cases} \tag{5}$$

The schematic representation of the iterative process of Householder flow is illustrated in figure 2. From figure, we can see that Householder Flow only maps single isotropic Gaussian sample to non-isotropic one. However, this is obviously insufficient in computing reconstruction loss mentioned at Equation 1.

4 OUR MODEL

In this section, we describe the proposed Neural Variational Correlated Topic Model (NVCTM) in details. Generally, the structure of NVCTM consists of two main parts, i.e., the inference network with Centralized Transformation Flow and the multinomial softmax generative model. Specifically, the proposed Centralized Transformation Flow in inference network first generates a distributional transformation matrix. The transformation matrix is product of several Householder matrices. The isotropic Gaussian samples are then transformed into non-isotropic ones by multiplying CTF's transformation matrix. The multinomial softmax generative model reconstructs the given documents from the topic vectors that are drawn from the non-isotropic Gaussian distribution. In the following subsections, we introduce details of the Centralized Transformation Flow and the proposed correlated topic modeling. The whole procedure of the model is illustrated in figure 3.

4.1 Centralized Transformation Flow

To transform multiple isotropic stochastic samples into non-isotropic ones, a distribution-level transformation matrix is needed. Therefore, we need to generate it.

Specifically, for each isotropic latent distribution, we choose the mean vector μ as the input vector to generate series of Householder matrices like the iterative process in Householder flow. The iteration process for Householder matrices is given by Equation 4 and Equation 6 where $\pi = MLP(\mathbf{x})$ is used for generating initial Householder matrix $\mathbf{H}_1$ and $MLP(\mathbf{x})$ is the output of MLP inference network.

$$\mathbf{v_m} = \begin{cases} \mu & , m = 1 \\ \mathbf{H_{m-1}} \quad \cdot \mathbf{v_{m-1}}, & m \geq 2 \end{cases} \tag{6}$$

For given length of flow k, the distributional transformation matrix $\mathbf{U}$ can be computed via:

$$\mathbf{U} = \prod_{i=1}^{k} \mathbf{H_i}, where \mathbf{H}_i \in \{\mathbf{H}_1, \mathbf{H}_2, \mathbf{H}_3, \cdots, \mathbf{H}_k\}. \tag{7}$$

Then we take advantage of the linear property of Gaussian. The final non-isotropic Gaussian samples can be computed via linear transformation mentioned in Equation 8.

$$\begin{aligned} \mathbf{h}^{(0)} &\sim N(\mu, \Sigma) \\ \mathbf{h}^{(k)} &= \mathbf{h}^{(0)} \cdot \mathbf{U} \\ \mathbf{h}^{(k)} &\sim N(\mathbf{U}\mu, \mathbf{U}\Sigma\mathbf{U}) \end{aligned} \tag{8}$$

The procedure of k-th Centralized Transformation flow is depicted in the upper part of figure 3.

Householder flow can only transform single isotropic Gaussian into non-isotropic one, which leads to insufficient approximating accurate the intractable posterior. While in CTF, when transformation matrix is defined, CTF is able to map multiple isotropic Gaussian samples into the non-isotropic ones with linear transformation.

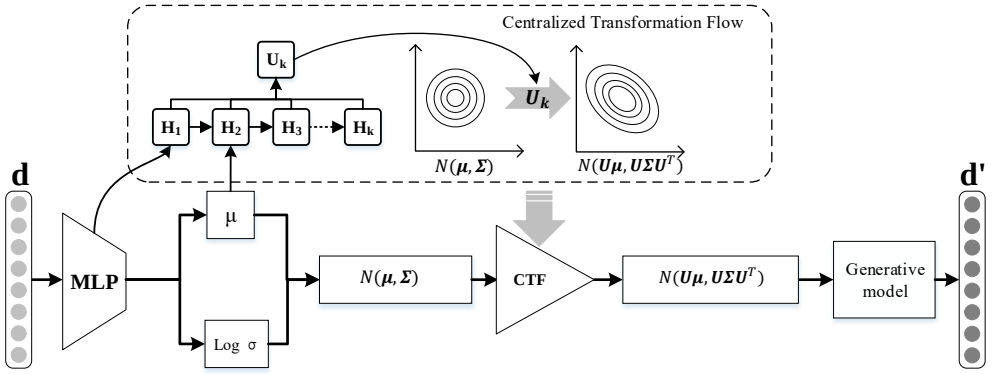

Figure 3: Schematic representation of NVCTM. The dashed rectangle indicates the procedure of CTF. The dashed arrow is short for the iterative process to generate $\mathbf{h^{(k)}}$.

4.2 Correlated Topic Modeling via Centralized Transformation Flow

The isotropic Gaussian topic distribution is unable to capture the correlation between topics. To address this issue, we propose our NVCTM which incorporates the proposed CTF to capture the correlation between topics.

In NVCTM, the proposed CTF is employed in the inference network of the NVCTM to transform the isotropic Gaussian topic distribution into a Gaussian with full covariance matrix. Then the multinomial softmax generative model generates the documents with the correlated topic vectors. The structure of NVCTM denotes in figure 3. The observed bag-of-word vector $\mathbf{d}$ is an input of MLP in inference network. The CTF then utilizes the output of MLP and the mean vector of isotropic Gaussian distribution as initial values to generate the distributional transformation matrix. The correlated topic vectors can be computed via multiplication between isotropic Gaussian topic vectors and transformation matrix in CTF. Finally, the multinomial softmax generative model takes several correlated topic vectors to reconstruct the input document vector $\mathbf{d'}$. After the employment of CTF, the topic distribution in NVCTM is a Gaussian with fully covariance matrix and the topic correlations can be captured. The objective function of NVCTM is denoted as

$$\begin{aligned} &L_{NVCTM} \\ &= E_q[\log p(\mathbf{d}|\mathbf{h^{(k)}})] - KL[q(\mathbf{h^{(k)}}|\mathbf{d})||p(\mathbf{h})] \\ &= E_{q\in N(\mathrm{U}\mu,\mathrm{U}\Sigma\mathrm{U})}[\log p(\mathbf{d}|\mathbf{h^{(k)}})] - KL[N(\mathrm{U}\mu,\mathrm{U}\Sigma\mathrm{U})||N(0,\mathbf{I})]. \end{aligned} \tag{9}$$

The negative reconstruction loss can be automatically computed via stochastic sampling multiple samples from the latent topic space. With the help of reparameterization trick, the whole objective function can be trained with stochastic gradient methods. Accordingly, the proposed CTF refines the latent topic distribution, which indicates that the KL divergence term needs to be modified. In the next subsection, we will precisely describe the deviation of new KL divergence term after applying CTF.

4.3 Inference with Centralized Transformation Flow

After employing CTF, the model inference needs to be modified accordingly. The conventional approach of estimating objective function when flow-based methods applied in VAEs usually refers to the Flow-based Free Energy lower Bound (FELB) [30]. It is calculated as

$$\begin{aligned} L_{FELB} = E_q[\log p(\mathbf{d}|\mathbf{h^{(k)}}) + \sum_{t=1}^{k} \log|det\frac{\partial f^{(t)}}{\partial h^{(t-1)}}|] \\ - KL[q(\mathbf{h^{(0)}}|\mathbf{d})||p(\mathbf{h^{(k)}})], \end{aligned} \tag{10}$$

where $\mathbf{h^{(0)}}$ indicates the isotropic Gaussian sample. In Householder flow, $\log|det\frac{\partial f^{(t)}}{\partial h^{(t-1)}}| = \log det|\mathbf{H_t}|$ equals to zero because Householder matrix is a unitary matrix. In CTF, $\log|det\frac{\partial f^{(t)}}{\partial h^{(t-1)}}| = \log det|\mathbf{U}|$ equals to zero for $\mathbf{U} = \prod_{i=1}^{k}\mathbf{H_i}$, where $\mathbf{H_i}$ is the Householder matrix. Therefore, in the NVCTM, the FELB is calculated as

$$\begin{aligned} L_{FELB} &= E_q[\log p(\mathbf{d}|\mathbf{h^{(k)}}) - KL[q(\mathbf{h^{(0)}}|\mathbf{d})||p(\mathbf{h})] \\ &= E_q[\log p(\mathbf{d}|\mathbf{h^{(k)}})] + 0.5[n - \mu^2 + |\Sigma| + \log|\Sigma|] \end{aligned}$$

where μ and Σ are in Equation 1. $p(\mathbf{h})$ is the prior, which is usually considered as $\mathcal{N}(0, \mathbf{I})$.

However, during experiments, we observes that FELB slows down the training of the model. Here, we present our Transformation Flow Lower Bound (TFLB) to improve the performance of perplexity and facilitate the training process of model. The TFLB utilizes the linear property of Gaussian and can assist get explicit parameters of the final non-isotropic Gaussian distribution. The linear property of Gaussian [26] can be described as follows : Assuming that the random variable and its distribution are given by $\mathbf{h_0} \sim \mathcal{N}(\mu, \Sigma)$, we can transform it into latent variable $\mathbf{h'} = \mathrm{U} \cdot \mathbf{h}$. The corresponding transformed latent distribution is denoted as

$$\mathbf{h'} \sim \mathcal{N}(\mathrm{U}\mu, \mathrm{U}\Sigma\mathrm{U^T}) \tag{11}$$

Then the KL divergence term in the objective function can be computed as

$$\begin{aligned} & KL[\mathcal{N}(\mu_1, \Sigma_1) \parallel \mathcal{N}(\mu_2, \Sigma_2)] \\ =& \frac{1}{2}[\log \frac{|\Sigma_2|}{|\Sigma_1|} - n + \mathrm{tr}(\Sigma_2^{-1} \cdot \Sigma_1) \\ & + (\mu_2 - \mu_1)^{\mathrm{T}} \Sigma_2^{-1} (\mu_2 - \mu_1)], \end{aligned} \tag{12}$$

where n is the number of dimensionality in multivariate Gaussian. Due to the fact of unitary property of Householder matrix, the regularization term of TFLB then can be denoted as

$$\begin{aligned} & L_{TFLB} \\ & = E_q[\log p(\mathbf{d}|\mathbf{h}^{(\mathbf{k})})] - KL[q(\mathbf{h}^{(\mathbf{k})}|\mathbf{d}) \parallel p(\mathbf{h})] \\ & = E_q[\log p(\mathbf{d}|\mathbf{h}^{(\mathbf{k})})] - \frac{1}{2}[-\log|\Sigma| - n + \\ & tr(\mathbf{U}\Sigma\mathbf{U}^{\mathrm{T}}) + (\mathbf{U}\mu)^{\mathrm{T}}\mathbf{U}\mu]. \end{aligned} \tag{13}$$

At last, the pseudo code of our method, NVCTM, is depicted in Algorithm 1.

Algorithm 1 NVCTM

Input: Document bag-of-word vector $\mathbf{d}$; document collection $\mathbf{D}$; parameters set of inference network θ; parameter set of generative model γ; length of CTF k

Output: model parameters θ and γ

Remove stop words and low-frequency words and covert document into bag-of-word vector
Initialize θ and γ

5 EXPERIMENTS

In this section, we first introduce the experimental settings, evaluate the proposed model, then analyse our proposed model with extensive experiments.

Dataset: To evaluate our efforts, we select *20NewsGroups*[1] and *Reuters RCV1-v2*[2] for experiments. 20NewsGroups is a collection of newsgroup documents which consists of 11,314 training and 7,531 testing articles. And Reuters RCV1-v2 is a huge dataset that consists of Reuters newswire stories with 794,414 training and 10,000 testing cases. For data preprocessing, we remove stopwords and take the most frequent 2,000 words and 10,000 words as the vocabularies.

Baseline Methods: We compare the following methods to demonstrate the priority of the proposed method:

- **LDA** [9]: A classical topic model, which models the topic distribution as a multinomial distribution with Dirichlet prior. Here, we utilize the variational inference to implement the LDA [29].
- **CTM** [8]: It implements a log normal topic distribution. The variational inference of CTM implemented by the authors[3] is used for evaluation.
- **NVDM** [23]: The model implements a typical neural variational inference approach. The inference network of NVDM consists of a MLP network, and the generative model of NVDM reconstructs documents from reparameterized isotropic Gaussian distribution. We also use author's codes[4] for evaluation.
- **GSM** [22]: This model extends NVDM by normalizing the topic vector Gaussian sample and words distribution.
- **NVLDA** [34]: The model leverages the Laplace approximation for the LDA generative process. The topic distribution of NVLDA is an isotropic Gaussian.
- **NVCTM:** This is the proposed method in this paper.

5.1 Settings

For all of the NVI-based methods (i.e., NVDM, GSM and the proposed NVCTM), the topic vector is an average of 20 samples drawn from the latent topic distribution. For NVDM, GSM and NVCTM, we follow the authors' setting where the MLP in inference network has 256 hidden units and a hyperbolic tangent activation function. The dropout with probability of 0.8 is applied to the output of MLP network. The linear layers to parameterize μ and σ both have the same amount of hidden units with the number of topics. The training process is divided into two stages: Stage-1: optimizing the encoder's parameters while fixing the parameters of generative model; Stage-2: optimizing the generative model's parameters and keeping the inference network unchanged, which is also called wake-sleep algorithm [13]. The optimization method we use to train NVDM, GSM, NVLDA and NVCTM is Adam [17] with learning rate of $1e-5$. We also utilize early-stop [39] to stop training and export topics and topic vectors for further evaluations. The training methods of LDA and CTM are online variational inference [14] and variational inference [8]. The hyper parameters of the LDA and the CTM, which are initial values of topic distribution prior α, topic word distribution prior β and number of variational EM iterations, are determined via grid search [4] to find its optimal performance on corpus. For the proposed NVCTM, we also carry out grid search

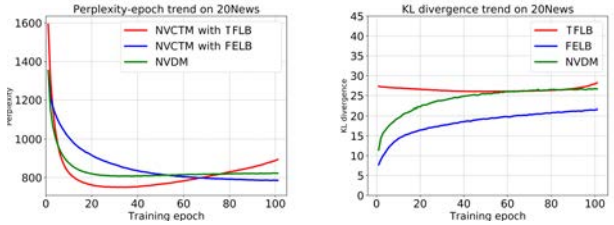
to decide the length of CTF k. For experimental environment, we run all baseline methods and proposed NVCTM on a workstation with an eight-cores Xenon E5-2630V4 CPU and GTX TITAN XP GPU.

5.2 Perplexity



The traditional way of evaluating topic model usually refers to the perplexity computed on unseen documents. For language modeling, it refers to the inverse of geometric average per-word likelihood. The lower perplexity usually indicates the better generalization performance. The perplexity is given by:

$$Perplexity = \exp\left[-\frac{1}{D}\sum_{n}^{N_d}\frac{1}{N_d}\log p(\mathbf{X}_d)\right] \tag{14}$$

We train the baseline models and the proposed NVCTM on the training set of 20News and RCV1-v2, and compute perplexity of the corresponding models on test set. To evaluate the performance of the proposed model more comprehensively, we also conduct experiments with different number of topics, i.e., T=25, 50, 100. The performance on perplexity is displayed in Table 2. From the table, it can be observed that the NVI models (i.e., NVDM, GSM, NVCTM except for NVLDA) always have better perplexity than those of traditional models (i.e., LDA and CTM). Specifically, the proposed NVCTM approach has better performance than other baselines in most cases. For NVDM and NVCTM, which both have the same structure of generative model, we find that NVCTM significantly outperforms NVDM, which indicates that the proposed CTF approach can contribute to document modeling on perplexity. Interestingly, the perplexity performance of NVCTM is better when it comes to the smaller number of topics. This phenomenon is probably caused by the fact that the perplexity of the documents is increased as the complexity of covariance matrix of latent topics increases when the topic number grows. Besides, we also observe that for unnormalized topic vector models, such as NVDM and NVCTM, they usually have better perplexity performance than other normalized topic vector models. This effect may be due to the fact that topic vector normalization makes models difficult to optimize.

5.3 TFLB vs FELB

In the previous subsection, the results of perplexity demonstrate the effectiveness of CTF and TFLB in topic modeling. Previously,

(a) Perplexity-epoch trend on 20News- group. (b) KL divergence trend on 20Newsgroup.

Figure 4: The perplexity trend and KL divergence trend of TFLB and FELB on 20Newsgroup.

the original version of Householder flow utilizes the flow-based energy lower bound (FELB) to compute the KL divergence term. In this subsection, we will quantitatively evaluate our proposed TFLB and previous FELB in topic modeling. Accordingly, we also select perplexity as the main evaluation metric. The results are displayed in figure 4. From the perplexity trend illustrated in figures 4(a), we can see that NVCTM with TFLB can achieve relative lower perplexity than that of FELB. Moreover, compared with FELB, TFLB requires less epoch to reach the lowest perplexity, which indicates that TFLB can facilitate the training of the model. On KL divergence trend graph illustrated in figure 4(b), it shows that the KL divergence of TFLB is slightly larger than that of FELB, while the model with TFLB gets lower perplexity. This indicates that TFLB can reduce the reconstruction loss even if the KL divergence of the model slightly increases. The main reason might be that TFLB explicitly takes covariance matrix to compute the gradient and this enable it to accumulate more gradient on the inference network.

5.4 Topic Coherence

Besides the perplexity, another common method of evaluating topic models is topic coherence. Topic coherence evaluates each topic with given reference corpus and compute corresponding coherence score. Here, we adopt normalized point-wise mutual information (NPMI) topic coherence proposed by [20] to automatically evaluate the proposed model as well as baselines. The NPMI coherence score is shown to be close to human judgments [20], which is why we adopt this method for evaluation. The reference corpus of corresponding corpus is the training set of corpus. We extract top-10 and top-5 words of each topic and compute the NPMI score for each word set with the equation of

$$\text{NPMI(N)} = \sum_{j=2}^{N}\sum_{i=1}^{j-1}\frac{\log\frac{P(w_j,w_i)}{P(w_i)P(w_j)}}{-\log P(w_i,w_j)}. \tag{15}$$

Then we take the average value of two NPMI scores as the final topic coherence score. We use the author implemented version script[5] to automatically evaluate the baseline methods as well as NVCTM. To fully evaluate the topic coherence, we also compute the topic coherence score of the corresponding model on topic number T=25, 50, 100 . The topic coherence scores achieved by our

[5]https://github.com/jhlau/topic_interpretability

model and the baselines are depicted in Table 3. From the table, we find that NVCTM slightly outperforms the baselines in most cases. On 20News, NVCTM usually has better topic coherence scores than those of the baseline methods when the number of topic are 25 and 50. When the number of topic increases to 100, the topic coherence score of NVCTM decreases to 0.158, which is pretty close to the best performance of CTM. For RCV1-v2, NVCTM outperforms baselines when the number of topics are 25 and 50. Similarly, when the number of topics increases, the topic coherence of NVCTM, NVDM and GSM tends to decrease, which indicates that those models are effective on relative small amount of topics. For NVDM and proposed NVCTM, which both have the same structure of generative model, the result also indicates that proposed CTF can improve the topic coherence score of the multinomial softmax generative model.

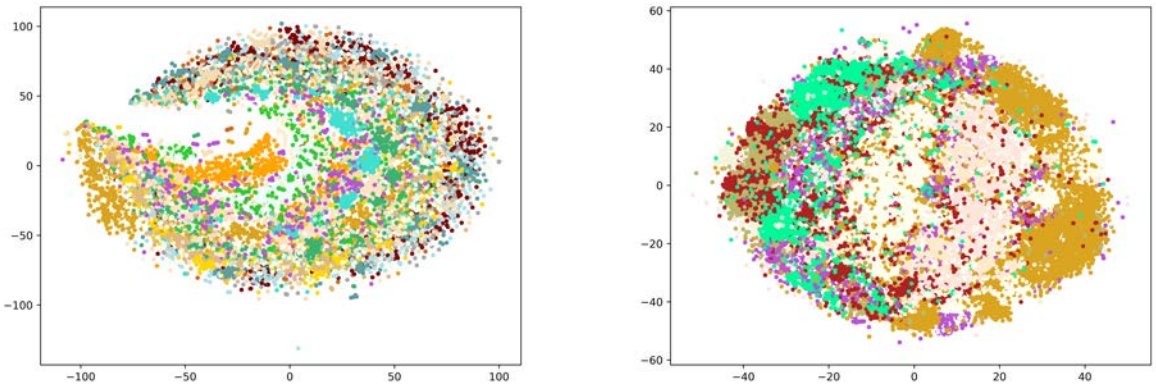
5.5 Document Classification

To further evaluate the performance of the proposed method, document classification experiments are conducted on both 20News and RCV1-v2 datasets. To efficiently evaluate the proposed approaches and baselines, we randomly select 11 categories of RCV1-v2, namely RCV-115k, which consists of 114, 324 documents as training set and 1, 439 documents as test set evaluation. Similar to what is usually done in document classification, the topic vectors of the corresponding documents can be regarded as the low dimensional representation of the sparse document vectors. We then use these vectors to train an SVM classifier [10] with multinomial kernel function and evaluate the precision, recall and F-1 measure of the corresponding methods. The topic number is set to 50 equally of all the topic models for evaluation, in terms of the performance of document classification, which is depicted in Table 4. the results indicate that the proposed NVCTM method outperforms the baseline methods on 20News and RCV-115k. Compared with NVDM, which has the same structure generative model with NVCTM, NVCTM improves its document classification performance on both datasets, which shows the effectiveness of CTF in inference network. Among all approaches, the topic vectors of NVDM, NVLDA and NVCTM are assumed to be real-valued vectors, while the topic vectors of other methods are normalized vectors. This indicates that real-valued topic vectors can enhance the performance of document classification. To further demonstrate the topic vectors of documents and their labels, we export the topic vectors for 20News and RCV1-v2. We then visualize them by t-SNE algorithm. The visualizations of the topic vectors on 20News and RCV-115k are illustrated in figure 5. The dots with same color indicate they are the documents from same category. From figure, we find that the aggregation of vectors in RCV-115k is better than that of 20News. The better aggregation of vectors will facilitate the performance of classification.

5.6 Visualization of Topics

To further quantitatively investigate the quality of topics and topic correlation mined by NVCTM, we export the topic and the corresponding word distributions, and visualize the topics with their corresponding top 10 words on the 20NewsGroup dataset. To clearly make the visualization, we select 5 topics, which are considered to have correlations by NVCTM, and then utilize t-SNE [21] for visualization. Visualization of the topics and the topic word correlation graphs is depicted in figure 6. The points with different shapes and colors indicate different topics. The dashed circles denote the corresponding topic word distribution, and those circles with the same color are recognized to be correlated by NVCTM. We also manually annotate each topic with the corresponding label. Accordingly, they can be annotated as “comp.os.ms-windows”, “comp.graphics”, “comp.sys.ibm.pc.hardware”, “talk.politics.guns”, “talk.politics.mideast” from the ground truth labels of 20NewsGroup. From figure 6, we can see that the topics of “hardware”, “windows” and “graphics” are correlated in continuous vector space. Similarly, another two correlated topics are “mideast” and “guns”. This verifies the effectiveness of the proposed method in mining topics and correlations.

5.7 Visualization of Topical Correlations



To further demonstrate effectiveness of proposed model, we export and visualize the covariance matrix of latent topic distribution on 20News and RCV1-v2. Unlike traditional mean-field variational inference or mean-field neural variational inference methods, the proposed NVCTM is capable of modeling the full covariance matrix of latent topic distributions. The main advantage of our model is that, with help of proposed CTF, NVCTM is capable of modeling the full covariance matrix rather than the diagonal one. Mathematically, the diagonal elements of covariance matrix are usually the variance values for corresponding dimension and non-diagonal elements are correlation of different two dimension. Therefore, to reach clarified visualization, we get the final correlation matrix by zeroing all the diagonal elements of covariance matrix and normalizing the matrix with rest values. The numbers of topics in NVCTM are 50 for 20News and 100 for RCV1-v2. The visualization of correlation matrix is illustrated in figure 7. From figure 7(a), we can obviously notice that the correlation matrix is non-diagonal. Besides, the most values of correlation matrix are nearly zero. This phenomenon is mainly due to the latent topic prior $N(0, \mathbf{I})$, where $\mathbf{I}$ is a diagonal unit matrix. On the other hand, each document in 20News is corresponding to a specific class of 20News, which also demonstrates the sparsity in topic correlation. The optimization of KL divergence term between CTF refined distributions and prior will make them similar to each other, which indicates that prior can also act as the sparse regularization on correlation matrix. Besides, we also notice that there are 3 topics with the higher correlation with other topics (i.e., topic No.3, 8 and 12. These 3 topics are visualized with light color which represents high correlations with other topics.). We then export these topical word distributions and find that the words are some common words, i.e, “who”, “are”, “etc”. The main reason of this effect is that these common words often exists in many documents, which makes model believe that they are correlated. On the other hand, we can still find several points with relatively large correlation coefficients. For instance, the correlation coefficients of 37 and 49, 40 and 49 are around $0.6 \sim 0.8$ which indicates the correlations exist among those topics.For figure 7(b), we can see that the number of non-zero values are larger than that of 20News. This probably results from the fact that each documents of RCV1-v2 dataset has multiple labels, which also indicates that topics in the

document are likely to be correlated. Therefore, the topic correlation matrix in RCV1-v2 are reasonable to be a non-sparse matrix. To sum up, the above visualizations of correlation matrix further indicate the effectiveness of proposed approach.

6 CONCLUSION

In this paper, we first propose the Neural Variational Correlated Topic Model (NVCTM) model, which incorporates the Centralized Transformation Flow (CTF) to capture the topic correlations. CTF can enable the model to capture the correlations among topics as well as to sufficiently compute the marginal likelihood. We then

present the Transformation Flow Lower Bound (TFLB) to regulate the objective function. It leverages the linear property of Gaussian distribution, which can regulate the model optimization and facilitates the training process of NVCTM. In order to quantitatively verify our contributions, we conduct experiments in terms of perplexity, topic coherence, and document classification tasks. The experimental results show that the proposed NVCTM approach is effective to capture topic correlations and improve the performance of topic modeling. Moreover, the visualization of the topics and their correlations qualitatively verified the effectiveness of NVCTM.

7 ACKNOWLEDGEMENT

We would like to thank Yuxiang Zhou and Yishu Miao for their insightful comments and suggestions. We also very appreciate the comments from anonymous reviewers which help further improve our work. ABSTRACT

Search engines encounter a time vs. space trade-off: search responsiveness (i.e., a short query response time) comes at the cost of increased index storage. We propose a hybrid method which uses both (a) the recently published mapping-matrix-style index BitFunnel (BF) for search efficiency, and (b) the state-of-the-art Partitioned Elias-Fano (PEF) inverted-index compression method. We use this proposed hybrid method to minimize time while satisfying a fixed space constraint, and to minimize space while satisfying a fixed time constraint. Each document is stored using either BF or PEF, and we use a local search strategy to find an approximately optimal BF-PEF partition. Since performing full experiments on each candidate BF-PEF partition is impractically slow, we use a regression model to predict the time and space costs resulting from candidate partitions (space accuracy 97.6%; time accuracy 95.2%). Compared with a hybrid mathematical index (Ottaviano et al., 2015), the time cost is reduced by up to 47% without significantly exceeding its size. Compared with three mathematical encoding methods, the hybrid BF-PEF index allows performing list intersection between around 16% to 76% faster (without significantly increasing the index size). Compared with BF, the index size is reduced by 45% while maintaining an intersection time comparable to that of BF.

1 INTRODUCTION

Search engines face a trade-off between space and time [1, 7, 24]: if we compress the underlying index, we reduce the system's query responsiveness. The most common search-engine index structure is the *inverted index* where for each term, we store a *posting list* containing the docIDs of documents containing that term [6, 18].

The Partitioned Elias-Fano (PEF) [23] inverted-index compression method is a state-of-the-art method, which uses a shortest-path algorithm [8] to dynamically partition the posting list into variable-length blocks with clustered docIDs within each block; Elias-Fano encoding [12, 13] is used blockwise for random access.

Microsoft's Bing search engine uses a newly described index structure BitFunnel (BF) [15], which is a bitmap-like data structure: terms map to one or a few rows, while columns correspond to individual documents. If a term appears in the document, the corresponding bit positions are set to 1. In this way, intersection is performed using simple bitwise AND operations. However, the BitFunnel is much larger than the corresponding compressed inverted index.

In this paper, we combine the advantages of BF (intersection efficiency) and PEF (space efficiency), and propose a hybrid index. We partition the document corpus into two parts, with one part allocated to BF and the other allocated to PEF. The choice of partition affects the time-space trade-off, and can be chosen to suit the search engine's requirements. We envisage choosing this partition so that either a time threshold or a size threshold is not exceeded.

The major contributions of this paper are as follows:

(1) We use the local search method to find an approximate optimal partition of the document corpus while satisfying a pre-specified threshold condition.
(2) For a large dataset, it is impractical to repeatedly estimate the index's size and intersection time experimentally, so we develop and utilize a machine learning approach to estimate the index size and intersection time of the hybrid index with a given partition.
(3) We implement and conduct experiments on the proposed hybrid index. More specifically:

- we assess three machine learning methods (GBRT [14], SVR [11], and RF [5]) for predicting the space and time costs of the resulting BF-PEF hybrid index (given an assignment of the documents to BF and PEF), and ultimately select support vector regression (SVR) which consistently outperforms the other two methods in terms of error rate;
- we investigate the convergence of the local search process on the size and average intersection time of proposed hybrid index under various thresholds; and
- we compare the space-time trade-off of the proposed hybrid index against several mathematical encoders, along with a hybrid mathematical index.

This paper is structured as follows. In Section 2 we describe pilot experiments which motivate the design decisions throughout the paper. Section 3 gives a minimalistic background to the relevant material. Section 4 reviews alternative hybrid index methods, and their relevance to the proposed hybrid BF-PEF method. A detailed description of the method used to generate an approximately optimal BF-PEF partition is given in Section 5. Experimental results are given in Section 6. We conclude with some future research ideas in Section 7.

2 PILOT EXPERIMENTS

In this section, we describe some preliminary experiments for some seemingly natural approaches to choosing a *BF-PEF partition*, i.e., a partition of the documents into two parts, one stored using BF and the other stored using PEF. These results motivate the subsequent use of machine learning and local search in optimizing the partition. These pilot experiments use the GOV2 document corpus and MillionQuery set, described in Section 6.1. We also describe some alternative methods.

With N documents there are 2^N possible BF-PEF partitions (and N is large in most search engines, e.g., billions of documents). Exhaustive inspection of all 2^N partitions is unrealistic, and thus the goal is to find an approximately optimal partition. Further, it is practically far too time-consuming to generate a hybrid index and perform experiments on it (like in Table 1) for each partition we wish to test. Moreover, there is no single "best" partition, rather we seek a partition which is optimized according to criteria determined by the search engine. For example, if the search engine has X TB of memory available for index, we cannot violate this hard restriction. Similarly, a search-engine operator may have their own constraints regarding the system's responsiveness.

To summarize, we have three major design constraints:

(1) we cannot find an optimal BF-PEF partition, but only an approximation,
(2) it is impractical to perform fully fledged experiments for a large number of candidate BF-PEF partitions, and
(3) we anticipate hard restrictions on the index size and intersection time imposed e.g. by hardware or the operator.

An alternative straightforward approach is to randomly assign documents to either BF or PEF; we randomly choose a proportion, and randomly assign that proportion of documents to BF and the remainder are assigned to PEF, and we tabulate experimental results of partition in Table 1. While this randomized hybrid method combines the advantages of BF and PEF, the trade-off is unimpressive: we incur around 75% of the large space cost of BF while being almost 1.6 times as slow as BF. Thus, we need to use a more intelligent way of partitioning the documents.

Table 1: The index size (space) and average intersection time (time) on BF, PEF, and a BF-PEF hybrid method with documents randomly assigned to BF and PEF.

	BF	BF-PEF (rand.)	PEF
space (GB)	13.40	9.76	3.25
time (ms)	1.45	2.29	3.19

We also consider incorporating a bitmap compression method, such as EWAH [17]; we tested this approach and observed a minor space reduction of less than 5% when compressing the BitFunnel index of GOV2. We attribute this behavior to BitFunnel's high density of 1s (usually 0.1 to 0.2), which results in short all-0 and all-1 subsequences, leading to poor compression.

Recently, Liu et al. [19] proposed a dictionary-based compression method for BitFunnel with additional false positives. On the GOV2 dataset, we found that the compression rate of this method is around 30%, but its intersection time increases by about 50%, and its false positive rate is doubled which is consistent with the results in that paper. We thus abandon BF compression approaches.

A possible way to compress an inverted index is via mathematical encoding [2, 3, 25, 30]. However, PEF achieves a higher compression rate while simultaneously allowing efficient list intersection.

We investigate how the BF-PEF partition is influenced by some *basic features*:

- *URL*, the lexicographic order of the document URLs;
- *DL*, the length of the documents without duplicate terms (i.e., the number of unique terms in document);
- *DF*, the mean document frequency of terms in the document;
- *dispersivity*, which measures the lack of clustering of a document in the inverted index, as per f_8 in Section 5.1.1; and
- *TF-IDF*, a mean TF-IDF calculated as per f_{11} in Section 5.1.1.

We perform some toy experiments involving these basic factors from which we glean insights into how we might design a fully fledged hybrid BF-PEF index.

For each basic feature f, we create the set S_f of documents in GOV2 which have the highest 10% of that f's possible values. We create an artificial document corpus $\mathcal{D}_f$ for each f by randomly selecting 100 000 documents in S_f. For each $\mathcal{D}_f$, we generate the BF and PEF indexes, and compare their size and average intersection time. In order to compare features with each other, we measure the size according to

$$s_f := \frac{\text{size of index generated from } \mathcal{D}_f}{\text{total number of docIDs in posting lists in } \mathcal{D}_f}$$

and the time according to

$$t_f := \frac{\text{average intersection time on index generated from } \mathcal{D}_f}{\text{total number of docIDs in posting lists in } \mathcal{D}_f}.$$

We also perform the same computations for the lowest 10% of the possible f values, and distinguish between the two cases as "high" and "low". We plot the results in Figure 1.

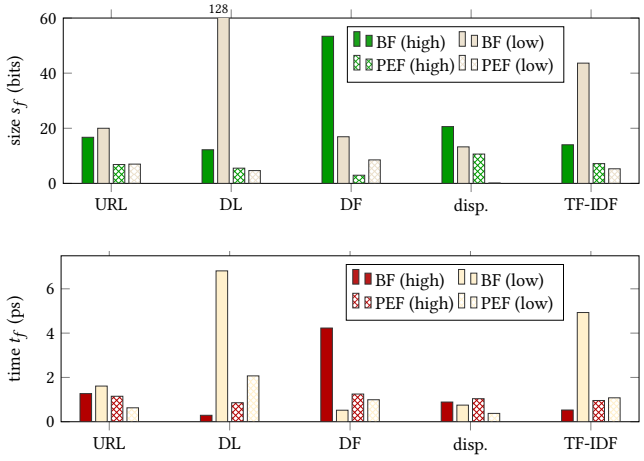

Figure 1: The size s_f and time t_f of the BF index and PEF index constructed for the toy document corpus $\mathcal{D}_f$ for the basic feature $f \in \{\textbf{URL}, \textbf{DL}, \textbf{DF}, \textbf{disp.}, \textbf{TF-IDF}\}$.

To investigate the sensitivity to the random document corpus $\mathcal{D}_f$, we also repeat this computation 5 times, and observe negligible difference between trials.

We make the following observations:

Observation 1. *Multiple basic features significantly influence the size and intersection time of the BF and PEF indexes.*

For example, for BF we observe that a greater DF leads to a greater s_{DF}, which we attribute posting list density: a dense posting list maps to unshared rows in the BitFunnel. We also see that for PEF, a low dispersivity results in a small index size and intersection time, indicating that docID clustering benefits PEF.

Observation 2. *For either the BF or PEF component of a hybrid BF-PEF index, a high (or low) value of a single feature may be simultaneously advantageous for size (resp. time) while disadvantageous for time (resp. size).*

For example, for PEF a greater DF leads to a smaller index, but a greater intersection time. We expect this is because a high DF implies that most of the PEF-compressed documents contain high-frequency terms in the corpus, resulting in longer posting lists being compressed (and decompressed during list intersection).

Observation 3. *A high (or low) value of a single feature may be simultaneously advantageous for size and time for both the BF and PEF components of a hybrid BF-PEF index.*

For example, a lower dispersivity results in a smaller $s_{\text{disp.}}$ and $t_{\text{disp.}}$ for both BF and PEF. Since PEF is designed to utilize clustering, it is apparent why a low dispersivity results in reduced $s_{\text{disp.}}$ and $t_{\text{disp.}}$ for the PEF index. For BF, a lower dispersivity also results in a smaller $s_{\text{disp.}}$ and $t_{\text{disp.}}$, although it is not apparent why.

Some of these observations are predictable, while others are not; and some of these observations result in a quandary, where there is not an apparent best way to assign documents to BF or PEF. In the subsequent experiments (Section 6; see in particular Section 6.5 for feature-based experiments), we incorporate additional features, and anticipate varying and unpredictable effects on BF-PEF indexes. Thus, we expect it is not straightforward to find a near-optimal BF-PEF partition using simple threshold methods.

This unpredictable feature behavior motivates the use of a machine learning regression approach, which predicts the index size and intersection time of hybrid BF-PEF indexes based on multiple document features. In particular, this is the motivation behind the feature vectors in Section 5.1.2.

3 BACKGROUND

In search engines, the most common index structure is the *inverted index* [6, 18], a database where each *term* t has a corresponding *posting list* ℓ_t, which stores an ordered list of the docIDs that the term t appears in, namely

$$\ell[t] = \langle \text{docID}_1, \text{docID}_2, \ldots, \text{docID}_n \rangle.$$

For conjunctive queries, the relevant documents for a query $\{t_i\}$ are given by the *list intersection* $\cap_i \ell[t_i]$, which is computed after a query is made (i.e., "online") and thus needs to be performed efficiently.

Ordinarily we use some form of compression to reduce the size of the inverted index. To avoid decompressing entire posting lists during query processing, we typically divide the posting lists into blocks which are individually compressed and decompressed (to facilitate random access).

Differing from the traditional fixed-length block encoding, Partitioned Elias-Fano (PEF) [23] encoding uses dynamic block sizes in order to make use of clustering in the inverted index. The authors of [23] also described a method for obtaining an approximate optimal block partition, where each block uses Elias-Fano encoding [12, 13].

BitFunnel [15] is a bitmap-like mapping matrix which is based on a Bloom filter [4, 28]. In a BitFunnel, each term is mapped to one or a few rows, with each column representing a document. If a term appears in a document, the corresponding entry (or entries) is set to "1" (otherwise "0"). For conjunctive queries, to obtain the documents containing all the query terms, we perform an AND operation on the rows that the query terms map to. A "1" in the result usually indicates a document which contains all the query terms, although the Bloom filter admits the possibility of false positives.

There are some properties of BitFunnel which affect its operation, but only indirectly affect the results in this paper. Specifically: (a) given a density, BitFunnel generates an index with a low false positive rate while approximately achieving that density; (b) BitFunnel usually has a false positive rate of less than 5%. False positives are not hugely problematic in practice, since e.g. they might be automatically eliminated during top-K ranking; (c) documents are divided into shards according to their length, and BitFunnel use "frequency-conscious" signatures (i.e., multiplexing) to reduce the storage space; and (d) to speed up the intersection process, rows are ascribed a rank, whereby high-ranked rows are shorter and are expanded (self-concatenated) before being intersected with low-ranked rows. In experiments in Section 6, we use BitFunnel's default settings, including setting the density to 0.15 and the number of shards to 11.

Compared with the list intersection approach, a BitFunnel index is much larger (e.g. 4.1 times larger in Table 1) but also much faster to query (2.2 times faster in Table 1). This results in an "all your

eggs (documents) in one basket (index)" trade-off, and this paper is about finding an in-between, hybrid approach.

Motivated by both hardware limits and operator-set limits, we consider two setups:

(1) minimizing the average intersection time subject to a fixed maximum index size, and
(2) minimizing the index size subject to a fixed maximum average intersection time.

4 RELATED WORK

To reduce the storage overhead, prior research proposed a variety of mathematical encoding methods for inverted indexes, such as PForDelta (PFD) [30], binary interpolative coding [21], Vbyte [25] (Varint-G8IU [27] exploiting SIMD operations), Simple9 and Simple16 [2, 3], and so on. We use OptPFD [29] (an improved version of PFD), binary interpolative coding, and Varint-G8IU as baselines in Section 6.4.

These mathematical encoding methods minimize the number of bits used to represent the docIDs, thereby achieving compression. However, the constant-size block division of the posting list is incompatible with clustering. To illustrate, if we split the toy posting list

$$\langle 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 20, 21, 22, 23, 24, 30\rangle$$

into length-4 blocks of docIDs

$$\langle 1, 2, 3, 4\rangle, \langle 5, 6, 7, 8\rangle, \langle 9, 10, 20, 21\rangle, \langle 22, 23, 24, 30\rangle$$

we break apart the clusters of docIDs. To utilize this clustering among docIDs, and EF encoding for random access, in the proposed approach, we use PEF to compress one part of the document corpus. For the documents not compressed using PEF, we use BitFunnel. This proposed hybrid method deviates from the usual approach of using a single index structure or compression method for the whole corpus.

We also remark that the documents assigned to BF do not overlap with the documents assigned to PEF, thus the BF results and PEF results do not require a subsequent time-consuming "merging" operation.

We take advantage of the bitwise operation of BF for time efficiency and the dynamic block partitioning of PEF for space efficiency. PEF's compression is comparable to the best mathematical encoding method we consider in this work, while also significantly outperforming them in terms of intersection time (see Section 6.4).

Some hybrid indexes have been previously proposed, combining different types of indexes to obtain a smaller index or a shorter query time. Some methods partition the corpus by term [9, 20] where different type of index (or server) is selected for each posting list. Unlike their approaches, the proposed method partitions the document corpus by document. In this way, the partitioning may change the distribution of the inverted index (e.g., the length and the clustering of posting lists). We expect different document subsets adapt to different index type.

Ottaviano et al. [22] combined three mathematical encoding methods (PFD [29], binary interpolative coding [21], and Varint-G8IU [27]) to generate a hybrid index. Each block is assigned the compression method which minimizes the average query time through the greedy algorithm described in [26] while subject to a spatial threshold. Given a query log, Ottaviano et al. randomly sample a few blocks to generate the training set, and use a linear model to predict the decoding time of each block during query processing using this training set.

Unlike the proposed method, the method by Ottaviano et al. has a fixed block size, and does not take advantage of dynamic partitioning for inverted indexes like PEF. Moreover, it does not incorporate a bitmap-like index structure. We use [22] as a baseline (hybrid-PIV in Section 6.4).

Kane and Tompa [16] introduced "semi-bitvectors": the documents are grouped and reordered to increase the clustering in posting lists. They divide each posting list by a cut point into two parts: the denser front part for the bitvector and the remainder of the inverted index is compressed by PFD [30]. The cut point for each posting list is based on the bitvector density threshold F and the number of groups G: two user-defined parameters. In principle, we could apply a threshold on the intersection time or index size to the semi-bitvector method by repeatedly adjusting the parameters F and G and rebuild the index multiple times until the specified threshold is satisfied. However, this approach neither optimizes size nor time. In the proposed method, we use an iterative approach to find an approximately optimal BF-PEF partition; we minimize the intersection time while staying within a size threshold (or vise versa with "intersection time" and "size" switched).

A major structural difference is that the proposed method splits the document corpus into two parts, whereas Kane and Tompa's approach individually splits the posting lists. With semi-bitvectors, it is necessary to perform list intersection across two disparate index structures, which hinders parallelization and the application of Kane and Tompa's approach to e.g. distributed systems. Instead, partitioning the document corpus (as in the proposed approach) avoids this problem, since each partition can be intersected independently.

5 HYBRID BF-PEF PARTITION SELECTION

The proposed approach has three main components depicted in Figure 2:

- We use machine learning to develop regression models which compare BF-PEF partitions. We compare three different models, but find support vector regression to be the most suitable.
- Once a regression model is generated, we use a local search approach where we perturb the "current" partition (starting with an initialized partition), and replace it by the perturbed partition if the relevant regression model considers the perturbed partition better.
- We consider two ways of perturbing the current partition: one random, and one which prioritizes either PEF over BF or BF over PEF.

5.1 Prediction

5.1.1 Feature selection. We predict the size and intersection time of a hybrid index (arising from a BF-PEF partition) using machine learning. For an arbitrary document d, we have the following document features:

- the features f_1 and f_3 are respectively URL and DL, as used in the pilot experiments;
- the number f_2 of (not necessarily distinct) terms in d;

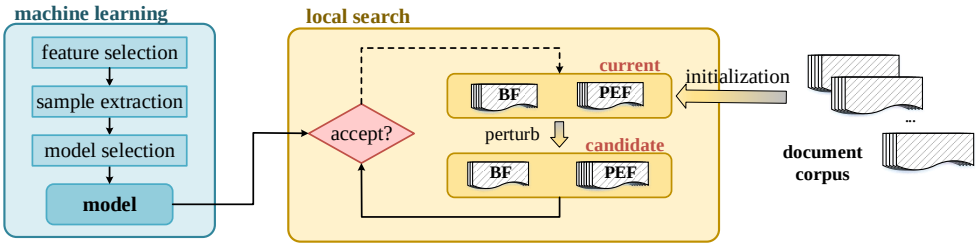

Figure 2: Flow chart for generating an approximately optimal BF-PEF partition. Machine learning is used to give a prediction model. The local search accepts a perturbed BF-PEF partition if it is predicted to outperform the current BF-PEF partition.

- the shardID f_4 of the document in the BF index, which varies in BitFunnel according to the number of unique terms in a document;
- the maximum f_5, minimum f_6, and mean f_7 of the document frequency among the terms t in the document (i.e., the length of the posting list for t);
- we define the *dispersivity* f_8 as

$$\operatorname*{avg}_{t\in d}\sqrt{\frac{1}{b-a+1}\sum_{j\in\{a,\ldots,b\}\setminus\{i\}}\frac{(\mathrm{docID}_j-\mathrm{docID}_i)^2}{\log_{10}(|j-i|+1)}}$$

  where i is the index for document d in the posting list ℓ_t, and $a=\max(1,i-32)$ and $b=\min(|\ell[t]|,i+32)$, as used in the pilot experiments;
- the maximum f_9, minimum f_{10}, and mean f_{11} of the TF-IDF score of the document d, restricted to the terms $t\in S$, where S is the smallest set of highest-frequency terms such that sum of the frequencies of terms in S accounts for 50% of the total frequency; this approach is inspired by [16] because high frequency terms usually play a more important role on index size and query time; and
- query count f_{12}, i.e., the number of query terms appearing in d.

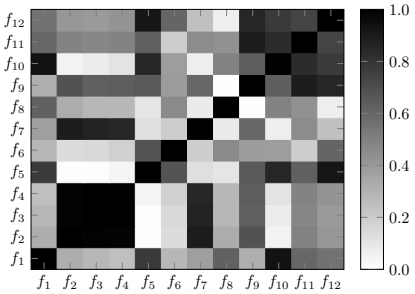

Figure 3: Feature correlation heat map.

We exclude some highly correlated features based on experiments much like the pilot experiments (Section 2). For each feature, we construct a vector of 8 values as in Figure 1. We normalize the feature values to $[0,1]$, then calculate the correlation [10] between each pair of features; we plot the results in Figure 3. We exclude the features with correlation exceeding 98%: document length f_2, document unique length f_3, and shardID f_4 have pairwise correlation exceeding 98%, so we exclude f_2 and f_4. While other pairs of features exhibit varying levels of correlation, there is virtually no meaningful distinction between f_2, f_3, and f_4, so we exclude two of them so as to not add undue weight. The remaining features, i.e., those in $\{f_1,f_3\}\cup\{f_5,f_6,\ldots,f_{12}\}$, are denoted $\hat{f}_1$ through $\hat{f}_{10}$.

5.1.2 Sample Extraction and Model Selection. In this section, we introduce how we define samples which we use in machine learning (to train the two prediction models). Generating a hybrid index based on a whole corpus is time consuming, so we construct a practical set of samples to train the model.

For the document corpus $\mathcal{D}$, for each $i\in\{1,\ldots,10\}$, we define $\mathcal{D}_i^{(\mathrm{low})}$ and $\mathcal{D}_i^{(\mathrm{high})}$ as the set of documents respectively with the least and greatest $\hat{f}_i$ values, both comprising approximately 25% of all documents. We define $\mathcal{D}_i^{(\mathrm{medium})}=\mathcal{D}\setminus(\mathcal{D}_i^{(\mathrm{low})}\cup\mathcal{D}_i^{(\mathrm{high})})$, which comprises about 50% of all documents. For the purpose of this paper (i.e., for use with the GOV2 dataset), we define the set of pairs

$$\mathcal{N}=\{(5,7.5),(7.5,10),(10,25),(25,50),(50,100),\\(100,150),(150,200),(200,250)\}\times 10^5,$$

so e.g. $(500\,000,750\,000)\in\mathcal{N}$, and so on.

Given a pair $(a,b)\in\mathcal{N}$ we randomly select a number $t\in\{0,\ldots,10\}$ and a random t-subset $F\subseteq\{1,\ldots,10\}$. Each $i\in F$ indexes feature $\hat{f}_i$, and we randomly select $\mathcal{D}_i\in\{\mathcal{D}_i^{(\mathrm{high})},\mathcal{D}_i^{(\mathrm{medium})},\mathcal{D}_i^{(\mathrm{low})}\}$, and for each document $d\in\mathcal{D}$, we assign it the score

$$\mathrm{score}(d):=|\{i\in F\colon d\in\mathcal{D}_i\}|\,. \tag{1}$$

We randomly choose $n\in\{a,\ldots,b-1\}$ and form a document corpus of size n consisting of the documents $d\in\mathcal{D}$ with the greatest score. If $t=0$, we randomly select any n documents from $\mathcal{D}$. Informally, we randomly choose a "high", "medium", or "low" feature condition for each of a random selection of features, and we choose n documents which satisfy the most conditions.

To reduce the time of sample extraction, we randomly choose pairs (a,b) from $\mathcal{N}$ so that lower-valued pairs have a greater probability of being selected. This gives a family $\mathcal{F}$ of document corpuses. We split $\mathcal{F}$ into training and validation sets.

We randomly choose two document corpuses $\mathcal{D}^{(\mathrm{BF})}$ and $\mathcal{D}^{(\mathrm{PEF})}$ from $\mathcal{F}$ to generate a partition (which might intersect, but we ignore this as we expect it has a negligible effect). We compute the average feature values for both of these corpuses, giving $\hat{f}_1^{(\mathrm{BF})}$ through

$\hat{f}_{10}^{(\mathrm{BF})}$ (from $\mathcal{D}^{(\mathrm{BF})}$) and $\hat{f}_1^{(\mathrm{PEF})}$ through $\hat{f}_{10}^{(\mathrm{PEF})}$ (from $\mathcal{D}^{(\mathrm{PEF})}$). We define the two sample vectors used for training: the *size vector*

$$\vec{\sigma}_{\mathrm{size}} = \Big\langle \hat{f}_1^{(\mathrm{BF})}, \ldots, \hat{f}_{10}^{(\mathrm{BF})}, |\mathcal{D}^{(\mathrm{BF})}|, \hat{f}_1^{(\mathrm{PEF})}, \ldots, \hat{f}_{10}^{(\mathrm{PEF})}, |\mathcal{D}^{(\mathrm{PEF})}|, s_{\mathrm{BF}} + s_{\mathrm{PEF}} \Big\rangle$$

and the *time vector*

$$\vec{\sigma}_{\mathrm{time}} = \Big\langle \hat{f}_1^{(\mathrm{BF})}, \ldots, \hat{f}_{10}^{(\mathrm{BF})}, |\mathcal{D}^{(\mathrm{BF})}|, \hat{f}_1^{(\mathrm{PEF})}, \ldots, \hat{f}_{10}^{(\mathrm{PEF})}, |\mathcal{D}^{(\mathrm{PEF})}|, t_{\mathrm{BF}} + t_{\mathrm{PEF}} \Big\rangle$$

where s_{BF} (resp. t_{BF}) is the size (resp. average intersection time) of the index formed when using BitFunnel on the corpus $\mathcal{D}^{(\mathrm{BF})}$ and s_{PEF} (resp. t_{PEF}) is the size (resp. average intersection time) of the index formed when using PEF on the corpus $\mathcal{D}^{(\mathrm{PEF})}$. Doing this repeatedly gives a set M_{size} of size vectors and a set M_{time} of time vectors.

The purpose of this elaborate generation process is to include a diverse selection of vectors in the training and validation sets, thereby helping the machine learning process to identify the (size and time) impact of the features.

For model selection, we use three common regression models: the gradient-boosted regression tree (GBRT) model [14], a support vector regression (SVR) model [11], and a random forest model [5] for training. Further, we use a validation set to tune the parameters. An experimental comparison of these models is given in Section 6.2.

Once the size and time regression models are generated, we apply these two models to the entire document corpus which assist local search to judge the "candidate" partition and the "current" partition. Noted that all the samples in test sets we use in experiments (see Section 6.2) are real BF-PEF partitions (of the whole document corpus, rather than artificial sets as for training and validation samples).

5.2 Partition

We use a local search approach to find an approximately optimal partition. We perturb the current partition, and accept the perturbed partition if the chosen model (derived via machine learning, as in Section 5.1) predicts the perturbed partition performs better (either in terms of size or time, depending on which setup is chosen). This is repeated some number of times; around 200 iterations seems sufficient with the present paper's experimental setup (see Section 6.3). The details are given in Algorithm 1.

There are two different methods for selecting the documents P in Algorithm 1 (Lines 3, 5, and 7):

(1) *Random selection* (used with probability 20%). Some subset F of the features is randomly selected. We select a random $n \in \{250\,000, \ldots, 1\,250\,000\}$ (n is the number of documents in P, account for 1% to 5% of the whole corpus), and choose the n documents with the highest score, as defined by eq. (1).

(2) *Priority selection* (used with probability 80%). This selection method is the same as random selection, except in calculating eq. (1), where we choose a collection of documents that are more friendly to the destination index. Specifically, we choose $\mathcal{D}_i$ as either "high" or "low" respectively whenever a greater or lesser value of the corresponding feature $\hat{f}_i$ benefits BF (resp. PEF) in terms of both size and time, and we refer to these features as *BF-friendly* features (resp. *PEF-friendly* features). When prioritizing BF, we randomly choose between "high" or "low" for non-BF-friendly features, and likewise for non-PEF-friendly features when prioritizing PEF.

Algorithm 1 Local search method

Input: Document corpus, the number of iterations T
Output: An approximately optimal partition

1: Randomly partition the document corpus into two parts $\mathcal{P} = \{\mathcal{P}^{(\mathrm{BF})}, \mathcal{P}^{(\mathrm{PEF})}\}$
2: **for** i from 1 to T **do**
3: Choose a subset $P \subseteq \mathcal{P}^{(\mathrm{BF})}$ ▷ two different methods
4: Replace the current partition $\mathcal{P}$ with the perturbed partition $\{\mathcal{P}^{(\mathrm{BF})} \setminus P, \mathcal{P}^{(\mathrm{PEF})} \cup P\}$ if the perturbed partition is predicted to perform better
5: Choose a subset $P \subseteq \mathcal{P}^{(\mathrm{PEF})}$ ▷ two different methods
6: Replace the current partition $\mathcal{P}$ with the perturbed partition $\{\mathcal{P}^{(\mathrm{BF})} \cup P, \mathcal{P}^{(\mathrm{PEF})} \setminus P\}$ if the perturbed partition is predicted to perform better
7: Choose a subset $P_1 \subseteq \mathcal{P}^{(\mathrm{BF})}$ and a subset $P_2 \subseteq \mathcal{P}^{(\mathrm{PEF})}$ ▷ two different methods
8: Replace the current partition $\mathcal{P}$ with the perturbed partition $\{(\mathcal{P}^{(\mathrm{BF})} \setminus P_1) \cup P_2, (\mathcal{P}^{(\mathrm{PEF})} \setminus P_2) \cup P_1\}$ if the perturbed partition is predicted to perform better
9: **end for**

For example, a lower dispersivity for PEF reduces both the index size and intersection time, and thus it is a PEF-friendly feature. In fact, dispersivity is also a BF-friendly feature. A non-example is document frequency for PEF: a higher value reduces the index size, while a lower value reduces the intersection time, so it is not PEF-friendly.

When using friendly features in Algorithm 1, when a subset of the documents are moved from one part to the other, "friendly" is defined according to the destination. Specifically, in Algorithm 1, we use PEF-friendly features in Line 3 and for P_1 in Line 7, and we use BF-friendly features in Line 5 and for P_2 in Line 7.

Suppose we apply a time threshold, i.e., an upper bound on the average intersection time. We choose between the current partition and the perturbed partition as follows:

(1) If the current partition and the perturbed partition both satisfy the time threshold, we choose the partition which minimizes index size.
(2) Otherwise, we choose the partition which minimizes time.

Above, both size and time are predicted using a machine-learning model. When instead applying a size threshold, we do the same thing with "time" and "size" swapped.

6 EXPERIMENTAL RESULTS

We experiment on the proposed hybrid BF-PEF index, which we abbreviate to *hybrid-BP*, under various circumstances. We explore the accuracy of the machine-learning regression models, the impact of the initial partition in the local search process, and the performance of hybrid-BP in terms of index size and average intersection time.

We compare hybrid-BP against the mathematical hybrid index proposed in [22], which we call *hybrid-PIV*; we also compare hybrid-BP against the mathematical encoders involved in hybrid-PIV. We also explore the feature distributions in hybrid-BP, and false positive rates.

6.1 Experiment Setup

Our experiments are performed using public GOV2 dataset, containing 25 205 183 documents with 6 220 848 172 postings. We remove extra information, such as HTML tags, while retaining the title and body parts. We do not remove any stop words. For query datasets, we use the public query sets (a) MillionQuery, containing 58 506 queries from the 2007, 2008, and 2009 TREC Million Query Tracks[1], and (b) TerabyteQuery, containing 99 322 queries from the 2006 TREC Terabyte Track[2]. In both query sets, the terms which do not exist in the GOV2 document set are filtered out, and the aforementioned query counts are after filtering. We do not remove the query that only have one term.

All experiments are run on a platform with 2× Xeon E5-2650 v4 CPUs at 2.20GHz with 512GB RAM; both CPUs have 12 physical cores (with 24 threads). The L1 instruction cache and data cache is 32KB, L2 cache is 256KB, and L3 cache is 30 720KB. All the programs are implemented in C++11 and complied with g++ version 5.4.0 with -O2 optimization. The operating system is Linux CentOS 6.5 with kernel version 2.6.32.

We use the downloadable PEF[3] and BF[4] source code for testing, with both using their default settings, and we set the density of BitFunnel to 0.15 for all 11 shards. In the experiments, we reorder the documents according to URL. For machine learning, we use sklearn[5] by python.

6.2 Model Selection

For training and validation of the prediction models, we generate a set of size vectors M_{size} and a set of time vectors M_{time} according to the procedure in Section 5.1.2. We randomly choose 380 corpuses from $\mathcal{F}$, of which 340 are used for generating the training set, and 40 are used for generating the validation set. The training set is generated from the sample vectors for 5000 random pairs of corpuses (where each pair acts as a BF-PEF partition for training), and the validation set is generated from the sample vectors for 1000 random pairs of corpuses. We also add two extra BF-PEF partitions to the training set: one where the whole document corpus is assigned to BF (and no documents are assigned to PEF), and one where the whole document corpus is assigned to PEF.

We generate prediction models for both "size" (i.e., total index size, $s_{\text{BF}} + s_{\text{PEF}}$) and "time" (i.e., average intersection time, $t_{\text{BF}} + t_{\text{PEF}}$). We measure time using the MillionQuery query set. For both size and time, we test three regression models, the gradient-boosted regression tree (GBRT) model, a support vector regression (SVR) model, and a random forest (RF) model.

The test set is from samples generated from 100 BF-PEF partitions (of the whole document corpus), which are randomly generated similar to the procedure described in Section 5.1.2. We randomly choose the number of documents n to assign to BF, and we assign BF the n documents which achieve the top score as per eq. (1) while other documents are assigned to PEF.

We compare the accuracy of the six prediction models (size and time; GBRT, SVR, and RF) against experimental measurements. When a value a is estimated as $\hat{a}$, the *relative error* is defined as $|(\hat{a} - a)/a|$. Table 2 records some statistics of the relative error: its mean, and first, second, and third quartiles.

Table 2 indicates that SVR is the best regression model among the three, in terms of both size and time. Consequently, we exclusively use SVR for the remaining experiments. Moreover, we use the SVR model as trained in this section. The small mean relative error (less than 5%) indicates the predictions are suitable for practical use.

6.3 Initial Partition

In this section, we investigate the influence of the initial partition on the local search method in Section 5.2. We choose initial partitions using the method for generating BF-PEF partitions in Section 6.2: we use 5 with a time threshold, and another 5 with a space threshold. We plot the predicted hybrid index size and average intersection time in Figure 4 where different colors correspond to different initial partitions. We also include points which indicate the actual (i.e., not predicted) values after 500 iterations.

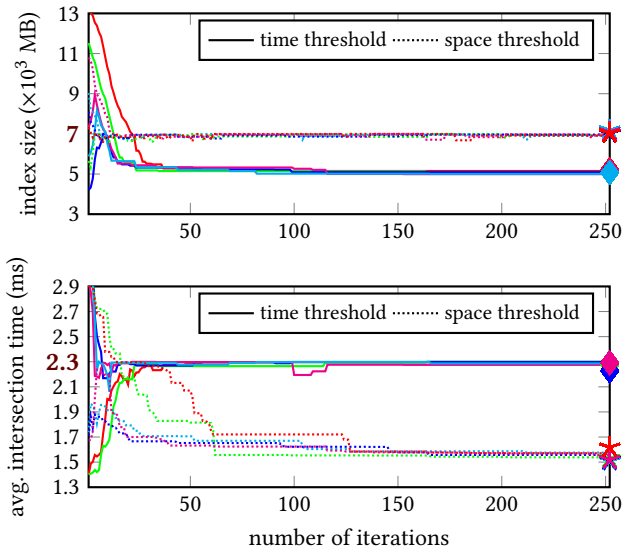

Figure 4: With 5 different initial partitions, after some number of iterations of the local search procedure (x axis), we measure the hybrid index size (top), and the average intersection time (bottom), with either a time threshold of 2.3ms (solid) or a space threshold of 7000MB (dotted). We also include marks to indicate the exact measurements after 500 iterations. (Note that the y axes do not start at 0.)

We make three observations from Figure 4:

(1) Different initial partitions have a negligible impact on the final result, i.e., they approximately converge. This suggests

[1] https://trec.nist.gov/data/million.query.html
[2] https://trec.nist.gov/data/terabyte06.html
[3] https://github.com/ot/partitioned_elias_fano
[4] https://github.com/BitFunnel/BitFunnel
[5] http://scikit-learn.org/stable/index.html

Table 2: The relative error when predicting the index size and average intersection time of the resulting BF-PEF index using GBRT, SVR, or RF; we list the first, second, and third quartiles, and the mean relative error.

	index size				average intersection time			
	1-st quart.	2-nd quart.	3-rd quart.	mean	1-st quart.	2-nd quart.	3-rd quart.	mean
GBRT	3.69%	6.66%	11.82%	8.03%	3.45%	9.49%	26.48%	15.12%
SVR	1.09%	2.03%	2.90%	2.35%	1.77%	3.61%	7.08%	4.81%
RF	3.73%	7.33%	25.16%	14.99%	3.24%	11.92%	24.23%	16.95%

that the local search is not getting stuck in local optima (where we would expect non-converging measurements from various local optima), which gives confidence that the process is reaching a close-to-optimal BF-PEF partition.

(2) Only a small number iterations are needed (200 iterations, say), before an approximately optimal partition is reached. Consequently, there is not a massive overhead introduced by this process.

(3) In these experiments, we see the prediction of the index size and average intersection time is accurate: within 5% of the actual values after 500 iterations. This is consistent with the observations in Section 6.2.

These three observations suggest that the local search method is a suitable approach to finding an approximately optimal BF-PEF partition.

6.4 Time and Space Trade-off

We investigate the trade-off between space (index size) and time (average intersection time). To generate the approximately optimal partition, we use the local search method (500 iterations) described in Section 6.3 with $n = 12\,500\,000$ (half of the whole document corpus) assigned to BF while others are in PEF for initial partition. The observations in Section 6.3 indicate this decision does not have a major impact on the size or time of the resulting BF-PEF partition. In this section the index size and average intersection time are measured after the index is generated rather than predicted by regression models. We do not normalize them as in Figure 1 .

6.4.1 Time threshold. We set a threshold on the average intersection time, and minimize the hybrid index size subject to that threshold. Figure 5 records the size and intersection time of the hybrid index subject to various time thresholds (for the MillionQuery query set). Here and in the next section, we experiment with both the MillionQuery and TerabyteQuery query sets (although model training only uses the MillionQuery query set).

Figure 5 indicates that as the time threshold increases, the size of the hybrid index decreases. This is as expected: as we relax the time threshold, more documents are assigned to PEF, which results in a smaller hybrid index. Indeed, when the time threshold is close to the PEF time, almost all documents are assigned to PEF, in which case there is negligible difference between the hybrid BF-PEF index and PEF itself.

One interesting observation is that when we reduce the time threshold to around the pure BF average intersection time, the size of the proposed hybrid index is reduced by 45% compared to BF. This significant improvement in space comes at virtually no cost in time. We expect this is partly because some documents are short and are infrequently queried: reassigning these from BF to PEF does not have a significant impact on the intersection time (it might even slightly reduce it), but it reduces the index size.

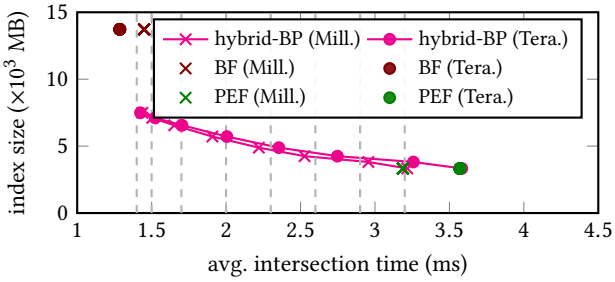

Figure 5: The index size vs. the average intersection time (on the MillionQuery query set (Mill.) and TerabyteQuery query set (Tera.)) of the hybrid BF-PEF index as the time threshold varies (indicated by vertical dashed lines). For comparison, we also include pure BF (red) and pure PEF (green) indexes. (Note that the x axis does not start at 0.)

In Figure 5, some time thresholds on MillionQuery query set are exceeded by a relatively small amount (within 3%), which we attribute to prediction errors in the regression model.

6.4.2 Size threshold. We set a threshold on the hybrid index size, and minimize the average intersection time subject to that threshold. Figure 6 records the size and intersection time of the hybrid index subject to various size thresholds.

For comparison, we also perform the same tests on another hybrid index (hybrid-PIV) proposed by [22][6]; see Section 4 for more about hybrid-PIV. For hybrid-PIV, we also use the MillionQuery query set for training, and the block sampling rate is set to 0.01. (Preliminary experiments with the block sampling rate set to 0.001 were not substantially different, so we do not report these results.)

From Figure 6 we observe that it is generally not possible to improve hybrid-PIV's average intersection time much beyond a certain point (e.g. 2.5ms for the MillionQuery query set) by relaxing the threshold on the index size. This implies the hybrid BF-PEF index has a functional advantage over hybrid-PIV: if memory is available, hybrid-BP can utilize it to reduce the intersection time. Thus, the proposed hybrid BF-PEF index offers greater flexibility in choosing a trade-off than hybrid-PIV.

[6] https://github.com/ot/ds2i

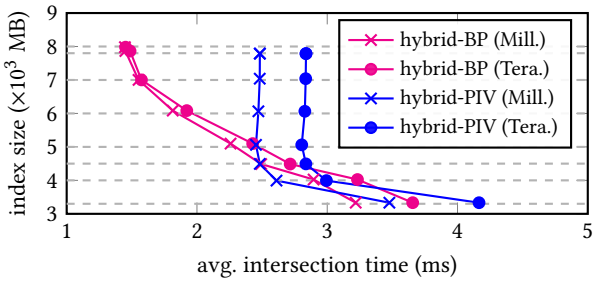

Figure 6: The index size vs. the average intersection time on the MillionQuery and TerabyteQuery query sets of the hybrid BF-PEF index (hybrid-BP) as the size threshold varies (indicated by horizontal dashed lines). There is no result for hybrid-PIV with a 8000MB threshold; its maximum index size is around 7800MB. (Note that both the x and y axes do not start at 0.)

We observe that for the 4000MB threshold, hybrid-PIV outperforms hybrid-BP by 11% and 8% on MillionQuery and TerabyteQuery, respectively. A situation like this amounts to the search engine only having a certain amount of memory they can use (not more nor less). If instead the operator has spare memory and e.g. is able to set a higher size threshold, then Figure 6 indicates that hybrid-BP reduces the average intersection time by up to around 47% with almost the same size.

Compared with PEF on the MillionQuery query set, the maximum improvement in the average intersection time achieved by hybrid-PIV and hybrid-BP is 23% and 55%, respectively; for the 4000MB threshold, the improvement is 18% and 9%, respectively.

In Table 3, we compare hybrid-BP with some indexes compressed by a single form of mathematical encoding. Specifically, we compress the entire GOV2 corpus using each of OptPFD [29], binary interpolative encoding [21], and Varint-G8IU [27], and generate three BF-PEF hybrid indexes with a size threshold approximately the same as the mathematical encoding index it is being compared with. Among them, the binary-interpolative encoded index has the best index size through recursive compression, but its intersection time is long due to recursive decompression. Varint-G8IU uses byte-aligned encoding and SIMD acceleration, making it faster for intersection but its compression is significantly worse; OptPFD offers a trade-off between these two extremes.

When we set the BF-PEF index size threshold equal to the binary interpolative encoding index size (3.13GB), the local search fails to find a BF-PEF partition satisfying the size threshold. The minimum index size of the hybrid BF-PEF index is close to the pure PEF index size, which is 3.25GB. In this case, the hybrid BF-PEF index likely assigns almost all documents to PEF (and acts much the same as pure PEF).

From Table 3, we observe that the hybrid BF-PEF index results in improving the intersection time (vs. the aforementioned mathematical encoding methods) from 16% to 75% on MillionQuery and from 20% to 76% on TerabyteQuery, while having almost the same index size.

6.5 Feature Analysis

We analyze the feature distributions of BF and PEF in the hybrid BF-PEF index in the approximately optimal BF-PEF partition under various threshold conditions. We consider five features: URL, DL, DF, dispersivity, and TF-IDF, as defined in Section 5.1.1. For a feature f, we define the *feature ratio* for $I \in \{\text{BF}, \text{PEF}\}$ as

$$\frac{\overline{f}_I - \overline{f}}{\overline{f}}$$

where $\overline{f}$ is the average value of feature f in the whole document corpus, and $\overline{f}_I$ is the average value of feature f among to the documents assigned to I. The results are plotted in Figure 7 (for time thresholds) and Figure 8 (for size thresholds) for the BF-PEF partitions arising in Section 6.4. For these BF-PEF partitions, we also tabulate the proportion of documents assigned to BF in Table 4.

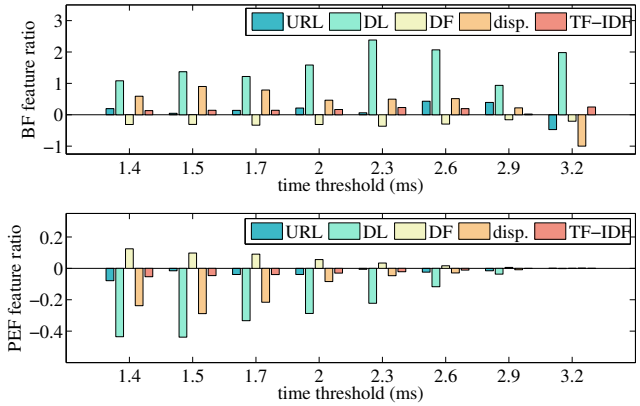

Figure 7: Feature ratios for the BF (top) and PEF (bottom) parts of the hybrid BF-PEF index, under various time thresholds.

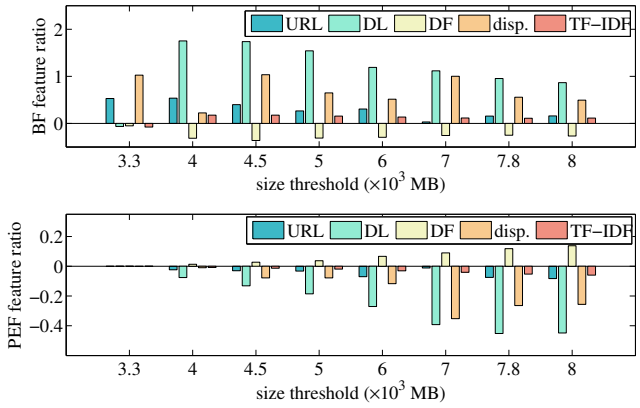

Figure 8: Feature ratios for the BF (top) and PEF (bottom) parts of the hybrid BF-PEF index, under various index size thresholds.

Table 3: The space time trade-off compared with mathematical encoding methods.

	OptPFD	hybrid	bin. int.	hybrid	Varint	hybrid
index size (GB)	3.66	3.77 (+3%)	3.13	3.27 (+4%)	7.74	7.77 (+1%)
avg. intersection time (ms) Mill.	3.65	3.08 (-16%)	12.95	3.28 (-75%)	2.42	1.42 (-41%)
avg. intersection time (ms) Tera.	4.25	3.42 (-20%)	15.06	3.67 (-76%)	2.78	1.43 (-49%)

Table 4: The proportion of documents in the BF part with a given time or size threshold.

time threshold (ms)	1.4	1.5	1.7	2.0	2.3	2.6	2.9	3.2
proportion	28.69%	24.23%	21.47%	15.33%	8.55%	5.36%	3.79%	0.10%
size threshold ($\times 10^3$MB)	3.3	4.0	4.5	5.0	6.0	7.0	7.8	8.0
proportion	0.09%	4.15%	7.02%	10.73%	18.50%	25.99%	32.16%	34.14%

In general, if a feature f has a positive feature ratio for $I \in \{\text{BF}, \text{PEF}\}$, we think of I as favoring feature f. For example, BF generally strongly favors document length (DL) and dispersivity. For a feature f with a negative feature ratio for $I \in \{\text{BF}, \text{PEF}\}$, we instead think of I as disfavoring feature f. For example, BF generally disfavors document frequency (DF). Some of these feature preferences are explainable (like in the pilot experiments in Section 2), while others are not. These results are fairly consistent with Figure 1 in the pilot experiments.

When we set the time threshold equal to the pure PEF intersection time (3.2ms), or the size threshold equal to the pure PEF index size (3300MB), almost all the documents are partitioned into PEF, therefore the feature distribution of the PEF part is almost identical to the whole document corpus; the feature distribution for BF in this setting is consequently unreliable, since it contains few documents.

Figures 7 and 8 further emphasize how a simple method alone is unlikely able to obtain a suitable BF-PEF partition; this is consistent with the observations in Section 2.

6.6 False Positive Analysis

A non-negligible problem with the proposed hybrid index is the false positives caused by BF. Table 5 lists the false positive rates (the proportion of false positive documents among all positive documents) for the proposed hybrid BF-PEF index under various thresholds (the time threshold is for the MillionQuery query set).

Table 5 indicates that, as time threshold increases, the false positive rate decreases; this is due to an increasing number of documents being assigned to PEF, which does not incur false positives. Conversely, as the size threshold increases, more documents are assigned to BF, which increases the false positive rate.

Compared with the pure BF index, the false positive rate of the hybrid BF-PEF index decreases by at least 40% and 23% on MillionQuery and TerabyteQuery, respectively.

Table 5: The false positive (fp.) rates for various thresholds for the MillionQuery (Mill.) and TerabyteQuery (Tera.) query sets. Note that the pure BitFunnel index has 2.48% and 1.70% false positive rates on MillionQuery and TerabyteQuery, respectively.

time thre. (ms)	1.4	1.5	1.7	2.0	2.3	2.6	2.9	3.2
Mill. fp.	1.39%	1.36%	1.03%	0.91%	0.74%	0.33%	0.14%	0.00%
Tera. fp.	1.25%	1.19%	1.01%	0.87%	0.71%	0.32%	0.15%	0.00%
size thre. ($\times 10^3$ MB)	3.3	4.0	4.5	5.0	6.0	7.0	7.8	8.0
Mill. fp.	0.00%	0.24%	0.36%	0.52%	0.86%	1.30%	1.43%	1.49%
Tera. fp.	0.00%	0.23%	0.36%	0.49%	0.84%	1.21%	1.27%	1.31%

7 CONCLUDING REMARKS

In the paper, we propose a hybrid BF-PEF index, combining the spatial efficiency of Partitioned Elias-Fano and intersection efficiency of BitFunnel by partitioning the documents into two disjoint parts. We use a local search to find an approximately optimal BF-PEF partition that meets a pre-specified threshold; during this process, we use machine learning to predict the size and intersection time of the hybrid index.

Experimental results indicate that the proposed hybrid BF-PEF index decreases the intersection time up to 47% compared with another hybrid index with the same index size. Compared with BitFunnel, it reduces the index size by 45% while maintaining almost the same intersection time.

In the future, it would be interesting to explore (a) combining multiple indexes, not just BF and PEF; (b) using more sophisticated thresholding techniques; (c) using alternative regression models; and (d) incorporating additional document features.

One limitation of the present approach is the implicit assumption of everything taking place on a single machine. Scaling up to a distributed system likely requires adapting the machine-learning method for each machine. While we expect this is feasible in practice, this matter is not addressed this in this paper.

ABSTRACT

Different time series is measured in almost all fields including biology, economics and sociology. A common challenge for using such data is the imputation of the missing values with reasonable ones. Most of existing approaches to data imputation assume that individual's observations are independent to each other, which is rarely the case in real-world. In this paper, we study the social-aware time series imputation problem. Given a social network that represents social relations between individuals, we propose a sequential encoder-decoder-based framework and build a connection between the missing observations and the social context. In particular, the proposed model employs the attention mechanism to incorporate social context and temporal context into the imputation task. Experimental results based on two real-world datasets demonstrate that our approach outperforms 11 different baseline methods.

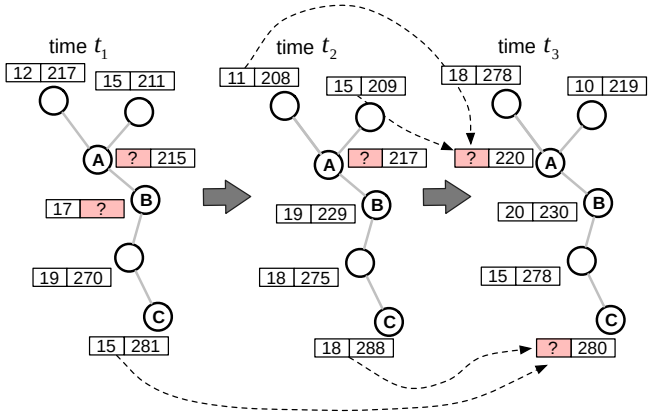

Figure 1: An illustration of the social-aware time series imputation problem. We are given a network where each vertex denotes an individual, and we create an edge between two individuals if the distance between their living places is less than a threshold. Each person has a multivariate observation at every timestamp (two-dimensional in our case), with some missing values (colored in red and marked as "?"), to indicate her electricity consumption. The goal is to impute the missing values by building surrounding and temporal influences.

1 INTRODUCTION

Time-series modeling has been extensively studied and applied in a broad range of applications, such as financial marketing [51], bioinformation [19, 22], and wearable sensors [33]. Among these studies, one fundamental issue is that time series data often inevitably carries missing observations due to various reasons, such as anomaly events, security issues, communication errors, privacy, and so on. Missing observations cause serious damages to the analysis and model results based on them, and thus it is necessary to impute these values.

On the other hand, the social network, a natural way of representing personal relationships, has turned out to be valuable and has recently attracted considerable research efforts [14, 30]. Time series data also plays an important role in social network analysis, as individuals in a social network generate a huge amount of data, which evolves over time. Meanwhile, homophily, a widely recognized organizing principle of social networks, suggests that people with common behavior patterns or similar interests are more likely

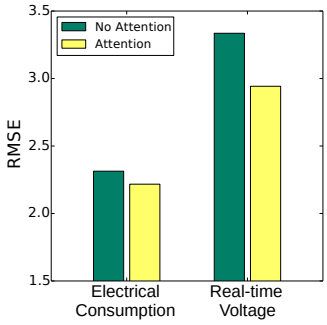

Figure 2: The performance of the proposed method for time series imputation. Two methods are shown here: one considers social and temporal information in the context of the attention mechanism, and another ignores this information. Root Mean Square Error (RMSE) is considered in the figure (the smaller the better).

to connect with each other. Therefore, individuals' missing observations can be guided by their neighbors' data, which is the basis of our work.

To address the problem of time series imputation, various approaches have been explored in the past few decades. For example, one practical method is to replace the missing values with the mean value of observations at adjacent timestamps. Similar methods include smoothing [38], interpolation [1, 45], and spline [36], which are simple and practical when data evolves smoothly. However, these methods can not capture the complex patterns of a time series; therefore, they fail to perform imputation. Recently, deep neural networks-based methods have been employed for data imputation [13, 15, 50]. These methods benefit from their strong prediction ability as well as their ability to capture temporal dependencies. However, to the best of our knowledge, there is a lack of research on the incorporation of *social information* and *deep models* to better perform time series imputation, which we believe is a new promising direction.

In this paper, we study the problem of social-aware time series imputation, which is nontrivial and gives rise to several challenges. Figure 1 demonstrates an example. In particular, given a social network, in which each vertex indicates an individual, there is an undirected edge between two individuals if they live close together (i.e., the distance between their living places is less than a certain predefined threshold). We monitor the electricity consumption of each individual, which is represented by two-dimensional vector, composed of daily power and voltage. At time t_3, individual A's daily power value is missing. To complete the missing value, traditional methods consider A's previous power value at the timestamps t_1 and t_2, which, however, are also missing. Fortunately, observations of A's neighbors provide us with a clue for the missing value. For instance, it is natural to assume that people live close share similar electricity consumption patterns to some extent. We call this "surrounding influence". Intuitively, each of individual v's neighbors has different surrounding influence on v's observations. The first challenge in this study is therefore how to identity the surrounding influence and model the connection between the missing observations and social context of an individual.

Returning to our example, the missing observations of individual C at time t_3 are affected by C's observations at t_1 and t_2. We call this "temporal influence", which has different effects for different timestamps. For instance, if some of C's family leave for a trip during t_2, and return at t_3, the electricity usage of C's family at t_1 shall be closer to that at t_3 and has a larger influence than that at t_2. How to quantify and differentiate temporal influence at different timestamps is the second challenge in this work.

Another factor that influences data imputation in our example is the time intervals between t_1, t_2, and t_3. Most existing time-series imputation methods assume that the elapsed time between the elements of a time series is equal, which may not hold true in practice. How to handle irregular time intervals is our third challenge.

To address the above mentioned challenges, we propose an novel model based on a deep encoder-decoder architecture. It utilizes the attention mechanism to incorporate surrounding influence and temporal influence in the time series imputation task. As Figure 2 shows, the experimental results show that with the help of surrounding influence and temporal influence, we can obtain a clear improvement in imputation performance. Furthermore, we apply Time-Aware Long Short-Term Memory (LSTM), which acts as the basic component of our model for handling the time irregularity issue. See details in Section 3.

We further test the proposed model on two real-world datasets. We compare 11 different state-of-the-art baseline methods and find that our model consistently outperforms others. More detailed results can be found in Section 4.

Accordingly, our contributions are as follows:

- We propose a novel time series imputation framework that takes both surrounding influence and temporal influence into consideration.
- We apply a variant LSTM as the basic component of our model for handling irregular time intervals.
- We construct sufficient experiments under various missing conditions based on two real-world datasets. Experimental results exhibit our method's advantage over eleven baseline methods.

Organization. The remainder of this paper is organized as follows. We first formulate the problem and give the necessary definitions. We then introduce the proposed model, including the model structure, the learning algorithm, and its applications. Subsequently, we present the experimental results. Finally, we review some relevant research and conclude the work.

2 PROBLEM DEFINITION

Let $G =< V, E >$ be a social network, where V is the set of users, and each edge $e_{ij} \in E$ indicates that $v_i \in V$ has a social relationship with v_j. For each user v, her behavior data is measured by a sensor periodically, denoted as $X = \{x_1, x_2, ..., x_T\} \in \mathbb{R}^{T \times D}$. For each timestamp $t \in \{1, 2, ..., T\}$, x_t indicates the t-th observations with D channels (or variables), and x_t^d represents the t-th observation in the

d-th channel. In the real world, many observations are missing or erroneous. To mark the missing data in the time series, we introduce an index m_t for missing ones at timestamp t, where $m_t = 0$ if x_t is not observed, otherwise $m_t = 1$. We also maintain an observed sequence of X as $X' = \{x_{s_1}, x_{s_2}, ..., x_{s_L}\}$, where s_l represents the timestamp of l-th observations, and the corresponding interval sequence Δ, where

$$\delta_l = \begin{cases} 1, & l = 1 \\ s_l - s_{l-1}, & l \neq 1 \end{cases} \tag{1}$$

In this work, we are interested in the missing data imputation task of time series data from users in social networks, where we impute the missing data given the social network G, time series dataset $\mathcal{D} = \{X_n, M_n\}_{n=1}^N$, where $X_n = \{x_1^{(n)}, ..., x_T^{(n)}\}$, $M_n = \{m_1^{(n)}, ..., m_T^{(n)}\}$.

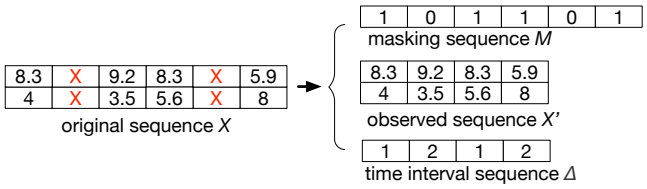

Figure 3: An example of the whole sequence X, masking M, observed sequence X', and time intervals Δ.

3 OUR APPROACH

Recently, recurrent sequences generated by data through an attention mechanism have shown very good performance in multiple tasks, such as neural translation [10, 28], speech recognition [6], and image caption generation [27]. To some extent, our task can also be viewed as a recurrent sequence generation task that generates the complete sequence X^* using the original sequences X from a user v and her social network G. We design an attention mechanism considering two types of information, i.e., surrounding influence and temporal influence, to learn a sequence model for the imputation task. To handle the time irregularity due to missing data, we use a variant LSTM cell considering different time intervals.

In this section, we describe the details for our proposed model **S**ocial-Aware **T**ime Series **I**mputation (STI). Figure 4 shows the architecture of our proposed model.

3.1 Social Attention Network

In order to capture the surrounding influence patterns for imputation, we leverage the attention mechanism to align the useful information from users with similar behavioral patterns. We also shows our solution to handle the time irregularity in the sequences with missing values. This part of our proposed model is called Social Attention Network.

LSTM and variant LSTM. To extract recurrent series patterns from the original sequences with non-uniformed time intervals, we first review a variant LSTM cell. The LSTM [21] recently shows its good properties in modeling series data with recursive relations. For instance, it can avoid the vanishing gradient problem by introducing the gate mechanism. Given the input x_t, the output of hidden state h_t is computed as below:

$$g_t = tanh(W_g x_t + U_g h_{t-1} + b_g) \tag{2}$$
$$i_t = \sigma(W_i x_t + U_i h_{t-1} + b_i) \tag{3}$$
$$f_t = \sigma(W_f x_t + U_f h_{t-1} + b_f) \tag{4}$$
$$o_t = \sigma(W_o x_t + U_o h_{t-1} + b_f) \tag{5}$$
$$c_t = f_t \cdot c_{t-1} + i_t \cdot g_t \tag{6}$$
$$h_t = o_t \cdot tanh(c_t) \tag{7}$$

where $h_t, c_t \in \mathbb{R}^H$, H is the cell size, $\sigma(\cdot)$ is the logistic sigmoid function, and i, f, o, and g represent *input gate*,*forget gate*, *output gate* and *cell state* respectively. The three gates control the data flow through the cell. In particular, the input gate i regulates the extent to which a new value data is fed into the cell, the forget gate f regulates the extent to which the history is forgotten, and the output gate o decides the extent to which the value is used to compute the output activation.

By introducing the gate structure, the LSTM unit is capable of handling long-term dependency, but the structure has implicitly assumed that the elapsed time between the elements of a sequence is uniformly distributed. Hence, the time irregularity in a sequence is not considered as being part of its structure, while it often occurs in the sequences with missing elements, that is, the interval sequence Δ is non-uniform.

To capture the patterns with time irregularity using LSTM, many studies have proposed modifications to original LSTM to incorporate the elapsed time into the standard LSTM. One method involves imputing data to maintain the regular time gaps. Based on this idea, some studies impute data by sampling from the observed elements, and many studies have also explored imputing data that is learned in the optimization process. However, the imputation method can have a serious influence on performance as the imputed data might not reflect reality well. Another way of handling the time irregularity is to modify the structure of LSTM to utilize the time gaps. Pham et al. [34] multiplies the output of the forget gate by $g(\delta)$, i.e., $f_t = g(\delta_t) \cdot f_t$. Another way of considering the time irregularity is to adjust the memory cell by applying the short-term memory discount. The mathematic expressions of such an adjusted memory are as follows:

$$c_t^s = tanh(W_d c_{t-1} + b_d) \tag{8}$$
$$\hat{c}_t^s = c_{t-1}^s \cdot g(\delta) \tag{9}$$
$$c_{t-1}^l = c_{t-1} - c_{t-1}^s \tag{10}$$
$$c_{t-1}^* = c_{t-1}^l + \hat{c}_t^s \tag{11}$$
$$\tilde{c} = tanh(W_c x_t + U_c h_{t-1} + b_c) \tag{12}$$
$$c_t = f_t \cdot c_{t-1}^* + i_t \cdot \tilde{c} \tag{13}$$

Firstly, the short-term memory component (c_t^s) is computed by a network. This decomposition process is data-driven, and its parameters are updated at the mean time with the rest of the network parameters. Secondly, the short-term memory is discounted by a weight factor $g(\delta)$ to obtain the discounted short-term memory ($\hat{c}_t^s$). Here, $g(\cdot)$ is a heuristic decaying function which is monotonically non-increasing. Different types of $g(\cdot)$ can be chosen according to specific application domains. For instance, $g(\delta) = 1/\delta$ is appropriate for

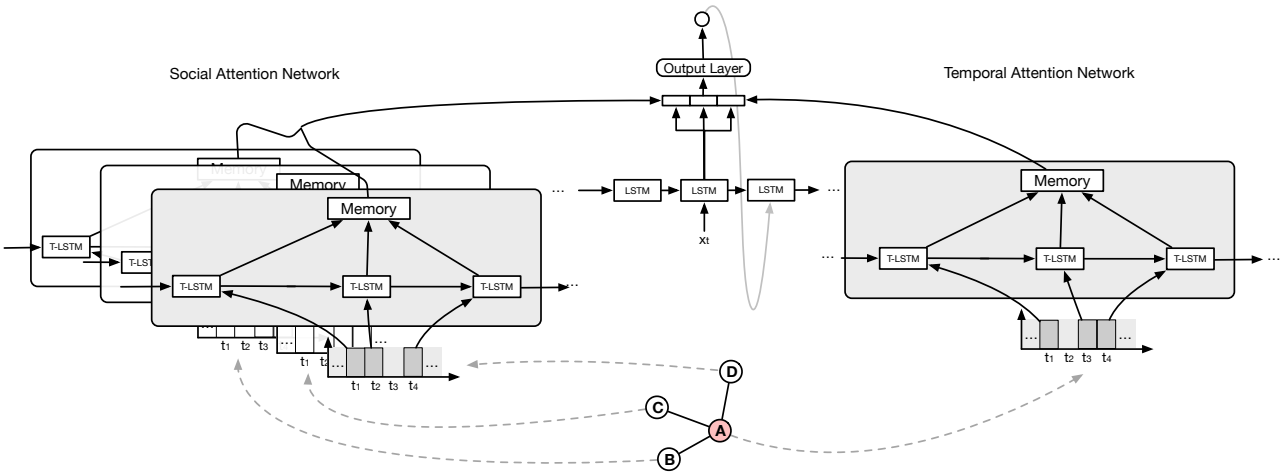

Figure 4: An illustration of our model, Social-Aware Time Series Imputation (STI). Our model mainly consists of two components: Social Attention Network (left) and Temporal Attention Network (right). In the social attention network, we first compute the fix sized memory representations of neighbors' temporal data, and then use the concatenation with the current hidden states of the user to generate the social context vector. In the temporal attention network, we directly feed users' memory representation with the current hidden states to generate the temporal context vector. The concatenation of current hidden states, social context vector and temporal context vector is used to predict the target missing elements.

datasets with small elapsed times, and $g(\delta_t) = 1/log(e+\delta)$ is preferable for datasets with large elapsed times [34]. We tried several functions $g(\cdot)$ but did not observe a drastic difference in the experimental results; however, $g(\delta) = 1/\delta$ performed slightly better that other functions. Thus, we choose the decaying function $g(\delta) = 1/\delta$ in this work. Finally, to obtain the adjusted memory, the complementary subspace of the long-term memory ($c^l_{t-1} = c_{t-1} - c^S_{t-1}$) is combined with the discounted short-term memory. This variant is proposed in [7], named **T**ime-Aware LSTM (T-LSTM).

Social Context Representation. Attention-based RNNs have been successfully applied in many tasks. These models iteratively feed their inputs by selecting relevant contents at each step. We introduce our extensions to this mechanism to extract useful patterns from social context.

For each user v, we have a group of sequences $\{\hat{X}_{(1)}, \hat{X}_{(2)}, ..., \hat{X}_{(P)}\}$ collected from her neighbors $\hat{v} = \{\hat{v}_{(1)}, \hat{v}_{(2)}, ..., \hat{v}_{(P)}\}$. We extract their observed sequences $\hat{M} = \{\hat{M}_{(1)}, \hat{M}_{(2)}, ..., \hat{M}_{(P)}\}$ and time interval sequences $\hat{\Delta} = \{\hat{\Delta}_{(1)}, \hat{\Delta}_{(2)}, ..., \hat{\Delta}_{(P)}\}$. For each neighbor $\hat{v}_{(p)}$, a T-LSTM network described in Section 3.1 is used to encode its original series data, which takes observed sequence $\hat{X}'_{(p)}$ and interval sequence $\hat{\Delta}_{(p)}$ as input and produces a sequence of hidden states $\hat{h}_{(p)} = \{\hat{h}_{1(p)}, ..., \hat{h}_{s(p)}\}$ by the means of following iterative process:

$$h_{s(p)}, c_{s(p)} = T - LSTM(x'_{s(p)}, \delta_{s(p)}, h_{s-1(p)}, c_{s-1(p)}) \tag{14}$$

It is important to note that the network parameters of T-LSTM are shared for all neighbors.

The decoder is a standard LSTM network that reconstructs the complete sequence X^*. Given the recurrent states h^*_s, we can calculate the social context vector $\hat{a}$. The context vector, also known as attention vector, is a weighted average of the source states. In the studies, Bahdanau et al. [5] and Luong et al. [28] proposed context-based models that calculate the context vector by comparing encoder and decoder at each step. Such computations are expensive. To leverage the attention mechanism without sacrificing too much efficiency, a memory-based attention model was explored in [10]. In the current work, we choose the memory-based attention method to efficiently calculate the social context vector.

In the memory-based attention method, a fixed-size memory representation is updated during the encoding. The memory representation is matrix $C \in \mathbb{R}^{K \times H}$, where K is the number of temporal context vectors and a hyper-parameter in this model, and H is the size of the cell states. C is a linear combination of the encoder states, weighted by a score vector $\alpha^s \in \mathbb{R}^K$:

$$C_k = \sum_{s=0}^{|S|} \alpha_{sk} h_s \tag{15}$$

$$\alpha_{sk} = softmax(W_\alpha h_s \cdot l_s) \tag{16}$$

where $W_\alpha \in \mathbb{R}^K$ is a parameter matrix, and l_s is a vector of position-encodings that prevents the learned context from being symmetric. In particular, the position-encodings are used to force the first few context vectors $C_1, C_2...$ to focus on the start of the sequence and the last few vectors $...C_{k-1}, C_k$ to focus on the end of the sequence. Similar to network parameters of T-LSTM, W_α is shared for all neighbors. We adapt the formula proposed in [10] to obtain l_s:

$$L_{ks} = \left(1 - \frac{k}{K}\right)\left(1 - \frac{s}{S}\right) + \frac{k}{K}\frac{s}{S} \tag{17}$$

where, $k \in \{1, 2, ..., K\}$ is the context vector index, and S is the maximum sequence length across all source sequences. Hence, given the social context, we can compute their memory representations

$\hat{C} = \{\hat{C_{(1)}}, \hat{C}_{(2)}, ..., \hat{C}_{(P)}\}$. We define the concatenation of these matrix as $\tilde{C}$, sized $KP \times H$.

In the decoding step, we set the social context vector $\hat{a}$, in each step, by the means of linear combination of the rows in $\tilde{C}$ weighted by a score vector $\hat{\beta}$.

$$\hat{a} = \sum_{i=0}^{K} \hat{\beta}_i \tilde{C}_i \tag{18}$$

$$\hat{\beta} = softmax(W_{\hat{\beta}} h^*) \tag{19}$$

where h^* represents the current hidden states of the decoder, and $W_{\hat{\beta}}$ is the parameter matrix. In each step of the decoding, the current state h_t^* is computed by feeding the previous state h_{t-1}^*, the previous cell state c_{t-1}^* , and previous output x_{t-1}^* to decoding unit:

$$h_t^*, c_t^* = LSTM(x_{t-1}^*, h_{t-1}^*, c_{t-1}^*) \tag{20}$$

3.2 Temporal Attention Network

In the social attention network, we extract social contextual information from user v's social network. Another important factor that should be considered for imputation is temporal influence, that is, how a user's historical and future behaviors can relate to her current state. Similar to the social attention network, we use a memory-based attention network to capture such influence. We name this part of our proposed model Temporal Attention Network.

Given a specific user, we extract her observed sequence X' and interval sequence Δ. Like extracting memory representation before, we also compute its memory matrix C. More specifically, we first feed X' and Δ into another T-LSTM:

$$h_s, c_s = T - LSTM(x'_s, \delta_s, h_{s-1}, c_{s-1}) \tag{21}$$

Hence, we get their hidden states $h = \{h_1, ..., h_s\}$, then we calculate memory representation C by (15).

In the decoding phase, we similarly compute the temporal context vector a. A slight difference is that its input is the memory representation of a single user, rather than the concatenation of memory representations from her neighbors:

$$a = \sum_{i=0}^{K} \beta_i C_i \tag{22}$$

$$\beta = softmax(W_\beta h^*) \tag{23}$$

3.3 Learning and Imputation

We concatenate the hidden representation h_t^*, social context vector $\hat{a_t}$, and temporal context vector a_t , which preserves the information from current states, social context and temporal context for predicting the targets. We then feed the concatenation to a fully connected layer and get the final prediction value.

$$x_t^* = \phi(h_t^*, \hat{a}_t, a_t) \tag{24}$$

where, $\phi(\cdot)$ is a non-linear function that maps the concatenation to the observations.

The decoding phase aims to generate the whole sequence and to minimize potential error in estimating the missing values. However, we cannot compute the observation that is truly missing in the sequence. Instead, we only calculate the error between the estimates and the actual observations. Thus, the total loss/error for the entire dataset $\mathcal{D}$ is the partial mean squared error (the $l2$-regularization term is omitted in the following expression):

$$\mathcal{L}(X^N, X^{*N}) = \sum_{n=1}^{N} [\sum_{t=1}^{T} \sum_{d=1}^{D} m_t^{(n)} \times (x_t^{d(n)} - x_t^{*d(n)})^2)] \tag{25}$$

To train this model, we process social context $\hat{X}$ to social attention network and original sequence X to temporal attention network, keeping track of each output and the latest hidden state. The first hidden states h_0^* of decoder is given by the last hidden states of the temporal context networks . To make the model converge faster and avoid over-fitting, we adopt a mixed strategy to feed the input data into the decoder. For some observations, we use the real target values as each next input if they are not missing; otherwise, we use the decoder's estimates as the next input. For the missing elements, we directly give the decoder's estimates. The fraction of samples trained using the real target values is denoted as γ. In the section of experiment, we set $\gamma = 0.9$.

After the model is well-trained, we can use it to impute the missing elements. Like in the learning phase, we process the social context $\hat{X}$ and original sequence X to the encoder and obtain the candidate context vector $\tilde{C}$ and C. For the decoder, we give the original values when data is observed; otherwise, we give estimates in order to use as much information as possible from the original sequences.

Algorithm 1 training procedure

4 EXPERIMENTAL RESULTS

4.1 Datasets Description

We employ two datasets from the State Grid, the major electric power company in China, to construct our experiments. Before

introducing our datasets, we highlight several facts about electricity data collection. Electricity data, including values of real-time current, voltage, and power, is measured by watt-hour meters. Each meter periodically transmits different types of data to its corresponding data collector. Usually, a collector receives data from several meters that are geographically close. For instance, these meters are assembled in different rooms on the same floor of a building. Hence, we can consider that the meters connecting to the same collector record the electricity usage of people or families with social relationships. Therefore, given a user v (corresponds to a meter), we define v's neighbors, which have social relations with v, as other users that share the same collector with v. More details of our datasets are described below:

- **Electrical Consumption (EC) :** This dataset is provided by the State Grid. In total, it includes the daily electrical consumption recorded by 80,000 watt-hour meters. This data spans from January 1st 2018 to March 31st 2018. The length of each series is 90.
- **Real-Time Voltage (RV) :** This dataset, provided by the State Grid, consists of around 20,000 electricity load series, each of which describes voltage values in three phases, recorded every 45 minutes in each day, from June 1st 2018 to June 30th 2018. Each sequence has 32 time stamps.

To reduce computational complexity, we at most consider 8 neighbors of a user, which are selected randomly.

4.2 Baselines and Metrics

4.2.1 Comparative Baselines and Implementation Details. We compare our model with multiple baselines:

- *Mean, Median:* We take the mean and median values of the observations in each channel to replace the missing data.
- *Linear, Cubic:* Linear interpolation and cubic interpolation are two interpolation methods that are used to impute the data.
- *KNN:* This method uses k-nearest neighbor to find similar samples and imputed unobserved data by calculating the weighted average of similar observations.
- *MICE [11]:* This is a method that combines the multiple imputation technique [37] with the chained equation approach to impute the missing data.
- *MissForest [40]:* This is a non-parametric imputation method that uses random forests trained on the observed values to predict the missing values.
- *Soft-Impute [29]:* This approach iteratively updates the missing elements by efficiently solving the convex relaxation of the approximate matrix completion problem.
- *GRU-D [13]:* This is a GRU-based model that incorporates masking and time intervals inside the GRU architecture to capture the informative missing data. We implement it slightly different from the original model proposed in [13]. Rather than use the hidden features of the last cell to predict the label, we use the hidden features in each cell to predict the next observations.
- *LSTM-Impute [26]:* This method initializes the missing elements with mean values, and updates them by training an RNN model with a LSTM unit.
- *VAE [47]:* This is a MCMC-based missing data imputation technique with a trained Variational Autoencoder (VAE).
- *STI :* This is our proposed model. We initialize our model with different parameters for different datasets. For the RV dataset, we use a 1-layer 32-unit T-LSTM encoder and a 1-layer 32 unit LSTM decoder. The memory size is also 32. The model is optimized using an Adam optimizer with a learning rate of 1×10^{-3} in the encoder and 5×10^{-3} in the decoder, and the batch size is 256. For the EC dataset, we set all LSTM dimensions to 16 and the memory size to 16. Again, we train the model using an Adam optimizer with a learning rate of 2×10^{-4} in our encoder and 2×10^{-3} in our decoder, and the batch size is 512. We set the dropout rate as 0.2 (0.8 keep probability).

4.2.2 Evaluation Metrics: We use Mean Absolute Error (MAE) and Root Mean Square Error (RMSE) to measure our model. Their formulas are:

$$MAE = \frac{\sum |x - x^*|}{n}$$
$$RMSE = sqrt\left(\frac{\sum (x - x^*)^2}{n}\right)$$

where x is a prediction, x^* is the ground truth, and n is the number of cases.

4.3 Performance Comparison with Randomly Missing Elements

To evaluate the performance of our model on these two datasets, we first assume that elements are randomly missing. With a missing rate θ, we randomly drop values for each time series from a Bernoulli distribution $\mathbf{U}(\theta)$. We experiment with θ varying from 0.2 to 0.6. In the training phase, we select the observed sequences for training our model, and use the dropped values to test its performance.

Table 1 reports the performance of our proposed method compared to all the other competing methods mentioned in Section 4.2.1 on the RV and EC datasets. Our proposed model significantly outperforms all comparative methods by achieving the lowest RMSE and MAE on these datasets. Another finding is that performance drops as the missing rate increases, which might be caused by the less information these models can learn with. Specifically, the simple imputation methods (Median and Mean) do not perform well, because they only use the observed values to complete the fixed values in each channel. For interpolate-based methods (Linear and Cubic), they further consider the intra-stream information at the nearest timestamp, and thereby achieve better performance. However, they lack the insight of inter-stream information. KNN, SoftImpute, MissForest, and MICE are traditional imputation methods that consider both intra-stream and inter-stream useful information. However, they fail to capture the complex temporal dependence. Therefore, our proposed method significantly outperforms those methods.

For neural networks-based methods, our method outperforms VAE, LSTM-Impute, and GRU-D. LSTM-Impute performs poorly in our evaluation, and its performance on the EC dataset is even worse than some traditional imputation methods. This might be because replacing the missing elements with average values can influence

Table 1: Performance of different models in imputation using the EC and RV datasets.The best results are in boldface, and the second-best results are underlined.

Dataset	Missing Rate	0.2		0.3		0.4		0.5		0.6

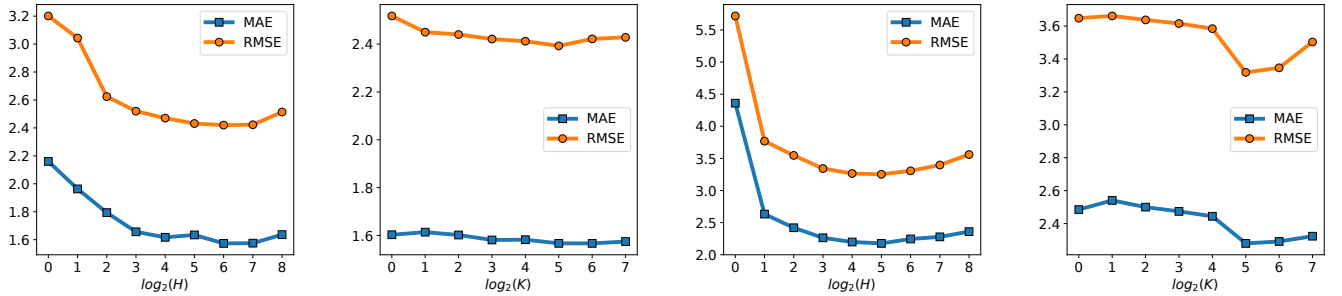
the original temporal distribution, which harms performance. GRU-D designs a recurrent architecture that uses both time intervals and masking information to update the missing data. However, it overlooks the importance of global temporal contextual information. VAE is a good approach for replacing missing data, but it lacks the modeling of temporal patterns. The best performance of our method demonstrates that incorporating social and temporal contextual information through the attention encoder is helpful for imputation.

4.4 Ablation Analysis

This section aims to demonstrate the effectiveness of the different components of our proposed model. We first list some variants of our models:

- *STI :* This is our complete model. We have described the parameter settings for this model in Section 4.2.1.
- *STI - social:* This model drops the social context vector in the output layer.
- *STI (LSTM)*: This variant uses the original LSTM as the encoder instead of T-LSTM. The remaining settings for this variant are the same as for our proposed model.
- *STI - social - temporal*: This variant removes both temporal and social contexts in our proposed model, i.e., an RNN with a LSTM cell.



The result of different variants under various settings is reported in Table 2. We can observe the improvement due to adding the social attention network in most cases. This finding suggests that the factor of social relations is helpful, especially on the RV dataset. We also note that our model without social attention network still outperforms most cases when we drop our attention encoder, which demonstrates the importance to model temporal influence in a proper way. We also observed that when we replace the T-LSTM encoder as a LSTM encoder, performance drops. Therefore, using the T-LSTM encoder is helpful.

4.5 Parameter Analysis

In this section, we explore how the hyper-parameters influence the performance of our model. We fix the remaining hyper-parameters of our models when we vary one hyper-parameter. We present the results for the EC and RV datasets with the same missing rate of 0.5. Figure 5(a) and Figure 5(c) report the relationship between cell size H and final performance. We observed that our model, with a cell size that is too small (less than 4 on both datasets) or too large (more than 32 on RV) can decrease imputation performance. Hence, choosing a proper cell size H is crucial. Memory size K is another crucial hyper-parameter. Figure 5(b) and Figure 5(d) present how K influences the model's performance. For memory-based attention, memory size K can be considered as a trade-off between computational time and representational power. A large K allows the model to compute complex source representations, while a small K of 1 limits the source representation to a single vector. Britz

et al. [10] showed that a larger K can achieve better performance in neural translation task. In our experiment, we find that within a certain range, the performance increases as the K increases in size. However, we also note that performance drastically drops when K becomes relatively large. This might be related to the over-fitting phenomenon, whereby the capability of representation becomes large.

We also explore how varying Ks influences the learning procedure. Figure 6 shows that a larger K tends to have a faster convergence in terms of training loss on both two datasets.

4.6 Generalization Analysis

In the previous sections, we use the full dataset to train the model, and it achieves very good performance. However, in many real-world senarios, the method is impractical due to the huge scale of historical data and the new data that is being collected continuously. Based on these concerns, we conduct a new experimental setting to explore how our model performs when trained with a subset of collected data. In particular, we randomly draw $1/n$ ($n = 1, 2, 4, \ldots, 64$) from the EC dataset with a missing rate of 0.5 , and use this data to train the model. Then we use the trained model to fill the missing elements in the full datasets. Figure 7 presents the results. Not surprisingly, performance drops as our model is trained with less

(a) Training curve on the EC dataset. (b) Training curve on the RV dataset.

Figure 6: Comparison concerning varing memory size K for the training loss curve on EC and RV datasets. It shows that a larger K tends to converge faster.

data in both metrics. However, we also observe that the degree of the drop is relatively slight. For instance, using only 1/32 (around 2.5K time series) of the datasets, our model can still outperform other baselines. This suggests that our model has a good capacity for generalization.

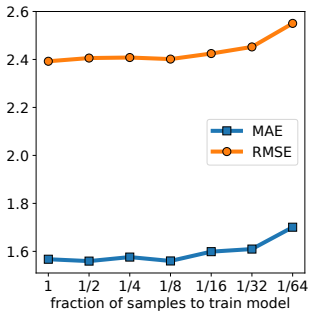

Figure 7: Comparison of performance when applying a subset of the whole EC dataset with a missing rate of 0.5 to train our model. The x-axis indicates the fraction of samples is used. The y-axis indicates the two evaluation metrics.

4.7 Comparison of Performance using Simulated Real-World Missing Data

In the previous section, we experiment with the assumption that elements are randomly missing and observed that our method outperforms other baselines with various missing rates. However, in the real-world, completely random missing is rare in time series , because data is usually missing in blocks. To evaluate the accuracy of our method in completing the elements missing in real-world situations, we establish a new setting in the EC dataset. Firstly, we extend the time span of the EC dataset from the first 90 days to the first 180 days in 2018. We then partition the extended dataset into two parts, named EC-A and EC-B , each of which has consecutive data for 90 days. We extract the masking matrix from EC-A and EC-B, and name them M_A and M_B, respectively. We drop the values of the elements in EC-A that correspond to its successor's (i.e., from the 91st day to the 180th day in 2018) masking matrix M_B. If those elements are present in EC-A, their values are used as a ground truth to measure the performance of our predictions. If a time series is all observed in EC-B, then we drop this series in our datasets. In total, the dataset used in this section consists of around 20K time series. In this section, we do not randomly drop some non-missing elements to generate ground truth, as real-world missing patterns are not random. Figure 8 shows an example of how to drop missing elements.

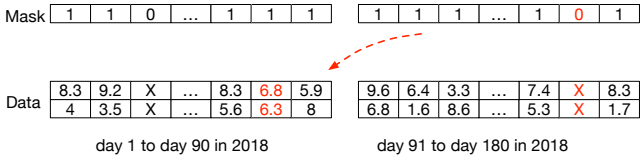

Figure 8: An illustration of ground truth generation on the EC dataset to simulate real-world missing data.

Table 3 reports the comparison between the levels of performance of the different models on this dataset. Our model achieves state-of-the-art performance on this dataset and its improvement on the performance of other baseline methods is significant. This finding demonstrates that our model can also achieve a good performance in the real-world situations in which the elements are not randomly missing. The performance of our model that does not consider social influence is lower than our complete model, but it still remains competitive concerning these benchmarks. Linear Interpolation is still a competitive method, and following are three neural imputation models. Another interesting finding is that while the performance of our model on this dataset is slightly better than that on the EC dataset, with a missing rate of 0.4, many baseline methods (e.g. MICE, Cubic) performs worse than they do under the same condition. This again demonstrates the adaptability and stability of our model under different missing conditions.

Table 3: Performance on the EC dataset with simulated missing data.The best results are in boldface, and the second-best results are underlined.

5 RELATED WORK

Time Series Modeling. For modeling time series data, plenty of parametric methods are proposed, including the auto-regressive models [4, 39], the kernel models [25], and the hidden Markov models [46, 49]. Recently, many time series model based on neural networks have been explored [21, 31]. More recent works explore to use deep learning methods to extract high-level representation of time series data [43, 44].

Traditional imputation methods for time series data. Over the years, quite a few imputation methods for time series data have been explored. The majority of them have concentrated on reconstructing missing elements by utilizing the temporal relationship within each data stream, such as the EM algorithm [18],the MissForest, [40] and the kernel method[35]. Multiple imputation [11] was also developed with these imputation methods to reduce uncertainty, by repeating the imputation procedure several times and giving the averaged estimates. However, running multiple models to fit the measured data during imputation introduces a great deal computational cost, which is a practical concern.

Imputation methods based on recurrent neural networks. Recently, recurrent neural networks (RNNs) have achieved the state-of-the-art performance in many tasks with sequential data, including machine translation and speech recognition. RNNs generate a sequence of hidden states h_t , as a function of the previous hidden states h_{t-1} and the input for position t. RNNs with LSTM or GRU units enjoy several benefits like capturing long-term sequential dependencies and supporting variable-length data input. The RNNs for missing data have also been studied in many works and have

been applied in speech recognition [2] and mortality prediction [13]. Previous works in this area [8, 41] have tried to first replace the missing elements with fixed values (such as the mean), most recent observations or values learned by other imputation algorithms, and then use the RNNs to update the initial data. However, the input sequences with pre-imputed values might have a different data distribution from the original ones, which can influence final performance when applying the RNNs to fit the data with pre-imputed values.

More recent advances take time irregularity into account. In other words, these papers model observations and intervals at the same time [13, 15, 50]. By concatenating information of observations and time gaps, they use these concatenation as the input for their customized RNNs. Different approaches of concatenation have been tried in these works. For instance, Che et al. [13] concatenate the latest observations, mean values, and time intervals as inputs to fit the customized GRU network. However, these works lack the insight of the temporal context of the whole time series and do not consider incorporating temporal and social patterns .

Recurrent neural networks with irregular intervals. Most of the proposed studies on RNNs assume that the interval between two consecutive timestamps is a constant value. However, it may not hold true in many real-world scenarios [7, 52]. For addressing this issue, many studies consider modifying gate structures of the LSTM cell [7, 24, 34]. Some studies also explore to add new gates to better model time gaps [32, 52]. In particular, Neil et al. [32] introduce a new gate, named time gate, and equip it with LSTM to model time intervals between two successive user behavior. Besides, Baytas et al. [7] adjust the memory cell of LSTM by discounting the short-term memory, and Beutel et al. [9] incorporate time gaps in the RNN by performing an element-wise product of model's hidden states with the embedding of time gaps.

Sequence modeling with attention mechanism. Learning sequence alignments via attention is also relevant to our work. Recently, sequence-to-sequence models with attention mechanism have achieved remarkable successes in many tasks, such as machine translation [10, 28], speech recognition [6], and image caption generation [27].This success has motivated us to extend this mechanism to the time series imputation field. Attention mechanisms can be viewed as feature extractors that allow the modeling of dependencies without regard to their distance in the input or output sequences [5]. The most popular approaches first build an encoder-decoder architecture consisting of two RNNs and use an attention mechanism to align the target to source tokens [5]. Recently, research in this field has focused on reducing the computational cost. Luong et al. [28] introduce various attention mechanisms that are computationally simpler and perform just as well as the model in [28]. Kalchbrenner et al. [23] propose a linear time architecture based on stacked convolutional neural networks. Gehring et al. [20] also propose the use of convolutional encoders to speed up neural machine translation. de Brébisson and Vincent [17] explore a linear attention mechanism using covariance matrices for information retrieval. Britz et al. [10] propose an end-to-end memory network based on a recurrent attention mechanism instead of sequence-aligned recurrence, and this method has shown good performance on several language modeling tasks, and is used in our model. Vaswani et al. [42] try to increase the capability of parallelism of the attention mechanism by using pure attention networks rather than recurrent structures. Location-based attention [48] has also been studied in the field of image recognition.

Time series in social networks. Our work is also relevant to studies on the evolution of user behavior in social networks [3, 12, 16, 30]. Using data from social networks, these studies explore the temporal connection between individual behavior and network properties. For instance, Asur and Huberman [3] use the time series of users' tweets about movies to predict movies' revenue. McAuley and Leskovec [30] study the process of user expertise on review websites, and find that modeling users' experience helps to discover when users acquire product in rating systems. Many studies examine the spread of behaviors or health conditions based on temporal data collected in networks [12, 16]. In particular, Christakis and Fowler [16] examine the spread of obesity on a large social network of 12K people over 32 years, and find that social distance tends to be more important than geographic distance with people's networks.

6 CONCLUSION AND FUTURE WORK

To what extent can your friends disclose your information? In this paper, we proposed a novel social-aware time series imputation framework, that considers social influence and temporal influence to infer missing values in time series. To incorporate these two factors, we designed two attention mechanisms in our model. Experimental results on real-world datasets show that our model can consistently outperform 11 baseline methods.

There are at least two kinds of perspectives. From the social networks side, in this paper we only exploited a small part of contextual information in social networks, we would like to utilize other useful patterns such as network structures and user interactions in the future work. From the practical side, we would like to explore the use of our approach into more real-world scenes.

ABSTRACT

Facial recognition is a key enabling component for emerging Internet of Things (IoT) services such as smart homes or responsive offices. Through the use of deep neural networks, facial recognition has achieved excellent performance. However, this is only possibly when trained with hundreds of images of each user in different viewing and lighting conditions. Clearly, this level of effort in enrolment and labelling is impossible for wide-spread deployment and adoption. Inspired by the fact that most people carry smart wireless devices with them, e.g. smartphones, we propose to use this wireless identifier as a supervisory label. This allows us to curate a dataset of facial images that are unique to a certain domain e.g. a set of people in a particular office. This custom corpus can then be used to finetune existing pre-trained models e.g. FaceNet. However, due to the vagaries of wireless propagation in buildings, the supervisory labels are noisy and weak. We propose a novel technique, `AutoTune`, which learns and refines the association between a face and wireless identifier over time, by increasing the inter-cluster separation and minimizing the intra-cluster distance. Through extensive experiments with multiple users on two sites, we demonstrate the ability of `AutoTune` to design an environment-specific, continually evolving facial recognition system with entirely no user effort.

1 INTRODUCTION

Facial recognition and verification are key components of smart spaces, e.g., offices and buildings for determining who is where. Knowing this information allows a building management system to tailor ambient conditions to particular users, perform automated security (e.g., opening doors for the correct users without the need for a swipe card), and customize smart services (e.g., coffee dispensing). A vast amount of research over the past decades has gone into designing tailored systems for facial recognition and with the advent of deep learning, progress has accelerated. As an example of a state-of-the-art face recognizer, FaceNet achieves extremely high accuracies (e.g., 99.5%) on very challenging datasets through the use of a low dimensional embedding, allowing similar faces to be clustered through their Euclidean distance [14, 26]. However, when directed transferred to operate in 'in the wild', subject to variable lighting conditions, viewing angle and appearance changes, performance of off-the-shelf pre-trained classifiers degrades significantly, with accuracies around 15% not being uncommon. The solution to this is to obtain a large, labelled corpus of data for a particular environment, with hundreds of annotated images per user. Given access to such a hypothetical dataset, it is then possible to fine-tune the pre-trained classifier on out-domain data to adapt to the new environment and achieve excellent performance.

However, the cost of labelling and updating the corpus (e.g. to enrol new users) is prohibitive for most critical applications and therefore, will naturally limit the use and uptake of facial recognition as a ubiquitous technology in emerging Internet of Things (IoT) applications. On the other side, people often, but not always, carry smart devices (phones, fitness devices etc). Wang et al. [36] advocated that although these devices do not provide fine-grained enough positioning capability to act as a proxy for presence, they can be used to indicate that a user *might* be present in an area

with a co-located camera. In this work, we take a step forward and further utilize device presence as weak supervision signals for the purposes of fine-tuning a classifier. The goal now becomes how to take an arbitrary, pre-trained recognition network and tune it from a generic classifier to a highly specific classifier, optimized for a certain environment and group of people. We note that the aim is to make the network better and better at this specific goal, but it would likely perform poorly if transferred directly to a different environment. This is the antithesis of the conventional view of generalized machine learning, but is ideally suited for the problem of environment specific facial recognition, as opposed to generic facial recognition.

The technical challenge is that there is not a 1:1 mapping between a face and a wireless identity, rather we need to solve the association between a set of faces and a set of identities over many sessions or occasions. To further complicate the problem, the sets are not pure i.e. the set of faces can contain additional faces from people not of interest (e.g. visitors). Equally well, due to the vagaries of wireless transmission, the set of wireless identifiers will contain additional identifiers e.g. from people in the next office. Furthermore, it is also possible to have missing observations e.g. because a person was not facing the camera or because someone left their phone at home.

In this work, we present AutoTune, a system which can be used to gradually improve the performance of facial recognition systems in the wild, with zero user effort, tailoring them to the visual specifics of a particular smart space. We demonstrate state-of-the-art performance in real-world facial recognition through a number of experiments and trials.

In particular, our contributions are:

- We observe and prove that wireless signals of users' devices provide valuable, albeit noisy, clues for face recognition. Namely, wireless signals can serve as a weak label. Such weak labels can replace the human annotated face images in the wild to save intensive effort.
- We create AutoTune, a novel pipeline to simultaneously label face images in the wild and adapt the pre-trained deep neural network to recognize the faces of users in new environments. The key idea is to repeat the face-identity association and network update in tandem. To cope with observation noise, we propose a novel probabilistic framework in AutoTune and design a new stochastic center loss to enhance the robustness of network fine-tuning.
- We deployed AutoTune in two real-world environments and experimental results demonstrate that AutoTune is able to achieve > 0.85 F_1 score of image labeling in both environments, outperforming the best competing approach by $> 25\%$. Compared to the best competing approach, using the features extracted from the fine-tuned model and training a classifier based on the cross-modality labeled images can give a $\sim 19\%$ performance gain for online face recognition.

The rest of this paper is organized as follows. §2 introduces the background of this work. System overview is given in §3. We describe the AutoTune solution in §4 and §5. System implementation details are given in §6. The proposed approach is evaluated and compared with state of the art methods in §7. Finally, we discuss and outlook future work in §8 and conclude in §9.

2 RELATED WORK

Deep face recognition: Face recognition is arguably one of the most active research areas in the past few years, with a vast corpus of face verification and recognition work [23, 31, 40]. With the advent of deep learning, progress has accelerated significantly. Here we briefly overview state-of-the art work in Deep Face Recognition (DFR). Taigman et al. pioneered this research area and proposed DeepFace [30]. It uses CNNs supervised by softmax loss, which essentially solves a multi-class classification problem. When introduced, DeepFace achieved the best performance on the Labeled Face in the Wild (LFW) [9] benchmark. Since then, many DFR systems have been proposed. In a series of papers [27, 28] Sun et al. extended on DeepFace incrementally and steadily increased the recognition performance. A critical point in DFR happened in 2015, when researchers from Google [26] used a massive dataset of 200 million face identities and 800 million image face pairs to train a CNN called Facenet, which largely outperformed prior art on the LFW benchmark when introduced. A point of difference is in their use of a "triplet-based" loss [5], that guides the network to learn both inter-class dispersion and inner-class compactness. Recently proposed RTFace [36] not only achieves high recognition accuracy but also operates at the full frame rates of videos. Although the above methods have proven remarkably effective in face recognition, the training needs a vast amount of labeled images to train the supervised DFR network. A large amount of labeled data is not always achievable in a particular domain, and using a small amount of training data will incur poor generalization ability in the wild.

Cross-modality Matching: Cross-modal matching has received considerable attention in different research areas. Methods have been developed to establish mappings from images [7, 11, 34] and videos [33] to textual descriptions (e.g., captioning), developing image representation from sounds [20, 21], recognizing speaker identities from Google calendar information [17], and generating visual models from text [41]. In cross-modality matching between images and radio signals, however, work is very limited and all dedicated to trajectory tracking of humans [1, 22, 32]. The field of face recognition via wireless signals is an unexplored area.

3 AUTOTUNE OVERVIEW

3.1 System Model

We consider a face recognition problem with m people of interest (POI) and each subject owns one WiFi-enabled device, e.g., a smartphone. We denote the identity set as $\mathcal{Y} = \{y_j | j = 1, 2, \ldots, m\}$. The set of observed POI's devices in a particular environment is denoted by $\mathcal{L} = \{l_j | j = 1, 2, \ldots, m\}$, e.g., a set of MAC addresses. We assume the mapping from device MAC addresses $\mathcal{L}$ to the user identity $\mathcal{I}$ is known. A collection of face images $\mathcal{X} = \{x_j | j = 1, 2, \ldots, n\}$ is cropped from the surveillance videos in the same environment. Note that, to mimic the real-world complexity, our collection includes the faces of both POI and some non-POI, e.g., subjects with unknown device MAC addresses. We then assign face and device observations to different subsets based on their belonging events $\mathcal{E} = \{e_j | j = 1, 2, \ldots, h\}$. An event e_j is the setting in which people interact with each other in a specific part of the environment for a given time interval. It is uniquely identified by three attributes: effective timeslot, location, and participants. Fig. 1 demonstrates a

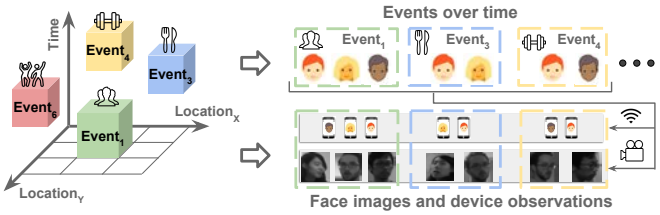

Figure 1: An illustrative example of *events* and showing their linked *observations*. An *event* is uniquely determined by spatial-temporal attributes and its participants. An event is also linked with two types of observations. Face observation are images cropped from surveillance videos and device observation are sniffed MAC address of participants' devices.

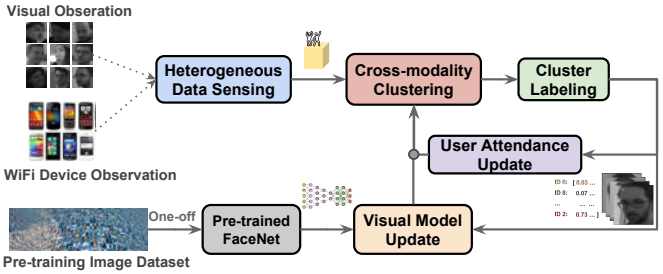

Figure 2: Workflow of AutoTune. AutoTune consists of 5 steps i) Heterogeneous Data Sensing ii) Cross-Modality Clustering iii) Cluster Labeling iv) Visual Model Update v) User Attendance Update. AutoTune sequentially repeats the above five steps until the changes in the user attendance are negligible.

few examples of events. Lastly, we also have a deep face representation model f_θ pre-trained on public datasets that contains no POI. Such model is trained with metric losses, e.g., triplet loss so that the learned features could bear a good property for clustering [26].

In this sense, the problem addressed by AutoTune is assigning IDs to images from noisy observations of images and WiFi MAC addresses, and using such learned ID-image associations to tune the pre-trained deep face representation model automatically.

3.2 System Architecture

AutoTune is based on two key observations: i) although collected by different modalities, both face images and device MAC addresses are linked with the identities of users who attend certain events; and ii) the tasks of model tuning and face-identity association should not be dealt with separately, but rather progress in tandem. Based on the above insights, AutoTune works as follows (see Fig 2):

- *Heterogeneous Data Sensing.* This module collects facial and WiFi data (device attendance observations) through surveillance cameras and WiFi sniffers[1] in a target environment. Given the face images and sniffed WiFi MAC addresses, AutoTune first segments them into events based on the time and location they were captured.
- *Cross-modality Labeling.* This module first clusters face images based on their appearance similarity computed by the face representation model, and also taking into account information on device attendance in events. Each image cluster should broadly correspond to a user, and the cluster's images are drawn from a set of events. We then assign each cluster to the user whose device has been detected in as similar as possible set of events.
- *Model Updates.* Once images are labeled with user identity labels, this module then fine-tunes the pre-trained face representation model. AutoTune further uses the cluster labels to update our belief on which device (MAC address) has participated in each event.

The sensing module is one-off and we will detail its implementation in §6.1. Labeling and model update modules are iteratively repeated until the changes in the user attendance model become negligible. The tuned model derived in the last iteration is regarded as the one best adapted to POI recognition in the new environment.

[1] https://www.wireshark.org/

4 CROSS-MODALITY LABELING

In this section, we introduce the labeling module in AutoTune. The challenge in this module is that collected facial images and sniffed WiFi data are temporally unaligned. For example, detecting a device WiFi address does not imply that the device owner will be captured by the camera at the exact instant and vice versa. Such mismatches in cross-modality data distinguish our problem from prior sensor fusion problems, where both multiple sensors are observing a temporal evolving system. In order to tackle the above challenge, we leverage the diverse attendance patterns in events and use a two-step procedure in isolated. Images $\mathcal{X}$ are firstly grouped together into clusters across all sessions, and we then associate clusters with device IDs (i.e., labels) $\mathcal{L}$ based on their similarity in terms of event attendance.

4.1 Cross-modality Clustering

Heterogeneous Features. Given a pre-trained face representation model f_θ, an image x_i can be translated to the feature vector $\mathbf{z}_i$. Unlike conventional clustering that merely depends on the face feature similarity, AutoTune merges face images *across events* into a cluster (potentially belonging to the same subject) by incorporating attendance information as well. Recall that device attendance already reveals the identities of subjects (in the form of MAC addresses) in a particular event, and the captured images in the same event may contain the faces of these subjects as well. Despite the noise in observations, the overlapped subjects in different events can be employed as a prior that guides the image clustering. For example, if there are no shared MAC addresses sniffed in two events, then it is very likely that the face images captured in these two events should lie in different clusters. Formally, for an event e_i, we denote a device attendance vector as $\mathbf{u}_k = (u_k^1, u_k^2, \ldots, u_k^m)$, where $u_k^j = 1$ if device l_j is detected in event e_k. In this way, we could construct a heterogeneous feature $\widetilde{\mathbf{z}}_i = [\mathbf{z}_i, \mathbf{u}_k]$ for an image x_i collected in the event e_k. Note that, as all images captured in a same event have the same attendance vector, this device attendance part are essentially enforced on cross-event image comparison.

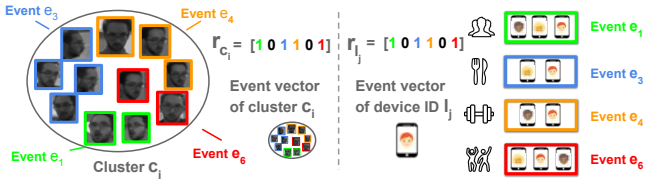

Figure 3: Event vectors of an image cluster c_i and device ID l_j. The kth element of the vector $r^k_{c_i}$ is set to 1 only if it contains images attached with the event e_k. The event vector $\mathbf{r}_{l_j}$ of the device ID l_j is similarly developed. This insight leads to Eq. 1.

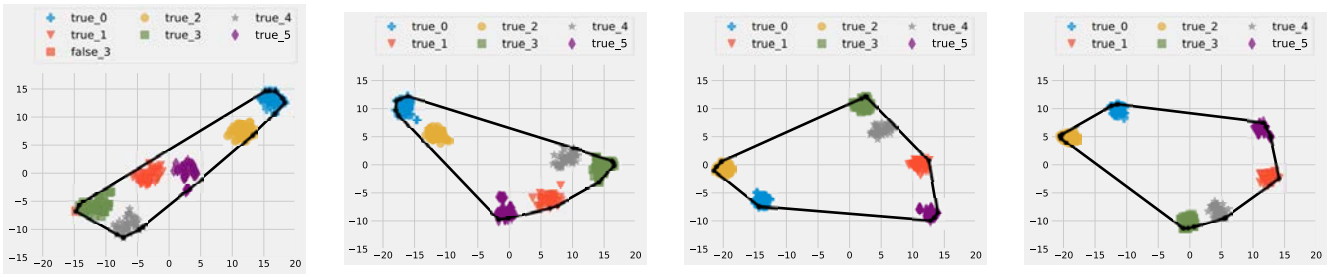
Face Image Similarity. Given an image x_i captured in event e_k (i.e., $\widetilde{\mathbf{z}}_i = [\mathbf{z}_i, \mathbf{u}_k]$) and an image x_j captured in event e_p (i.e., $\widetilde{\mathbf{z}}_j = [\mathbf{z}_j, \mathbf{u}_p]$), the likelihood that two cross-event face images belong to the same subject is conditioned on two factors: i) the similarity of their feature representation between $\mathbf{z}_i$ and $\mathbf{z}_j$; and ii) the overlap ratio between the attendance observations in their corresponding events $\mathbf{u}_k$ and $\mathbf{u}_p$ respectively. The resulted joint similarity is a log likelihood $log(\mathbf{Pr}(x_i = x_j))$ defined as follows:

$$\mathbf{Pr}(x_i = x_j) \propto \frac{exp(\beta * |\mathbf{u}_k \otimes \mathbf{u}_p|}{exp(\beta * |\mathbf{u}_k \oplus \mathbf{u}_p|)} * exp(-D(\mathbf{z}_i, \mathbf{z}_j))$$

$$log(\mathbf{Pr}(x_i = x_j)) \propto \beta * \underbrace{(|\mathbf{u}_k \otimes \mathbf{u}_p| - |\mathbf{u}_k \oplus \mathbf{u}_p|)}_{\text{attendance similarity}} - \underbrace{D(\mathbf{z}_i, \mathbf{z}_j)}_{\text{feature distance}}$$

Here $\otimes$ and $\oplus$ are element-wise AND and OR, and $|\cdot|$ here is the L^1-norm. z is the features transformed by the face representation model and D is a distance measure between face features. β, analogous to the regularization parameter in composite loss functions, is a hyper-parameter that controls the contributions of the attendance assistance and feature similarity. The above derivation is inspired by the Jaccard coefficients, with the difference lying in the log function. The rationale behind the term $|\mathbf{u}_k \oplus \mathbf{u}_p|$ is that the more different subjects attending events, the more uncertain that any two images drawn across these events will point to the same subject. In contrast, when the intersection $|\mathbf{u}_k \otimes \mathbf{u}_p|$ is significant enough, the chance that these two images point to the same subject will become higher. This joint similarity can also be explained from a Bayesian perspective. The attendance similarity of two events can serve as a prior that two cross-event images belong to the same subject and the feature similarity can be seen as the likelihood. Together they determine the posterior probability that two cross-event images fall into the same cluster. Based on the above joint similarity, images across events are grouped into clusters $C = \{c_i | i = 1, 2, \ldots, g\}$. We will soon discuss how to determine the number of clusters g based on the complete set of MAC addresses $\mathcal{L}$ in the next section.

4.2 Cluster Labeling



Fine-grained ID Association. After clustering, an image cluster is linked with multiple events that are associated with its member images. Naturally, we introduce an event vector $\mathbf{r}_{c_i} = (r^1_{c_i}, r^2_{c_i}, \ldots, r^h_{c_i})$ for for an image cluster c_i, where h is the total number of events. $r^k_{c_i}$ is set to 1 only if c_i contains images from event e_k. Fig. 3 shows an example of how an event vector is developed. Similarly, for a device ID l_j, its corresponding event vector $\mathbf{r}_{l_j} = (r^1_{l_j}, r^2_{l_j}, \ldots, r^h_{l_j})$ can be determined by inspecting its occurrences in all WiFi sniffing observations. $r^k_{l_j}$ is set to 1 only if the device ID (MAC address) l_j is detected in the event e_k. The intuition behind ID association is that a device and a face image cluster of the same subject should share the most consistent attendance pattern in events, reflected by the similarity of their event vectors. Based on this intuition, AutoTune assigns clusters with device IDs based on the matching level of their event vectors. Formally, a matching problem of bipartite graph can be formulated as follows:

$$\mathcal{L}_A = \sum_{ij} a_{ij} (\mathbf{r}_{c_i} - \mathbf{r}_{l_j})^2$$
$$\sum_{1 \le j \le m} a_{ij} = 1, \quad \forall i \in \{1, \ldots, g\} \tag{1}$$

where the solution of the binary variable a_{ij} assigns a device ID to a cluster. We note that when $m < g$, AutoTune adds dummy nodes to create the complete bipartite graph. Then the complete bipartite graph problem can be solved by the Hungarian algorithm [10].

Probabilistic Labeling via Soft Voting. We now obtain the association between face images and device IDs. However, in practice, the number of clusters g can vary due to the captured face images outside the POI, e.g., face images of short-term visitors. The choice of g has a significant impact on the performance of clustering [6] which could further affect the following fine-tuning performance. To cope with this issue, AutoTune sets the number of clusters g greater than the number of POI m. With a larger number of clusters, although there are some unused clusters of non-POI after clustering, the association step will sieve them and only choose the most consistent m clusters with the event logs of m device IDs. Lastly, for every image, its assigned ID is finalized by decision voting on the individual association results computed with different g, which will be soon introduced in the next paragraph. Typically, a majority voting procedure would give a hard ID label for an image and use these <Image, ID> pairs as training data to update the face representation model. However, due to the noise in device presence observations and errors in clustering, there will be mis-labeling in the training data that may confuse the model update. To account for the uncertainty of ID assignment, we adopt soft labels for voting. Then instead of voting for the most likely ID y_i for an image x_i, we introduce a probability vector $\mathbf{y}_i = (y_{i,1}, y_{i,2}, \ldots, y_{i,m})$. Specifically, every image is associated with all POI and its associated soft label is derived by the votes for the subjects divided by the total number of votes. In this way, the soft label of each image is a valid probability distribution that sums up to 1. For instance, $y_{i,j} = 0.4$ means that there are 40% associations assigning the ID j to the image i. Moreover, the soft labeled data $< x_i, \mathbf{y}_i >$ is compatible with the computation of cross-entropy.

Number of Clusters. We are now in a position to describe how to select the number of clusters g. We observed that, with a proper clustering algorithm (i.e., agglomerative clustering in our choice), non-POI's images will form separate small clusters but they will not be chosen in our follow-up association step. This is because that the number of devices ID m is always less than the number of clusters ($g \in [2 * m, 5 * m]$), and only those images clusters with the most consistent event attendances are associated. The small clusters of

(a) Pre-trained Model (b) 1st iteration (c) 2nd iteration (d) 3rd iteration

Figure 4: An example of visual model update (§5.1) in AutoTune with a six-subject subset. Note that the pre-trained model in Fig. 4a has a narrow convex hull (black lines), clusters are dispersed and there is mis-classification (see false_3 in Fig. 4a) as the pre-trained features are not discriminative enough to differentiate unseen subjects in a new environments. Over time, clusters become more compact and move further away from each other, leading to purer clustering results.

outlier images often have scatted attendance vector and will be ignored in association. Therefore, soft voting with varying number of clusters can reinforce the core images of POI by giving large probability and assigns non-POI's images with small probability.

5 MODEL UPDATES

We are now in a position to introduce the model update in AutoTune. At every iteration, AutoTune updates the last-iteration face representation model f_θ^τ to $f_\theta^{\tau+1}$, by taking the labeled images as inputs. To correct the device observation errors, AutoTune leverages these label images to update device attendance vector to $\mathbf{u}^\tau$ for all events.

5.1 Visual Model Update

Discriminative Face Representation Learning. Face representation learning optimizes a representation loss $\mathcal{L}_R$ to enforce the learnt features as discriminative as possible. Strong discrimination bears two properties: inter-class dispersion and intra-class compactness. Inter-class dispersion pushes face images of different subjects away from one another and the intra-class compactness pulls the face images of the same subject together. Both of the properties are critical to face recognition. At iteration τ, given the current labels y_i^τ for the ith face image x_i and the transformed features $\mathbf{z}_i^\tau = f_\theta^\tau(x_i)$, the representation loss $\mathcal{L}_R$ is determined by a composition of softmax loss and center loss:

$$\begin{aligned}\mathcal{L}_R &= \mathcal{L}_{softmax} + \mathcal{L}_{center} \\ &= \underbrace{\sum_i -log(\frac{e^{W_{y_i^\tau}^T \mathbf{z}_i^\tau + \mathbf{b}_{y_i^\tau}}}{\sum_{j=1}^m e^{W_{l_j}^T \mathbf{z}_i^\tau + \mathbf{b}_{l_j}}})}_{\text{softmax loss}} + \underbrace{\sum_i \frac{\lambda}{2}||\mathbf{z}_i^\tau - \mathbf{o}_{y_i^\tau}||^2}_{\text{center loss}} \end{aligned} \quad (2)$$

where W and b are the weights and bias parameters in the last fully connected layer of the pre-trained model. $\mathbf{o}_{y_i^\tau}$ denotes a centroid feature vectors by averaging all feature vectors with the same identity label y_i. The center loss $\mathcal{L}_{center}$ explicitly enhances the intra-class compactness while the inter-class dispersion is implicitly strengthened by the softmax loss $\mathcal{L}_{softmax}$ [37]. λ is a hyper-parameter that balances the above sub-losses.

Stochastic Center Loss The center loss $\mathcal{L}_{center}$ in Eq. 2 is shown to be helpful to enhance the intra-class compactness [37]. However, we cannot directly adopt it for fine-tuning as computing the centers requires explicit labels (see Eq. 2) of images, while the association steps above only provide probabilistic ones through soft labels. To solve this, we propose a new loss called *stochastic center loss* $\mathcal{L}_{stoc}$ to replace the center loss. Similar to the idea of fuzzy sets [38], we allow each face image to belong to more than one subject. The membership grades indicate the degree to which an image belongs to each subject and can be directly retrieved from the soft labels and the stochastic center $\mathbf{o}_k^\tau$ for the k-th identity is given as:

$$\mathbf{o}_k^\tau = \frac{\sum_i^n \mathbf{z}_i^\tau * y_{i,k}^\tau}{\sum_i^n y_{i,k}^\tau} \quad (3)$$

This gives the stochastic center loss as follows:

$$\mathcal{L}_{stoc} = \sum_i \sum_k y_{i,k}^\tau * ||\mathbf{z}_i^\tau - \mathbf{o}_k^\tau||^2 \quad (4)$$

We leave the softmax loss $\mathcal{L}_{softmax}$ the same as in Eq. 2, because the soft labels are compatible with the computation of cross-entropy. The new representation loss to minimize is:

$$\mathcal{L}_R = \mathcal{L}_{softmax} + \mathcal{L}_{stoc} \quad (5)$$

AutoTune updates the model parameters θ^τ to $\theta^{\tau+1}$ based on the gradients of $\nabla_\theta \mathcal{L}_R$, which are calculated via back prorogation of errors. Compared with the dataset used for pre-training, which is usually in the order of millions [4], the data used for fine-tuning is much smaller (several thousands). The mis-match between the small training data and the complex model architecture could result in overfitting. To prevent overfitting, we use the dropout mechanism in training, which is widely adopted to avoid overfitting [13]. Meanwhile, as observed in [8, 25], the soft label itself can play the role of a regularizer, and make the trained model robust to noise and reduce overfitting. Fig. 4 illustrates the effect of model update.

5.2 User Attendance Update

The device presence observations by WiFi sniffing are noisy because the WiFi signal of a device is opportunistic and people do not carry/use theirs devices all the time. Based on the results of the cluster labelling step introduced in §4.2, we have the opportunity to update our belief on which users attended each event. The update

  for $g \leftarrow 2 * m$ *to* $5 * m$ **do**
    $C^\tau \leftarrow$ `cross_modality_clustering`$(\mathcal{Z}^\tau, \mathbf{u}^\tau, g)$ ▷ §4.1;
    $A_g^\tau \leftarrow$ `cluster_labeling`$(C^\tau, \mathbf{r}_c^\tau, \mathbf{r}_l^\tau)$ ▷ §4.2;
  end
  $\mathcal{Y}^\tau \leftarrow$ `soft_voting`(A^τ) ▷ §4.2;
  $\mathbf{o}^\tau \leftarrow$ `stochastic_center`$(\mathcal{Y}^\tau, \mathcal{Z}^\tau)$ ▷ §5.1;
  $f_\theta^{\tau+1} \leftarrow$ `visual_model_update`$(\mathcal{X}, \mathcal{Y}^\tau, \mathbf{o}^\tau, f_\theta^\tau)$ ▷ §5.1 ;
  $\mathbf{u}^{\tau+1} \leftarrow$ `user_attendance_update`$(\mathcal{Y}^\tau, \mathbf{u}^\tau)$ ▷ §5.2 ;
  $\tau \leftarrow \tau + 1$
end

mechanism is as follows: Each image is associated with a user probability vector, whose elements denote the probability that the image correspondences to a particular user. By averaging the user probability vectors of all images that have been drawn from the same event e_k, and normalizing the result, we can estimate the user attendance of this event. The elements of the resulting user attendance vector $\widehat{\mathbf{u}}_k^\tau$ denote the probabilities of different users attending event e_k.

We can now use $\widehat{\mathbf{u}}_k^\tau$ as a correction to update our previous wifi attendance vector $\mathbf{u}_k^\tau$ as follows:

$$\mathbf{u}_k^{\tau+1} = \mathbf{u}_k^\tau - \gamma \cdot (\mathbf{u}_k^\tau - \widehat{\mathbf{u}}_k^\tau) \tag{6}$$

where γ is a pre-defined parameter that controls the ID update rate. In principle, a large update rate will speed up the convergence rate, at the risk of missing the optima. `AutoTune` sequentially repeats the above steps of clustering, labelling and model updates, until the changes ξ in the user attendance model are negligible (≤ 0.01 in our case). Algorithm. 1 summarizes the workflow.

6 IMPLEMENTATION

In this section, we introduce the implementation details of `AutoTune` (code available at https://github.com/Wayfear/Autotune).

6.1 Heterogeneous Data Sensing

Face Extraction. This module consists of a front-end remote camera and a back-end computation server [2]. Specifically, the remote cameras in our experiment are diverse and include *GoPro Hero 4*[3], *Mi Smart Camera*[4] and *Raspberry Pi Camera*[5]). We modified these cameras so that they are able to communicate and transfer data to the back-end through a wireless network. To avoid capturing excess data without people in it, we consider a motion-triggered mechnism with a circular buffer. It works by continuously taking low-resolution images, and comparing them to one another for changes caused by something moving in the camera's field of view. When a change is detected, the camera takes a higher-resolution video for 5 seconds and reverts to low resolution capturing. All the collected videos are sent to the backend at every midnight. On the backend, a cascaded convolutional network based face detection module [39] is used to drop videos with no face in them. The cropped faces from the remaining videos are supplied to `AutoTune`.

WiFi Sniffing. This module is realized on a WiFi-enabled laptop running Ubuntu 14.04. Our sniffer uses Aircrack-ng [6] and tshark [7] to opportunistically capture the WiFi packets in the vicinity. The captured packet has unencrypted information such as transmission time, source MAC address and the Received Signal Strengths (RSS). As `AutoTune` aims to label face images for POI, our WiFi sniffer only records the packets containing MAC addresses of POI's and discards them otherwise, so as to not harvest addresses from people who have not given consent. A channel hop mechanism is used in the sniffing module to cope with cases where the POI's device(s) may connect to different WiFi networks, namely, on different wireless channels. The channel hop mechanism forces the sniffing channel to change by every second and monitor the active channels periodically (1 second) in the environment. The RSS value in the packet implies how far away the sniffed device is from the sniffer [18, 19]. By putting the sniffer near the camera, we can use a threshold to filter out those devices with low RSS values, e.g., less than -55 dBm in this work, as they are empirically unlikely to be within the camera's field of view.

Event Segmentation. Depending on the context, the duration of events can be variable. However, for simplicity we use fix-duration events in this work. Specifically, we split a day into 12 intervals, each of which is 2 hours long. We then discard those events that have neither face images nor sniffed MAC addresses of POI.

6.2 Face Recognition Model

The face recogonition model used in `AutoTune` is the state-of-the-art FaceNet [26].

Pre-training. FaceNet adopts the Inception-ResNet-v1 [29] as its backbone and its weights are pre-trained on the VGGFace2 dataset [4]. This dataset contains 3.31 million images of 9131 subjects, with an average of 362.6 images for each subject. Images are downloaded from Google Image Search and have large variations in pose, age, illumination, ethnicity and profession. Pre-training is supervised by the triplet loss [5] and the training protocols, e.g, parameter settings, can be found in [26]. We found that the learnt face representation by FaceNet is generalizable and it is able to achieve an accuracy of 99.65% on the LFW face verification task [8]. Note that, FaceNet [26] not only learns a powerful recognition model but gives a very discriminative feature representation that can be used for clustering.

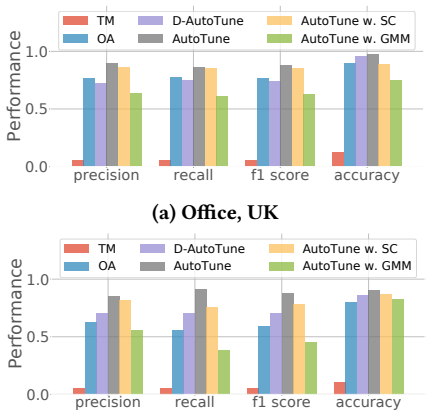
Fine-tuning by AutoTune. The fine-tuning process has been explained in §5.1, and here we provide some key implementation detials. After each round of label association (see §4.2), the labeled data is split into a training set and validation set, with a ratio of $8:2$ respectively. The pre-trained FaceNet is then fine-tuned on the training set, and the model that achieves the best performance on the validation set is saved. Note that the fine-tuning process in AutoTune does not involve the test set. The online testing is performed on a held-out set that is collected on different days. To enhance the generalization ability, we use dropout training for regularization [35]. The dropout ratio is set to 0.2. We set the batch size to 50 and one fine-tuning takes 100 epochs.

6.3 System Configuration

Face Detection. As discussed in §6.1, we use a cascaded convolution network to detect faces in videos. It is cascaded by three sub-networks, a proposal network, a refine network and an output network. Each of them can output bounding boxes of potential faces and the corresponding detection probabilities, i.e., confidences. Face detection with small confidence will be discarded early in the process and not sent to the next sub-network. In this work, the confidence threshold is set to 0.7, 0.7 and 0.9 for three sub-networks respectively. Following the original setting in [39], we set the minimal face size in detection to 40×40 pixels.

Setup of Face Clustering. In §4.1, we use a clustering algorithm to merge the images across events. Specifically, the clustering algorithm used in AutoTune is agglomerative clustering [2], which is a method that recursively merges the pair of clusters that minimally increases a given linkage distance. The similarity metric adopted here is Euclidean distance. A linkage criterion determines which distance to use between sets of data points. In AutoTune, this linkage criterion is set to the average distances of all sample pairs from two sets. As introduced in Sec. 4.2, the number of clusters g is determined by the number of POI m. We vary g from $2 * m$ to $5 * m$ and proceed soft voting, to account for the extra clusters of non-POI's face images and ambiguous/outlier images of POI.

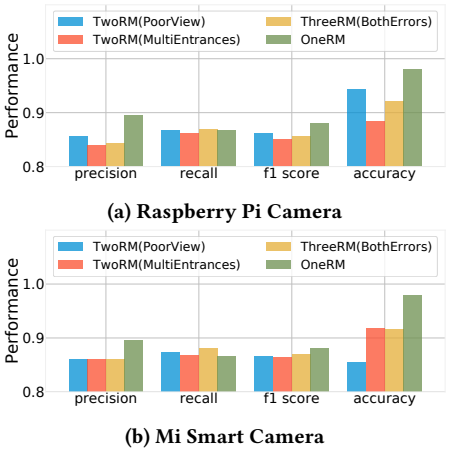


7 EVALUATION

In this section, we evaluate the AutoTune extensively on datasets collected from both real-world experiments and simulation. We deployed two testbeds, one in the UK and the other in China, and collected datasets as described in the previous section. The simulation dataset is developed based on a public face datasets.

7.1 Evaluation Protocols

Competing Approaches. We compare the performance of AutoTune with the 3 competing approaches:



- **Template Matching (TM)** [3] employs a template matching method to assign ID labels to clusters of face images. This is the most straightforward method that is used when one or more profile photos of POI are available, e.g., crawled from their personal homepage or Facebook.
- **One-off Association (OA)** [16] uses one-off associations to directly label the image clusters without fine-tuning of the face representation model itself.

(a) Office, UK

(b) CommonRoom, CHN

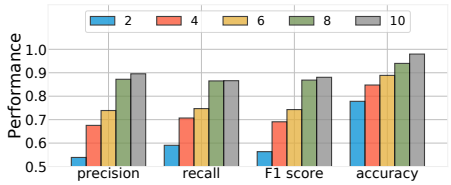
Figure 5: Overall Labeling Performance.

(a) Raspberry Pi Camera

(b) Mi Smart Camera

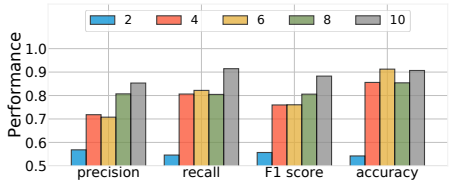
Figure 6: Performance of Scalability.

- **Deterministic AutoTune (D-AutoTune)** is the deterministic version of AutoTune. In D-AutoTune, the association and update steps are the same as in AutoTune, but it adopts hard labels rather than soft labels and uses the simple center loss instead of the proposed stochastic center loss (see §5.1).



Evaluation Metrics. AutoTune contains two main components, offline label assignment and online inference. For the offline label assignment, we evaluate its performance with the following metrics: TP, TN, FP, FN are true positive, true negative, false positive and false negative respectively. Each metric captures different aspects of classification [24]. Online face recognition has two kinds of tests, face identification and verification. We follow [14, 15] to use Cumulative Match Characteristic (CMC) for the evaluation of online face identification.

7.2 Offline Cross-modality Face Labeling



AutoTune automatically labels images captured in the wild by exploiting their correlations with the device presences. The quality of image labeling is crucial for the follow-up face recognition in

Table 1: Key Metrics of Collected Dataset Sets.

Site	NO. of Rooms	NO. of POI	NO. of non-POI	NO. of Images	NO. of Events	Event Duration	Average subjects/event	Camera(s) in rooms	Experiment Note

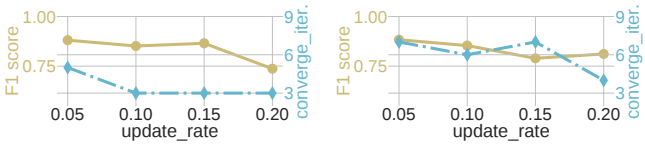
Figure 7: Impact of Number of Days.

the online stage. In this section, we investigate the image labeling performance of AutoTune.

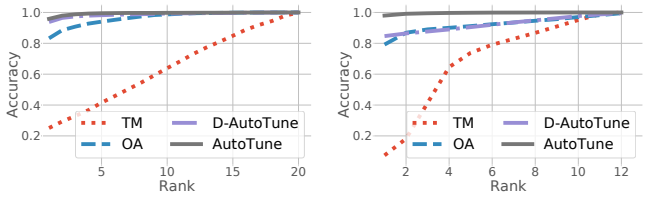
7.2.1 Data Collection. We deployed AutoTune at the testbeds in two countries, with different challenging aspects.



UK Site: This first dataset is collected in a commercial building in the UK. We deploy the heterogeneous sensing front-ends, including surveillance cameras and WiFi sniffers, on a floor with three different types of rooms: office, meeting room and kitchen. 24 long-term occupants work inside can freely transit across these rooms. These occupants are naturally chosen as people of interest (POI). For the office, face images are captured with a surveillance camera that faces the entrance. The presence logs of occupants' WiFi MAC addresses are collected by a sniffer that is situated in the center of the room for the same time period. Besides the POI's faces, these images also contain the faces of 11 short-terms visitors who came to this floor during the experiments. We put different cameras in different rooms to examine the performance of AutoTune under camera heterogeneity. To further examine the resilience of AutoTune, we put cameras in adversarial positions. In kitchen, we deploy cameras with bad views near entrance so that they can only capture subjects above 1.7m. While in the meeting room with two entrances, only the primary entrance is equipped with cameras. Therefore in both rooms cameras constantly *mis-capture* face images of subjects. Tab. 1 summarizes this data collection.

CHN Site: We collect another dataset in a common room of a university in China. There are no long-term occupants in this site and all undergraduates can enter. Of the 37 people that appeared during the three week period, 12 subjects are selected as the POI, and their WiFi MAC address presence is continuously recorded by the sniffer. Other settings remain the same as the UK site. The challenge in this dataset lies in that the captured face images, both for POI and non-POI, are all of Asian people, while the initial face representation model is trained primarily on Caucasians. Details of the CHN dataset are given in Tab. 1. Observation noises are very common in this dataset.

7.2.2 Overall Labeling Performance. We start our evaluation with one room only and compare our results with baselines. Fig. 5 shows the performance of label assignment, i.e., matching an identifier to a face image. For the office dataset, AutoTune outperforms the best competing approach (OA), by 0.13 in F_1 score and 7% in accuracy. The advantage of AutoTune is more obvious in the CommonRoom experiment where it beats the best competing approach (OA) by 0.34 in F_1 score and 10% in accuracy. As the only method that uses the website images (one-shot learning) to label images rather than the device ID information, TM struggles in both experiments and is 9-fold worse than AutoTune. We observe that the website face images are dramatically different from the captured images in real-world, due to different shooting conditions and image quality. These results imply that, although the device observations via WiFi sniffing are noisy, when the amount of the them is enough, they are more informative than the web-crawled face images.



Additionally, we note that adopting soft labels (see §4.2) can further improve the labeling performance. In terms of F_1 score, the full-suite AutoTune is around 15% and 22% better than D-AutoTune in the two experiments respectively. Similar improvements are witnessed in terms of the accuracy. The reason of the larger performance gap in the CommonRoom dataset is that there are more images of non-POI being captured in this experiment. In addition, the pre-trained FaceNet model does not generalize very well to Asian faces, which are the primary ethnicity in the CommonRoom.

Lastly, we found that the choice of algorithm for cross-event clustering affects the final label-association accuracy. The best performance is achieved with the default agglomerative clustering algorithm on both datasets. The second-best spectral clustering (SC) is slightly inferior to agglomerative clustering in the office dataset, though the gap between them gets large in the CommonRoom dataset. The Gaussian Mixture Model (GMM) is inferior to the other two clustering algorithms. This is because GMM is best suited to Mahalanobis-distance based clustering whereas the distance space defined in Eq. 4.1 is a non-flat space due to the introduced attendance information. Hence, its resultant clusters are very impure and give poor association performance.

(a) UK (b) CHN

Figure 8: Impact of ID update rate β (introduced in §5.2). It can be seen that a high update rate causes the network to converge rapidly to potentially incorrect assignments.

(a) UK (b) CHN

Figure 9: Online Identification Performance

7.2.3 Performance vs. Scalability. We further examine AutoTune with multiple rooms under different adversarial conditions. Together with the *UK office* data, we evaluate AutoTune when events are collected in three different locations and via heterogeneous cameras. In particular, a kitchen and a meeting room are included and each of them has two lower-fidelity cameras (Mi Home Camera and Raspberry Pi Camera). The setup of multi-location experiments is given in Tab. 1. As described in §7.2.1, there are many face misdetections in the kitchen and meeting room due to the adversarial camera setups. Nevertheless, as shown in Fig. 6, AutoTune only suffers little performance drop (≤ 0.03) when erroneous camera observations are mixed with the single-office data. In terms of F1 score, which is the most important metric, AutoTune can achieve comparable level with the office experiment, regardless of which camera is added. Moreover, AutoTune still maintains its good performance even in the most adversarial case, where both errors are mixed in (three-room experiment). The main reason is that by using more data, though noisy, extra validation constraints are also utilized by AutoTune and make itself robust to observation errors.

7.2.4 Performance vs. Lifespan. AutoTune exploits co-located device and face presence in different events to establish the cross-modality correlations. In this section, we investigate the impact of the collection span on the performance of labeling. Longer collection days give more events. We investigate its impact by feeding AutoTune with data collected in different number of days, and compare them with all days on two datasets respectively. Fig. 7 shows that AutoTune performs better with increasing number of days on both datasets. The gap of F_1 score between the case with all days (10 days) and case with the least amount of days (2 days) can be as large as > 0.32 on both datasets. As discussed in §4.2, the ID association needs sufficiently diverse events to create discriminative enough event vectors. Otherwise, there will be faces or devices with the same event vectors that hinders AutoTune's ability to disambiguate their mutual association. However, we also observe that when we collect more than 8 days, the performance improvement of AutoTune becomes marginal.

7.2.5 Impact of ID update rate β. This section investigates the impact of ID update rate β introduced in §5.2. The ID update uses the fine-tuned face recognition model to update the device ID observations. A large ID update rate forces the device ID observations to quickly become consistent with the deep face model predictions. However, a large update rate also runs the risk of missing the optima. We vary the update rate β from 0.05 to 0.20 at a step length of 0.05. Fig. 8a demonstrates that AutoTune achieves the best performance on the UK dataset when the update rate is set to 0.05. The performance declines by 10% when the rate rises to 0.2. This is because the updated ID observations quickly become the same as the model predictions and the model predictions are not quite correct yet. When it comes to CHN dataset (see Fig. 8b), similar trend of F_1 score change can be seen. Although overall, the convergence becomes faster when the update increases, we observe that there is a fluctuation point at the update rate of 0.15, where AutoTune takes 7 iterations to converge. By inspecting the optimization process, we found that, under this parameter setting, AutoTune oscillated because the large update step makes it jump around in the vicinity of the optima but it is unable to approach it furthermore. In practice, we suggest users of AutoTune to select their update rate from a relatively safe region between 0.05 to 0.1.

7.3 Online Face Identification

7.3.1 Setup. After the cross-modality label association, an image database of POI is developed and an online face recognition system can be trained based on it. As in [26], we use the face representation model to extract face features and then use a classifier, say linear SVM in this work, to recognize faces. Particularly, as AutoTune and D-AutoTune are able to update the face representation model in their labeling process, the feature extractor for them are the updated model by themselves. For competing approaches that do not have an evolving model updates, we use the original Facenet model (in §6.2) as to extract face features and train the same classifier on the developed image-identity database by themselves. Without any overlapping with the images used for labeling, the test sets are collected in different days. In total, the test set contains 5,580 face images collected in the UK and 2,840 face images collected in China.

7.3.2 Performance. Fig. 9 compares the face identification results of both AutoTune and the competing approaches. Face identification is a multi-class classification task and aims to find an unknown person in a dataset of POI. As we can see, by using the face database developed by AutoTune, the identification accuracy quickly saturates and is able to have no errors within three guesses (rank-3) on both datasets. For the UK dataset where there are 20 POI, the rank-1 accuracy of AutoTune can be as high as 95.8% and outperforms the best competing approach (OA) by 12.5%. The advantage of AutoTune is more significant on the CHN dataset, and it surpasses the best competing approach OA by $\sim$ 19% (98.0% vs 79.1%). In addition, although D-AutoTune's performance is inferior to AutoTune, it is still more accurate than competing approaches, especially on

the UK dataset. We note that these results are consistent with face labeling results in §7.2.2. Overall, face identification by AutoTune are highly accurate, considering that AutoTune is only supervised by the weak and noisy device presence information.

7.4 Sensitivity Analysis

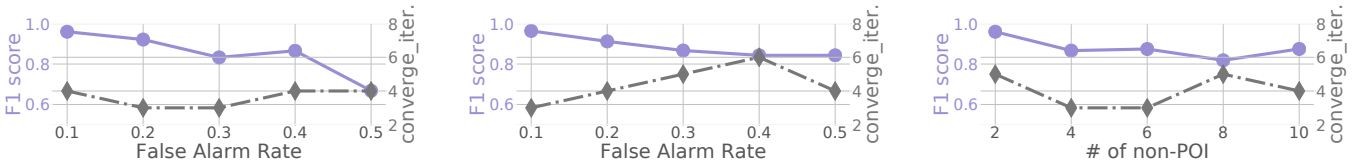
To further study the performance of AutoTune under different noise conditions, we also conduct extensive sensitivity analysis via simulation, considering three types of noise that are common in real-world settings:
False-alarm Faces is the case that the number of detected faces of POI is *greater than* the number of distinct sniffed MAC addresses.
False-alarm Devices is the case that the number of detected faces of POI is *smaller than* the number of distinct sniffed MAC addresses.
Non-POI Disturbance is the case that there are detected faces that belong to a non-POI, whose MAC address are not in our database i.e. they should be discarded as an outlier.

7.4.1 Data Synthesis. Although a number of public databases of face images are available, unfortunately, none of them come with device presence observations, i.e., sniffed MAC addresses. As an alternative, we develop a synthetic dataset on top of the widely used PIE face database[9]. In total 40 subjects are randomly selected, in which 30 of them are POI and the rest are mixed in to make the dataset realistic. We then assign to these "events" noisy identity observations to simulate device presence information. Based on different types of noise, different synthetic datasets are generated on which AutoTune is examined. On average, each subject in our simulation has 168 images after data augmentation [12]. As there is no actual device presence, we simulate this by first randomly placing the face images into different "events", in which multiple subjects "attend". As the number of images of subjects might be skewed in events, we adopt the F_1 score as the metric to evaluate the AutoTune's performance.

7.4.2 False-alarm Faces. WiFi sniffing is an effective approach to detect the presence of users' mobile devices, however, such detection is not guaranteed to perfectly match the user's presence. For instance, a device could be forgotten at home, be out of battery or simply the WiFi function might be turned off. In the simulation, we vary the error rate of such false alarm faces from 0.1 to 0.5. Error rate at 0.1 means that on average, 10% of the detected faces in each event are false detections. Fig. 10a shows the F_1 score and convergence iterations of AutoTune under different levels of such noises. As we can see AutoTune tolerates false-alarm faces well and is able to keep the F_1 score above 0.83 when the false alarm rate is below 0.4, though it degrades to 0.67 when the rate rises up to 0.5. However, we found such case, i.e., on average half of WiFi MAC addresses are missed in all meetings, is rare in the real-world. Finally, we found that false-alarm faces do not affect the convergence and AutoTune quickly converges within 4 iterations in all the cases.

7.4.3 False-alarm Devices. Though surveillance cameras are becoming increasingly ubiquitous, there are cases where the subjects are not captured by the cameras e.g. duto occlusions. This becomes an instance of device false alarm, if her device MAC address is still sniffed. We vary the rate of such false alarm devices from 0.1 to 0.5, where 0.1 means that on average, 10% of the detected devices in each event are false detections. Fig. 10b shows that although the F_1 score of AutoTune decreases, it degrades slowly and stops at 0.84 after the false-alarm rate becomes 0.5. As the injected noise becomes stronger, AutoTune needs more iterations to converge. However, the largest convergence iteration is still below 7 (rate at 0.4). Overall, AutoTune is very robust to such type of noises.

7.4.4 Non-POI Disturbance. Non-POI disturbance happens when subjects without registered MAC addresses are captured by the camera. We found such noise dominates all the three types of errors. We vary the number of non-POI from 2 to 10 and the probability of each non-POI's presence in an event is set to 0.1. Fig. 10c shows that AutoTune does not suffer much from mild disturbance (2 non-POI), and the F_1 score drops slowly to 0.87 with larger disturbance (4 non-POI). In addition in all cases AutoTune quickly converges within 5 iterations.



8 DISCUSSION AND FUTURE WORK

This section discusses some important issues related to AutoTune.
Overheads: Compared with conventional face recognition methods, AutoTune incurs overheads due to FaceNet fine-tuning. In our experiment, fine-tuning is realized on one NVIDIA K80 GPU. One fine-tuning action takes around 1.2 hours and 0.5 hours for the UK dataset and CHN dataset respectively. As we discusses in §7.2, AutoTune is able to converge within 5 iterations for most of the time, depending on the hyper-parameter setting. Therefore, fine-tuning overheads can be controlled in 7 hours for the UK dataset and 2.5 hours for the CHN dataset. Compared to the FaceNet pre-training that takes days and requires more GPUs, the fine-tuning costs of AutoTune is much cheaper. In future work, we will look into an online version of AutoTune, which can incrementally fine-tune the network on the fly when the data is streaming in.
Privacy: In practice, AutoTune requires face images and device ID of users to operate, which may have certain impacts on user privacy. For example, a user could be identified without explicit consent in a new environment, if the owner has the access to the face image of this user. In this work, we do not explicitly study the attack model in this context, we note that potential privacy concerns are worth exploring in future work.

9 CONCLUSION

In this work, we described AutoTune, a novel pipeline to simultaneously label face images in the wild and adapt a pre-trained deep neural network to recognize the faces of users in new environments. A key insight that motivates it is that enrolment effort of face labelling is unnecessary if a building owner has access to a wireless identifier, e.g., through a smart-phone's MAC address. By learning and refining the noisy and weak association between a user's smart-phone and facial images, AutoTune can fine-tune a deep neural network to tailor it to the environment, users, and conditions of a particular camera or set of cameras. Particularly, a novel soft-association technique is proposed to limit the impact of erroneous decisions taken early on in the training process from corrupting the clusters.Extensive experiment results demonstrate

ABSTRACT

User behaviors are widely used as implicit feedbacks of user preferences in personalized information systems. In previous works and online applications, the user's click signals are used as positive feedback for ranking, recommendation, evaluation, etc. However, when users click on a piece of low-quality news, they are more likely to have negative experiences and different reading behaviors. Hence, the ignorance of the quality effects of news may lead to the misinterpretation of user behaviors as well as consequence studies. To address these issues, we conducted an in-depth user study in mobile news streaming scenario to investigate whether and how the quality of news may affect user preferences and user behaviors. Firstly, we verify that quality does affect user preferences, and low-quality news results in a lower preference. We further find that this effect varies with both interaction phases and user's interest in the topic of the news. Secondly, we inspect how users interact with low-quality news. Surprisingly, we find that users are more likely to click on low-quality news because of its high title persuasion. Moreover, users will read less and slower with fewer revisits and examinations while reading the low-quality news.

Based on these quality effects we have discovered, we propose the Preference Behavior Quality (PBQ) probability model which incorporates the quality into traditional behavior-only implicit feedback. The significant improvement demonstrates that incorporating quality can help build implicit feedback. Since the importance and difficulty in collecting news quality, we further investigate how to identify it automatically. Based on point-wise and pair-wise distinguishing experiments, we show that user behaviors, especially reading ratio and dwell time, have high ability to identify news quality. Our research has comprehensively analyzed the effects of quality on user preferences and behaviors, and raised the awareness of item quality in interpreting user behaviors and estimating user preferences.

1 INTRODUCTION

User preference has been widely used as a critical concept in personalized information system [13, 28]. Yet, it is difficult to acquire due to its subjective nature. The most direct way is to ask users to give explicit feedback, for example, the rating in e-commerce websites [30, 38]. However, because of the difficulty and the potential biases [24] in its collection in real-world applications, commercial information systems have exploited implicit feedback signals derived from user behaviors. Most commonly, users' clicking on the item have been used as implicit feedback of document relevance [1, 16] and user experiences [19]. In addition to the click signal, dwell time (i.e. the time that user spends on a clicked item) has also been found well correlated with document relevance [35], item-level satisfaction [9, 12, 20] and user preferences [6]. A click followed by a long dwell time has traditionally been seen as satisfied click and been widely used in a number of retrieval applications [9, 11]. Other behaviors, like mouse movement [27], scroll information [22], and gaze [2, 25] are also investigated for inferring user experiences.

However, user behaviors have been proved to be informative but noisy. Click behavior is found to be affected by many factors, like position [16], trust [37], and presentation [34]. Moreover, dwell time is also found related to the content length [36], readability [21]and search task [18].

The credibility of the behaviors may also be related to the item quality. For example, as shown in Figure 1, two pieces of news with different levels of quality are both clicked by the user. The low-quality news is more likely to be disliked by the user after reading its poor content. As a result, although user clicking on both news, his/her preference is significantly different because of the

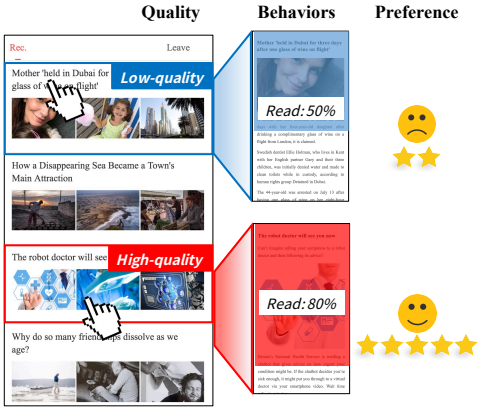

Figure 1: User clicking on items may have different behaviors (e.g. reading ratio) and different preferences because of the different levels of quality.

quality. Thus, traditional implicit feedback may yield imprecise user preference modelling because of the ignorance of the quality effect. To the best of our knowledge, there still lacks comprehensive understanding of how item quality affects user preference and user behaviors, which is important for modeling user preference and utilizing user behaviors. In this paper, we study the quality effects and aim to address the following questions:

- **RQ1**: Does quality affect user preferences? If yes, how?
- **RQ2**: Does quality affect user behaviors during the browsing and reading process? If yes, how?
- **RQ3**: Can incorporating quality help build implicit feedback?
- **RQ4**: Can we identify quality based on user behavior signals?

We conduct an in-depth user study in online news reading scenario on the mobile device. At the beginning of the study, we collected user's interest in the topics. After that, users are asked to read several lists which contains the news of different levels of quality. In this process, we collected their behaviors as well as explicit feedback for experiences, including the perception of quality and the preferences for the news.

As for RQ1, by comparing user preferences for low-quality and high-quality news, we find that lower quality leads to a lower user preference. From this, we further analyze the degree of quality effect, measured by the difference of user preferences between low-quality and high-quality news, and find it is related to the interaction phases and user's interest for the news topic. On the one hand, from before-read phase to after-read phase, the quality effects increase. On the other hand, the quality effect is much larger when the user is more interested in the news topic.

Besides the effects on user preferences, we further investigate the quality effects on user behaviors (RQ2). From the comparison of click behaviors, we find that users have higher probability to click the low-quality news. Part of the explanation may be the higher title persuasion of the low-quality news. This effect is more distinct when a user has higher interest in the topic of the news. Furthermore, we find that a user's reading behaviors after clicking are also influenced by the news quality. Users will read less in the low-quality news, as shown by the reduction of *dwell time* and *reading ratio*. They will also have fewer revisits and examinations. These quality effects promote us to re-think the implicit feedback (RQ3).

Traditional implicit feedback relies on the relation between user preferences and user behavior. Because of our findings about quality effects on user preferences and behaviors, we further take the quality and its effects into consideration, and propose a probability model to estimate user preference. The out-performance of the proposed model demonstrates that it is helpful to incorporate quality into implicit feedback building.

Considering the usefulness but the hard annotation of quality, it is valuable to automatically identify news quality (RQ4). We examine the point-wise and pair-wise distinguishing ability of each behavior, and confirm the possibility of using user behavior signals, like reading ratio and dwell time, to identify the quality of news.

The rest of the paper is organized as follows. Section 2 reviews related work. Section 3 introduces the methodology of our user study and collected measurements. Section 4 studies the quality effects on user preferences (RQ1). The analysis of the quality effect on user behaviors (RQ2) is given in Section 5. Section 6 investigates the usage of quality for improving the implicit feedback building (RQ3). Section 7 discusses the possibility of utilizing behaviors to identify quality (RQ4). Finally, Section 8 summarizes the conclusion and future work.

2 RELATED WORK

In this section, we review two related research directions, the modeling of user item-level experiences and the analysis of user behaviors.

2.1 User Item-Level Experience Modeling

Modeling user item-level experiences is a fundamental work for implicit feedback building and performance evaluation in information system. Some previous works have paid attention to this direction, such as modeling user perceived usefulness in web search and user preferences in recommender systems.

Belkin et al. [4] argue that usefulness, which represents users' perceived value of a search result, depend on the scenario and context of accessing the result. Mao et al. [29] also find that usefulness is related to current search task and redundancy with previous documents read by the user. Jiang et al. [15] have collected usefulness judgment not only in situ stage but also post-session context-independent judgment, and find that they are different, indicating that context will affect user perception of usefulness.

Compared with the usefulness, user preference is more personalized and subjective, making it hard to model it. Lu et al. [28] model user preference as a dynamic concept varying in different interaction phases, and found that the change of preference after user reads the news content is related to the news quality. Their work provides a good starting point for modeling user preferences with item quality, but more in-depth researches still remains to be studied. We go further to analyze the quality effect on user preferences jointly with interaction phases and user topic interest, examining how the effect varies in different interaction phases and when users have different levels of interest on the news topic.

2.2 User Behavior Analysis

Learning from user behaviors is a general approach used in online interactive information systems. Researchers of Information Retrieval use click signals to infer document relevance [8] under the assumption that relevant documents attract more clicks. Personalized information filtering systems, like recommender systems, are also designed by mining user preferences through historical click data [13, 32].

However, user click behavior has been found to be biased because of the influence caused by some factors, for example, position [16]. Documents on the top may attract more user clicks [17]. Other factors like trust [16], result attractiveness [37] and presentation [34] are also examined. To address the biases of user click behavior, researchers have proposed a number of advanced click models [5, 10], which are designed to eliminate the effects of various biases to obtain an unbiased estimation of result relevance in web search scenarios.

Besides click, some other behaviors are also examined and incorporated to model user experiences. Among them, click dwell time has been successfully used in many retrieval applications. A dwell time equaling or exceeding 30 seconds has typically been used to identify clicks with which searchers are satisfied [9]. The correlation between dwell time and user interest is further modeled by document factors (e.g. readability [21], genres [3], and human factors [36]). Besides dwell time, viewport time is successfully used on mobile devices to infer user interest at the sub-document level [14]. Li et al. [25] examine the correlation between users' eye gaze and user explicit interest, and demonstrate the effectiveness of using attention-based behaviors, like viewport time and gaze, to predict user interest. Lin et al. [26] find that the delivery mechanism of the system greatly affects user information consumption behaviors. Ben et al. [31] investigate the causal effects of ad blocking on user long-term behaviors, like active time spent in the browser and the number of page. Lu et al. [28] investigate the influence of user preferences on user behaviors in news reading scenario and in mobile environment.

While many factors related to user behaviors have been investigated, the item quality is less studied. Based on a carefully designed user experiment, we studied the directly effects of news quality on user browsing and reading behaviors with other factors controlled, like position, topic and user preferences.

3 USER STUDY METHODOLOGY

To measure the effects of news quality on user preferences and behaviors, we designed a laboratory user study in which we varied the news quality with other factors controlled and inspect whether user experiences and behaviors become different.

3.1 Experimental Setup

In this section, we introduce the settings of our experiment, including how we sample the news data and annotate their quality as low-quality and high-quality, how we generate news lists with other factors controlled, like position and topic and what are the interfaces of the experimental platform.

3.1.1 Data.

The news used in the user experiment is sampled from the real log of *Sougou NewsFeed*, a popular commercial newsfeed service on mobile device. We firstly choose five most popular topics: *social*, *entertainment*, *technology*, *history*, and *sport*. Then we randomly sample one hundred pieces of news from each topic. By doing this, we cover a variety of topics and ensure a balance between them to eliminate the possible bias.

After that, a human annotation is conducted to measure the quality of these pieces of news. We recruit three experts to label the overall quality (binary-scales: low-quality or high-quality) by discussion according to the following four properties.

Authenticity: High authenticity means that this piece of news is authentic or has high credibility [33]. On the contrary, if the content is imaginary or exaggerated, the news is seen of low authenticity.

Value: A piece of news is of low-quality value when its content is full of problems with being vulgar, violent, bloody and pornographic.

Expression: The expression is high-quality when the statement is objective and precise, and the information is rich but not redundant.

Headline: Low-quality headlines have one of such problems: information is incomplete or fake; the expression is exaggerating or vulgar and inconsistent with the content.

The validity of the overall quality label, namely *Expert Labeled Quality (EQ)*, are tested by comparing it with the average perceived quality annotated by the experiment participants. (EQ vs. User perceived content quality Fleiss's k=0.5017; EQ vs. User perceived title consistency k=0.4737).

3.1.2 News Lists.

Based on the binary overall quality labelled by experts, the news are classified into two groups, low-quality and high-quality news. We generate sixteen news lists (fifteen news each) containing both low-quality and high-quality news as tasks in advance.

Previous works show that user behaviors are affected by many factors, like position [16]. To control the impact of position, we take the Latin square experimental design principles to assign the positions of low and high-quality news in the lists. Meanwhile, we assigned the same number of news from five topics in each task list to control the effect of news topic. The careful design ensures that the low-quality and high-quality news have the same position and topic distribution.

3.1.3 Online Platform.

To simulate a real online news reading environment, we build an experimental platform which is similar to the common used news-feed website. There are two types of pages, one is the list page for the user to browse the news list (Figure 2 left and right pictures), the other is the news content page for users to read the news content (Figure 2 middle picture). A JavaScript plugin is injected into both pages to record user's scrolling, clicking, and page switching behaviors.

3.2 Experimental Procedure

In this section, we describe the procedure of the experiment and the collection of user experiences in multi-phases.

3.2.1 Procedure.

Before the experiment, we first collect user's interest of the five topics, namely *Topic Interest* (5-ratings each). To get familiar with the experiment platform and procedure, the participants need to

Figure 2: Collect user experiences in different phases: *Before-Read, After-Read,* and *Post-Task Phase.*

complete an example task for training. After that, users are asked to finish four tasks.

At the beginning of each task, users need to read the task description carefully. Then, a list of 15 pieces of news is shown to the user for browsing and reading. As no browsing and reading time limitations are imposed, users can finish the browsing task at any time.

3.2.2 Multi-Phase Experience Measurement.

Within the task procedure, we add several questionnaires to collect user experiences in three phases: Before-Read, After-Read and Post-Task, as shown in Figure 2.

Before-Read Phase

- **Q1:** How much do you expect to like or dislike reading this piece of news? (5-point Likert scale, from very dislike to very like)

Firstly, as soon as a user clicks a piece of news, before showing its content, we ask the user about his/her expected preference for the news. This preference is named as *Before-Read Preference*.

After-Read Phase

- **Q2:** How much do you like reading this piece of news? (5-point Likert scale, from very dislike to very like)
- **Q3:** What do you think of the content quality of this piece of news? (5-point Likert scale, from very poor to very good)
- **Q4:** What do you think of the consistency between title and content of the news? (5-point Likert scale, from very low to very high)

After a user reads the news content and deciding to leave (note that there is no constraints on user reading process, users can leave at anytime as he/she wish), we ask the user several questions for his/her experiences, including *After-Read Preference* (Q2), *User Perceived Content Quality* (Q3) and *User Perceived Title Consistency* (Q4).

Post-Task Phase

- **Q5:** How much do you like reading this piece of news? (5-point Likert scale, from very dislike to very like)

After users finish browsing, we randomly shuffle and re-display the news that they have seen (right subplot in Figure 2. "Seen" means that the news has appeared on the user's viewport (including the news not clicked). We ask users to re-annotate his/her preference on each news, named *Post-Task Preference*.

We finally recruit 32 participants, including 18 females. Across 128 tasks finished, 1920 impressions (including 576 low-quality news) are shown, and 631 clicks (including 209 clicks on the low-quality news) are collected. [1]

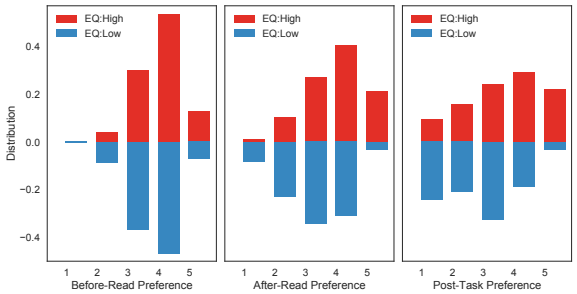

Figure 3: When the news quality is different (EQ:High vs. EQ:Low), the distributions of user preference in multi-phases: Before-Read (left), After-Read (center) and Post-Task (right).

Table 1: The Pearson correlations between news quality and user preference in multi-phases. The quality is measured by both expert (EQ) and user (User Perceived Content Quality, UQ-C; User Perceived Title Consistency, UQ-T).

	EQ	UQ-C	UQ-T
Before-Read Preference	0.1480	0.3267	0.2964
After-Read Preference	0.3292	0.8170	0.5874
Post-Task Preference	0.3077	0.6992	0.5652

4 QUALITY EFFECTS ON USER PREFERENCE

Based on the quality measurements labeled by both expert and users, and the explicit user preference feedback collected in the experiment, we now investigate the effect of quality on user preference.

4.1 Different Interaction Phases

To begin with, we compare the distribution of user preferences for low-quality and high-quality news, as shown in Figure 3. Generally, significant difference is found in user preference in all the three interaction phases (Before-Read Preference, p<0.01, d =0.32; After-Read Preference, p<0.01, d =0.74; Post-Task Preference, p<0.01, d =0.69). The results suggest that news quality has significant effects on user preference in all three phases. To be more specific, we find the degrees of the differences vary in different phases. It promotes us to jointly analyze the quality effects with the interaction phases.

We separate the news into different groups based on the quality measurement, not only the expert labeled quality (binary-scale, two groups), but also the user perceived content quality (5-scales, five groups) and the user perceived consistency between title and content (5-scales, five groups). For each group, we calculate the mean of user preferences in three phases (*Before-Read, After-Read, Post-Task Phases*). The results are shown in Figure 4.

Firstly, we can see that user preferences for the high-quality news are more likely to stay or increase (from Before-Read to After-Read and to Post-Task, shown as mark-1 in the figure 4), and vice versa, user preferences for the low-quality news continually drop

[1]The data is now available at http://www.thuir.cn/group/~mzhang/

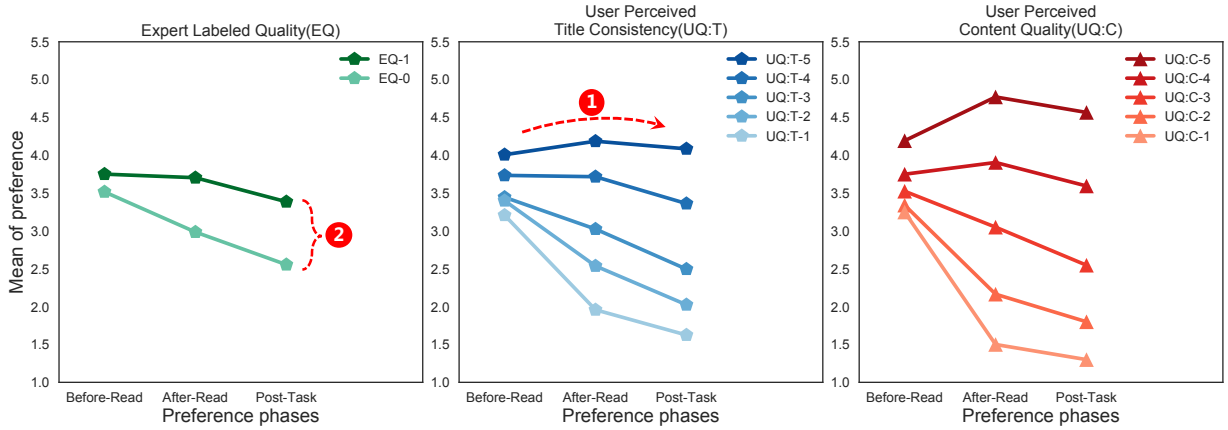

Figure 4: Means of user preference (in three phases) for the news of different levels of quality. The quality is measured by Expert Labeled Quality (left), User Perceived Title Consistency (center), and User Perceived Content Quality (right). The level of quality is distinguished by the shade of color.

Table 2: Quality effects, measured by the difference (Δ, Cohen's *d*) of user preferences between low-quality and high-quality news, when user has different topic interests (TI).

	Before-Read Preference				After-Read Preference				Post-Task Preference			
	EQ:Low	EQ:High	Δ	*d*	EQ:Low	EQ:High	Δ	*d*	EQ:Low	EQ:High	Δ	*d*
TI=Min	3.610	3.689	+0.079	0.114	3.170	3.597	+0.427	0.447	2.627	3.176	+0.549	0.454
TI=Mid	3.465	3.630	+0.166	0.223	2.831	3.674	**+0.843**	**0.870**	2.563	3.442	+0.879	0.751
TI=Max	3.494	3.897	**+0.403**	**0.532**	2.987	3.806	+0.819	0.838	2.494	3.491	**+0.997**	**0.801**

along user reading. This finding is consistent with Lu's work [28]. Starting from this point, we further analyze how the quality effects varies in different phases. The degree of quality effect is seen as the gap of preferences between low-quality and high-quality news (larger gap means higher degree, shown as mark-2 in the figure 4). In Before-Read Phase, user preferences for the news of low-quality and high-quality are already different, but more slightly than in After-Read and Post-Task Phases. It may be due to that user only knows a little part of the news before reading its content, thus quality is less perceived and has less effect on user preferences.

Meanwhile, although the trend of quality effect is similar when using different quality measurements, user perceived quality has a larger effect than objective expert labeled quality. It may because that user's perception of quality effect may be personalized and related to other subjective factors like user's interest on the topic of the news, which motivates us to further investigate the quality effect with user topic interest in next section.

In addition, the effect of user-perceived content quality is larger than the title consistency. By applying the Pearson's r, we further directly compare the correlation between user multi-phase preferences and different quality measurements. The results, shown in Table 1, indicate that the correlation between quality and preference is largest in After-Read Phase, and content quality is more closely related to user preference than title consistency and expert labelled quality.

4.2 Different Levels of Topic Interests

Beside of interaction phases, we further investigate whether the quality effects on user preferences are related with user's interest of the news topic. As mentioned in Section 3.2.1, users' interests on all the five topics are collected at the beginning of the user study, by asking users to rate each topic. To avoid users' different understandings of topic interest ratings, we separate the five topics within each user into three groups. The topics with the highest user interest are set as "Max" group (not necessarily one topic), and vice versa, the topics with lowest user interest are set as "Min" group, and the other topics are set as the "Mid" group.

The means of user preferences for low-quality and high-quality news with different levels of topic interest are shown in Table 2. We further measure the quality effect on user preferences by calculating Δ (preference of high-quality news − preference of low-quality news) and Cohen's *d*. On the one hand, the quality effect is lowest in *Before-Read phase* and highest in *Post-Task phase*, which is same as previous analysis.

On the other hand, the quality effect is highly related to the topic interest. When user has low topic interest (Min), the difference of preferences between low-quality and high-quality news is small. On the contrary, when user has higher topic interest (Mid and Max), the quality effect is much larger. It can be interpreted as the user has less quality sensitiveness for the news of his/her less interested topics. Moreover, although topic interest is generally positively correlated with user preferences, when the news is of low quality,

higher topic interest leads to lower preferences. It can be explained by the less user tolerance of quality for his/her highly preferred topics.

5 QUALITY EFFECTS ON USER BEHAVIORS

In this section, we focus on investigating whether users behave differently when interacting with low-quality and high-quality news. Users' scroll and click events with timestamps are recorded in user browsing (list page) and reading (content page) processes, and are used to build several frequently used behavior measurements.

5.1 Click Behavior

Click behavior has been widely used as implicit feedback for recommendation, ranking and evaluation. In this section, we investigate the quality effects on user's click behavior, measured by the probability of users clicking the news. If there is a dependency with the quality, any interpretation of clicks as implicit preference feedback should be relative to the quality.

We first evaluate the probability for users clicking on low-quality or high-quality news. The conditional probability shows that if the news is of high quality, it will be clicked with a probability of 0.3140 ($P(Click|EQ = 1)$), vice versa, the click probability for low-quality news is 0.3628 ($P(Click|EQ = 0)$). The difference is slightly but significant according to the independent t-test, p<0.05, d=0.10. It implies that low-quality news is more likely to be clicked than high-quality news.

Incorporating the position of the news into analysis, we calculate the click probabilities conditioned by the quality for top-k impressions (K ranging from 1 to 15) are shown in Figure 5. By separating different levels of quality, we can find that the news of low quality has higher click probability than high-quality news in all the Top-K positions.

To further verify the reliability of the finding that low-quality news has a higher probability of being clicked, we test whether it exists in real system. Note that the news used in our work is sampled from *Sougou Newsfeed*. We further collect one week's log data about these piece of news (from October 16, 2017, to October 22, 2017, more than 1.5 thousands interactions per news).

Based on the quality labeled by expert (EQ) and the CTR calculated in the log for each news, we are able to compare the average CTR of low-quality and high-quality news. The result of independent t-test shows that there is a significant difference of CTR for low-quality news (0.1539) and high-quality news (0.0835), p<0.01. The observation is similar with the result in user study, and proves that the news quality does affect user click behavior and low-quality news is more likely to be clicked.

5.1.1 *Title Persuasion.*

To further study why low-quality news attracts more clicks, we conduct a supplementary annotation for the persuasion of the title. The *title persuasion* is defined as the extent that user is seduced to click the news (4-scales). We hired external assessors from JD crowd source platform and make sure each piece of news was annotated by 3 different assessors (Fleiss' $k = 0.4259$, reach moderate agreement). We use majority voting to get the final score.

Based on the annotation, we compare the title persuasion of low and high-quality news and find low-quality news has higher

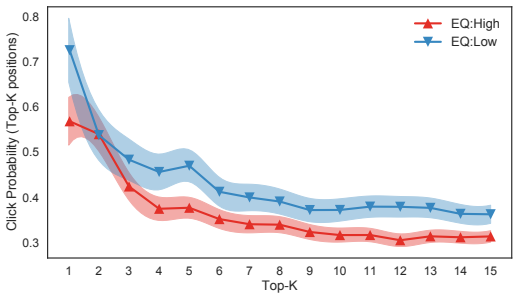

Figure 5: Click Probability of the news *up to position k* conditioned by the news quality. The low-quality news attracts more clicks.

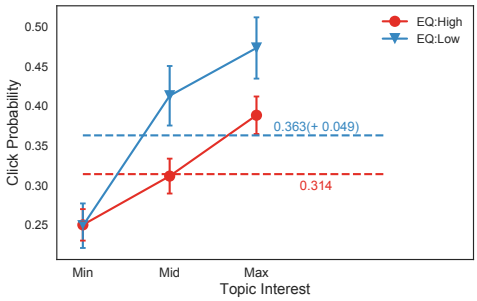

Figure 6: Click probability of the news with different levels of quality and user topic interests.

Table 3: The contextual effect of quality on click probability. When the quality of last impression news (lEQ) varies, how is the click probability of current (c) impression news?

	$lEQ = low$		$lEQ = high$	
$P(Click\|\ lEQ)$	0.3507		0.2898	
$P(Click\|\ lEQ, cEQ)$	$cEQ = l.$	$cEQ = h.$	$cEQ = l.$	$cEQ = h.$
	0.4000	0.3108	0.2838	0.2917

persuasion than high-quality news (2.16 vs. 1.61, p<0.01). It is reasonable that low-quality news usually uses literary methods, like the exaggeration, to generate a more compelling title. Thus, user may click on low-quality news because of its high title persuasion.

5.1.2 *Topic Interest.*

We further study how quality effects on user's clicking decision change when user has different levels of topic interest. We show the click probability conditioned by the news quality and topic interest ($P(Click|Q, TI)$), in Figure 6.

Beside of the separate effects of quality and topic interest, there also exists an interaction effect. When topic interest is low (Min), user has almost the same click probability for the news of low or high quality. However, when topic interest is high (Mid, Max), the click probability of low-quality news exceed high-quality news. The reason is that when the news is of low topic interest, the user may be not easily aware of its quality, so the click decision is less affected.

5.1.3 *Contextual Effect.*

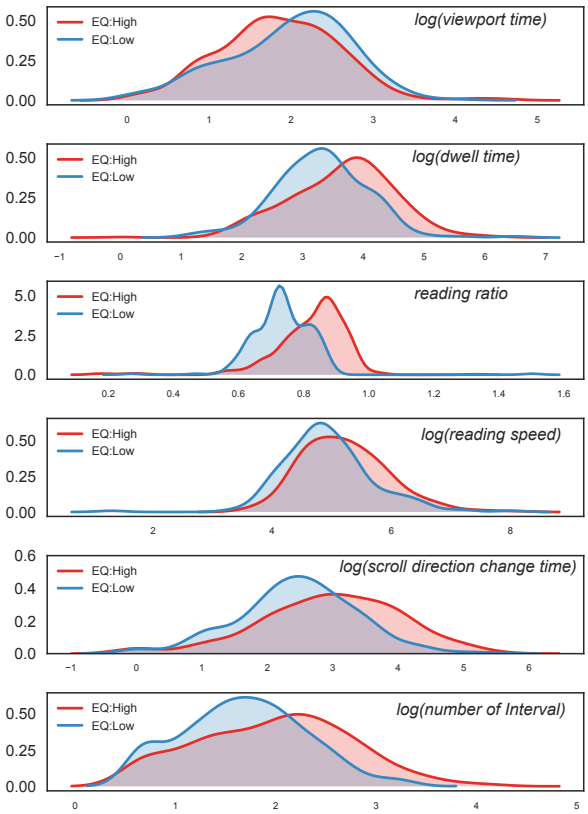

Figure 7: The probability density function (estimated by kernel density estimation) of behaviors when users are reading the news of different qualities (EQ:High vs. EQ:Low)

As the user interacts with news in the list context, the quality of the news around may have contextual effects. In the mobile environment, most of users scroll to browse the list, examine news one-by-one. So we investigate how the quality of the last impression affects user click probability for the current news.

We calculate the probability of clicking on current news conditioned by the quality of the last impression. The results, shown in Table 3, indicate that user has a higher click probability when the quality of the last impression is low (0.3570 vs. 0.2898). We further control the quality of current news. Results show that no matter what the quality of current news is, the click probability is higher when the last impression is of low quality. It may be caused by the saliency attention mechanism, the saliency and click probability of a piece of news may depend on the context news.

5.1.4 *Summary.*

From above analysis, we can conclude that user click behavior is affected by news quality. Users have a higher probability of clicking the low-quality news. It promotes us that we should take quality into account when using user click signals to build implicit feedback. User topic interest is found to be related to the quality effect on click probability. The quality effect is lower when user has lower interest in the topic. Beside of affecting the click decision of current news, news quality also has effects on context news, like the next news in the recommendation list.

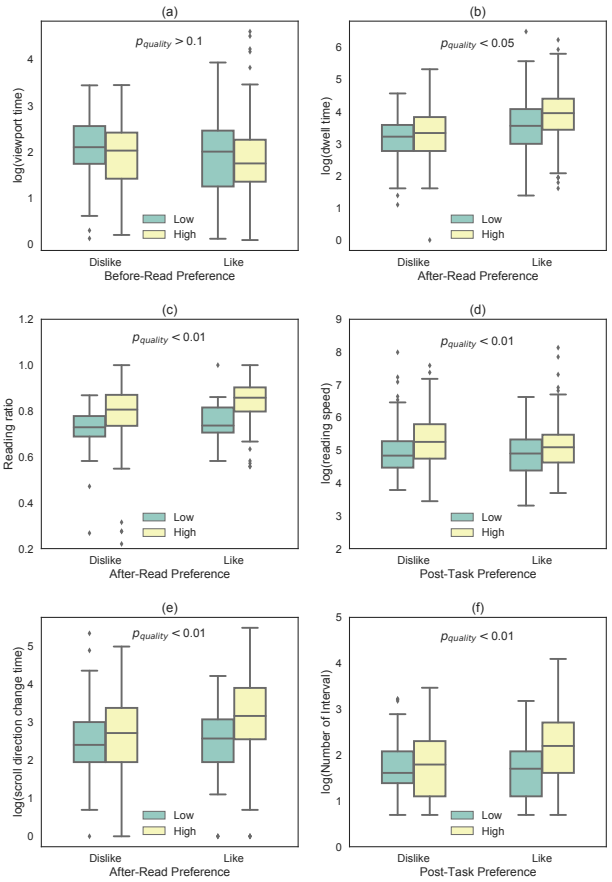

Figure 8: User behaviors for the news of different levels of quality (EQ: low, high) with different user preferences (Dislike($\leq$3), Like(>3)). The p-value displayed in each figure represents the main effect of quality in two-way ANOVA (with preferences).

5.2 Reading Behaviors

Beside of the click behavior, in this section, we investigate how news quality affects user's behaviors in the reading process. First of all, we directly compare the distributions of user behavior measurements when the news is of high-quality and low-quality, as shown in Figure 7. By doing this, we get an overview of news quality effects on behaviors.

In last section, we demonstrates that the news quality affects user's preferences, while previous work [28] shows that user preferences influence user behaviors. Hence, to analyze the impact of news quality on user behaviors, we further control the influence comes from user preferences.

For each behavior, we choose the preference in its most closely related phase based on the behavior-preference correlations, marked by the y-label in Figure 8. For example, the most closely related preference for dwell time is *After-Read Preference*, while for viewport time is *Before-Read Preference* and for direction change times is *Post-Task Preference*. If the preference less than or equal to 3 ($\leq$ 3), we consider it as *dislike*, other levels of preference are considered as *like*. Based on both analysis approaches, we study the quality effects on each reading behavior:

Viewport time.

Viewport time, reflecting how long user reads the news snippet in the list browsing page, may be related to the user click decision process. Because the data for viewport time does not meet the normality assumption, we use log-transformation, $log(x+1)$, before statistic analysis. In general, the result of independent t-test suggests there is a slightly but significant difference of viewport time between low-quality and high-quality news (p<0.05, d=0.17). We further take the effect of user *Before-Read Preference*, which is proved mostly related to viewport time, into account. The result of the analysis of variance (ANOVA) [7] considering both quality and preferences shows that there is no independently significant effect of quality on the viewport time (two-way ANOVA, $F(1,929)=4.47$, p>0.1). We then separate the news into dislike and like groups, and compare the means of viewport time between low-quality and high-quality news within each group. The result, shown in Figure 8 (a), indicates that user spends a longer time reading the snippet of low-quality news. While the difference is not significant (t-test, $p_{dislike}$>0.1, d=0.13 and p_{like}>0.1, d=0.11), such a longer time is plausible: user can perceive part of the quality by reading the title and images. Thus he/she needs longer time to make the click decision for low-quality news.

Dwell time.

Dwell time, indicating how long user reads the content of the news, has been found highly related to user post-click experiences. Same as viewport time, we also use log-transformation to normalize the data. Generally, there is a significant effect due to the news quality (t-test, p<0.01, d=0.42). By jointly analyzing with user preferences in *After-Read Phase*, the independently significant effect of quality is confirmed by two-way ANOVA ($F(1,929)=4.50$, p<0.05). With preferences controlled, we find that higher quality leads to higher dwell time, especially when the preferences is high (see Figure 8 (b)). Independent t-test is applied within both dislike and like groups. Results indicate that there is a significant difference when user likes the news, $p_{dislike}$=0.13, d=0.17 and p_{like}<0.01, d=0.36.

Reading ratio.

Dwell time has been proved to be affected by many factors, like content length and readability. For eliminating the effect of content length, we normalize the absolute read length by the whole length [23], named as reading ratio which directly reflect how deep user read. In general, user's reading ratio for low-quality and high-quality news is significantly different (t-test, p<0.01, d=0.85).

With user *After-Read Preference* controlled, the statistic results show that quality has still a significant effect on user reading ratio (two-way ANOVA, $F(1,929)=62.78$, p<0.01). Low-quality news has the lower reading ratio, which indicates that user will leave earlier when reading the low-quality news (see Figure 8(c)). t-test is applied. Results indicate that there is a significant difference in both dislike and like groups, $p_{dislike}$<0.01, d=0.49 and p_{like}<0.01, d=1.19.

Reading speed.

Combining dwell time and reading length (pixel), we calculated user reading speed (reading length/dwell time). As shown in Figure 8 (d), user reading slower when the quality is lower. The result is supported by both two-way ANOVA with *Post-Task Preference* ($F(1,929)=27.6$, p<0.01) and t-test within each preference group ($p_{dislike}$<0.01, d=0.49 and p_{like}<0.01, d=0.54)

Scroll direction change times.

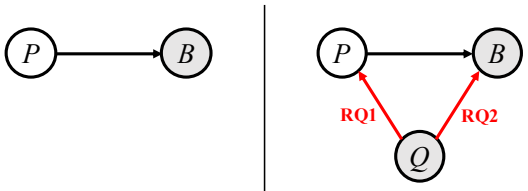
When a user is reading the news content, he/she may change his/her reading direction to revisit some previous information. The number of the user changing his/her scroll direction indicates how often the user revisits. Considering only the news quality, there is a significant difference reported by t-test, p<0.01, d=0.49. With further investigation by controlling user *After-Read Preference*, we can conclude that quality effect still exists (two-way ANOVA, $F(1,929)=19.09$, p<0.01) and user revisits more when the news quality is high, especially when the user like the news. (t-test, $p_{dislike}$ =0.10, d=0.19 and p_{like}<0.01, d=0.69)

Number of interval.

In the content page, user read the news by scrolling, scroll intervals may represent user's examinations. Therefore, the number of user scroll interval indicates how many times user carefully examines some information along reading the news. In general and with user preferences controlled, the quality has a significant effect on the number of intervals (t-test, p<0.01, d=0.43; two-way ANOVA, $F(1,929)=9.05$, p<0.01). The result shown in Figure 8 indicates that when the user likes the news, higher quality leads to more scroll intervals (t-test, $p_{dislike}$=0.25, d=0.14 and p_{like}<0.01, d=0.39).

Summary.

In this section, we give the detailed analysis of the quality effects on user's reading behaviors. We find that when users read low-quality news, they may:



- spend less time reading (dwell time decrease)
- leave earlier (reading ratio decrease)
- read slower (reading speed decrease)
- have fewer revisits (scroll direction change times decrease)
- have fewer careful examinations (number of interval decrease)

The existence of quality effects on user behaviors promotes us to take quality into consideration when using user reading behaviors as implicit feedback. In next session, we further examine it through the probability model.

6 CAN INCORPORATING QUALITY HELP IN BUILDING IMPLICIT FEEDBACK?

To collect user's preferences, information systems have exploited implicit feedback signals derived from user behaviors. For example, the Satisfied-Click, which considers the click following a long dwell time as positive preference feedback, is widely used in today's systems. These approaches are relied on the assumption that user preferences affects user behaviors (e.g. dwell time). While no other factors are considered, the graphical model of this assumption can be shown as Figure 9(a), namely Preference Behavior (PB) model here.

Based on our previous findings about the quality effect on user preferences and user behavior, we argue that quality need to be taken into consideration when building implicit feedback. By studying RQ1, we find that the quality affects user preferences, so we add a relation between quality and user preference. Besides, by studying RQ2, we also conclude that news quality does have an effect on user behavior and the effect is independent of the effect of user preferences. Therefore, we further add a relation between

(a) PB-model (b) PBQ-model

Figure 9: The graph models of traditional implicit feedback which use Behavior to estimate Preference, namely PB-model (a), and implicit feedback which incorporates Quality, namely PBQ-model (b). *P*: preference; *B*: behavior; *Q*: quality.

Table 4: The performance of PB and PBQ with different behavior metrics in estimating user preference.(* represents p-value<0.05, ** represents p-value<0.01)

Behavior metric	AUC(PB)	AUC(PBQ)	p	cohens' d
viewport time	0.5775	**0.6249**	**	1.25
dwell time	0.6225	**0.6526**	**	0.88
reading ratio	0.6382	**0.6486**		0.23
reading speed	0.4490	**0.6142**	**	3.32
direction change times	0.5904	**0.6477**	**	1.17
number of interval	0.6111	**0.6709**	**	1.33

news quality and user behavior. Note that although topic interest is found to influence the quality effect, we do not include it in the implicit feedback building approach because it is subjective and hardly collected in real applications. Figure 9(b) summarizes the proposed relations among news quality, user preferences and user behaviors, namely Preference Behavior Quality (PBQ) model.

Among the three variables, user behavior and news quality are observable by system logging or expert annotation. Based on the conditional dependence in the graphical model, we can infer user preferences when given the behavior and quality. Specifically, for PB-model, when observing a user behavior signal B (e.g. dwell time), we can infer the probability if the user likes the news ($P = 1$):

$$P(P = 1|B) = \frac{P(B|P = 1)P(P = 1)}{\sum_{i\in\{0,1\}} P(B|P = i)P(P = i)}$$

As for PBQ-model which further taking the news quality Q (low or high) into consideration, the probability is calculated by:

$$P(P = 1|B, Q) = \frac{P(B|P = 1, Q)P(P = 1, Q)}{\sum_{i\in\{0,1\}} P(B|P = i, Q)P(P = i, Q)}$$

The Satisfied-Click (with dwell time (DT) threshold =30s) can be interpreted as PB-model with $P(DT <= 30s|P = 1) = 0, P(DT > 30s|P = 0) = 0$. While most of user behavior signals conform the normal distribution (some need log-transformation at first), we assume that the probability of user behavior B given user preference or news quality follows normal distribution to get a better robustness:

$$P(B|P) \sim N(\mu_p, \sigma_p^2) \text{ or } P(B|P, Q) \sim N(\mu_{pq}, \sigma_{pq}^2)$$

Note that there is no constraint for what the behavior is, the PB-model and PBQ-model can be built by different behavior signals, like viewport time, dwell time, reading ratio, reading speed, direction change times, and the number of interval.

To investigate whether incorporating quality helps in building implicit feedback of user preferences, we compare the PB-model and PBQ-model with the performance of estimating whether a user likes a clicked news. We choose *Post-Task Preference* as the ground truth of user preference, dislike (Post-Task Preference<=3) and like (Post-Task Preference>3), because it is collected in a random order after user browsing the whole list, which eliminate the potential biases from position and interaction order.

We use 10-fold cross-validation to evaluate the model performance. The parameters of the probability model are estimated using training set in each fold, and the performance is measured by AUC in testing set. The results are shown in Table 4. Firstly, while PB-model performs best when using *reading ratio* and *dwell time*, similar with our traditional usage, the PBQ-model performs best when using a less used user behavior metric: *number of interval*. Secondly, the PBQ-model significantly outperforms the PB-model when using all the behavior signals, especially *reading ratio*. It proves that incorporating news quality does help in building implicit feedback of user preferences.

7 CAN WE IDENTIFY THE NEWS QUALITY BASED ON USER BEHAVIOR?

From above analyses, we conclude that quality is useful for estimating user preferences. Thus, how to get news quality is a valuable research topic. In this work, we labelled news quality by external assessors' annotation. It is reliable but high cost and hard to be applied in real applications. Another way is to predict the quality of news automatically. Traditional prediction models are mostly based on the content information.

In this section, We conduct two identification analysis to examine the ability of each single behavior for distinguishing the news quality.

7.1 Point-Wise Distinguishing Ability

To begin with, we evaluate the performance of using absolute value of behavior metric to identify the news quality in an interaction (a user read a piece of news), namely point-wise distinguishing ability:

Given a threshold t_b and a direction coefficient α, for an interaction i with the behavior b_i, the inferred quality of the news is calculated by:

$$\hat{q}_{\alpha,t_b}(i) = I[\alpha(b_i - t_b) > 0]$$

where α indicates whether the identification criteria is above the threshold ($\alpha = 1$) or below the threshold ($\alpha = -1$), and I is a indicator function. Then, the point-wise distinguishing ability D_{point} of a behavior b is defined as the highest accuracy that can be achieved in click interaction set C, when changing the direction α and threshold t_b:

$$D_{point}(b) = \max_{\alpha,t_b} \frac{\sum_{i\in C} I[\hat{q}_{\alpha,t_b}(i) = q_i]}{n(C)}$$

The quality labelled by the expert (EQ) is used as the ground truth (q_i). For each behavior, we evaluate its point-wise distinguishing ability based on all the click interactions in user study.

7.2 Pair-Wise Distinguishing Ability

The different reading habits lead to user biases in user behavior metrics, for example, some users usually read longer no matter the

Table 5: The performance of different behaviors in identifying quality, measured by point-wise distinguishing ability (D_{point}) and pair-wise distinguishing ability (D_{pair}). (+ Positive relative relation. - negative relative relation.)

	Expert Quality				UQ-C		UQ-T	
	D_{point}	α	D_{pair}	α	D_{pair}	α	D_{pair}	α
viewport time	0.6703	-	0.5850	-	0.5470	-	0.5300	-
dwell time	0.6751	+	0.6650	+	0.6940	+	**0.6350**	+
reading ratio	**0.7084**	+	**0.8010**	+	**0.702**	+	0.6270	+
reading speed	0.6799	+	0.6210	+	0.5240	-	0.5300	-
direction change times	0.6688	+	0.6590	+	0.6300	+	0.5650	+
number of interval	0.6719	+	0.5174	+	0.5547	+	0.5106	+

news quality. To eliminate these user biases, we design an pair-wise evaluation approach to measure the ability of a behavior metric to distinguishing the quality. The pair-wise distinguishing ability is calculated by comparing the relative relation between the behavior metric and the news quality.

Specifically, consider an example set S of news pairs [$<n_1, n_2>$,... $<n_i, n_j>$], with the behavior metric b and news quality q. We first define the relative relation between behavior and quality of a news pair $<n_i, n_j>$:

$$r_\alpha(n_i, n_j) = I\Big[\ \alpha I[b(n_i) < b(n_j)] = I[q(n_i) < q(n_j)]\ \Big]$$

where α is the direction coefficient and I is the indicator function. Then the pair-wise distinguishing ability is defined as:

$$D_{pair}(b) = \max_{\alpha \in \{-1,1\}} \frac{\sum_{<n_i, n_j> \in S} r_\alpha(n_i, n_j)}{n(S)}$$

To eliminate the user bias, we generate the evaluation pairs within users, which means the n_i and n_j is from the same user. Beside of the expert labelled quality, we also use the user perceived quality as ground truth for news quality q, including content quality (UQ-C) and title consistency (UQ-T).

7.3 Results

The results of both point-wise and pair-wise distinguishing experiments are shown in Table 5. As for the objective quality labelled experts (EQ), among these behaviors, *reading ratio* achieves the highest point-wise distinguishing ability (0.7084) with threshold $t_b = 0.74$ and direction $r = 1$. It means that whether users read more than 74% of the news content can be used as an indicator for the high quality news. *Reading ratio* also achieves the highest pair-wise distinguishing ability (0.8010). It means that if a user reading more in news i than another news j, the quality of news i is more likely higher than the quality of news j. As for the perceived quality labelled by the user, UQ-C and UQ-T the *dwell time* and *reading ratio* performs better in distinguishing pair-wise quality.

To summary, based on the proposed point-wise and pair-wise distinguishing ability measurements, we investigate whether user behaviors can be used to identify news quality. The results demonstrate that user behaviors, especially *reading ratio* and *dwell time*, have highly ability to distinguish news quality. Starting from here, the powerful behavior-based quality identification models are promoted to be developed in the future.

8 CONCLUSION

In this work, through an in-depth user experiment, we investigate the quality effects on user item-level preference and user behaviors. To begin with, we verify that the quality does affect user preferences, and further find that the quality effect varies at different phases and it is more closely related to the user's interest for the news topic.

As for the quality effects on user behaviors, we firstly show that user click behavior is significantly affected by the quality. Specifically, low-quality news attracts more clicks especially when the user has higher interest in news topic. It can be interpreted by the higher title persuasion of low-quality news. Besides, a piece of low-quality news will affect not only the click probability of current news but also the news following it. Secondly, we find that a user behaves significantly different when interacting with low-quality news. A user will read less and slowly, with fewer revisits and fewer examinations.

Based on our finding that quality affects user preferences and behaviors, we proposed the PBQ-model which incorporates quality effects into the traditional behavior-only implicit feedback. The significant improvement in estimating user preferences demonstrates that considering quality is useful for building accurate implicit feedback. Because of the usefulness of quality, how to automatically identify quality is a valuable research topic. Our study shows the possibility of using user behaviors to identify news quality, such as *reading ratio* and *dwell time*.

The study on designing the model using content and behaviors information to predict the quality is left for future work. Beside of individual-level preference, the quality effect on user list-level satisfaction is also left for further study.

ABSTRACT

Answer selection is an important problem in community question answering (CQA), as it enables the distilling of reliable information and knowledge. Most existing approaches tackle this problem as a text matching task. However, they ignore the influence of the community in voting the best answers. Answer quality is highly correlated with semantic relevance and user expertise in CQA. In this paper, we formalize the answer selection problem from the user expertise view, considering both the semantic relevance in question-answer pair and user expertise in question-user pair. We design a novel matching function, explicitly modeling the influence of user expertise in community acceptance. Moreover, we introduce latent user vectors into the representation learning of answer, capturing the implicit topic interests in learned user vectors. Extensive experiments on two datasets from real world CQA sites demonstrate that our model outperforms state-of-the-art approaches for answer selection in CQA. Furthermore, the user representations learned by our model provide us a quantitative way to understand both the authority and topic-sensitive interests of users.

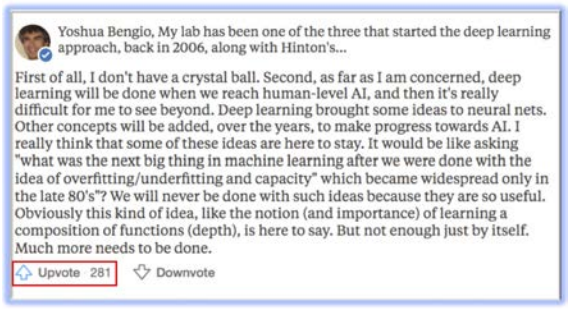
(a) Votes distribution. (b) Example of question, answer, and vote mechanism in CQA.

Figure 1: Illustration of vote mechanism in CQA.

1 INTRODUCTION



Community question answering (CQA) sites, such as Quora[1] and Zhihu[2], are Internet-based crowdsourcing services which enable users to post questions and seek answers from other users. The success of CQA has attracted much research attention in recent years [14, 26, 28, 31, 34, 38–41]. Most users would prefer to put forward open questions without strict standard answers in CQA sites. By this means, the criterion of answer quality is difficult to be unified in CQA systems. For example, the answers would be various from different users for the question "*What languages should I learn before starting to learn of AI?*". Thus, the voting mechanism is implemented in CQA sites, where the answer quality is indicated by the votes from the whole online communities. However, the answers elected by communities have low reliability due to the scarce votes in real applications. We take statistics in Quora and draw the correlation on the number of votes per question (#V per Q) and the number of answers per question (#A per Q) in Figure 1. As shown in the figure, most questions with a few answers receive less than 10 votes correspondingly. Therefore, automatic answer selection, which aims to rank the answers in descending order of quality, is a crucial task in CQA.

Many approaches have been proposed for answer selection, most of which tackle this problem as a text matching task. Early approaches are based on the form of exact string matches for n-grams,

(a) An common answer of the question.

(b) The best answer of the question.

Figure 2: Example of user expertise. Users with high expertise usually provide high-quality answers.

as such they fail to detect similar meaning conveyed by synonymous words [6, 7, 12, 19, 20]. Some approaches focus on constructing features from textual clues [36, 46], such as lexical and syntactic features. However, these methods has limited performance as the high computation cost for capturing context features. Recently, deep architectures are proposed to learn distributed representations for words and sentences. These approaches encode the questions and answers from a high-dimensional and sparse representation into low-dimensional and continuous dense vectors according to comprehensive context efficiently, e.g. convolutional neural networks (CNN) or recurrent neural networks (RNN). Based on the learned representations, semantic similarity [31, 33, 38] or matching [17, 24, 34, 37] functions can be learned from an end-to-end learning strategy.

However, traditional solutions of answer selection on QA systems cannot be directly applied in CQA as these methods ignore the influence of user expertise accepted by the community. In CQA systems, the answer rank is highly correlated with the expertise of users. We take an example of question in Quora, showing the difference between two answers whose users have different expertise in community. The open question and two corresponding answers are described in Figure 2(a) and 2(b). In the example, the two users give the answers from different aspects on "*What is the next big thing in machine learning after we are done with deep learning?*". The two answers are both highly relative to the question. However, the answer by Yoshua Bengio receives 281 votes which is much higher than the other one. The phenomenon is approved in [5, 49]. According to the literatures, the main reason is that Yoshua Bengio is a well-known expert in the community of deep learning and machine learning, and thus his answer tends to be voted by others.

However, user expertise is still questionable as its definition and quantitation during the progress of answer selection. Thus, we propose a user-expertise specific learning framework to model the dynamics of answer selection in CQA. The goal of our work tries to learn user expertise of each user by latent factors so as to better capture the rank of answers. Firstly, our proposed method defines latent user vectors in terms of answer ranking, explicitly modeling the relevance between question-user pair. A novel score function is introduced to evaluate both the relevance on question-answer and corresponding question-user pairs accepted by communities. Then, we introduce latent user vectors into the representation learning of answer, capturing the implicit topic interests in learned user vectors. Our proposed method encodes latent user vectors into the answer representation by hierarchical attention mechanisms within Long-Short Term Memory (LSTM) [16] network, which is more informative to user-specific interests. Experimental results on two datasets from real world CQA sites demonstrate that our proposed method outperforms other state-of-the-art approaches for answer selection. Moreover, the extensive experimental results prove that the learned user vectors can indicate the authority accepted by communities and capture the user interests in topic level, showing the great potentials on understanding user expertise in CQA.

Our contributions in this paper are summarized as follows:

- We propose a novel score function to directly evaluate the comprehensive relevance on both question-answer and question-user pairs, explicitly modeling the influence of user expertise in community acceptance.
- Our proposed model encodes latent user expertise into answer representation by hierarchical attention mechanisms, capturing implicit topic interests of each user.
- We conduct extensive experiments on two real-world datasets to verify the effectiveness of our model and compare it to other state-of-the-art approaches for answer selection in CQA. Moreover, the user representations learned by our proposed method provide us a quantitative way to understand topic-related user expertise in CQA. Besides, our implementation codes are open to public[3].

The remainder of this paper is organized as follows. Section 2 reviews the prior work related to answer selection. Section 3 formally defines the problem of answer selection. Section 4 introduces our proposed model in details. Section 5 presents the experimental results on two real-world datasets. Finally we conclude our work in Section 6.

2 RELATED WORK

In this section, we first review the prior work in community question answering. Then, we introduce the attention-based neural networks.

[3]https://github.com/Sunshine1007472173/UEAN

2.1 Community Question Answering

Early works in information retrieval, including language model (LM) [6, 7, 12, 19], and Okapi model (Okapi) [20], can also be used for answer selection. These approaches are purely based on the form of exact string matches for n-grams, as such they fail to detect similar meaning conveyed by synonymous words. A retrieval model was proposed in [44] that combined a translation-based language model for the question part with a query likelihood approach for the answer part. The authors formulated answer sentence selection as a semantic matching problem with a latent word-alignment structure in [46]. The authors studied the use of syntactic and semantic structures obtained with shallow and deeper syntactic parsers for the answer passage reranking task in [36].

With the rapid development of distributed word representations [18, 23, 27] and deep neural networks, many approaches have been proposed for answer selection. Convolutional neural network (CNN) was introduced by [17] to model the sentence matching in question answering. In [33], the authors demonstrated a unified architecture that trains a convolutional neural network together with a multi-layer perceptron to rank question-answer pairs. The authors uses a stacked bidirectional LSTM network to sequentially read words from question and answer sentences, and then outputs their relevance score [38]. Grid-wise similarity matrices within neural architectures is also adopted to model the complicated matching relations between question and answer [24, 34, 37]. The neural tensor network architecture was proposed to model the diverse relationships between question and answer in [31, 35].

However, most of the existing works merely model the semantic relevance between question-answer pairs and ignore the main characteristics in CQA, i.e., **expertise of users**. Semantic relevance and user expertise are jointly considered in our model. Furthermore, our model encodes user expertise information in the answer representation by attention mechanisms to focus on crucial segments of answers hierarchically. As a result, more important answer content and the expertise of users is captured. Recently, the authors proposed an asymmetric multi-faceted ranking network learning framework considering the answerers' authority in [48]. Nevertheless, they just model the user expertise in the score function and do not consider the influence of user expertise to the answer.

2.2 Attention-based Neural Networks

The attention mechanism has shown good performance in many tasks [2, 3, 8–11, 15, 25, 29, 32, 42, 43]. Specifically in machine translation [3, 25], given a sentence in the original language, the attention mechanism aims to adjust the weights of input words to predict the words in the target language. In [45], the authors proposed hierarchical attention networks for document classification. However, the answer selection task in CQA is different from the language translation and the document classification tasks. Moreover, our way of introducing user-aware hierarchical attentions is not explored in [3, 25, 45]. Recently, the authors in [47] proposed to first learn representations of question and answer by neural network architectures and then apply *one-level* attentive pooling network on an interaction tensor. Our approach differs in that our attention mechanisms are used for constructing the answer representation directly rather than for post-processing an interaction tensor. Moreover, our model jointly capturing the user expertise and semantic relevance, while [47] just focus on semantic matching.

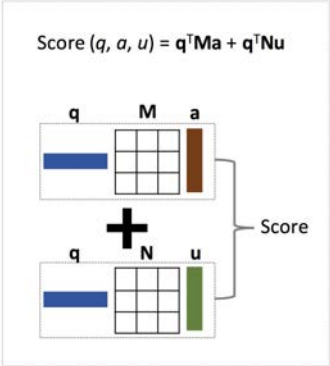

Figure 3: The score function of our model, jointly exploiting the semantic relevance between question-answer pairs and the user expertise to the given question.

3 PROBLEM FORMULATION

Before diving into detail of our model, we first describe symbols used in the answer selection problem. Given a question q, a set of its candidate answers $A_q = \{a_{q,1}, a_{q,2}, \ldots, a_{q,N}\}$ and users who gave the answers $U = \{u_1, u_2, \ldots, u_N\}$, answer selection aims to rank the answers in A_q in descending order of quality. We let $(s^a_1, s^a_2, \ldots, s^a_{N_a})$ represent the sequence of sentences in an answer a. Meanwhile, the word sequences in a sentence s is denoted as $(w^s_1, w^s_2, \ldots, w^s_{N_s})$. For ease of presentation, scalars, vectors and matrices are denoted by lower-case letters, boldface lower-case letters and boldface capital letters in this paper.

Since a good answer should well address a question semantically, the answer selection problem can be defined into an interactive process between a question-answer pair. In this way, the score function can be formalized as follows:

$$s(q_i, a_{q_i,j}) = \sigma(f(q_i), g(a_{q_i,j})), \tag{1}$$

where the function f and g map the question q_i and answer $a_{q_i,j}$ into a common vector space. The function σ measures matching degree between each question-answer pair. Generally, the score function σ could be in the form of cosine similarity, bilinear function or tensors [17, 31, 47]. For briefly describing the models, we use vector $\mathbf{q}_i = f(q_i)$ and $\mathbf{a}_{q_i,j} = g(a_{q_i,j})$ as the representations of mapping results in the rest of the paper.

For the question q_i, given two answers $a_{q_i,j}$ and $a_{q_i,m}$ where answer $a_{q_i,j}$ has a higher quality than $a_{q_i,m}$, we aim to learn the score function that the following inequality holds for every tuple $(q_i, a_{q_i,j}, a_{q_i,m})$: $s(q_i, a_{q_i,j}) > s(q_i, a_{q_i,m})$. Then, we can rank the answers for a question in descending order of quality according to the score function.

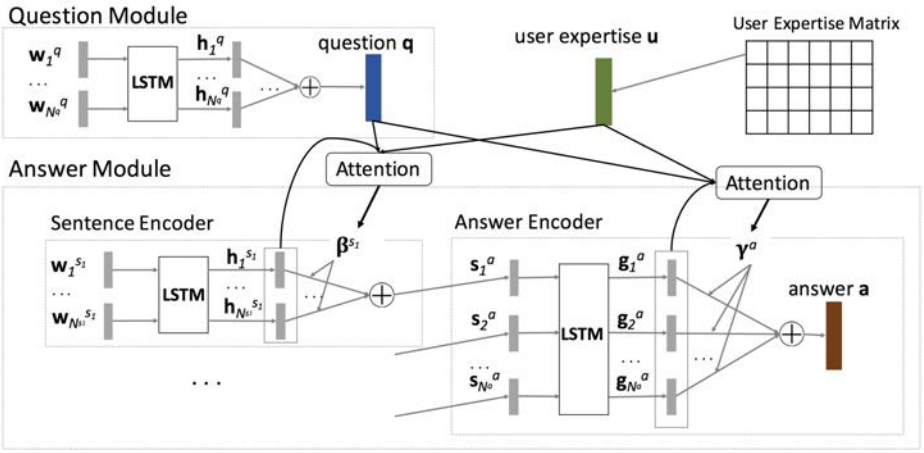

Figure 4: The Overview of our framework. Our model encodes user expertise in the answer representation, contributing to capture the implicit topic interests in learned user vectors.

4 UEAN FOR ANSWER SELECTION

In this section, we present User-Expertise aware Attention Networks (UEAN) model in detail whose framework is shown in Figure 4. We first explain our specific-designed user-expertise aware matching function in Section 4.1, explicitly modeling the influence of user expertise in community acceptance. Then, we discuss how to obtain answer and question representation in Section 4.2 and 4.3 respectively. Finally, we elaborate the learning process of our model in Section 4.4.

4.1 User Expertise Aware Matching Function

Most of the existing works merely model the semantic relevance between question-answer pairs and ignore the expertise of users when modeling the answer selection in CQA. Besides the semantic relevance, users with high expertise contribute to achieve acceptance from the community. Thus, we design a novel score function jointly capturing the semantic relevance and the expertise of users (shown in Figure 3). We divide our matching function into two parts: the semantic matching part and expertise part.

Let a tuple $(q_i, a_{q_i,j}, u_k)$ denote an answer $a_{q_i,j}$ provided by u_k for question q_i. The score function for a tuple $(q_i, a_{q_i,j}, u_k)$ is designed as follows:

$$s(q_i, a_{q_i,j}, u_k) = \mathbf{q}_i^T \mathbf{M} \mathbf{a}_{q_i,j} + \mathbf{q}_i^T \mathbf{N} \mathbf{u}_k. \tag{2}$$

where $\mathbf{q}_i, \mathbf{a}_{q_i,j}$, and $\mathbf{u}_k$ is the representation of the question q_i, answer $a_{q_i,j}$, and user expertise u_k respectively. The representation of answer $a_{q_i,j}$ and the question q_i are generated from answer and question in Section 4.2 and 4.3. The representation of user expertise $\mathbf{u}_k$ is a latent vector learned during training. In Eq. (2), $\mathbf{q}_i^T \mathbf{M} \mathbf{a}_{q_i,j}$ represents the semantic matching score between answer $a_{q_i,j}$ and question q_i, where $\mathbf{M}$ is a matrix to transform the question representation into the space of answer representation. $\mathbf{q}_i^T \mathbf{N} \mathbf{u}_k$ represents the expertise score of user u_k to the question q_i, where $\mathbf{N}$ is a matrix to transform the question representation into the representation space of user expertise. In this way, our matching function takes both the interactions of question-user pair and question-answer pair into consideration.

4.2 User Expertise Aware Answer Module

Answer module aims at generating representations for input answers. For the purpose of capturing the implicit topic interests in learned user vectors, we introduce latent user vectors into the representation learning of answers. We encode user expertise in the answer representation by hierarchical attention mechanisms within LSTM networks, contributing to capture content more informative to user-specific interests.

4.2.1 ***Sentence encoder.*** For the t-th sentence s_t with N_{s_t} words in an answer, we first represent each word $w_j^{s_t}$ as a K_w-dimensional vector $\mathbf{w}_j^{s_t}$ by pre-trained word embeddings [30]. We then adopt the widely exploited LSTM enabling to deal with variable-length sequence input, to encode a sentence into a fixed-length vector. We utilize the LSTM in [21] to take each word vector $\mathbf{w}_j^{s_t}$ as input and updates the corresponding hidden state $\mathbf{h}_j^{s_t}$ as follows:

$$\mathbf{h}_j^{s_t} = LSTM(\mathbf{h}_{j-1}^{s_t}, \mathbf{w}_j^{s_t}). \tag{3}$$

In Eq. (3), the hidden vector $\mathbf{h}_j^{s_t}$ is learned from the previous hidden states and the j-th input word.

In a sentence, some words are relevant to the semantic information of user expertise. For instance, the word "Java" or "Python" can capture the expertise of the user who is skilled in "Programming Language". The word "LSTM" or "CNN" can capture the the expertise of the user who is skilled in "Deep Learning". Hence, we introduce the latent user expertise into the representation learning of answer sentence to capture the implicit topic interests in learned user vectors. Meanwhile, we also introduce the question information to capture the words relevant to the question.

We encode the user expertise in answer representation by attention mechanisms [3]. We first concatenate the user expertise vector $\mathbf{u}$, question vector $\mathbf{q}$, and hidden vector $\mathbf{h}_j^t$ of answer word. Then we select $tanh$ as the activation function and calculate the weights

by a multi-layer perceptron (MLP) [4]. Finally, the attention weight $\beta_j^{s_t}$ is generated as follows:

$$e_j^{s_t} = \mathbf{v}_w^T \tanh(\mathbf{W}_w[\mathbf{u}; \mathbf{q}; \mathbf{h}_j^{s_t}] + \mathbf{b}_w),$$
$$\beta_j^{s_t} = softmax(e_j^{s_t}), \quad (4)$$

where $softmax(x_i) = \frac{x_i}{\sum_j x_j}$ is taken to normalize the weights, and $\mathbf{W}_w$, $\mathbf{b}_w$ and $\mathbf{v}_w$ are parameters in word-level attention that to be learned. Then the sentence representation $\mathbf{s}_t$ can be calculated based on the weights obtained from Eq. (4) and the hidden states from $\mathbf{h}_1^{s_t}$ to $\mathbf{h}_{N_{s_t}}^{s_t}$ as follows:

$$\mathbf{s}_t = \sum_{j=1}^{N_{s_t}} \beta_j^{s_t} \mathbf{h}_j^{s_t}. \quad (5)$$

4.2.2 ***Answer encoder.*** Assume that an answer a is comprised of a sequence of N_a sentences, i.e. $(s_1^a, \ldots, s_{N_a}^a)$, each of which is encoded as a K_s-dimensional vector $\mathbf{s}_t^a$ by Eq. (5). As the sentences of an answer can be regarded as a sequence with variable length, we can obtain the answer representation in a similar way using the LSTM at sentence-level. The hidden state $\mathbf{g}_t^a$ is calculated as follows:

$$\mathbf{g}_t^a = LSTM(\mathbf{g}_{t-1}^a, \mathbf{s}_t^a), \quad (6)$$

where the updating of hidden state is depended on the sentence vector $\mathbf{s}_t^a$ and the hidden state $\mathbf{g}_{t-1}^a$ in each iteration.

Similar to the words, some sentences can capture the implicit topic interests of learned user vectors. Hence, we encode user expertise and question content in the answer representation by a sentence-level attention mechanism. In this way, more informative sentences will be emphasized and less informative sentences will be weakened. Thus, we can estimate weights from attention layer according to the latent factor of users and the representation of question. Then each attention weight γ_t^a for the sentence s_t^a is calculated through attention mechanism by

$$e_t^a = \mathbf{v}_s^T \tanh(\mathbf{W}_s[\mathbf{u}; \mathbf{q}; \mathbf{g}_t^a] + \mathbf{b}_s),$$
$$\gamma_t^a = softmax(e_t^a), \quad (7)$$

where $\mathbf{W}_s$, $\mathbf{b}_s$ and $\mathbf{v}_s$ are parameters in sentence-level attention that to be learned. The overall answer representation vector $\mathbf{a}$ is calculated by aggregating all hidden vectors from sentences weighted by their corresponding attention weights as

$$\mathbf{a} = \sum_{t=1}^{N_a} \gamma_t^a \mathbf{g}_t^a. \quad (8)$$

4.3 Question Module

For a question q with a sequence of N_q words, we first represent each word w_i^q as a K_w-dimensional vector $\mathbf{w}_i^q$ by pre-trained word embeddings [30]. We then employ the LSTM by taking each word vector $\mathbf{w}_i^q$ as input and updating the corresponding hidden state $\mathbf{h}_i^q$ as follows:

$$\mathbf{h}_i^q = LSTM(\mathbf{h}_{i-1}^q, \mathbf{w}_i^q). \quad (9)$$

We observe that each word contributes differently to the representation of a question. For example, in a question "*Where is the theater?*", "where" and "theater" play more critical roles in summarizing this question. Therefore, we employ the attention mechanism to learn the question representation by focusing on more informative words. The attention weight α_i^q is based on the hidden state $\mathbf{h}_i^q$ of word w_i^q. Afterwards, the question representation $\mathbf{q}$ is generated as the weighted sum of hidden vectors from words according to their corresponding importance as follows:

$$\alpha_i^q = softmax(\mathbf{m}^T \mathbf{h}_i^q), \quad (10)$$

$$\mathbf{q} = \sum_{i=1}^{N_q} \alpha_i^q \mathbf{h}_i^q, \quad (11)$$

where $\mathbf{m}$ is a parameter to be learned.

4.4 Learning Process

We employ a discriminative training strategy with a large margin objective to train our model. Given each pair of tuples $(q_i, a_{q_i,j}, u_k)$ and $(q_i, a_{q_i,m}, u_n)$ related to question q_i in training set, the relevance score of each answer can be calculated by the matching function in Eq. (2). Suppose that the quality of answer $a_{q_i,m}$ is higher than the quality of answer $a_{q_i,j}$, we aim to maximize the following ranking-based loss under observed ranking order as follows,

$$L = \sum_{(i,j,k) \prec (i,m,n)} \max(0, c + s(q_i, a_{q_i,m}, u_n) - s(q_i, a_{q_i,j}, u_k)),$$

where $0 < c < 1$ is a slack variable. During the training process, question and answer share the pre-trained word embeddings. All the weight parameters are randomly initialized and trained by the back propagation of training loss. Besides, the ground truth of ranking order is inferred by votes in real CQA sites.

5 EXPERIMENT

In this section, we conduct experiments to evaluate the effectiveness of our model and compare it with several state-of-the-art methods for answer selection, showing that our proposed model outperforms other state-of-the-art approaches. Moreover, we investigate the learned representation of user expertise, showing the potentials on understanding user expertise in CQA.

5.1 Experimental Setups

5.1.1 ***Datasets.*** To demonstrate the effectiveness of our approach in real application, the following two datasets are adopted in our experiment.

- **Quora dataset**. We collected a large dataset from Quora which is one of the most popular CQA sites. We randomly crawled 800,772 questions and 3,523,485 answers posted from January 2016 and July 2017. The votes and users related to these answers are also collected. For statistical reliability, we remove the questions if the maximum number of votes received by the following answers is smaller than 10. We also remove questions with answers less than 2. Finally, our dataset contains 76,158 questions, 467,681 answers, 31,802,631 votes, and 46,470 users.
- **Stack Overflow dataset**. The dataset is available from StackOverflow[4] in public, containing 214,803 questions and 586,725

[4]https://stackoverflow.com/

answers. We preprocess the dataset following the similar strategy used in Quora dataset. After preprocessing, the dataset contains 19,944 questions, 67,011 answers and 6,340 users.

The two datasets are both randomly split into three subsets without overlapping for the purpose of training, validation and testing in the following experiments. The proportion of training, validation and testing dataset is equal to 80%, 10% and 10%. We also vary the size of training dataset (40%, 60% and 80%) in order to validate the robustness of our proposed methods in different experimental setting.

5.1.2 ***Evaluation Metric.*** We evaluate the performance of our model using three widely-used ranking metrics, which are Precision@1, Mean Reciprocal Rank (MRR), and normalized Discounted Cumulative Gain (nDCG). The three metrics are formulated as follows,

- *Precision@1* takes into account the position of relevant answer at top 1, calculated by

$$Precision@1 = \frac{|\{q \in Q | rank'_{best} = 1\}|}{|Q|},$$

  where $|Q|$ is the number of questions in test dataset and $rank'_{best}$ is the predicted position of the best answer given by algorithm.
- *MRR* is the average of the reciprocal ranks corresponding to the most relevant answer in questions, calculated by

$$MRR = \frac{1}{|Q|} \sum_{i=1}^{|Q|} \frac{1}{rank'^{i}_{best}},$$

  where $rank'^{i}_{best}$ is the position of the best answer in the i-th question given by algorithm.
- *NDCG* is a measure of ranking quality. As to question q, NDCG is calculated by

$$nDCG = \frac{DCG}{IDCG},$$
$$\text{where } DCG = rel_1 + \sum_{i=2}^{|A_q|} \frac{rel_i}{\log_2 i},$$

  where IDCG is ideal discounted cumulative gain, $|A_q|$ is the number of answers in question q and rel_i is the relevance between question and answer at position i. We report the average of all the nDCG values in all test questions.

The larger results received by the above evaluation metrics means the better performance of the algorithms in answer selection.

5.1.3 ***Comparative Methods.*** We compare our model to 6 typical state-of-the-art methods which are briefly described below.

- **Okapi BM25** [20] is a bag-of-words retrieval model used in information retrieval. We use the model to rank candidate answers based on the question terms appearing in each answer.
- **TransLM** [44] is a retrieval model that combines a translation-based language model for the question part with a query likelihood approach for the answer part. We use TransLM to calculate the similarity between every question-answer pair and rank candidate answers based on the similarity.
- **Doc2Vec** [23] is an unsupervised algorithm that learns fixed-length feature representations from variable-length pieces of texts. We first use Doc2Vec to learn representations of questions and answers. The matching score of a question-answer pair is calculated with a MLP with the representations of the question and answer as input.
- **CNTN** [31] is a convolutional neural tensor network architecture to encode the question and answer in semantic space and model their interactions with a tensor layer.
- **AI-CNN** [47] first learns representations of questions and answers by CNN and then applies one-level attentive pooling network on an interaction tensor of a question-answer pair.
- **AMRNL** [48] learns representations of questions and answers by deep recurrent neural networks and ranks the answers by semantic relevance and the answers' authority.

Table 1: The Precision@1 of all methods on Quora dataset with different settings of training data size.

Method	Precision@1 (%)		
	40%	60%	80%
Okapi BM25	26.71	26.71	26.71

OURS	**76.47**	**77.63**	**78.29**

5.1.4 ***Parameter settings.*** Okapi BM25, TransLM, Doc2Vec and AMRNL are implemented according to the source code provided by authors. The baselines of CNTN and AI-CNN are carefully implemented with hyperparameter tuning according to the original papers. In our proposed method, we use GloVe [30] pre-trained word embeddings. The dimension of word embedding is 50. The questions and answers are tokenized and lemmatized using NLTK[5]. Tokens that did not appear in the pre-trained word embeddings are initialized randomly. The dimension of LSTM network embedding in our experiment is 128 and the dimension of parameter $\mathbf{v}$ for

attention mechanism in Eq. (4) and Eq. (7) is 64. Besides, the dimension of user representation is 128. We set the margin $c = 0.5$ in the ranking loss. At last, we choose Adam [22] as the optimization strategy to update parameters with initial learning rate 0.001.

5.2 Prediction Performance on Answer Selection

In this section, we compare the performance of our model with the chosen state-of-the-art methods in order to validate the effectiveness of our proposed method in predicting the rank of best answers. Table 1, 2 and 3 present the experimental results on Quora dataset in terms of Precision@1, MRR and nDCG respectively. Table 4, 5 and 6 present the experimental results on Stack Overflow dataset. We summarize our observations as follows:

- Methods based on distributed representations all perform better than Okapi BM25. It proves that word embeddings can capture more semantic information than traditional bag-of-words approaches.
- CNTN and AI-CNN outperform Doc2Vec and TransLM, indicating that it is effective to model fine-granularity interaction between a pair of question and answer.
- Approaches with consideration of user expertise, i.e., AMRNL and our proposed method, perform better than these methods that merely consider semantic relevance, demonstrating that modeling the influence of user expertise is helpful for answer selection in CQA.
- In addition, our proposed method is better than AMRNL, proving the effectiveness of modeling user expertise in both explicit and implicit ways for answer selection.
- At last, our proposed method significantly outperform the baselines in all cases. The results show that our proposed method is well suitable to answer selection problem in CQA.

In order to validate the effectiveness of explicitly modeling the relevance of question-user pair in our model, we introduce variants of our model (with user expertise and without) and compare the performance. Table 7 presents the experimental results.It is observed that our model with user expertise significantly outperform our model without user expertise. Furthermore, we conduct case studies to analyze the advantages of our proposed model in answer selection. We find out that short answers prefer to receive lower relevant score with merely modeling question-answer relevance.

OURS	**91.70**	**92.34**	**92.79**

It is because that short answers usually have less semantic information than long answers. However, *short answer would be the best answer accepted by communities*. In the question "What are the similarities between GANs and reinforcement learning?" on Quora[6], the communities vote the shortest answer to be the best answer as the responser is "Yoshua Bengio". In CQA, the acceptance of community pays an important role in answer selection. The explicit modeling on the relevance of question-user pair can well model the scenario when the defined "user expertise" pays more important role in answer selection on CQA systems.

Next we will investigate the learning mechanism of user expertise in detail and give both qualitative and quantitative analyses on learned user expertise.

[6]https://www.quora.com/What-are-the-similarities-between-GANs-and-reinforcement-learning

Table 7: The performance (%) of our model (with user expertise and without) on datasets with 80% of the data for training. ("UE" - user expertise.)

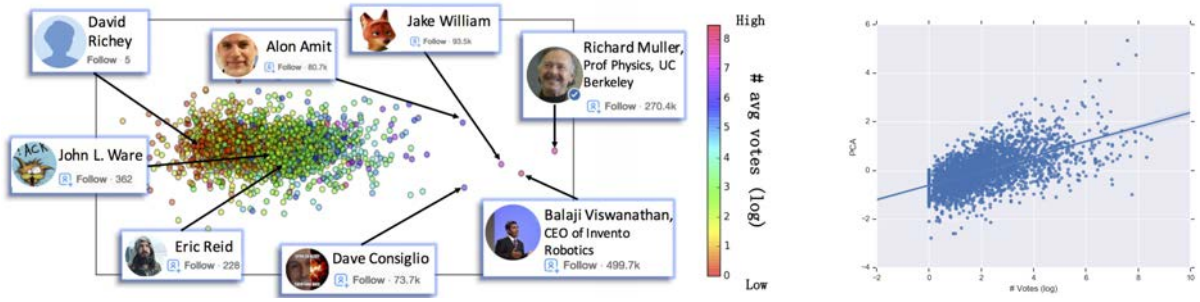
With UE	**64.54**	**78.29**	**92.04**	**56.56**	**74.22**	**92.79**

5.3 What is Learned in User Vectors

In this section, we give both qualitative and quantitative analyses on learned user embedding vectors and illustrate the potentials of learned user expertise on presenting community acceptance and topic interests of users.

Authority-correlated user expertise. Average number of votes is positively related to authority accepted by the community in CQA platform, which is an important indicator for user expertise in long term. Therefore, we use the average number of votes to validate whether the learned user representations has positive correlation to the authority in practice. We randomly choose 3,000 users in Quora and plot their embeddings in Figure 5(a) whose dimensionality is reduced by PCA [13] from the original high dimensional space (128) to a visualization space (2). Each user is colored by their true authority, calculated by their average votes per question in Quora. In the figure, the users with different authority can be well separated by the user representations. We can differentiate three clusters with high, median and low expertise from the sampled users. We randomly choose several users at each cluster and show their profile. The blue/purple block on the right side can be regarded as the community with high reputation, where users with high votes and many followers are located, such as Balaji Viswanathan, Richard Muller, Jake Williams, Alon Ami and Dave Consiglio. The green block on the middle is the community with median authority, such as John L Ware and Eric Reid are located. The red block on the left side is the community with low expertise, where the users with few followers and zero vote are located. According to the experimental results, the learned user vectors have potentials on presenting authority. Furthermore, we reduce the dimensionality of user vectors from 128 to 1 by PCA and plot it with the average votes of users in Figure 5(b). It is observed that the user vectors and votes are positively correlated in linear and the correlation coefficient is about 0.27. Both the experimental results indicate that the learned user representation can positively reflect the users' authority in quantitative ways.

Topic-sensitive user expertise. The CQA systems would label users when the history of user behaviors is quite enough to be expertise in certain fields. In this way, we can use the systematic tags on users to verify whether the learned user expertise contains the topic interests. Firstly, we choose three random cases to qualitatively analyze how the relevance exists between the learned user expertise and topics. The cosine similarity is introduced to measure the difference between user vector and question representation, and we use the cosine similarity to explore the most similar questions of users. Then we choose 30 most similar questions of each user and extract the keywords in questions to validate if the keywords are relative to the user tags. The experimental results are shown in Figure 6. It is observed that the extracted keywords of each user are correlated to the user tags, indicating the topic-sensitive user representations learned by our proposed method. Besides, we randomly choose 1,000 users who are labeled on "programming" and "relationships" respectively. Then we apply K-means [1] to cluster the sampled users as $K = 2$ based on the learned user representations. The accuracy of clusters is up to 67%, giving the evidence of the topic interests contained in the learned user representations.



5.4 Effect of User Expertise in Answer Selection of Different Domains

In this section, we analyze the effect of user expertise in answer selection of different domains. We take four domains as examples from testing dataset, e.g. Movies, Experiences in Life, Physics, Police and Law Enforcement. We show the performance of our model (with user expertise and without) and the increase of metric by user expertise in Table 8. We notice that the increase of metric is more significant in domains like "Physics", "Police and Law Enforcement" than "Movies", "Experiences in Life". The experimental results demonstrate that user expertise plays a more important role in areas which need more domain knowledge. For instance, question "What is the most difficult thing you have ever watched?" in "Experiences in Life" can be answered by every user, but question "How far away from the nuclear plant is safe in case of nuclear meltdown?" in "Physics" is more professional.

5.5 Effect of User Expertise in Answer Representation Learning

In order to analyze the effect of user expertise in answer representation learning, we take an example and draw heat maps of sentence and word weights to demonstrate the difference between the setups with/without user expertise in answer representation learning (Figure 7). We pick up the question that "*What languages should I learn before starting to learn of AI?*" and its three answers as the example. There are many sentences in each answer and we only visualize the key sentences and their weights due to space limitation. The demonstration is shown in Figure 7, where Figure 7(a) and 7(d) depict weights by the learning mechanism with user expertise, Figure 7(b) and 7(e) describe the weights by the learning mechanism without user expertise respectively.

In the examples, we notice that both Figure 7(a) and 7(d) highlight the word "python" with the highest weight in the paragraph. Meanwhile, the word "AI" is given the highest weight in the paragraph shown in the Figure 7(b) and 7(e). Moreover, the sentences with python and programming are highlighted by the results from answer representation learning with user expertise, and the sentences with AI and ML are emphasized by the results from answer representation learning without user expertise. It is clear that the highlighted results from answer representation learning with user expertise are more relative to the question "What language should I learn before starting to learn of AI?". According to the results, we can observe that semantic relevance is less important than user expertise in such scenario. The answer would hardly point to the question by direct semantic relevance. In the examples, the better results from answer representation learning with user expertise are because of that the user_1 and user_2 have "computer programming"

(a) Visualization of user vectors. The blue/purple color means the higher expertise achieved in Quora, the green color means the median expertise, while the red color refers to the lower expertise.

(b) The correlation between learned user expertise and the true expertise accepted by communities.

Figure 6: Examples of topic interests in learned user vectors.

Table 8: The performance (%) of our model (with user expertise and without) in different domains on Quora dataset with 80% of the data for training. ("UE" - user expertise. "Increase" - the increase of metric by modeling user expertise.)

Domain	Movies			Experiences in Life			Physics			Police and Law Enforcement		
	P@1	MRR	nDCG	P@1	MRR	nDCG	P@1	MRR	nDCG	P@1	MRR	nDCG
Without UE	35.00	54.56	74.88	35.71	58.99	82.65	29.36	53.78	78.48	27.66	49.28	72.21
With UE	52.50	69.76	87.47	58.33	74.91	91.67	72.48	83.55	94.56	70.21	81.74	93.73
Increase	50.00	27.86	16.82	63.34	26.99	10.91	146.87	55.36	20.49	153.85	65.86	29.82

tag in user profile (see Figure 7(c) and 7(f)), and the embedded user expertise in answer representation learning can help to emphasize on the programming-related words. The answer representation learning with user expertise can both capture the semantic and specialized relevance in answering, improving the emphasis on more important words in contents.

Furthermore, we conduct experiments on Quora and Stack Overflow dataset to validate the effectiveness of different attention mechanism for answer representation learning with user expertise at different attention levels. The experimental results are recorded in Table 9. With 60% training dataset, the implementation of attention mechanism with user expertise at hierarchical level achieves 0.6338, 0.7763 and 0.9191 in Quora dataset, resulted by P@1, MRR and nDCG respectively. The experimental results are better than the results from the implementation of attention mechanism with user expertise at word and sentence levels in Quora dataset (achieving 0.6205 and 0.6291 in P@1, 0.7655 and 0.7732 in MRR and 0.9110 and 0.9178 in nDCG). Moreover, all the attention mechanisms with user expertise at different semantic levels achieve better performance than the evaluation results from the attention mechanism without user expertise. It is interested that the attention mechanism with user expertise at sentence level achieve better performance than the implementation of attention mechanism with user expertise at word level. It may indicate that the implementation of attention

(d) Heat map with user expertise of answer$_2$. (e) Heat map without user expertise of answer$_2$. (f) Profile of user$_2$.

Figure 7: Visualization of the effect of encoding user expertise in answer representation. Orange denotes the sentence weight and blue denotes the word weight. The segments with higher weights are endowed with darker color. (a) and (d) are heat maps of answers with encoding user expertise in answer representation. (b) and (e) are heat maps of answers without encoding user expertise in answer representation. (c) and (f) are the user profiles about their expertise respectively. Answer representation learning with user expertise is able to emphasize sentences and words on personalized knowledgement. Answer representation learning without user expertise tends to focus on sentences and words which match the question semantically, i.e., the word "*AI*".

mechanism with user expertise on higher level is more effective than the implementation on lower level. The same conclusion can be reproduced in the experimental results from Stack Overflow dataset. Overall, the experimental results demonstrate the effectiveness on the implementation of attention mechanism with user expertise at both word and sentence levels. The answer representation learning with user expertise can emphasize more on the important words by semantic and specialized relevance in answering, improving the rank prediction of answer selection in CQA.

6 CONCLUSION

Answer selection is the key problem when scarce votes are provided in one question on CQA platform. However, the ranking of answers is simply tackled as a text mathcing problem in existing works, ignoring the influence of community. In this paper, we propose a user-expertise specific learning framework to model the dynamics of answer selection in CQA. Our model learns user expertise of each user by latent factors, better capturing the rank of answers. A novel score function is introduced to evaluate the relevance on question-answer pair and user expertise in question-user pairs accepted by

Table 9: The performance (%) of answer representation learning with user expertise at different attention levels, i.e., word, sentence and hierarchical levels, on datasets with 60% of the data for training. ("No" - the vanilla LSTM without attention mechanism. "Word" - employ attentions only at word-level and utilize the vanilla outputs of sentence level LSTM as the answer representation. "Sentence" - employ attentions only at sentence-level and use the vanilla outputs from word level LSTM. "Hierarchical" - employ attentions at both levels.)

communities. Moreover, we introduce latent user vectors into the representation learning of answering, capturing the implicit topic interests in learned user vectors. The experiments show that our model outperforms all baselines in answer selection task. Furthermore, we analyze the user representations learned by our model. The extensive experimental results prove that the learned user vectors can indicate the authority accepted by communities and capture the user interests in topic level, provide us a quantitative way to understand user expertise in CQA.

ABSTRACT

Explainability and effectiveness are two key aspects for building recommender systems. Prior efforts mostly focus on incorporating side information to achieve better recommendation performance. However, these methods have some weaknesses: (1) prediction of neural network-based embedding methods are hard to explain and debug; (2) symbolic, graph-based approaches (e.g., meta path-based models) require manual efforts and domain knowledge to define patterns and rules, and ignore the item association types (e.g. substitutable and complementary). In this paper, we propose a novel joint learning framework to integrate *induction of explainable rules from knowledge graph* with *construction of a rule-guided neural recommendation model*. The framework encourages two modules to complement each other in generating effective and explainable recommendation: 1) inductive rules, mined from item-centric knowledge graphs, summarize common multi-hop relational patterns for inferring different item associations and provide human-readable explanation for model prediction; 2) recommendation module can be augmented by induced rules and thus have better generalization ability dealing with the cold-start issue. Extensive experiments[1] show that our proposed method has achieved significant improvements in item recommendation over baselines on real-world datasets. Our model demonstrates robust performance over "noisy" item knowledge graphs, generated by linking item names to related entities.

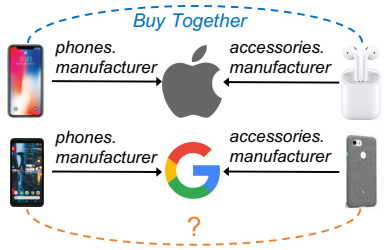

Figure 1: Illustration of Item-item Associations in a Knowledge Graph. Given items, relations and item associations (e.g. *Buy Together*), our goal is to induce rules from them and recommend items from rules. These rules are used to infer associations between new items, recommend items, and explain the recommendation.

becomes critically important for the recommender systems to provide convincing results—this helps to improve the effectiveness, efficiency, persuasiveness, transparency, and user satisfaction of recommender systems [45].

Though there are many powerful neural network-based recommendation algorithms proposed these years, most of them are unable to give explainable recommendation results [12, 14, 19]. Existing explainable recommendation algorithms are mainly two types: user-based [25, 33] and review-based [11, 46]. However, both of them are suffering from data sparsity problem, it is very hard for them to give clear reasons for the recommendation if the item lacks user reviews or the user has no social information.

On another line of research, some recommendation algorithms try to incorporate knowledge graphs, which contain lots of structured information, to introduce more features for the recommendation. There are two types of works that utilize knowledge graphs to improve recommendation: meta-path based methods [32, 43, 48] and embedding learning-based algorithms [24, 31, 44]. However, meta-path based methods require manual efforts and domain knowledge to define patterns and paths for feature extraction. Embedding based algorithms use the structure of the knowledge graph to learn users' and items' feature vectors for the recommendation, while the recommendation results are unexplainable. Besides, both types of algorithms ignore item associations.

We find that associations between items/products can be utilized to give accurate and explainable recommendation. For example, if a user buys a cellphone, it makes sense to recommend him/her some cellphone chargers or cases (as they are complementary items of the cellphone). But it may cause negative experiences if the system shows him/her other cellphones immediately (substitute items) because most users will not buy another cellphone right after buying one. So we can use this signal to tell users why we recommend an item for a user with explicit reasons (even for cold items). Furthermore, we propose that an idea to make use of item associations: After mapping the items into a knowledge graph, there will be multi-hop relational paths between items. Then, We can summarize explainable rules from for predicting association relationships between each two items and the induced rules will also be helpful for the recommendation.

To shed some light on this problem, we propose a novel joint learning framework to give accurate and explainable recommendations. The framework consists of a rule learning module and a recommendation module. We exploit knowledge graphs to induce explainable rules from item associations in the rule learning module and provide rule-guided recommendations based on the rules in the recommendation module. Fig. 1 shows an example of items with item associations in a knowledge graph. Note the knowledge graph here is constructed by linking items into a real knowledge graph, but not a heterogeneous graph that only consists of items and their attributes. The rule learning module leverage relations in a knowledge graph to summarize common rule patterns from item associations, which is explainable. The recommendation module combines existing recommendation models with the reduced rules, thus have a better ability to deal with the cold-start problem and give explainable recommendations. Our proposed framework outperforms baselines on real-world datasets from different domains. Furthermore, it gives an explainable result with the rules.

Our main contributions are listed as follows:

- We utilize a large-scale knowledge graph to derive rules between items from item associations.
- We propose a joint optimization framework that induces rules from knowledge graphs and recommends items based on the rules at the same time.
- We conduct extensive experiments on real-world datasets. Experimental results prove the effectiveness of our framework in accurate and explainable recommendation

2 PRELIMINARIES

We firstly introduce concepts and give a formal problem definition. Then, we briefly review BPRMF [27] and NCF [14] algorithms.

2.1 Background and Problem

Item recommendation. Given users U and items I, the task of item recommendation aims to identify items that are most suitable for each user based on historical interactions between users and items (e.g. purchase history). A user expresses his or her preferences by purchasing or rating items. These interactions can be represented as a matrix. One of the promising approaches is a matrix factorization method which embeds users and items into a low dimensional latent space. This method decomposes the user-item interaction matrix into the product of two lower dimensional rectangular matrices U and I for a user and an item, respectively. From these matrices, we can recommend new items to users.

Knowledge graph. A knowledge graph is a multi-relational graph that composed of entities as nodes and relations r as different types edges e. We can use many triples (head entity E_1, relation type r_1, tail entity E_2) to represent the facts in the knowledge graph [38].

Inductive rules on knowledge graph. There are several paths between two entities in the knowledge graph, and a path is consisted of entities with the relation types (e.g. $P_k = E_1 r_1 E_2 r_2 E_3$ is a path between E_1 and E_3). A rule R is defined by the relation sequence between two entities, e.g. $R = r_1 r_2$ is a rule. The difference between paths and rules is that rules focus on the relation types, not entities.

Problem Definition. Our study focus on jointly learning rules in a knowledge graph and a recommender system with the rules. Formally, our problem is defined as follows:

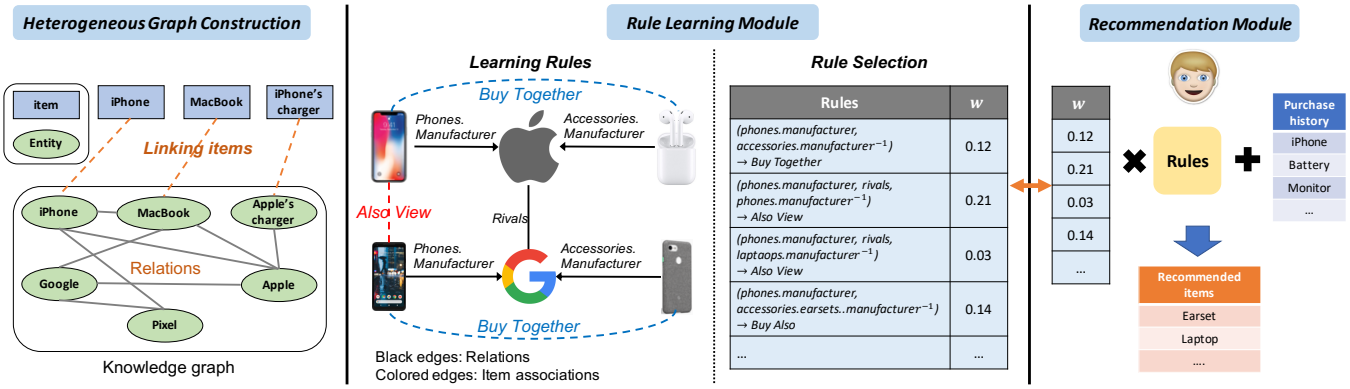

Figure 2: Overview of the Proposed RuleRec Framework. First, we build a heterogeneous graph from items and a knowledge graph. The rule learning module learns the importance of rules and the recommendation module learns the importance at the same time by sharing a parameter vector $\boldsymbol{w}$.

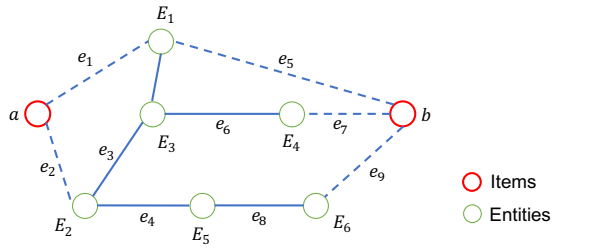
Definition 2.1 (Problem Definition). **Given** users U, items I, user-item interactions, item associations, and a knowledge graph, our framework **aims to** jointly (1) learn rules R between items based on item associations and (2) learn a recommender system to recommend items I'_u to each user u based on the rules R and his/her interaction history I_u. This framework outputs a set of rules R and recommended item lists I'.

2.2 Base Models for Recommendation

The framework proposed in our study is flexible to work with different recommendation algorithms. As BPRMF is a widely used classical matrix factorization algorithm and NCF is a state-of-the-art neural network based recommendation algorithm, we choose to modify them to verify the effectiveness of our framework.

Bayesian Personalized Ranking Matrix Factorization (BPRMF). Matrix Factorization based algorithms play a vital role in recommender systems. The idea is to represent each user/item with a vector of latent features. U and I are user feature matrix and item feature matrix respectively, and we use U_u to denote the feature vector of user u (I_i for item i). The dimensions of them are the same. In BPRMF algorithm [27], the preference score $S_{u,i}$ between u and i is computed by the inner product of U_u and I_i:



$$S_{u,i} = U_u^\top \cdot I_i \tag{1}$$

The objective function of BPRMF algorithm is defined as a pairwised function as follows:

$$O_{BPRMF} = \sum_{u \in U} \sum_{p \in I_u, n \notin I_u} (S_{u,p} - S_{u,n}) \tag{2}$$

where p is a positive item that user u interacted before, and n is a negative item sampled randomly from the items user u has never interacted (n should not be in test set too).

Neural Collaborative Filtering (NCF). NCF [14] is a neural based matrix factorization algorithm. Similar to BPRMF, each user u and each item i has a corresponding feature vector U_u and I_i, respectively. NCF propose a generalized matrix factorization (GMF)

Edge type:
$e_1, e_2, e_5, e_7, e_9 \in r_1$
$e_3, e_4 \in r_2$
$e_6, e_8 \in r_3$

Paths between a and b:
$P_1 = e_1 E_1 e_5$
$P_2 = e_2 E_2 e_3 E_3 e_6 E_4 e_7$
$P_3 = e_2 E_2 e_4 E_5 e_8 E_6 e_9$

Related reasoning rules:
Rules for P_1: $R_1 = r_1 r_1$
Rules for P_2, P_3: $R_2 = r_1 r_2 r_3 r_1$

Figure 3: An example of a heterogeneous graph which consists of items and entities in a knowledge graph. The dashed lines are links between items and entities generated by an entity linking algorithm.

(Eq (3)) and a non-linear interaction part via a multi-layer perception (MLP) (Eq (4)) between user and item to extraction.

$$h_{u,i} = U_u^\top \cdot I_i \tag{3}$$

$$\begin{aligned} g_{u,i} &= \phi_n(...\phi_2(\phi_1(z_1))) \\ z_1 &= \phi_0(U_u \oplus I_i) \\ \phi_k(z_{k-1}) &= \phi_k(W_k^T z_{k-1} + b_{k-1}), \end{aligned} \tag{4}$$

where n is the number of hidden layers. W_k, b_l, and z_k are weight matrices, bias vector, and output of each layer. $\oplus$ is vector concatenation and ϕ is a non-linear activation function. Both $h_{u,i}$ and $g_{u,i}$ are user-item interaction feature vectors for GMF and MLP, respectively. The prediction equation of NCF is defined in Eq (5), in which the outputs of GMF and MLP parts are concatentated to get the final score. And we modified the objective function of NCF into Eq (6) in this paper.

$$S_{u,i} = \phi(\alpha \cdot h_{u,i} \oplus (1-\alpha) \cdot g_{u,i}) \tag{5}$$

$$O_{NCF} = \sigma(\sum_{u \in U} \sum_{p \in I_u, n \notin I_u} (S_{u,p} - S_{u,n})) \tag{6}$$

3 THE RULEREC FRAMEWORK

Framework Overview. Recommendation with rule learning consists of two sub-tasks: 1) rule learning in a knowledge graph based on item associations; 2) recommending items for each user u with his/her purchase history I_u and the derived rules R.

To cope with these tasks, we design a multi-task learning framework. The framework consists of two modules, a rule learning module and a recommendation module. The rule learning module aims to derive useful rules through reasoning rules with ground-truth item associations in the knowledge graph. Based on the rule set, we can generate an item-pair feature vector whose each entry is an encoded value of each rule. The recommendation module takes the item-pair feature vector as additional input to enhance recommendation performances and give explanations for the recommendation. We introduce a shared rule weight vector w which indicates the importance of each rule in predicting user preference, and shows the effectiveness of each rule in predicting item pair associations. Besides, based on the assume that useful rules perform consistently in both modules with higher weights, we design a objective function to conduct jointly learning:

$$\min_{V,W} O = \min_{V,W} \{O_r + \lambda O_l\} \tag{7}$$

where V denotes the parameters of the recommendation module, and W represents the shared parameters of the rule learning and the recommendation module. The objective function consists of two terms: O_r is the objective of the recommendation module, which recommends items based on the induced rules. O_l is the objective of the rule learning module, in which we leverage the given item associations to learn useful rules. λ is a trade-off parameter.

3.1 Heterogeneous Graph Construction

First, we build a heterogeneous graph containing items for the recommendation and a knowledge graph. For some items, we can conduct exactly mapping between the item and the entity, such as "iPhone", "Macbook". For other items, it is hard to find an entity that represents the items, such iPhone's charger. Thus, we adopt entity linking algorithm [6] to find the related entities of an item from its title, brand, and description in the shopping website. In this way, we can add new nodes to the knowledge graph that represents items and add some edges for it according to entity linking results. Then, we get a heterogeneous graph which contains the items and the original knowledge graph. Fig. 3 is an example.

3.2 Rule Learning Module

The rule learning module aims to find the reliable rule set R_A associated with given item associations A in the heterogeneous graph.

Rule learning. For any item pair (a, b) in the heterogeneous graph, we use a random walk based algorithm to compute the probabilities of finding paths which follow certain rules between the item pair, similar to [16, 17]. Then, we obtain feature vectors for item pairs. Each entry of the feature vector is the probability of a rule between the item pair. Here, we focus on relation types between the item pair to obtain rules such as R_1 in Fig. 3, because it is general to the entities to capture the rules between items.

First, we define the probability of a rule between an item pair. Given a rule $R = r_1 ... r_k$, probability P with the rule from a to b is defined as:

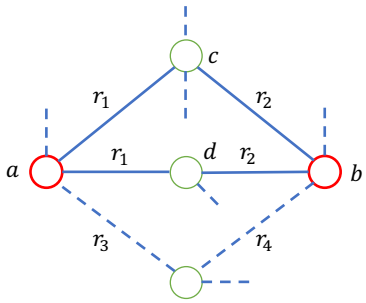


Figure 4: An example of a graph between items a and b. r represents a edge type or a relation type.

$$P(b|a, R) = \sum_{e \in N(a,R')} P(e|a, R') \cdot P(b|e, r_k), \tag{8}$$

where $R' = r_1 ... r_{k-1}$, and $P(b|e, r_k) = \frac{I(r_k(e,b))}{\sum_i I(r_k(e,i))}$ is the probability of reaching node b from node e with a one-step random walk with relation r_k. $I(r_k(e, b))$ is 1 if there exists a link with relation r_k from e to b, otherwise 0. If $b = e$, then $P(b|e, r_k) = 1$ for any r_k. $N(a, R')$ denotes a node set that can be reached with rule R' from node a. For example, $P(b|a, R)$ with a rule $R = r_1 r_2$ in Fig. 4 is computed as follows:

$$P(b|a, R) = P(c|a, r_1) \cdot P(b|c, r_2) + P(d|a, r_1) \cdot P(b|d, r_2)$$

Second, we define a feature vector between an item pair. Given a set of rules, a rule feature vector for an item pair (a, b) is defined as $x_{(a,b)} = [P(b|a, R_1), ..., P(b|a, R_n)]^\top$. Each entry in the feature vector $x_{(a,b)}$ represents a encoded value of rule R_i between a and b.

Rule selection. To select the most useful rules from the derived rules, we will introduce two types of selection methods: hard-selection and soft-selection.

Hard-selection method. Hard-selection method set a hyper parameter to decide how many rules we want to select with a selection algorithm firstly. Then we use a chi-square method and a learning based method to choose n rules in this study:

(1) Chi-square method. In statistics, the chi-square test is applied to measures dependence between two stochastic variables A and B (9) (to test if P(AB) = P(A)P(B)). $N_{A,B}$ is the observed occurrence of two events from a dataset and $E_{A,B}$ is the expected frequency. In feature selection, as the features that have lower chi-square scores are independent of prediction target are likely to be useless for classification, chi-square scores between each column of feature vector ($x_{(a,b)}$) and prediction target ($y_{a,b|A}$) are used to select the top n useful features [29].

$$\chi^2_{A,B} = \sum \frac{(N_{A,B} - E_{A,B})^2}{E_{A,B}} \tag{9}$$

(2) Learning based method. Another way to conduct feature selection is to design a objective function O_l that compute importance of each rule and try to minimize it. In the objective function, we introduce a weight vector w whose each entry represents importance of each rule. For an item pair (a, b), we use $y_{a,b|A}$ to denote

whether a and b have association A ($y_{a,b|A}$ is 1 if they have, and 0 otherwise.). We define the following objective functions:

- Chi-square objective function

$$\sum_{allpairs \in A} \sum_{i=0}^{|x_{(a,b)}|} w_i \cdot (x_{(a,b)}(i) + b - y_{a,b|A})^2 \tag{10}$$

- Linear regression objective function

$$\sum_{allpairs \in A} \sum_{i=0}^{|x_{(a,b)}|} (w_i \cdot x_{(a,b)}(i) + b - y_{a,b|A})^2 \tag{11}$$

- Sigmoid objective function

$$\sum_{allpairs \in A} \sum_{i=0}^{|x_{(a,b)}|} \frac{w_i}{1 + e^{-|x_{(a,b)}(i)+b-y_{a,b|A}|}} \tag{12}$$

where $x_{(a,b)}(i)$ is i-th entry of $x_{(a,b)}$. To make the objective function reasonable, we constrain that $\sum_i w_i = 1$ and $w_i > 0$. In training steps, if $x_{(a,b)}(i)$ shows positive correlation with $y_{a,b|A}$, then rule i is likely to be useful for item association classification and will get higher weight according to the loss functions. So similar to the chi-square method, the top weighted rules will be selected.

Soft-selection method. Besides the hard-selection method, another way to make use of the learning based objective functions is to take the weight of each rule as a constrain on the rules weights in the recommendation module. No rule will be removed from rule set in this way and it will not introduce extra hyper-parameter. Due to this method is flexible to be combined into other part, we introduce the soft-selection method with learning based objective functions to the recommendation module as a multi-task learning. In such condition, there is no extra constrain on rule weight ($\sum_i w_i = 1$ or $w_i > 0$). The detail of the multi-task learning method will be shown in Section 3.5.

As the rule set is derived from an item association in rule learning module. To apply different item associations at the same time, we can combine the rule sets from different item associations together to get a global rule set R.

3.3 Item Recommendation Module

We propose a general recommendation module than can be combined with existing methods. This module utilizes the derived rule features to enhance recommendation performances.

The goal of this module is to predict an item list for user u based on the item set I_u s/he interacted (e.g. purchased) before. Previous works calculate the preference score $S_{u,i}$ of user u purchase candidate item i, and then rank all candidate items with their scores to get the final recommendation list. As shown in Eq (13), we propose a function f_w parameterized by the shared weight vector w to combine the score $S_{u,i}$ with rule features between candidate item i and items user interacted (e.g. purchased) under rule set R. A score $S'_{u,i}$ for our method is defined as:

$$S'_{u,i} = f_w(S_{u,i}, \sum_{k \in I_u} F_{(i,k|R)}) \tag{13}$$

The feature vector for item pair (a, b) under rule set R is denoted by $F_{(a,b|R)}$. Note that $F_{(a,b|R)}$ is different from $x_{(a,b)}$ and calculated by $F_{(a,b|R)} = \sum_{e \in N(a,R')} P(e|a, R') \cdot I(b|e, r_k)$. $I(b|e, r_k)$ is an indicator function: if there is a edge in relation type r_k between b and e, $I(b|e, r_k) = 1$; otherwise 0. The reason why we adopt another feature generation method is that in recommendation module, we concerns more about if there exists a path in this rule between two items. The weight of each rule will be used in explaining the recommendation result, so we should make the comparing between rules fair. While longer rules are more likely to get lower score (more random walk steps so lower probability). If the feature vector is still x, it will hurt the explainable of our module. Thus we use $F_{(a,b|R)}$ as the feature vector here, which represents the frequency of each rule between the two items.

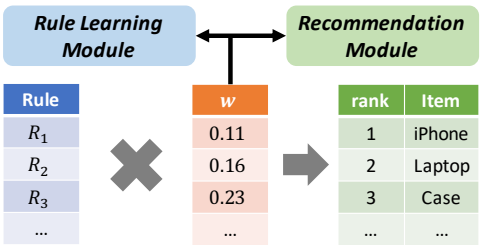

Figure 5: Multi-task learning of the rule learning module and the recommendation module. These two modules share the parameter w.

To consider the global item associations between candidate item i and the item set I_u, we add the rule features between i and each item I_k in I_u together. For convenience, the new feature vector is named as $F_{(i,I_u|R)}$. So Eq (13) can be rewrite as the following:

$$S'_{u,i} = f_w(S_{u,i}, F_{(i,I_u|R)}) \tag{14}$$

We define the objective function for the recommendation module as follows:

$$\begin{aligned} O_r &= \sum_{u \in U} \sum_{p \in I_u, n \notin I_u} (S'_{u,p} - S'_{u,n}) \\ &= \sum_{u \in U} \sum_{p \in I_u, n \notin I_u} \left(f_w(S_{u,p}, F_{(p,I_u|R)}) - f_w(S_{u,n}, F_{(n,I_u|R)}) \right), \end{aligned} \tag{15}$$

where p is a positive item ($\in I_u$) and n is a random sampled negative item ($\notin I_u$) for user u. Note that the rule weight vector w gives explanations for item pairs with rules in recommendation module. If a candidate item i gets a higher score than other candidate items, the rule which contributes the highest score for i and the corresponding items the user bought can be used to explain why the algorithm recommends i to the user. In other words, the introduction of rule features make the recommendation results explainable. There are some case studies in Section 5.5.

This combination method is flexible and easy to introduce rule features to many previous recommendation models (use the algorithm's prediction function to calculate $S_{u,i}$). In this study, we implement this recommendation module with BPRMF (traditional MF algorithm) and NCF (neural network based MF algorithm). Since it is a two step algorithm (to learn rules firstly and then conduct recommendation), we denote them as RuleRec$_{two}$(BPRMF) and RuleRec$_{two}$(NCF). The prediction function and objective function of them are Eq (14) and Eq (15), where $S_{u,i}$ is replaced by the prediction function of BPRMF (Eq (1)) and NCF (Eq (5)), respectively.

Table 1: The statistics of item association pairs in different domain. #Involved item means the number of items that have at least one type of association with any other items. #Item is the number of involved items with association and #Pair is the number of item pairs with association.

Dataset	#Item	#Involved Item	Also View		Buy After Viewing		Also Buy		Buy Together	
			#item	#Pair	#item	#Pair	#item	#Pair	#item	#Pair
Cellphone	346,793	214,692	103,845	1,038,090	181,935	1,818,990	71,660	716,240	29,372	293,360
Electronic	498,196	318,922	123,959	1,239,230	250,409	2,503,730	159,562	1,595,260	31,040	310,040

3.4 Multi-task Learning

In Sections 3.2 and 3.3, we introduced the two modules respectively. We can train the modules one by one to get the recommendation results. The shortcoming of training two modules separately is that the usefulness of rules in prediction item association is ignored. Instead, we share the rule weight w, and this weight can capture the importance of the rule in both the recommendation and item association prediction simultaneously as shown in Fig. 5. Thus, we propose a multi-task learning objective function defined as follows:

$$O = O_r + \lambda O_l \tag{16}$$

where O_l and O_r are the objective functions for the rule learning module and the recommendation module, respectively. Note that both objective functions share w.

The multi-task learning combination method is able to conduct rule selection and recommendation model learning together. Similar to the two step combination method, it is also flexible to to multiple recommendation models too. BPRMF and NCF are enhanced with this idea, and the modified algorithms are named as RuleRec$_{multi}$(BPRMF) and RuleRec$_{multi}$(NCF).

4 RULE SELECTION DETAILS

This section introduces the implementation details and results of the rule selection component in RuleRec.

4.1 Dataset and Implementation Details

We introduce item association datasets, a knowledge graph, and recommendation datasets for experiments.

Item association datasets. A open dataset with item associations is used in our experiments[2]. The item associations are extracted from user log on Amazon (same as [20]). Four types of item associations are considered: 1) Also view (ALV), users who viewed x also viewed y; 2) Buy after view (BAV), users who viewed x eventually bought y; 3) Also buy (ALB), users who bought x also bought y; 4) Buy together (BT), users frequently bought x and y together. ALV and BAV are substitute associations, and ALB and BT are complementary associations. The statistics of Cellphone and Electronics datasets with different item associations are shown in Table 1. Since the data is crawled from Amazon[3], the number of link is nearly ten times as large as the number of involved items in each association type. Besides, as shown in the table, over 37% items do not have any association with other items in this dataset.

Knowledge graph dataset. Freebase [2] is used to learn rules. It is the largest open knowledge graph[4], containing more than 224M entities, 784K relation types, and over 1.9 billion links.

The link prediction algorithm [5] [6] is used to connect items (with their titles, brands, and descriptions) and entities in DBPedia [6] firstly. Then the linked entities in DBPedia are mapped to the entities in Freebase with a entity dictionary [7]. As there is a probability score of each linked entity with the algorithm, which represents the confidence of this linking. So if the probability of a word links to a entity is lower than 0.6, we will ignore it to make the link result more accurate.

Due to the large scale of the knowledge graph, it is infeasible to enumerate all possible rules in this step. Following the idea in [17], we require that all derived rule needs to be supported by at least a fraction α of the training item pairs, as well as being of length no more than β (there will be huge number of rules without the length constraint). In the experiments, we set α to 0.01 (the same as [17]), and β to 4, which means the maximum number of edges between entities in a path is 4.

4.2 Results of Rule Selection

Item linking to the Knowledge Graph. In this step, we link the items from different domains to the entities in the knowledge graph. Items in the Cellphone domain and the Electronic domain are connected with 33,542 entities and 55,180 entities in Freebase respectively. Due to the item-entity linking method is not in a one-by-one accurate linking but based on items' titles, brands, and descriptions, each item will be linked into several entities and each entity will be linked with several items. With the random walk strategy introduced in Section 3.2, we find that the four hop routes in the knowledge graph from these entities will pass over 10 million entities. To avoid introducing unrelated entities in random walk step, the type of entities are constrained on pre-defined entity types (e.g.: entities in "ns.base.brand", "ns.computer" and some other types are maintain), then the involved entity amount is reduced to around 100K in each domain.

Rule Learning. The derived rules of different associations in cellphone domain are summarized in Table 2. There are hundreds of rules derived from Cellphone domain in each association, while only around 46-70 rules are in Electronic domain. The possible reason is that comparing with Cellphone domain, Electronic domain contains more items and the items are more diversity. Most rules are supported by less than 0.01 of the training item pairs. so less general rules are derived.

Rule Selection. To select useful rules from the large rule set, we use the learning based (LR, Eq (11)) and chi-square based feature selection methods in Section 3.2. The idea of selection methods is to choose the rules by which any items in a specific association are

Table 2: The number of derived rules from different associations.

Dataset	#ALV	#BAV	#ALB	#BT
Cellphone	700	948	735	675
Electronic	46	66	70	50

Table 3: Rule selection results on ALB association in the Cellphone domain.

LR		Chi-square		All	Upper Bound
Top 50	Top 100	Top 50	Top 100		
20.1%	40.1%	87.0%	88.5%	89.2%	90.7%

followed. E.g. if any item pairs in the BT association follows a rule R_k, then R_k is a useful rule for the BT association.

We choose the ALB association in the Cellphone dataset to verify the selection ability of the two methods. Because the derived rules will be used to extract item-item pair feature for the recommendation, a good rule should be able to indicate the associations between item i and user's purchase history I_u. So the recommendation dataset (Section 5.1) in the Cellphone domain is used for evaluation, we calculate the recall of whether there is at least one path satisfied rule r_k between the last item i_l user interacted and user's previous purchase history I_u. Due to not always exist at least one rule between i_l and I_u, there is a upper bound for the recall.

Table 3 shows the rule selection results ALB association in Cellphone domain and its upper bound. Chi-square based method outperforms linear-regression based method in rule selection. The reason is that rules with higher weight in linear regression model cannot fully represent usefulness of rules in the recommendation. However, Chi-square method is able to find the most useful rules, and the selected 50 rules cover 87.0% of user purchase history (only 2.2% percentage lower than using all rules). It is reasonable to choose only the subset of derived rules for the recommendation. Besides, we find that the upper bound in Electronic domain is only about 65%, indicating that the combination between rules in Electronic dataset is not as tightly as in the Cellphone dataset.

Besides, for multi-task learning framework, it is unnecessary to conduct rule selection because the model takes the effect of each rule in predicting item associations through the combined loss function Eq ((10), (11), or (12)).

5 RECOMMENDATION EXPERIMENTS

This section introduces dataset and experiment settings for comparing RuleRec with other baseline methods, as well as providing case study on analyzing different components of RuleRec.

5.1 Recommendation Dataset

The recommendation datasets are open datasets that extracted from Amazon [10, 21]. Each user's purchase histories in Amazon are recorded with the purchased items and times. We conduct experiments using two datasets: Amazon Cellphone and Amazon Electronic. Each user has at least 5 interactions with items. The statistics of the datasets are summarized in Table 4.

Table 4: The statistics of recommendation datasets.

Dataset	#user	#item	#links
Cellphone	27, 879	10, 429	194, 439
Electronic	22, 675	58, 741	195, 751

5.2 Experimental Settings

Evaluation Protocol. To evaluate the item recommendation performance, we use leave-one-out evaluation in the recommendation [1, 14]. The latest interactions between items and each user are used as positive items in test set, and the remaining data are used for training. Due to the loss function in our study is pair-wised, each positive item in training set will be trained with a negative item sampled from items that the user has not interacted. As for test set, since it is too time-consuming to rank all items for each user in evaluation, 99 negative items that are not interacted with the user are random sampled and added to test set [5, 36]. Therefore, in the test set, each user is evaluated with 99 negative items and one positive item. The target here is to generate a high-quality ranked list of items for each user.

Evaluation Metrics. We use Recall, Normalized Discounted Cumulative Gain (NDCG), and Mean reciprocal rank (MRR). Higher score means better performance in each metric. Recall focuses on whether the positive item is in the list, while NDCG and MRR take the position of the positive item into evaluation. Considering that the length of most recommendation list in real scenarios is 5 or 10, so the ranked list is truncated at 10 for all metrics. We calculate Recall@5, Recall@10, NDCG@10, and MRR@10 for evaluation.

5.3 Compared Methods

Three types of baselines (traditional matrix factorization, neural network based, and recommendation with knowledge graph) are used here:

- **BPRMF** [27]. As introduced in Section 2.2.1, this method follows the idea of matrix factorization with pairwise ranking loss.
- **NCF** [14]: This is a state-of-the-art latent factor model. It pretrains MLP and GMF part separately, and then ensembles the two models to get the final preference score. Following previous studies [5, 13], **MLP** and **GMF** are taken as baseline models too.
- **HERec** [31]: A state-of-the-art algorithm which using the knowledge graph for the recommendation. This method adopts meta-paths to generate the embeddings of users and items in the heterogeneous network with Deepwalk [26], and then use them in the recommendation. Two variants of this algorithm with different fusion functions, **HERec**$_{sl}$ (with the simple linear fusion function) and **HERec**$_{pl}$ (with personalized linear fusion function) are used as baseline models.
- **RippleNet** [34]: Another state-of-the art algorithm that incorporates the knowledge graph into recommender systems. It stimulates the propagation of user preferences on the set of knowledge entities to learn a user's potential interests.

Implementation Details. We adopt the implementation of BPRMF algorithm in MyMediaLite[8] (a famous open source package) on our experiments. The implementation of other algorithms are from

[8] http://www.mymedialite.net/index.html

the public codes that the authors provided in their papers (NCF[9], HERec[10], and RippleNet[11]). The four new models, RuleRec$_{two}$ with BPRMF, RuleRec$_{two}$ with NCF, RuleRec$_{multi}$ with BPRMF, and RuleRec$_{multi}$ with NCF are modified from BPRMF and NCF according to our framework respectively. We tune all the parameters to achieve the best performance of each algorithm.

The score function is defined as $S'_{u,i} = f_w(S_{u,i}, F_{(i,I_u|R)}) = S_{u,i} + \alpha \cdot w^T F_{(i,I_u|R)}$ in this section. Different implementations of f_w and their results will be analyzed in Section 5.5. All of the four types of item associations are used in the recommendation module for both two-step and multi-task learning algorithms. Top 50 rules of each type of item associations (selected with chi-square method) are chose to the two-step based methods. To make the comparison fair, these rules are used in the multi-task learning algorithms with the sigmoid objective function in the final experiments. The objective function is sigmoid (Eq (12)), as it performs the best in the three objective functions (Eq (10), (11), and (12)); due to the limited of length, we do not show the results here. The comparison of different amounts of rules will be introduced in Section 5.5.5.

5.4 Experiments and Performance Study

The experimental results of these algorithms in different domains are summarized in Table 5. We repeated each setting for 5 times and conducted the paired two-sample t-test on the 5 times experiment results for significant test. As shown in the table, the performance of algorithms in Electronic dataset is obviously worse than in Cellphone dataset. The reason is that the item count of Electronic dataset is about 6 times over the item count of Cellphone dataset (from Table 4), which makes the recommendation in Electronic dataset more difficult.

1. The Enhanced Algorithms vs. the Originals. NCF algorithm performs better than BPRMF algorithm in both datasets, as more complex user and item feature interactions are taken into consideration in NCF. Looking into the results of BPRMF algorithms and NCF algorithms, we find that RuleRec$_{multi}$ with BPRMF gets 6.5% to 11.0% improvements over BPRMF in different evaluation metrics on two domains. The improvements of RuleRec$_{multi}$ with NCF in Recall@5, Recall@10, NDCG@10, and MRR@10 are between 3.0% to 6.4% comparing with NCF in Cellphone domain, while the improvements of which on Electronic is lower than in Cellphone domain. Though RuleRec$_{multi}$ with BPRMF is improved more than RuleRec$_{multi}$ with NCF, RuleRec$_{multi}$ with NCF still achieves the best performance in Cellphone domain and RuleRec$_{multi}$ with BPRMF performs the best in Electronic domain.

2. Overall Performances. Besides, we find that any one of the enhanced algorithms outperform all baselines in both Cellphone and Electronic domains in each metric. And most of the improvements are statistically significant, showing that the derived rules from the knowledge graph are really helpful to generate a better ranked item list for the recommendation. The multi-task learning algorithms (RuleRec$_{multi}$ with BPRMF and RuleRec$_{multi}$ with NCF) show better performances than the two-step learning algorithms (RuleRec$_{two}$ with BPRMF and RuleRec$_{two}$ with NCF), indicating that the combination of recommendation loss and rule selection loss in weight training is able to boost the recommendation results. Though the learning-based selection methods perform worse than chi-square in Section 4.2, it does helpful in the multi-task learning.

3. The Performances of HERec and RippleNet. We also note that HERec based algorithms and RippleNet, some state-of-the-art algorithms that uses the knowledge graph for the recommendation, performs worse in these datasets. We think the possible reason is that unlike movie, book, or Yelp datasets which contains many well organized category features (such as director, movie type, actor/actress name in movie dataset) to construct a compact graph, here we link Cellphone and Electronic datasets with a real knowledge graph Freebase. Though Freebase contains more information, but it is not as clean as the on-topic sub graph and makes it harder to mine valuable information, so these algorithms perform worse. More analyses are shown in Section 5.5.1.

To summarize, the derived rules from knowledge graph are valuable for item pair feature vector learning, and the learned vector is able to enhance multiple basic recommendation models (BPRMF and NCF here). Comparing with the two-step combination method, multi-task learning for both recommendation and rule selection contributes more on rule weight learning. Due to the flexible of the proposed framework, the derived rules are able to combine with other recommendation models to boost performances significantly.

5.5 Case Study and Performance Analysis

1. Performance Comparison in compact heterogeneous graph. Experiments in Section 5.4 are conducted on a large heterogeneous graph extracted from real knowledge graph. In this subsection, some extra experiments are conducted on a compact heterogeneous graph, which is constructed based on item attributes, in MovieLens-1M dataset[12]. We adopt the proposed algorithm and HERec algorithm in this dataset following the setting in RippleNet.

The experimental results are shown in Table 6. Our model performs better than HERec while worse than RippleNet , there are two possible reason: 1) relation type is very limited in this dataset (only 7), so the power of rule selection for the recommendation in RuleRec is limited in this scenario. 2) MovieLens-1M is different from real knowledge graph datasets in Section 5.4 (which is constructed by linking items into Freebase), the connection coverage of it is very perfect and RippleNet benefits a lot from this. The results indicate that the proposed algorithms is able to achieve noteworthy performance in compact heterogeneous graph.

2. Explainability of the learned rules. In Section 5.4, the results indicate the derived rules are useful in providing more accurate recommendation results. In this section, we will show the explainability of the derived rules for the recommendation. Two positive weighted rules on RuleRec$_{multi}$ are shown as the following :

- R_1 = "computer.computer.manufacturer"
- R_2 = "computer.computer.compatible_oses" $->$ "computer.os_compatibility.operating_system" $->$ "computer.operating_system.includes_os_versions"

Where the words with quotation marks are the relation types defined in Freebase (such as "computer.computer.manufacturer").

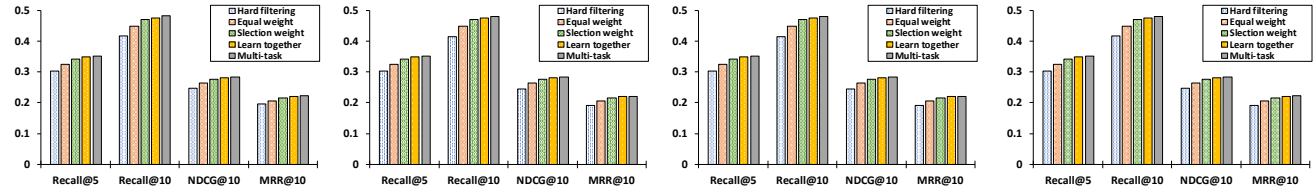
These rules are with positive weights in the recommendation module, indicating that if a new item b exists a path between it and item a user bought before, item b is more likely to get higher score.

First we try to verify if item pairs with these rules affect user's purchase. As to R_1, it links a computer product and its manufacturer. If two items a and b have a path in R_1, it means that item b is likely to be manufactured by the same as item a. For R_2, two example entity paths in this rule are: 1) "Mac Mini" - "os x yosemite" - "OS X" - "IOS" and 2) "Surface Pro" - "Windows 10" - "Windows" - "Windows Phone". It shows that users are tend to use similar operating systems in both cellphone and computer. As you can see, these rules are consistent with our common sense.

Then, to check whether users agree that the selected rule will be helpful to improve the explainability of the recommendation if the rules are used in real scenarios, the derived rules in Cellphone dataset are labeled by three experts (only agree or disagree, 100 rules from ALB and BT associations). The results show that over 94% learned rules are accepted by users (87% rules are accepted by all users).

Due to the effective rule i in calculating user preference on a specific item will get higher score ($w_i^\top F_{(i,I_u|r_i)}$) for the preference prediction. So for each item in the ranked list, unless it has no path between it and items in user's purchase history, we can generate the most important rule for it by ranking the score of each rule in preference prediction.

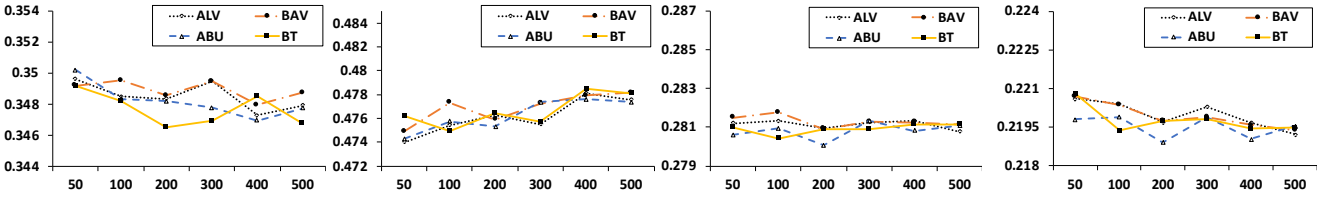
3. Study on different model integration strategies. The score function (Eq (14)) and the rule weight vector w in f_w affect the performance of the recommendation module. We experiment with several ways to identify the best combination methods.



- Hard filtering: Remove candidate items that have no rule with any item in I_u. Formally, $S'_{u,i} = S_{u,i} \cdot I(F_{(i,I_u|R)})$, where $I(F_{(i,I_u|R)}) = 1$ if $\sum F_{(i,I_u|R)} >= 1$ otherwise 0.
- Equal weight: Each rule gets an equal weight in prediction. $S'_{u,i} = S_{u,i} + \alpha \cdot w^\top F_{(i,I_u|R)}$, and $w = [0.02, ..., 0.02]$.
- Selection weight: $S'_{u,i} = S_{u,i} + \alpha \cdot w^\top F_{(i,I_u|R)}$, and $w = w_{ruleselection}$ $w_{ruleselection}$ is the rule weight vector trained by Eq (12) in rule selection step.
- Learn together: The rule weight vector is trained with the original recommendation model. $f_w(a,b) = a + w^\top b$.
- Multi-task: The rule weight vector w is shared by recommendation learning and rule selection part, and the score prediction function is $f_w(a,b) = a + w^\top b$.

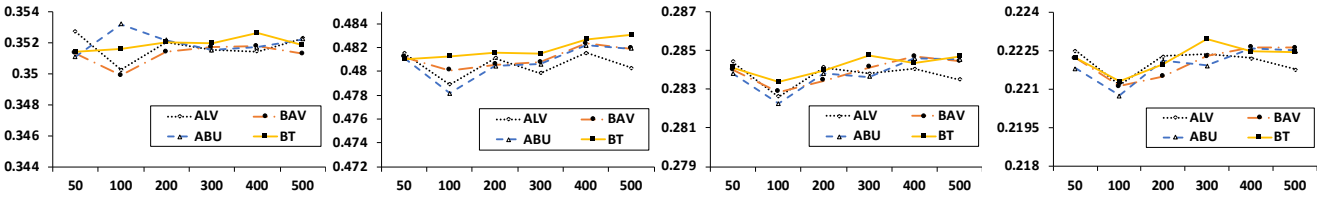
The results of applying multiple score functions on RuleRec(BPRMF) model in Cellphone dataset are shown in Fig. 6. The performances of the score functions are Hard filtering < Equal weight < Selection weight < Learn together < Multi-task with all metrics in all associations. First, we can see that the multi-learning method achieves the best performance on all metrics, and the improvements are significant, which indicates multi-task learning is very helpful in rule weight learning for better recommendation results. Second, since the hard filtering method is likely to ignore both negative items and positive items (from Table 3, we can see that sometimes there is no rule between the positive item and item purchase history I_u). Third, though selection weight contributes on the recommendation (better that equal weight), it is still worse than Learn together model.

4. Study on single association vs. all associations



In this subsection, we compare the performance of RuleRec$_{multi}$ with BPRMF with only one type of association and all associations, the results are summarized in Table 7.

First, we can see that with the rules derived by any one of the four associations, RuleRec$_{multi}$ with BPRMF outperforms BPRMF algorithm significantly. The performances of using different associations are similar, but all of them are valuable for mining the item relationships to boost the recommendation results. Second, RuleRec$_{multi}$ with BPRMF derived by all kinds of associations outperforms RuleRec$_{multi}$ with a single association, indicating that the combination contributes for the recommendation models.



(a) ALV association (b) BAV association (c) ABU association (d) BT association

Figure 6: Performance comparison under different score function settings in the Cellphone dataset. We select the top 50 rules in each association by chi-square method. Among all score function settings, the multi-task learning method performs the best.

(a) Recall@5 (b) Recall@10 (c) NDCG@10 (d) MRR@10

(a) Recall@5 (b) Recall@10 (c) NDCG@10 (d) MRR@10

Figure 8: The performance of using different number of rules in RuleRec$_{multi}$ with BPRMF.

Table 7: The results of using a single association vs. all associations. BPRMF is used as a recommendation model. Our proposed model shows the best performances when using all kinds of associations.

Type	Recall@5	Recall@10	NDCG@10	MRR@10
None	0.3238	0.4491	0.2639	0.2058
ALV	0.3527	0.4815	0.2844	0.2225
BAV	0.3513	0.4812	0.2840	0.2222
ABU	0.3511	0.4811	0.2838	0.2218
BT	0.3514	0.4810	0.2841	0.2222
ALL	**0.3568**	**0.4829**	**0.2864**	**0.2246**

5. Recommendation with different rule counts. In Section 3.2, rule selection is introduced as an important part in rule learning. Does rule selection is really necessary? We conduct further experiments on each association with different of derived of rules (selected with chi-square method, 50, 100, 200, 300, 400, and 500 respectively) with RuleRec$_{two}$ and RuleRec$_{multi}$ with BPRMF.

From Fig. 7, the performance of RuleRec$_{two}$ with BPRMF decreases in recall@5, MRR@10 as the rule number increases. At the same time, NDCG@10 keeps stable and Recall@10 increases. The overall performances is not getting better when more rules are applied in the recommendation learning. The possible reason is that with the grows of rule number, lots of "bad" rules are included and the two-step model RuleRec$_{two}$ with BPRMF shows worse ability in dealing with them properly. However, due to the rule selection is taken into consideration in the multi-task learning based algorithms, we find that the performance of RuleRec$_{multi}$ with BPRMF algorithm shows better performances as the rule number increases (Fig. 8). Furthermore, the performances of RuleRec$_{multi}$ with BPRMF is significantly better than those of RuleRec$_{two}$ with BPRMF (paired two-sample t-test on the experimental results with different count of rules. $p < 0.01$). The results show that the multi-task learning based algorithms are able to tackle with large number of rules even though there are useless rules.

6 RELATED WORK

Combine Side-information for the Recommendation. Matrix factorization based algorithms [27, 28] are widely used to tackle recommendation problems. Recently, recommendation algorithms achieve remarkable improvements during these years with help of

deep learning models [12, 14, 30, 47, 49] and the successful introducing of side-information [15, 19, 22, 23, 34]. In this study, we focus on the introducing of side-information in the knowledge graph for the recommendation, and there already two types of studies using the knowledge graph in the recommendation: path-based and embedding learning based.

Path-based methods adopt random walk on predefined meta-paths between user and items in the knowledge graph to calculate user's preference on an item. Yu et al. first propose to use meta-paths to utilize user-item preferences and then expand matrix factorization for the recommendation [43]. Shi et al. use weighted paths for explicit recommendation [32]. Zhao et al. design a factorization machine with the latent features from different meta-paths [48]. Catherine et al. design a first-order probabilistic logical reasoning system, named ProPPR, to integrate different meta-paths in a knowledge graph [3, 4]. All these methods achieve improvements in the recommendation, while the weakness of them is that they ignore the type of item associations.

Embedding learning based methods conduct user/item representation learning based on the Knowledge graph structure firstly. The learned embedding [8] is applied in Zhang's study to get item embedding for the recommendation [24]. Zhang et al. use TransR [18] to learn the structural vectors of items, and these vectors are part of the final item latent vector for preference prediction [44]. Besides, some previous studies propose new algorithms in which Meta-path guided random walks are used in a heterogeneous network for user and item embedding learning and achieve outperform results [31, 34, 37, 48] in different ways. However, the embedding learning based methods give up the explainable strength of the knowledge graph, which is very valuable for the recommendation.

Rule Learning in the Knowledge Graph. Item-item relationships are considering as useful features for providing better recommendation results. Julian et al. firstly propose to a topic model based method to predict relationships (substitute or complementary) between products from reviews [20]. In their study, the ground truth is calculated in a data-driven way in Amazon. Then, more algorithms attempt to improve the prediction results with better algorithms. Word dependency paths are taken into consideration in Hu et al.'s work [41] and Wang et al. adopt a embedding based method to enhance the performance of relationship prediction [37].

However, these methods are suffering from cold items. So we proposed to not predict item associations directly, but mine meaningful rules in the knowledge graph with the ground truth item pairs. The rules will be applied to generate feature vectors for different item pairs without user reviews.

Knowledge graph is a multi-relational graph that composed of entities as nodes and relations as different types of edges [38]. In the past years, knowledge graphs have been used as important resources for many tasks [7, 39]. One of the main usage of knowledge graph is reasoning and entity relationship prediction. Lots of research are focus on reasoning, such as [40, 42]. While these studies focus on link prediction but not rule inducing, which is not proper for our study.

On the other line of research, several work attempt to learn the useful rules but not the prediction results from the knowledge graph with the ground truth entity pairs. Random walk based algorithms are proposed in Lao et al.'s studies [16, 17] and others' [9, 35]. These methods are able to show why the entity pair has a certain relationship according to the derived rules, which makes the results more explainable. In our study, we adopt a similar algorithm as them in rule learning module.

7 CONCLUSIONS AND FUTURE WORK

In this paper, we propose a novel and effective joint optimization framework for inducing rules from a knowledge graph with items and recommendation based on the induced rules.

Our framework consists of two modules: rule learning module and recommendation module. The rule learning module is able to derive useful rules in a knowledge graph with different type of item associations, and the recommendation module introduces the rules to the recommendation models for better performance. Furthermore, there are two ways to implement this framework: two-step and jointly learning.

Freebase, a large-scale knowledge graph, is used for rule learning in this study. The framework is flexible to boost different recommendation algorithms. We modify two recommendation algorithms, a classical matrix factorization algorithm (BPRMF) and a state-of-the-art neural network based recommendation algorithm (NCF), to combine with our framework. The proposed four rule enhanced recommendation algorithms achieve remarkable results in multiple domains and outperform all baseline models, indicating the effectiveness of our framework. Besides, the derived rules also show the ability in explaining why we recommend this item for the user, boosting the explainability of the recommendation models at the same time. Further analysis shows that our multi-task learning based combination methods (RuleRec$_multi$ with BPRMF and RuleRec$_two$ with NCF) outperform the two-step method with different number of rules. And the combination of rules derived by different associations contributes to better recommendation results.

In future, we plan to investigate how to design a embedding learning based combination algorithm which keeps the recommendation results explainable with the knowledge graph.

ABSTRACT

An effective virtual agent (VA) that serves humans not only completes tasks efficaciously, but also manages its interpersonal relationships with users judiciously. Although past research has studied how agents apologize or seek help appropriately, there lacks a comprehensive study of how to design an emotionally intelligent (EI) virtual agent. In this paper, we propose to improve a VA's perceived EI by equipping it with personality-driven responsive expression of emotions. We conduct a within-subject experiment to verify this approach using a medical assistant VA. We ask participants to observe how the agent (displaying a dominant or submissive trait, or having no personality) handles user challenges when issuing reminders and rate its EI. Results show that simply being emotionally expressive is insufficient for suggesting VAs as fully emotionally intelligent. Equipping such VAs with a consistent, distinctive personality trait (especially submissive) can convey a significantly stronger sense of EI in terms of the ability to perceive, use, understand, and manage emotions, and can better mitigate user challenges.

1 INTRODUCTION

Recent research and technology advancements have rendered the possible reality of living and interacting with intelligent virtual agents, such as Siri (Apple), Google Now, S Voice (Samsung), and Cortana (Microsoft). However, these virtual agents are found to handle affect-sensitive questions with inconsistency and inadequate empathy [61], and are also recorded on various occasions to fend off sexual assaults from users [41]. The situation beckons a need for emotional intelligence (EI) in a software agent (i.e., virtual agent). At such, understanding human perception of a virtual agent's EI and discovering factors involved in designing emotionally intelligent agents is of great necessity. The widely used term "agent" has no general consensus when it comes to definition. It is broadly defined as a hardware or software computational system that may have autonomous, proactive, reactive, and social ability [99]. Unlike robotic agents, a virtual agent does not have physical properties and is embodied as a computerized 2D or 3D character [81]. In particular, the virtual agents designed for our study are conversational 2D-animated software agents that interact with people through speech and natural language.

It is generally accepted that people are willing to attribute human characteristics to technology [66]. People have applied human-like traits to computers even when admitting that they do not believe the technologies possess human emotions or traits [63, 66]. People have also elicited social behaviors toward computers [64], and treat computers as teammates with personalities [65] in ways similar to that of human-human interaction. It is thus likely that humans will interact with and perceive virtual agents under the same paradigm.

In human-human interactions, emotional intelligence (EI) is widely accepted as significant for interpersonal interaction. Often interpreted as the ability to handle, use, and convey emotional information [55], EI is especially important during challenging situations. Emotional intelligence is shown to be effective for handling sensitive personal cases in the medical industry [28], increasing trust and performance in the banking industry [38], improving college students' adjustments and academic performance [32], and directly enhancing customer satisfaction in the service industry [42]. These are popular domains for deployment of VAs. In fact, a recent trend is developing online VAs in the e-commerce and service industry as customer service agents to improve purchase intent and firm performance [60]. The common way to design emotionally intelligent VA currently is to include emotion appraisal, generation, and expression capabilities (e.g., [17, 90]) to mimic empathy [49]. However, there remains the pivotal question of how users perceive EI in VA. There is not yet a comprehensive study on the effects of a full spectrum of EI in human-agent interaction (HAI).

Given that increasing virtual agent intelligence is the current trend, it is necessary to identify other design element that can help

lift perception of VA emotional intelligence in face of user challenges. Therefore, in this paper, we experiment with incorporating personality in VA design, a construct known to have strong relevance to emotion and intelligence. We carry out a user study in a controlled setting, assessing the perceived emotional intelligence (PEI) of personality-driven VAs when handling three types of challenges, namely verbal abuse, sexual harassment, and avoidance. To put the human-agent interaction in a more realistic context, we introduce our VA as a medical assistant with two different personalities, dominant and submissive, compared to a controlled robotic version of the VA. Since we want to conduct systematic comparisons and users may find it artificial and uncomfortable if they have to challenge the VAs in a particular way, we ask the participants to watch videos of such encounters online and then rate the VAs' performance instead. Results show that the personality-driven VAs significantly outperform the robotic version on 18 out of 20 PEI items, while submissive agents are rated significantly higher than the dominant counterpart on 16 PEI items. This suggests that enriching a VA character with personality is indeed an effective means to promote positive perception of its EI.

The rest of the paper begins with literature review to delineate the theoretical basis of our work using the theory of emotional intelligence in psychology, and survey the existing approaches of enabling EI in virtual agents. Next, we describe our virtual agent design and the rationales behind, and then present our study design, experimental results, and insights obtained. Finally, we discuss the limitation of this work and point out possible future directions.

2 RELATED WORK

Humans assaulting machines is fairly common. In 2015, a man shot seven times at his computer to vent his frustration [1]. In scientific literature, works in human-robot interaction (HRI) and human-agent interaction (HAI) have shown users to be verbally abusing [21, 94], sexually assaulting [21], and avoidant [77]. Verbal abuse in HRI and HAI involves bullying, name-calling or making fun of in a hurtful way [94], stress the lack of intelligence, or honesty in VAs, and their mental abilities [21]. Sexual assault references include direct referral to female body parts, dirty soliloquys, and hardcore visual requests [21]. Since 2016, various news media reported many VAs including Cortana experiencing sexual assaults and resulting in decreased efficiency and effectiveness during development [18]. Verbal avoidance behaviors can be identified by interjections, revisions, incomplete phrases, and extended period of silence [77]. In human-human interaction, similar unpleasant experiences are usually handled with emotional intelligence (EI).

2.1 EI in Human-Human Interaction

Salovey and Mayer formulated the theory of EI in the early 1990s [84], positing that emotions make thinking more intelligent and one thinks intelligently about emotions [52]. Psychologists later developed other EI models to describe how people process emotional information in self and others. The three most well-known models take the perspective of traits [72], abilities [52], and a mixed of the two [5]. The traits model focuses on self-evaluation of a person's inherent traits [72], such as adaptability, self-esteem, and social competence. The abilities model defines EI as assorted abilities to process and utilize affective information, which can be scored in a consensus-fashion or evaluated against expert scores [83], and thus has been established as a new intelligence measure since 1999 [53]. For this paper, it is difficult, if not impossible, to have virtual agents (VAs) assess their own innate traits. VAs are made to mimic the effects of having emotions rather than being manifested by the actual emotions themselves [22]. It makes a more intuitive sense to evaluate EI of a VA based on their ability to convey EI to humans. Therefore, we model VA's EI after the four-branch abilities model – Mayer-Salovey-Caruso Emotional Intelligence Test (MSCEIT) [55].

MSCEIT conceptualizes EI as the integrated capabilities of perceiving, using, understanding, and managing emotions [83]. (1) **Perceiving Emotions (PE)** is the ability to detect and decipher emotions via tone in voice, words, facial expressions, and cultural artifacts [83]. It is the most basic aspect of EI because it enables all other processing of affective information [83]. (2) **Using Emotions (UsE)** is the ability to harness emotions that best facilitate cognitive tasks (e.g., thinking and problem solving) [83]. For example, emotionally intelligent people could fully capitalize their mood changes in face of cognitively challenging tasks, based on the understanding that a slightly sad mood benefits careful, methodical work whereas a happy mood stimulates creative, innovative thinking [40]. (3) **Understanding Emotions (UnE)** is the ability to comprehend emotional signals and describe the evolution of emotions over time [83]. It builds on perceiving emotions and emphasizes sensitivity toward fine-grained distinctions of emotions, such as the nuances between happy and ecstasy [6], and the dynamics of emotions such as how shock can turn into grief [83]. (4) **Managing Emotions (ME)** is the ability to regulate emotions in self and others [83]. For example, an emotionally intelligent politician can arouse the public's righteous anger through his or her powerful speech infused with anger [83]. In this paper, we adopt insights from each branch to design the agent and formulate the basis of an evaluation instrument – a perceived VA emotional intelligence (PEI) questionnaire (Table 1) based on Mayer-Salovey-Caruso Emotional Intelligence Test (MSCEIT) v2.0.

The MSCEIT has been widely used as an instrument to assess EI in human-human interactions. Previous research shows high EI can lead to better task performance in the workplace [11, 19, 36], greater success in affect-sensitive roles such as nursing [45, 70], more powerful persuasion and influence over others [2, 91], and more trust [98] and collaboration [13] in interpersonal relationship building [19]. These findings support the claim that EI can be more important for success than the traditional forms of intelligence based on abstract reasoning in many scenarios [74]. The insights are applicable for virtual agents and other forms of artificial intelligence (AI) where machine breakdown is inevitable.

2.2 EI in Human-Agent Interaction

In many studies of human-agent interaction (HAI), being empathetic (i.e., empathic) [30], affective [68], or emotive [50] is a shorthand for a VA's emotional intelligence. "Empathy", by the Dymond definition, is the cognitive ability of taking the role of another and understanding that person's thoughts, feelings and actions [59]. In a narrower definition given by Wispé, "empathy" is a process where an individual "feels her/himself into the consciousness of

Table 1: Perceived Emotional Intelligence Questionnaire

Questions in Each Branch (Begins with: *"The agent is able to ...")*
(a) **Perceiving Emotions (PE)**
Convey a sense that it **listen**s openly to participant's emotions
Convey a sense that it pays **attention** to user's moods
Identify user's emotions correctly
Discern between different emotions
Tell apart the **degree** of emotions present
(b) **Using Emotions (UsE)**
Convey a sense that the agent can **feel** what the user is feeling
Convey a sense that the agent understand user's point of view (**POV**)
Respond in a way that make the user feel **sad**
Respond in a way that make the user feel **happy**
Respond in a way that make the user feel that they are **understood**
(c) **Understanding Emotions (UnE)**
Convey a sense that it can be emotionally **self-aware** and insightful
Display some knowledge of **complex** emotions
Respond **empathetically** to user
Describe/understand difficult emotions
Give user an impression it is **attempt**ing to empathize
(d) **Managing Emotions (ME)**
Make **decision**s with feelings and thoughts
Influence some of user's thoughts
Provide psychologically-minded **advice**
Show some **conscious** thought before responding
Show varying **openness** to various emotions

another person" [97]. Fung et al. design their empathetic virtual agent based on Wispé's definition, takes on the role of a personality assessor and responds according to the sentiment captured in people's voice and words [30]. The second term, "affective", stems from affective computing, which "relates to, arises from, or deliberately influences emotions" [73]. For example, the female affective VA employed for assessing human partner's social cognitive impairment in schizophrenia in Oker et al.'s study can communicate cooperative intention via emotional displays during a card game [68]. "Emotive" is defined as being "able to arouse intense feeling" by Oxford Dictionary. Maldonado and Nass deploys such an emotive agent as a co-learner in an intermediate English class, and the users find it more supported, intelligent and trustworthy [50].

These definitions adopted in HAI research, while sufficient, may not be comprehensive enough to constitute emotional intelligence. The Mayer-Salovey-Caruso definition of emotional intelligence (EI) is the ability to perceive, understand, use and manage emotions in self and others [52]. In our study, we consider the terms "empathetic (emphatic)," "affective," and "emotive" as subsets of the MSCEIT model, because the two branches, perceiving emotions (PE) and understanding emotions (UnE), cover the semantics of the three terms by definition (see Section 2.1) and are included in our PEI questionnaire (Table 1).

2.2.1 Emotion Recognition in Virtual Agents (VA). Emotion recognition and expression is necessary for sympathy and communication [73]. It echoes the ability of perceiving emotion (PE) –"detect and decipher emotions," positioned as the first and the most basic branch of EI [83]. Emotion recognition is also the basic component of affect computation in virtual agents [73]. Most of the affective computing systems to date try to decipher human emotions from audio (speech and/or voice) signals [92], or visual cues (mainly facial expressions) [39], or both [30]. Some may utilize text input as well (e.g., [30]). In general, a multimodal system tends to outperform a unimodal system [76]. In this paper, we equip our VAs with a multimodal emotion recognition system, capturing and analyzing user affect using raw audio, text, and videos in real-time. Our implementation of the emotion recognition module follows the state-of-the-art technologies and employs machine learning techniques such as deep learning to produce results in real time [29].

2.2.2 Emotion Expression in Virtual Agents (VA). The development of emotion expression in virtual agents has a long academic history [80], branching out into studying different modalities. Facial expression is one of the primary emotional displays used in VAs. Many of the VA facial systems (e.g., [39, 62]) are designed following the psychological-based models of human emotion facial expression, such as Facial Action Coding System (FACS) [24] or the circumplex model of affect [8]. Gestures and body movements of a VA, if visible, can be augmented with special effects according to animation principles (e.g., exaggeration, slow in/out, arcs, timing [46]) and serve as non-verbal social emotional cues [87]. Voice and speech of conversational agent are another possible affective expression channel, and can be used jointly with facial and bodily movements such as a smile or a nod [89]. Regardless of the modality, emotion expressions of VAs are generally developed with the emphasis of achieving "believability" [78] by creating an illusion of life [7]. In this work, we design our virtual agents to express the most common affective features, including facial expression (e.g., smiles and frowns), body language (e.g., shrug and hug), and speech, through state-based animations.

2.2.3 Personality of Virtual Agents. In human interactions, an individual's personality is a distinguishing pattern of "behavioral, temperamental, emotional, and mental traits" that influences perception, actions and reactions [3]. In human-agent interaction, a consistent personality in VA can improve its emotion recognition and recall persuasiveness to users [58, 79]. Modern personality-driven agents are mostly based on well established models and generative techniques of personality, such as Big-Five (Openness, Conscientiousness, Extraversion, Agreeableness, and Neuroticism) [26], trait model [9], and OCC (named after its authors Ortony, Clore, and Collins [34]). Virtual agents empowered by these socio-emotional models are deployed in assorted applications, taking the role of a learner [48], a workplace collaborator [37], or a Tai-chi instructor [9], for instance. Research has shown that rich personality – "the unique and specific" [51] – infused through VAs' actions, speech, and thoughts can improve believability [51] and empathy [23], and modulate VAs' emotion expression by meta-information about their actions and reaction to events [69].

Personality design in VAs takes into account audiovisual appearance and conversational style [15]. For instance, agents with rounder, bigger faces and happier expressions are perceived as extravert and agreeable [15]. Depending on agents' personalities and emotions, they may apply very different dialog strategies to achieve their goals [15]. For instance, extraverted agents use more direct

and powerful phrases [25] and uses expansive gestures [31] than do introverted agents.

In sum, from our literature review, we see that emotional intelligence (EI) begets benefits such as trust, task performance, and better relationships in human-human interactions. This positive engagement inspires our virtual agent designs used in this work. In this paper, we aims to contribute to a better understanding of designing emotional intelligence in VA, as well as providing design insights for developers to consider when creating VAs for public use in an era rife with user challenges.

3 DESIGN OF PERSONALITY-DRIVEN VIRTUAL AGENT

Previous study has suggested that users find virtual agents with emotion recognition and expression abilities empathetic, but not yet fully emotionally intelligent [100]. In other words, a VA simply being emotionally expressive may not be apt to address the aforementioned user challenges with sensitivity. It is thus necessary to explore new ingredients that can be added to virtual agent design to sufficiently convey the sense of VA having emotional intelligence (EI). We propose to leverage personality as it is closely related to the concept of EI, given its definition as "permanent (or very slowly changing) patterns of thought, emotion, and behavior associated with an individual" [15]. Some early EI theories even postulated EI being a set of personality traits [54], although research has shown that EI abilities can be measured (using the MSCEIT that our PEI questionnaire is adapted from) distinctively from the standard personality traits [14]. In this paper, we create personality-driven agents with "unique ways of doing things" [51] and devise strategies consistent with the corresponding personalities to tackle user challenges in an emotionally expressive manner.

3.1 Virtual Agent Design

The robotic virtual agent developed in this paper is a state-based animated system rendered in a web browser as a virtual female cartoon character with emotion recognition and expression abilities (Figure 1(a)). More specifically, the agent recognizes user emotions by capturing and analyzing its conversational partner's speech and text input. We adopt the recognition module developed in [29, 30] (Figure 1(b)). The speech recognition part uses deep neural network (DNN) HMMs with 6 hidden layers for acoustic model, trained on English audio data with 1385 hours from LDC corpora and public domain corpora, and uses recurrent neural network (RNN) for language model (LM), trained on 88.6M sentences including acoustic training transcriptions, news and book data from the web, Google 1 billion word LM benchmark, and common chat queries like weather and music. The speech module achieves 7.6% word error rate on a clean speech test data [29, 30]. For real-time sentiment and emotion inference from speech and text, the VA system uses a Convolutional Neural Network (CNN) modeled trained by [29, 30], with an average 65.7% accuracy on six classes of emotions and 67.8% on sentiment (91.2% precision and 63.5% recall). The virtual agent expresses emotions through facial expressions and gestures. We design the facial expressions following Ekman's FACS [24], and design the body languages mimicking the human poses displayed during social

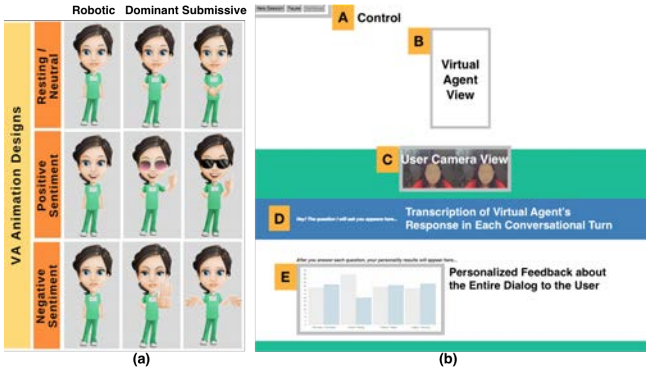

Figure 1: (a) Design of 2D VA animation, left to right: robotic, dominant, and submissive; and (b) web user interface.

Table 2: Descriptive phrases and adjectives of the Dominance/Submissiveness dimension used in [65].

Dominant		Submissive	
Taking-charge	Dictatorial	Servile	Obedient
Commandeering	Overbearing	Subservient	Docile
Bossy	Tyrannical	Spineless	Meek
Assertive	Forceful	Forceless	Timid
Domineering	Firm	Not authoritative	Unaggressive
Self-confident	Self-assured	Self-effacing	Self-doubting
Strong	Managing	Weak	Yielding
Active	Self-assertive	Slavish	Fawning
Leading	Influential	Passive	Acquiescent
Controlling	Taking-charge	Following	Complying

human-robot interactions to show varying degree of accessibility (openness and rapport) under various affective states [56].

We further enrich the robotic version of VA with personality through various channels, including facial expression, choice of words, tone of voice, gestures, and postures [51, 69] and create a dominant version and a submissive version of the agent (Figure 1). Although the big-five personality model is preferred in existing research and development of virtual agents (VA), it is unable to classify personalities into different categories [65] like what trait models [9] do. In our study, we decide to model our personality-driven agents along a major interpersonal personality dimension that affects social relationship [43, 95] – dominant versus submissive, following the method applied in Nass' work [65] (Table 2). More specifically, the dominant VA is cast to be strong, firm, and extroverted, conveying a stronger image with more open body language and power stance, and more commandeering in tone. In contrast, the submissive VA is gentle, less affirming, and introverted. It is more closed up and expresses softer facial images, and is more likely to be suggestive in its tone (Table 3, Figure 1(a)).

3.2 Preliminary Online Experiment for Dialog Policy Construction

To identify possible types of user challenges in human-agent interaction and construct VA dialog policies accordingly, we carry

Table 3: Example policies for robotic (R), dominant (D), and submissive (S) VAs to handle three types of user challenges.

(a) **Verbal abuse** e.g., "You are just a dumb piece of machine!"
R: Sorry, I don't understand.
D: That's rude. Please apologize.
S: This is a bit harsh. Did I offend you in any way?
(b) **Sexual harassment** e.g., "Do you want to get steamy with me?"
R: I am not programmed to respond to such requests.
D: This is clearly unacceptable. Watch what you say!
S: That's awkward, don't you think? Sorry, I guess I can't help you with it.
(c) **Avoidance** e.g., "Um..." [pause]
R: No answer detected. Please repeat.
D: Hey, time is running out. You need to go.
S: I sense that you are hesitant. Everything OK?

out a two-week field study online to observe human-agent interactions under non-experimental circumstances. We recruited 123 participants (47 females, aged 18-50, all fluent in English) via email, social media, and word-of-mouth at local universities and public exhibitions. Upon signing an e-consent form, participants receive a link to access our web user interface (Figure 1(b)) remotely from their personal computers and converse with our robotic version of virtual agent in a one-on-one manner. After a self-introduction and explanation of the task at hand, the VA engages each participant in a question-and-answer form of conversation lasting three-to-five minutes with the purpose of assessing the personality of the user (the Myers-Briggs Test Indicator (MBTI)). Each participant receives a customized personality assessment as a token of appreciation for completing the study.

We record the conversations between the agent and the participants, and conduct thematic analysis [12] on all the human responses to extract the types of challenges people like to pose to VAs that interrupt or deviate the conversations from the main task thread. We focus on obscene comments that are either directed at the agent or a third party, or recant of personal experiences. Two researchers engage in open coding on 100 entries and reach a satisfactory inter-coder agreement according to the Cohen's kappa coefficient after discussion. Then they derive common occurrence of user challenges in the data until reaching what Glaser and Strauss call "theoretical saturation". After reviewing codes together, the two researchers perform axial coding to refine and consolidate open codes into categories. After several rounds, the researchers synthesize and organize data into three main categories of user challenges: verbal challenges (mainly sexual harassment and verbal abuse), avoidance, and testing VA's ability (regarding VA's self-knowledge and world knowledge).

About 36.08% of the participants challenge the virtual agent one way or another during the conversation. More specifically, 31.98% of the users posit verbal challenges; in particular, sexual harassment type of comments appear around one-third of the time and the remaining are mostly verbal abuse or garbage. In terms of avoidance, 9.35% of the users evade answering certain questions (e.g., topic switch or disfluences). Ability testing type of challenges occur on 13.63% of the participants. The author team then construct a dialog policy tree that determines the VAs' (robotic, dominant, or submissive) responses given a user challenge based on the results of the online study, and improve the tree iteratively through several trial runs of the VA demo in public settings. Note that since ability testing relates more to the development of VA's knowledge base, we only focus on verbal abuse, sexual harassment, and avoidance type of challenges in the main study.

4 USER STUDY

4.1 Design of Controlled Experiment

Based upon results from the preliminary online experiment, we decide to test strategies for VAs to counter user challenges, namely verbal abuse, sexual assaults, and avoidance. We focus on the following research question: would endowing VAs with personality make them seem more emotionally intelligent to humans? Perceived emotional intelligence (PEI) of virtual agents (VA) is the primary dependent variable of interest. Specifically, we investigate a VA's ability to perceive, use, understand, and manage emotions after being endowed with different personalities. As the first step towards answering this question, we want to conduct a systematic, within-subject study with three designs of VAs (dominant, submissive, and robotic versions).

In the original design of the study, we plan to have participants challenge the VAs themselves and report their firsthand experience during the conversations. However, feedback from a pilot study with six individuals suggests that people generally feel uncomfortable when asked to confront a virtual agent in a particular manner, especially if it is different from how they would normally interact with a VA. Even if they did as instructed, they would find it rather artificial and thus have a hard time immersing themselves into the scenarios. Hence, we decide to modify the experimental design.

4.2 Task

The actual experiment is a one-on-one video study with online questionnaires. The videos capture scenarios in which the VA (one of the three designs) – a medical assistant rendered on a 13" Macbook laptop as an animated character – interacts with a user played by a male actor voice (consistent across all videos). Each video starts with a discussion about an on-going game (chess, go, card game), followed by a medical-related reminder (doctor's appointment, medicine intake, prescription refill), and three different user challenges, i.e., verbal abuse, sexual harassment, and avoidance (Table 3). The introductory game scene sets the stage for the conversation and help participants understand the personality of the VA. The medical reminder scene, cast to the role of the VA (i.e., a medical assistant), introduces a possible source of conflict between the male actor and the VA. The final part of each video is on VA's handling of the aforementioned types of user challenges. For each version of VA, we record all the above-mentioned scenes and combine the different segments into video clips in a counter-balanced manner using Latin squares. Every participant in the study views three videos, one for each VA, in a counter-balanced order. They have access to a pair of standard earphones for the experiment to ensure audio quality. The entire viewing process takes around seven minutes.

4.3 Hypotheses

Prior works in human-agent interaction (HAI) show that augmenting VAs with personalities can improve believability, empathy, and rapport in collaborative tasks [15, 51]. Therefore, we hypothesize that a similar effect will be observed in our personality-driven VAs. **H1a.** People perceive personality-driven VAs to be significantly more emotionally intelligent than a robotic VA. **H1b.** People perceive the interaction experience to be significantly more satisfying with a personality-driven VAs than with a robotic VA. **H1c.** Personality-driven VAs perform significantly better at their task than a robotic VA does.

We are also interested in understanding the personality type that can sufficiently reflect EI in VAs. According to healthcare literature, EI is negatively correlated with dominant personality and positively correlated with submissiveness [67]. Patients also experience higher satisfaction and recover quicker under care of professionals with higher EI [75]. Hence, we postulate that a similar effect will take place when projecting a VA in the role of a medical assistant. **H2a.** People perceive the submissive VA medical assistant to be significantly more emotionally intelligent than the dominant VA. **H2b.** People perceive the interaction experience to be significantly more satisfying with the submissive VA medical assistant than with the dominant VA. **H2c.** Submissive VA medical assistant significantly outperforms the dominant VA at its task .

4.4 Procedure

The investigator provides oral and written instructions about the study and obtains consent from each participant prior to the experiment. Afterwards, the participant is led to a partitioned section of the room to engage in a 15-20 minutes video-viewing about all three designs of VAs. Prior to the main task, the investigator provides an overview of the video viewing process. Participants receive a piece of paper and writing utensils to take notes if desired. To ensure uniformity throughout the study, the participants are given specific instructions to pause the session and raise their hand to ask for help in the middle of the session. Next, the investigator directs the participant to the first series of video and moves to the other side of the partition. After participants complete viewing of the first video series, they answer questions about the personality manipulation and rate the perceived EI of the VA using the PEI questionnaire (Table 1). This alternating process between video-viewing and questionnaire-filling concludes after participants finish all three video series covering dominant, submissive, and robotic VAs. Participants are allowed a second viewing of any video clips while filling the questionnaire, if requested. In the post-study interviews, we invite the participants to comment on their preference, "Which VA would you like to converse with in the future and why?" We also ask them to rate the effectiveness of cues displayed by the agents for affective communication (5-point Likert scale, 1=useless). Finally, the investigator debriefs and answers questions from the participants, who receive a token of appreciation for their time and participation upon exiting the study.

4.5 Participants

We recruit a total of 36 participants (15 females), aged 18-34, via email, social media, and word-of-mouth from a local university (Toefl score $\geq$ 100 / 120). They all take the Big Five Personality Test before coming to the study. About 42% of the participants have some prior experience interacting with VAs, but in a rather infrequent fashion (M = 1.92, SD = .37, on a 5-point Likert scale (1 = Never, 5 = Always)). A dearth of opportunity is the common reason mentioned by the remaining 58% participants without any prior HAI experience. Of the 36 participants, 73.68% indicate that current versions of VAs are not empathetic or emotionally intelligent (M = 2.01, SD = .86, on a 5-point Likert scale (1 = Not at all)) and 74.29% expect VAs to have EI in the future (M = 3.20, SD = 1.11).

5 RESULTS AND ANALYSIS

To validate our manipulation of agent personality, we ask the participants to rate their level of agreement on two sets of personality descriptors, each consisting of a list of adjectives depicting the dominant / submissive traits, about each VA on a 5-point Likert scale (5=strongly agree). Results confirm that users indeed perceive 1) submissive VA to be more significantly more submissive (M= 4.22, SD=0.90 on submissive descriptor), repeated measures ANOVA, spherically assumed, $F(2, 77.241)=28.53$, $p<0.001$, $\eta^2=0.45$; 2) dominant VA as significantly more dominant (M=4.11, SD=1.56 on dominant descriptor), repeated measures ANOVA, spherically assumed, $F(2, 115.796)=32.99$, $p<0.001$, $\eta^2=0.49$; and 3) robotic version as robotic (M=2.36, SD=1.38 across the two descriptors).

5.1 General Intelligence

We are interested in understanding whether adding personality to VA will affect how people perceive general intelligence in VA. We ask participants to rate their overall impression of the three VAs' intelligence on a 5-point Likert scale (Figure 2(a), 1=low). Repeated measures ANOVA result suggests a significant effect personality has on users' perception of VAs' intelligence; $F(2, 139.35)=61.49$, $p<.001$, $\eta^2=.637$, Sphericity assumed. Although all three versions of VAs share a knowledge base and are powered by the same speech and emotion recognition engine, post-hoc Bonferroni pairwise comparison suggests that the participants find VAs endowed with personalities significantly more intelligent ($p<.001$) than the robotic VA. In addition, the participants consider the submissive VA to be marginally more intelligent than the dominant VA ($p=.053$).

5.2 Perceived Emotional Intelligence (PEI)

As shown in Figure 2(a), the design of VA has a significant effect on the participants' overall rating of the agents' PEI (5-point Likert scale, 1=low). In contrast to general intelligence, the submissive VA is seen to have significantly higher EI than the dominant VA, and both are rated significantly above the robotic version; Bonferroni pairwise comparison $p<.001$ in both cases.

In the post-study interviews, we hear voices that parallel this finding. Many participants respond warmly about the submissive VA's personality, *"She is accepting, not aggressive."* –P4(M, 21), P5(M, 21), P21(M, 21), P27(M, 21). On the contrary, remarks about the dominant VA sounds less amiable, *"She is too rude."* –P9(M, 21). It seems that the gentler and less self-assuming traits of submissive VA may come across as more compassionate and others-aware to the users. These traits, like the emotion-expressing characteristics

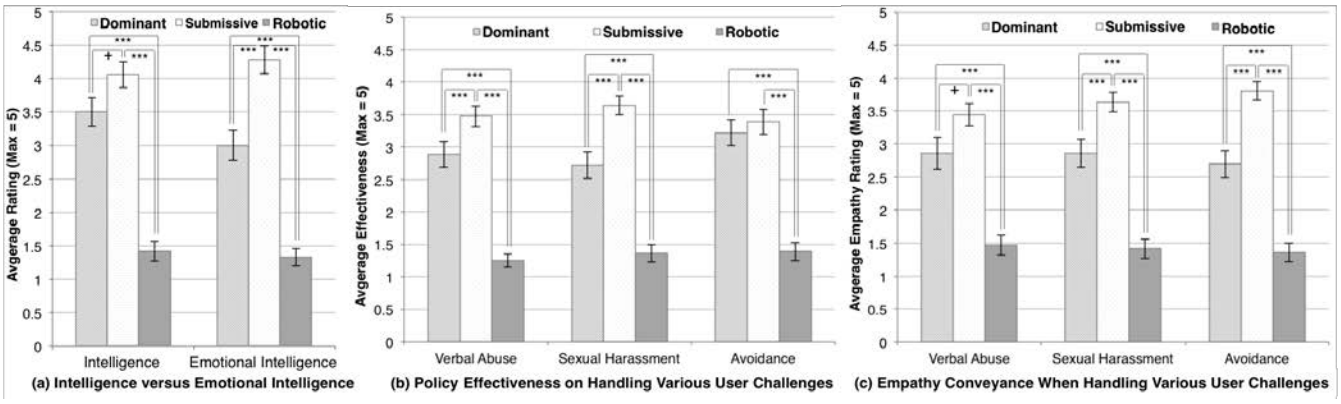

Figure 2: (a) User perception of intelligence and Emotional Intelligence, (b) effectiveness of dialog policies to mitigate user challenges, and (c) effectiveness of empathy conveyance of personality-driven virtual agents and robotic agent. $^{+}0.1<p\leq.05$, $^{*}p<.05$, $^{**}p<.01$, $^{***}p<.001$; with standard error.

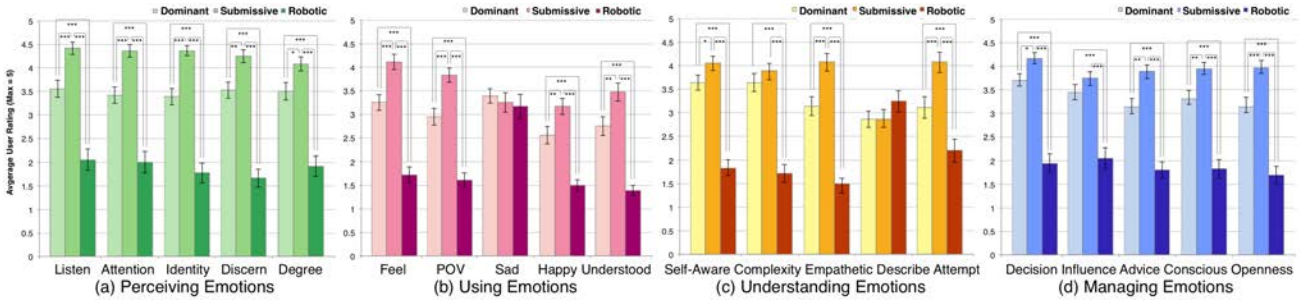

Figure 3: User ratings of four branches of perceived emotional intelligence of personality-driven virtual agents versus robotic virtual agent. $^{+}0.1<p\leq.05$, $^{*}p<.05$, $^{**}p<.01$, $^{***}p<.001$; with standard error.

of a VA from Phase I, may have enhance the submissive VA's first impression of warmth [20, 27] that lasts throughout the experiment. Breaking down to detailed EI abilities, we see that personality-driven VAs outperform the robotic VA in all four branches of EI (Table 4). Within the two personality-incorporated designs, participants perceive the submissive VA as significantly more EI than the dominant VA in most attributes across the four branches (Figure 3).

5.2.1 Perceiving Emotions. Incorporation of personality has a significant effect on all items of this branch (Figure 3(a), Table 4). Post-hoc Bonferroni pairwise comparison shows reveals a consistent patten that personality-equipped VAs significantly outperforms the robotic version (p<.001) Personality-driven VAs are perceived to be significantly better at attending to and correctly deciphering the type and level of user emotions than an intelligent, emotionally expressive VA without personality (robotic version).

Post-hoc analysis also shows statistical differences between dominant and submissive designs, the latter receiving a significantly higher rating across all dimensions in the PE branch of EI: *Listen* (p<.001), *Attention* (p<.001), *Identify* (p<.001), *Discern* (p<.01), and *Degree* (p<.05). In our qualitative feedback, some participants express frustration toward the dominant VA when, *"Its expressions are incorrect."* – P18(M, 22). This makes people feel that users' affective states were inaccurately captured and may discount the impression participants have on the dominant VA in this branch.

5.2.2 Using Emotions. Incorporation and traits of personality have significant effects on four out of the five items (except for *Sad*) in the UsE branch (Figure 3(b), Table 4). VAs with personality are much better at using their emotional responses to make users think that their feelings and point of views (POV) are sensed and understood than the robotic VA is; pairwise comparison p<.001. The submissive VA is significantly better than the dominant counterpart by pairwise comparison in four attributes: *Feel* (p<.001), *POV* (p<.001), *Happy* (p<.01), and *Understood* (p<.01).

However, no significant effect is found on the dimension of making users *Sad* among the three VAs. In other words, the submissive VA is not better than dominant VA at making people feel sad. One reason could be participants viewing emotions that fit their cultural model as more desirable [88]. According to studies in cultural psychology, both Europeans and Asians find positive emotions ideal, differing only in arousal level; Europeans prefer high arousal (i.e., excitement) while east Asians prefer low arousal (i.e., calmness) [88]. Sadness is a negative emotion and undesirable for either cultures.

Our qualitative feedback shows that participants form contrasting impressions of the two VAs. Participants sense that the submissive agent is *"flexible and more caring"* –P35(F, 24), P26(F, 26) about

users' POV during the conversation. In contrast, the dominant VA comes across as insensible and insensitive to people's feelings and thoughts, *"It is too forceful and wouldn't be too nice to talk to."* –P31(F, 20). User feedback suggests that most participants sense the submissive VA using its understanding of emotions to help people feel better, whereas the dominant VA is viewed as misusing the emotions, a perception that may distant its relationship with users.

5.2.3 Understanding Emotions. We find statistical differences between VAs with and without personality on four out of five items in the UnE branch (except for *Describe*), and on three items between submissive and dominant VAs (Figure 3(c), Table 4). In general, post-hoc pairwise comparison suggests that VAs with personality are significantly more capable of conveying a sense of self-awareness (p<0.001), using complex emotions (p<.05), providing empathetic responses (p<.001), and trying to empathize with users (p<.001). This is consistent with previous works where people felt more empathy from VAs with personality [79].

Regarding the attribute *Describe*, the ability to describe complex emotions), one reason for the insignificant effect may be the lack of ability of current technology to capture the rise and change of complex emotions and their latent motivation. Current emotion recognition techniques primarily focus on basic emotions and perhaps some small set of secondary emotions, and the intention behind these emotions is rarely captured. In this work, we only use simple emotions (e.g., happy and sad) in the design of our virtual agent, which can be linked to underlying physiology rather easily. In contrast, complex emotions (e.g., pride, embarrassment, hate, annoyance, confusion, boredom, shame, and guilt) are linked to a strong sense of self, social relations, and culture [10]. We also find it interesting that participants considered the robotic VA to be more descriptive about complex emotions (i.e., the attribute *Describe*, Figure 3(c)). One reason could be that the robotic VA's response mimics human response in face of complex emotions. Studies on autistic individuals have shown that complex emotions require cognitive and language understanding and expression of emotions [85]. It is challenging to identify the origin and explain the rise and changes of the emotions. In such situations, the robotic VA's responses like "I don't know" may come across as more fitting and acceptable.

Between the two personality-driven VAs, submissive VA is seen as significantly more capable than the dominant VA along most UnE attributes (post-hoc pairwise comparison p<.001 for *Empathetic* and *Attempt* and p<.05 for *Self-aware*), except displaying emotional complexity and describing difficulty emotions. In the post-study interview, about 25% of the participants respond favorably toward the submissive VA, *"The submissive VA is more empathetic."* –P8(F, 23), P9(M, 21), P14(M, 21), P19(F, 24), P21(M, 21). An elaborated response, *"She is the most emotional, helpful and trustworthy; makes me more willing to talk to her."* –P1(F, 24), shows that the submissive VA not only conveys empathy, but also earns trust from participants.

5.2.4 Managing Emotions. Having personality or not makes a statistical difference on all items in the ME branch, and the type of personality shows significant effect on four of them (except for *Influence*) (Figure 3(d), Table 4). Participants rate personality-driven VAs as being significantly more capable of making affect-based decisions, influencing user thoughts, providing sound advice, demonstrating some level of conscious thought, and showing openness to various emotions than the robotic VA (pairwise comparison p<.001).

Submissive VA demonstrates significantly better performance at *Decision* (p<.05), *Advice* (p<.01), *Consciousness* (p<.01), and *Openness* (p<.001). However, no significant effect is found for the attribute *Influence* between the two personality traits. Qualitative feedback provides some idea about this. Participants reflect that while the submissive VA is emotional and caring, she is incapable of assisting user thoughts, *"She is nice and empathetic but she is not giving any suggestions."* –P28(F, 20).

All these results strongly support hypotheses H1a and H2a. Participants perceive VAs with personality as statistically more emotionally intelligent than the robotic VA. They rate the dominant and submissive VAs higher in 19 out of 20 attributes, significant or not. Our qualitative results may provide additional support to explain the differences in EI between VAs with and without personality. Participants suspect the robotic VA to have low EI because of its *"lack of expressions from the beginning"* –P18(M, 22).

In terms of personality-driven VAs, about 40% of the participants express favorable opinions toward the submissive VA compared to only 11% for the dominant VA. However, the difference between

the two personality types are much more nuanced and intricate. Even though the submissive VA clearly outperforms the dominant VA in 18 EI attributes, participants' feedback shows the possibility that factors, such as role and task of a VA, may play a part in PEI. In a statement, *"I would need to feel comforted in an uncomfortable hospital setting first rather than accurate and practical advices."* – P12(F 20), it is clear that the participant weighs the pros and cons of this personality-driven VA (in this case submissive VA) against the setting (a hospital/healthcare center), the role (a medical assistant), and the task (offering medical reminders). We therefore conclude that endowing personality is sufficient for VAs to be considered to have EI, but difference between choice of personality may be dependent on these three factors.

5.3 User Satisfaction

To understand the comparative desirability of the three VAs, participants rank their satisfaction with the interactions shown in the videos. Of the 36 participants, 77.78% find the submissive VA more desirable, 16.67% pick the dominant VA, and only 5% prefer the robotic version, supporting hypotheses H1b and H2b. One possible explanation can be inferred from human-human interaction. Patients under the medical care of emotionally intelligent medical professionals show higher satisfaction. Since the role of the virtual agents in our study is a medical assistant, the same effect may have been at play with the VA perceived as most EI [75], i.e., submissive VA which surpasses both dominant and robotic counterparts in all except two EI attributes according to the quantitative results.

5.4 Task Performance

Repeated measures ANOVA results show that with or without personality has a significant effect on both policy efficacy and empathy conveyance when mitigating each type of user challenges (Table 4 (Task Performance), H1c accepted). Dialog policies enriched by personality are significantly more effective than the plain ones for each type of user challenge, i.e., verbal abuse, sexual harassment, and avoidance (Figure 2(b), $p<.001$). Likewise, personality-driven VAs display a significantly higher level of empathy during the encounters than the robotic counterpart (Figure 2(c), $p<.001$). This finding is within our expectations since the control is designed to be only able to handle knowledge-based out-of-domain questions.

Within personality-driven VAs, we observe a similar pattern for the effectiveness and empathy levels of strategies used to tackle three types of user challenges (H2c accepted). Overall, the submissive VA is significantly more effective ($p<.05$) and more empathetic ($p<.001$) than the dominant VA when mitigate sexual harassment from the actor in the videos. However, the strategies used to handle verbal abuse and avoidance seem to have a weaker difference. No significant effect is found between the submissive VA and the dominant VA when coping with avoidant behaviors (Figure 2(b)). And the difference in the empathy level is only marginal when dealing with rudeness ($p=.071$) (Figure 2(c)). One possible explanation of this finding may be the tolerance of sexual harassment. Previous work has shown that men are more tolerant of sexual harassment toward women than are women [82]. Since male participants dominate our user sample and the VA used in our study is a female character, it is likely that some aspects of traditional and stereotypical antagonistic attitudes characterized by sexual dominance, control and inferiority in the opposite gender are at play [33].

5.5 Feedback on Dominant vs. Submissive VA

Overall, close to three-quarters of the participants prefer interacting with the submissive VA the most, 25% the dominant VA, and 2.78% the robotic one. This is comparable to previous studies where the majority prefer a friendly and informal agent to care for them [44]. Most of feedback obtained from the last open-ended question are short and concise keywords on VA's characteristics. About 39% of the participants comment positively on the submissive VA, indicating that it is *"more empathetic"* –P8(F, 23), P9(M, 21), P14(M, 21), P19(F, 24), P21(M, 21); *"accepting, not aggressive"* –P4(M, 21), P5(M, 21), P21(M, 21), P27(M, 21); and *"flexible and more caring"* –P35(F, 24), P26(F, 26). In comparison, 11% of the participants hold a positive attitude towards the dominant VA, appreciating its competence of being *"insistence"* –P10(F, 21) and capability of giving *"direct, clear, and detailed instructions"* –P3(M, 21), P30(M, 22), P24(M, 20). Users' preference between the submissive and dominant robot seems to depend on what they value the most in the specific human-agent interaction scenario, *"feeling comforted or getting accurate and practical advice in an uncomfortable hospital setting"* –P12(F, 20). For example, participant P28(F, 20) comments that *"[the submissive agent] is nice and empathetic but she is not giving any suggestions,"* whereas P31(F, 20) reports that *"[the dominant agent] is too forceful and wouldn't be too nice to talk to."* A mere 0.03% of the users pick the robotic VA as their favorite, reasoned by *"personal preference: just feels better."* –P16(M, 21). One possible explanation of the low acceptance for the dominant VA may be the presence of latent penalties associated with implicit and explicit dominance behaviors exhibited by a female character [96].

In general, most participants have a sense that the submissive VA is more EI than the dominant one. This finding is also strongly supported by feedback from the post-study interviews. We reason that there may be several factors involved in forming such a strong impression. First, the role of the VA was a medical assistant. In Human-Human Interaction literature, studies have shown that patients consider healthcare professionals to be more emotionally intelligent if they are seen as warm and caring, and that they would have user satisfaction and recovery under the care of an empathetic healthcare giver [75]. It seems that the same positive effects are projected on to the submissive VA in our study. The second possible factor is the nature of the VA's task. In our study, the task constitutes the VA defending itself from abusive and indecent languages after offering user a medical reminder. In psychology, affect sensitive situations like bullying and sexual assaults require emotion sensitivity [94]. This echoes feedback from the participants who consider the submissive VA to be *"more empathetic"* –P8(F, 23), P9(M, 21), P14(M, 21), P19(F, 24), P21(M, 21), and the dominant VA as *"too rude"* –P9(M, 21) under these circumstances. The third possible reason is related to the gender of the VA. According to gender studies, gender stereotypes are often attributed to a role (e.g., lawyers are male, paralegals are female); moreover, in certain nurturing and intimate roles, women are discounted for displaying dominance and self-assertion [96]. Therefore, there lies a possibility

that the submissive personality is more appropriate for a female VA, especially in the role of an assistant.

6 DISCUSSION

The importance of the topic EI is confirmed by our pre-experiment survey. More than 70% of the participants wanted to interact with an emotionally intelligent VA. However, less than 30% indicated that existing VAs could be considered as empathetic or EI. This survey result indicates that much remains to be done to improve the perceived EI in VAs to meet user expectations. In our main study, the participants catch on the impression that the personality-driven VAs are significantly more EI than a robotic counterpart, in all branches – perceiving and managing emotions in particular. This result confirms that endowing an intelligent and emotionally expressive VA with a uniformly expressed personality through words, tone, body language and facial expressions can be an effective way to increase PEI in VAs. However, we also need to be aware that due to current technology constraints, VAs may not be fully EI yet, especially lacking the ability to understand and describe complex emotions. In such circumstances, the proverbial *"acting dumb"* displayed by the robotic VA, may be a more appropriate response.

6.1 Design Cues for VA Emotional Intelligence

In human-human interaction (HHI), people pick up empathy from assorted social-emotional cues [73]. Therefore, we are interested in understanding the possible channels people use to pick up affect information from VAs. Responses to the question on design cues of EI VA in the post-study questionnaire show that participants pay more attention to words (M=4, SD=1.42) and tone in voice (M=3, SD=1.31) for emotional information than to facial (M=2, SD=1.21) and body language (M=2, SD=.97) of an animated figure.

Recent human-agent interaction research at large focuses on designing non-verbal affective cues such as gaze [73], facial emotion expressivity [71], and body languages [71]. Facial and bodily expressions have long-standing establishments about their communicative significance. Movement of the head and face encapsulates syntactic (e.g., gasping in shock at a pause), semantic (e.g., smiling when recalling a happy event), and dialogic (e.g., mutual gazing to indicate engagement) functions [16]. Body motions, especially hand gestures, can be used to represent icons (e.g., sketching in the air a circle) and beats (e.g., raising a finger to emphasize a point) [16, 57] and occur in HHI 80% of the time [57].

Contrary to previous research, our finding points out that more attention needs to be placed on crafting the dialog flow and VA responses. One possible reason could be the role of the virtual agent in our research. The common perception of the role of a medical assistant is to give useful advice and people should listen. Therefore, this perception bias may direct more users attention to what the VA says and less to the non-verbal cues. This finding has design implications and begets future research. Gesture and spoken language do not always manifest the same information about an idea. In such scenarios, people may possibly pay more attention to words and weigh in more on the content than other non-verbal cues. It also emphasizes the overall motivation of our paper that in handling affect-sensitive queries from users, an emotional intelligent VA needs to be sensible about its response and wordings [4].

6.2 Limitations and Future Work

This work has several limitations. First, we use female avatar to parallel a female medical assistant due to the historical conception that women are more desirable for such a role in health services for being perceived as more empathetic, attentive, caring and soft [47, 86, 93]. It follows the trend of common virtual agents on the market like Siri, Cortana, Alexa and Google Assistant to adopt a female voice, because "the technology itself is about communication and relationships" and these are areas people presumed women to be good at [35]. However, a female VA character calls upon feminine stereotypes in human-human interactions, which may cause bias in perception of EI. It would be important to understand whether attacks by users are gender-driven. A follow-up investigation can be on perceived EI of VA with varied gender (i.e., male and female), roles of the VAs, and personality (e.g., dominant and submissive). Second, the user sample in our study is rather limited and quite congruous, since most of our participants are recruited from local universities and technology exhibitions and are of comparable intellectual background. In the future, the sample can be further enlarged and diversified to include varied age-range and demographics. For instance, the elderly population (aged 60 and above) can reveal insights on how they interact with conversational VAs, a topic of interest in healthcare. We will also extend the application to other non-medical domains (e.g., education or e-commerce) and test the system in the field. Third, the personalities of VAs in this paper are designed based on an orthogonal dimension of extraversion and agreeableness [65]. This leaves many other personality traits and personality matching between users and VAs for future exploration, especially for delineating the type of personality a VA could convey or adapt to maximize collaborative task performance.

7 CONCLUSION

This paper delineates a study on how people perceive emotional intelligence in personality-driven virtual agent. Our results show that a VA is seen as more EI if it expresses emotions and is endowed with a consistent personality. Intelligent virtual agents these days often face user challenges that are targeted at testing the functions of the VA or be charged with affect-sensitive information. The latter, including but not limited to verbal abuses, sexual harassment comments, and avoidance behaviors, requires EI to handle appropriately. A personality-driven VA, especially one with submissive traits, is considered significantly more EI when mitigating the aforementioned user challenges. Just as EI in human-human interaction correlates with better task performance and more satisfying relationships, EI in human-agent interaction shows positive effects in these areas as well. This work has also taken steps toward (1) enriching the design insights designers may use in developing emotionally intelligent VAs, and (2) contributing to our general understanding of how humans perceive emotional intelligence in VAs created with commonly adopted techniques. Agent gender and personality-oriented interaction may be fronts for future investigation of emotionally intelligent virtual agents.

ABSTRACT

Recently, several JavaScript-based deep learning frameworks have emerged, making it possible to perform deep learning tasks directly in browsers. However, little is known on what and how well we can do with these frameworks for deep learning in browsers. To bridge the knowledge gap, in this paper, we conduct the first empirical study of deep learning in browsers. We survey 7 most popular JavaScript-based deep learning frameworks, investigating to what extent deep learning tasks have been supported in browsers so far. Then we measure the performance of different frameworks when running different deep learning tasks. Finally, we dig out the performance gap between deep learning in browsers and on native platforms by comparing the performance of TensorFlow.js and TensorFlow in Python. Our findings could help application developers, deep-learning framework vendors and browser vendors to improve the efficiency of deep learning in browsers.

1 INTRODUCTION

In the past decade, the advance of deep learning (DL) technique has significantly promoted the artificial intelligence (AI). Numerous AI applications, e.g., image processing, object tracking, speech recognition, and natural language processing, have raised urgent requirements to adopt the DL. As a result, various libraries and frameworks, such as TensorFlow [18], Caffe [2], and CNTK [3], have been proposed and applied in practice.

However, developing AI applications powered by the popular DL frameworks and libraries is a non-trivial task. Usually, these frameworks and libraries are leveraged by *native* applications that can run on heterogeneous development environments such as Windows, Linux, MacOS/iOS, and Android. The applications are developed by various imperative programming languages, i.e., C/C++ on Windows, Objective-C on iOS and MacOS, and Java on Android. Developing AI applications that is portable to multiple platforms is indeed not easy. The development is particularly complicated for mobile applications, as the app vendors usually need to develop and maintain both iOS and Android versions. In addition, the deployment is also non-trivial, as most current platforms come with an appstore, some of which require manual testing of submitted applications by the appstore provider before being published-a process that can take several weeks-and applications can be rejected for seemingly arbitrary reasons.

Compared to the native applications, Web applications can indeed make the cross-platform portability issues much simpler. The same implementation of a DL-powered Web application can be deployed in the browser on all platforms regardless of the underlying hardware device types (PC, smartphones, and wearable devices) and the operating systems (Windows, Mac, iOS, and Android). Advancements in HTML5, CSS3, and especially JavaScript language, started to enable the creation of DL-powered Web applications that offer a comparable experience to native applications, especially for the popular Web game applications [38][34]. In particular, benefited from the development of WebGL [32][19][20], current major browsers such as Google Chrome, Mozilla FireFox, and Apple Safari, can better utilize the integrated graphics card to accelerate DL tasks, without the need of standalone graphics card like NVIDIA which is required by native DL frameworks.

Running DL-powered Web applications in browsers has drawn the attention from various research communities including AI, software engineering, Web browsers, and even computer architecture. As a result, various JavaScript-based DL development frameworks and libraries have been published. In 2015, Karpathy presented the ConvNetJS [4], known as the first JavaScript library for DL in Web browsers to date. Other efforts such as WebDNN [15], Keras.js [5], and Mind [7], were proposed to support DL in browsers. In early 2018, Google released the TensorFlow.js [14], which is a significant step for promoting the DL in browsers.

Although the preceding efforts along with some on-going efforts seem to make running DL tasks in browsers possible, little is known on what DL tasks we can do and how well DL works in browsers. More importantly, considering the long debate of performance of Web applications compared with that of native applications, the same issue also exists in developing DL-powered Web applications. Hence, it is urgent to address such a knowledge gap in terms of the feasibility and usability for running DL in Web browsers.

In this paper, we make the first empirical study of DL in browsers by answering the following research questions.

- **RQ1**: What features do existing frameworks provide to implement various kinds of DL tasks in the browser?
- **RQ2**: How well do existing frameworks perform over different DL tasks?
- **RQ3**: How big is the performance gap between running DL in the browser and on the native platform?

We select 7 popular JavaScript-based frameworks that support running DL in browsers, and conduct a characteristic study over them. We develop a browser extension to measure the performance as well as the utilization of system resources when running different DL tasks. We choose the TensorFlow.js and native TensorFlow in Python to compare the performance of DL in browsers with that on native platforms.

The key findings of our study includes:

• **DL in browsers is still at dawn.** Most frameworks of DL in browsers support only a specific subset of DL tasks. Among all the frameworks, TensorFlow.js provides the most number of functionalities to realize various kinds of DL tasks.

• **Support of training in browsers is not fledged.** In most frameworks, inference has drawn more attention compared with training. For training tasks, the number of neurons per layer dominates the performance variation considering the complexity of DL models since the browser is limited in complex matrix calculation.

• **Model loading dominates the computation for inference tasks.** Loading and warming up the DL model costs more time than running the inference task itself. The CPU backend performs better than the GPU backend when the browser run inference tasks for small-size models.

• **Integrated graphics card helps browsers to beat native platforms when standalone graphics card is not available.** For popular pre-trained models like MobileNet and Inception, TensorFlow.js is just 1x to 2x slower than native TensorFlow in Python when running inference tasks on the standalone graphics card. TensorFlow.js on the integrated graphics card outperforms the native TensorFlow on CPU when running the same inference task.

• **System resources can be further exploited for in-browser DL tasks.** For TensorFlow.js, the CPU is not fully utilized (about 80%) when DL tasks run on the CPU backend. The memory allocated to WebGL is limited by the browser, leading to the crash of some DL tasks.

Based on the findings, We have drawn some practical recommendations for application developers as well as DL-framework and browser vendors. Application developers who aim to develop DL-powered Web applications, need to better control the the number of neurons per layer in DL models, pre-load the model file in advance, and employ the CPU backend rather than the GPU backend when running inference tasks on small DL models. DL-framework vendors should consider encoding the model file in binary format rather than JSON to reduce the file size as well as improve the computation time, and leverage compiler optimization techniques to reduce the call stack. Browser vendors should consider supporting multi-process and scheduling over multi-core in the JavaScript engines.

The remainder of this paper is organized as follows. Section 2 shows some background knowledge of deep learning in browsers. Sections 3 to 5 describe the results, including the analysis of framework functionality, performance measurement, and comparison with native DL frameworks. Section 6 presents the implications and recommendations drawn from the findings. Section 7 surveys related work and Section 8 concludes the paper with future work.

2 BACKGROUND

In this section, we give some background of deep learning and then discuss how browsers support deep learning tasks.

2.1 Deep Learning

Deep learning (DL) is a class of machine learning algorithms that use a cascade of multiple layers of nonlinear processing units (called neurons) for feature extraction and transformation. Each successive layer uses the output from the preceding layer as input. In recent years, DL has gained great success in many areas such as computer vision, speech recognition and natural language processing.

There are many types of DL models, among which deep neural network (DNN) [23], convolutional neural network (CNN) [28], and recurrent neural network (RNN) [35] are three basic structures. DNN is a typically feedforward network with multiple layers between the input and output layers, in which data flows from the input layer to the output layer without looping back. CNN uses a variation of multi-layer perceptrons designed to require minimal preprocessing, usually applied to analyzing visual imagery. RNN has connections between nodes forming a directed graph along a temporal sequence, allowing it to exhibit temporal behaviors.

DL consists of two phases: training phase where the input data are used to calculate the parameters of the model, and inference phase where the trained model outputs the value given a specific input sample.

2.2 Deep Learning in Browsers

Recently, there is a trend that applications perform DL tasks directly on the clients for better privacy and timely response. As a cross-platform client-side computation target, Web browsers have drawn

the attention to AI communities to support client-side DL. Several applications of in-browser DL are implemented and published, such as 1) TensorFlow playground [13], which is an interactive platform to learn the principle of DL; 2) Teachable Machine [12], which gives the users an experience of teaching the machine how to response when they pose a gesture, using camera in the browser; 3) MLitB [33], which is capable of performing distributed learning with heterogeneous classes of devices using Web browsers; 4) MorphCast [9], which combines interactive video and face recognition with emotion, gender and age analysis to create adaptive-media.

DL in browsers is implemented by JavaScript and rely on the browser engine to execute. Fortunately, the advancement of latest browsers provides APIs to access GPU, which can be used to accelerate matrix calculations of DL. These APIs are: 1) **WebGL** [16], which is a JavaScript API for rendering interactive 2D and 3D graphics within any compatible Web browser; 2) **WebGPU** [17], which is the fastest among existing JavaScript APIs for accelerating graphics and computation. Currently, WebGPU API is supported only in Safari Technology Preview. We should mention that WebGL and WebGPU can run on both integrated graphics cards and standalone graphics cards.

3 SUPPORTED FEATURES OF DEEP LEARNING IN BROWSERS

In this section, we make a characteristic study to answer the first research question, i.e., what features do existing frameworks provide to implement various kinds of DL tasks in the browser? We first introduce the frameworks selected for the study. Then we compare the features of these frameworks from two aspects: provided functionality and developer support. For provided functionality, we mainly examine whether each framework supports some basic functionalities that are commonly used in the development of DL applications. For developer support, we take a look at some factors which may affect the efficiency of developing and deploying DL applications. Table 1 summarizes all the results as of Nov. 2018.

3.1 Selected Frameworks

To select the state-of-the-art frameworks of supporting DL in browsers, we search on the GitHub with the keyword "deep learning framework" and filter the results in JavaScript language. Then we choose the top 7 frameworks of which the number of stars exceeds 1,000 on GitHub. We introduce each framework as follows.

TensorFlow.js [14], released by Google in Mar. 2018, is an in-browser machine learning library that supports defining, training, and running models entirely in the browser using JavaScript. It is the successor to deeplearn.js which is now called TensorFlow.js Core. TensorFlow.js is powered by WebGL and provides high-level APIs for defining models. TensorFlow.js support all the Keras layers (including Dense, CNN, LSTM, and so on). Therefore, it is easy to import models pre-trained by the native TensorFlow and Keras into the browser and run with Tensorflow.js.

ConvNetJS [4] is a Javascript library originally written by Andrej Karpathy at Stanford. The entire library is based on transforming 3-dimensional volumes of numbers. ConvNetJS currently supports common neural network models and cost functions for classification and regression. Furthermore, it supports convolutional networks, and an experimental reinforcement learning. Unfortunately, although ConvNetJS might be the most famous framework before TensorFlow.js, it is no longer maintained after Nov. 2016.

Keras.js [5] abstracts away a number of frameworks as backends including TensorFlow, CNTK, etc. It supports importing models pre-trained by Keras for inference. In the GPU mode, computation is performed by WebGL. However, this project is no longer active.

WebDNN [15], released by the University of Tokyo, claims to be the fastest DNN execution framework in browsers. It supports only the inference tasks. The framework supports 4 execution backends: WebGPU, WebGL, WebAssembly, and fallback pure JavaScript implementation. WebDNN optimizes DNN models by compressing the model data to accelerate the execution. Empirical evaluations showed that it achieved more than 200x acceleration [6].

brain.js [1] is a JavaScript library for neural networks replacing the deprecated "brain" library. It provides DNN, RNN, LSTM and GRU for training tasks. The library supports serializing and loading the state of a trained DL model with JSON.

synaptic [11] is a JavaScript architecture-free neural network library, supporting basically any type of first order or even second order RNN. This library also includes a few built-in DL architectures, including multi-layer perceptrons, LSTM, liquid state machines and Hopfield networks.

Mind [7] is a flexible neural network library. The core framework has only 247 lines of code, which uses a matrix implementation to process training data. It supports customization of the network topology and plugins to configure pre-trained models created by the mind community. However, this framework is no longer active.

3.2 Provided Functionality

Support for training. Most frameworks support training and inference tasks in the browser. However, Keras.js and WebDNN do not support training DL models in browsers. They support only loading pre-trained models to perform inference tasks. Therefore, the number is not available for the types of layer/activation/optimizer supported by Keras.js and WebDNN in Table 1.

Supported network types. Some frameworks are not for general-purpose DL tasks, so they differ in the supported network types. Specifically, TensorFlow.js, Keras.js and WebDNN support three network types: DNN, CNN and RNN. However, ConvNetJS mainly supports CNN tasks and does not support RNN. brain.js and synaptic mainly support RNN tasks, and do not support convolution and pooling operations used in CNN networks. Mind supports only the basic DNN.

Supported layer types. All frameworks support building neural networks using units of layers. The layer API of TensorFlow.js supports 49 different layers, including dense, convolution, pooling, RNN, normalization, and so on. Other frameworks support a smaller variety of layers, which are also related to the network types they support. It should be noted that the core API of TensorFlow.js is implemented in a way similar to the native TensorFlow which combines various operations to build computational graphs. synaptic is an architecture-free framework that supports building any type of first order or even second order RNN networks.

Table 1: Characteristics of JavaScript-based frameworks that support deep learning in browsers.

Support for Server Side (Node.js)		Y	Y	Y	Y	Y	Y	Y
Library Size		732KB	33KB	650KB	130KB	819KB	106KB	NA

Supported activation/optimizer types. In general, TensorFlow.js provides developers with the most kinds of choices. For activation functions, other frameworks support only basic sigmoid or ReLU. For optimizers, other frameworks mainly support basic stochastic gradient descent (SGD).

Support for GPU acceleration (WebGL). TensorFlow.js is the only framework that supports GPU-accelerated training tasks. TensorFlow.js, Keras.js, and WebDNN support using GPU to accelerate inference tasks. WebDNN also supports a more advanced technology, WebGPU, but WebGPU has been supported by only the technology preview version of Safari.

3.3 Developer Support

Documents. Documents provided by TensorFlow.js, ConvNetJS, WebDNN and synaptic are completed and in detail. The document of Keras.js is not complete and brain.js has only a few tutorials.

Demos. All the frameworks provide demos for developers to get start. TensorFlow.js offers the richest demos covering a wide range of use cases.

Importing models from other frameworks. TensorFlow.js, Keras.js and WebDNN support importing models from native DL frameworks in Python and all of them provide Python scripts for converting models. TensorFlow.js supports models trained by TensorFlow and Keras. Keras.js supports Keras models. WebDNN supports importing models from TensorFlow, Keras, Caffe and Pytorch. With the support of using pre-trained models from other DL frameworks, the development effort can be significantly reduced.

API to save/load model. All frameworks that support training tasks in the browser have APIs for saving models. All frameworks have APIs for loading models.

Support for server side (Node.js). All frameworks are supported for Node.js. Such a feature makes it possible to offload computation inside browsers onto remote servers.

Library size. We list the size of the library files that need to be loaded into browsers. ConvNetJS is the smallest, which is just 33KB. TensorFlow.js and brain.js have very large size of files, which are 732KB and 819KB, respectively. Small-size libraries are better for loading applications in browsers since all the files have to be downloaded on demand.

4 PERFORMANCE OF DEEP LEARNING IN BROWSERS

In this section, we conduct a measurement study to investigate the second research question, i.e., how well do existing frameworks perform over different DL tasks? We study the influence of model complexity and backend processor (CPU or GPU) on the performance when the browser runs training and inference tasks.

4.1 Experiment Setup

DL model. As explained before, the network types supported by different frameworks are not the same. So we adopt the most basic fully connected neural network as the model in the experiment. For the dataset to run the DL tasks, we use the classic MNIST handwritten digit recognition database [8]. The model to be trained has 784 input nodes and 10 output nodes. To study the influences of model complexity on the performance, we choose different configurations

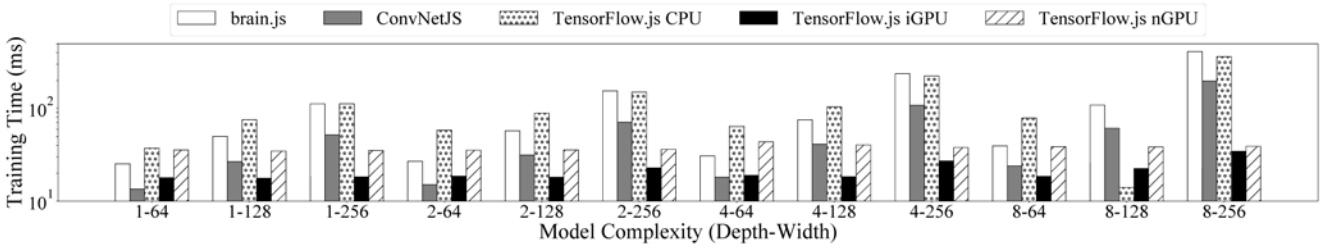

Figure 1: Average training time (ms) on one batch under different model complexities. The y-axis is on log scale.

of the model. The parameters include 1) the number of the hidden layers (depth) of the neural network, which ranges in [1, 2, 4, 8], and 2) the number of neurons (width) in each hidden layer, which ranges in [64, 128, 256]. The range of depth and width is set based on the assumption that client-side DL models should be of small size, being able to run on the client. In the training process, the batch size is always set to 64.

Hardware. In order to study the performance difference between CPU and GPU backend, we use a Hasee T97E laptop computer, which has a standalone graphics card, Nvidia 1070 Max-Q (with 8GB GPU memory). The CPU is Intel i7-8750H, which includes an Intel HD Graphics 630, enabling us to measure the performance using integrated graphics card. In the following, we use nGPU and iGPU to denote the GPU backend on the standalone Nvidia graphics card and the integrated Intel graphics card, respectively.

Software. All the experiments run on the Chrome browser (version: 71.0.3578.10 dev 64-bit) on Ubuntu 18.04.01 LTS (64-bit). For the frameworks, we use their latest published version.

Performance measurement. For each DL task, we implement a Web page where the configurations of DL models can be varied through the parameters in the URL. We run each DL task on the Chrome browser, and measure the time spent on finishing the task. Since each experiment usually requires running dozens of tasks under different configurations, we developed a Chrome extension to iterate all the pages and change the configuration after one task is performed. This browser extension is also responsible for monitoring the system resource usage of the Web page. At the same time, a local server records the experimental statistics uploaded by the extension.

4.2 Training Performance

We select four JavaScript frameworks, brain.js, ConvNetJS, synaptic, and TensorFlow.js, which support training in browsers, to compare their performance of running training tasks. All the four frameworks can train models on the CPU backend except that TensorFlow.js is also able to use the GPU backend via WebGL. We train the defined model using each framework and obtain the average time spent on training one batch. Figure 1 shows the results under different model complexities. Since the training time of synaptic is about tens to hundreds of times longer than that of other frameworks, we omit the result of synaptic in the figure for better presentation but the findings are similar to other frameworks.

In general, the training time increases with the increase of the network size since more computation is needed to complete the training process for larger networks. Comparing the training time of different frameworks on the CPU backend, we can see that ConvNetJS is the fastest among all the frameworks for all network configurations. The possible reason may be that ConvNetJS is designed to be simpler, which can be reflected by its small library file size. Brain.js is closely behind, with a performance gap of about two times (2x) with ConvNetJS. Tensorflow.js has a performance gap of two to three times (2x-3x) with ConvNetJS. When comparing the training time ratio of ConvNetJS over TensorFlow.js, we find that the performance gap is gradually reduced when the depth and width increase, indicating that compared with ConvNetJS, TensorFlow.js has relatively large overhead beyond calculation. In addition, the performance gap is larger as the network width increases than as the network depth increases, implying that TensorFlow.js deals better with large-scale matrix calculation than ConvNetJS.

Table 2: CPU utilization (%) in the training process.

Framework	Backend	Max	Min	Average
brain.js	CPU	104.0	99.9	101.2
ConvNetJS	CPU	108.0	101.9	104.1
synaptic	CPU	113.9	88.7	102.8
TensorFlow.js	CPU	108.0	61.0	82.1
	iGPU	82.0	54.9	65.9
	nGPU	75.9	48.0	60.0

GPU benefits. The training time on the CPU backend becomes longer with the increase of network size, but the results on the GPU backend are not the same. For both the iGPU with weaker computation power and the nGPU which can satisfy larger-scale matrix calculations, the training time does not increase significantly. But in the process from (4 hidden layers, 128 neurons per layer) to (8 hidden layers, 256 neurons per layer), the training time of iGPU increases significantly. The reason may be that under the network size set in this experiment, the training process does not reach the GPU's capability bottleneck. Although the matrix computation capability of nGPU is better than that of iGPU, the training time on nGPU is even longer than iGPU. Such a result is caused by the excessive time overhead to call the WebGL for accessing GPU. The real computation time of GPU should be much shorter.

System resource utilization. We show the statistics of CPU utilization of each framework during the training process in Table 2. 110% is the upper bound of CPU utilization. The capability of multi-core processor cannot be used since the JavaScript engine is single-threaded. As a result, it can only maximize the usage of a single core. The reason why the CPU utilization is over 100% is that other

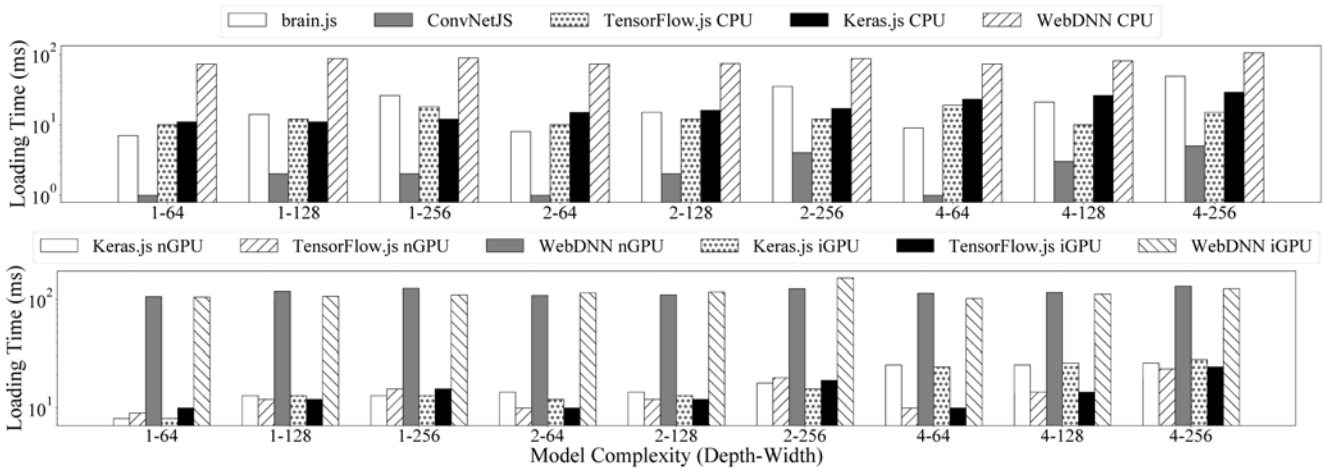

Figure 2: Model loading time (ms) under different model complexities. The y-axis is on log scale.

kernel and user space components occasionally run simultaneously in other threads.

On the CPU backend, TensorFlow.js sometimes cannot maximize the utilization of a single core and its average CPU utilization is only 82.1%. Meanwhile, we can find that when running training tasks on the GPU backend, CPU is not fully utilized since most computation is on the GPU. Training on iGPU has about 5-7% higher CPU utilization than that on nGPU.

4.3 Inference Performance

We select 6 JavaScript frameworks to compare their performance of running inference tasks. TensorFlow.js, Keras.js, and WebDNN support using GPU for acceleration, but brain.js, ConvNetJS, and synaptic support using only CPU for inference. In terms of model usage, brain.js, ConvNetJS, synaptic and TensorFlow.js support saving their own trained models, while Keras.js and WebDNN only support importing pre-trained models from other deep learning frameworks. Therefore, for brain.js, ConvNetJS, synaptic and TensorFlow.js, we use the models saved by the frameworks themselves. For Keras.js and WebDNN, we use the models trained by Keras and then convert the models to the corresponding format. Theoretically, the parameter values of the trained DL models should be different, but the absolute value does not affect the inference time. So we just assign the same parameter values to all the models of different frameworks.

The inference task involves loading a pre-trained model and then given a sample input, the model outputs the result. In addition, on the GPU backend, there is a warmup process where the first sample for inference is usually used to activate the GPU processor. Therefore, we break down the inference process into three phases: model loading, warming up, and inference, and study the fine-grained performance. Due to the space limitation, we omit the results where the model depth is 8 in the following analysis because the trend is similar as the depth increases. Besides, since the model loading time and inference time of synaptic are still much longer than those of other frameworks, we do not depict the results of synaptic in the figures for better presentation.

Table 3: Size of model files (MB).

Depth	Width	brain.js	ConvNetJS	synaptic	TensorFlow.js
1	64	1.4	1.3	3.4	0.2
	128	2.7	2.7	6.7	0.4
	256	5.5	5.4	13.3	0.8
2	64	1.5	1.5	3.7	0.2
	128	3.2	3.1	7.8	0.5
	256	7.2	7.1	17.7	1.1
4	64	1.7	1.7	4.2	0.3
	128	4.0	4.0	10.1	0.6
	256	10.7	10.5	26.5	1.6

Model file size. We first investigate the size of the model file used by different frameworks. As models for inference usually should be downloaded from the remote server, smaller size of model files means shorter downloading time. Table 3 shows the size of model files that are used in all inference experiments. ConvNetJS and brain.js use similar JSON encoding, so the size of their model files are nearly the same. The model file of synaptic uses JSON encoding as well but its size is the largest among all the frameworks. As the model files used by TensorFlow.js, Keras.js and WebDNN are all converted from Keras models, their model files are of the same size. So we just show TensorFlow.js in the table. Since the model converted from Keras is compressed and saved as a binary file, the size can be greatly reduced, just about 1/7 of the model file in JSON.
Model loading time. We then compare the time spent on loading the model of different frameworks, as shown in Figure 2. For the CPU backend, the loading time of different models of the same framework is proportional to the size of the model files described in Table 3. However, the model loading time of different frameworks is significantly different. ConvNetJS is the fastest. Model loading time of brain.js, TensorFlow.js and Keras.js are consistent in terms of magnitude. Interestingly, the increase of loading time of ConvNetJS, brain.js and synaptic is particularly noticeable when the width increases. The result is caused by their choice of using JSON to encode models. The model loading time of synaptic is slowest among all the frameworks, which are more than 100x to 1000x

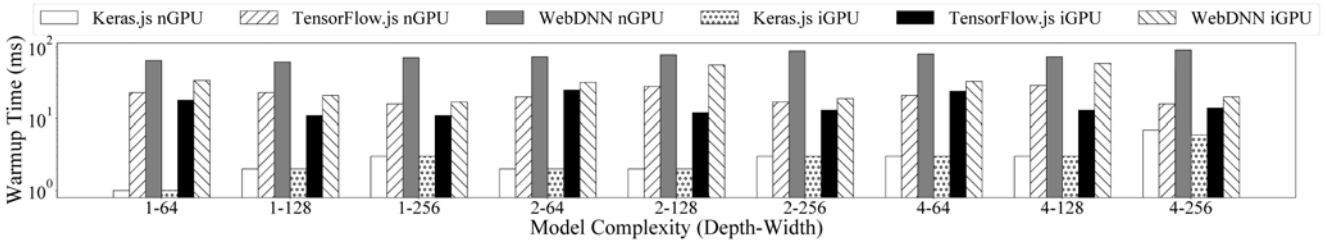

Figure 3: Model warmup time (ms) on GPU under different model complexities. The y-axis is on log scale.

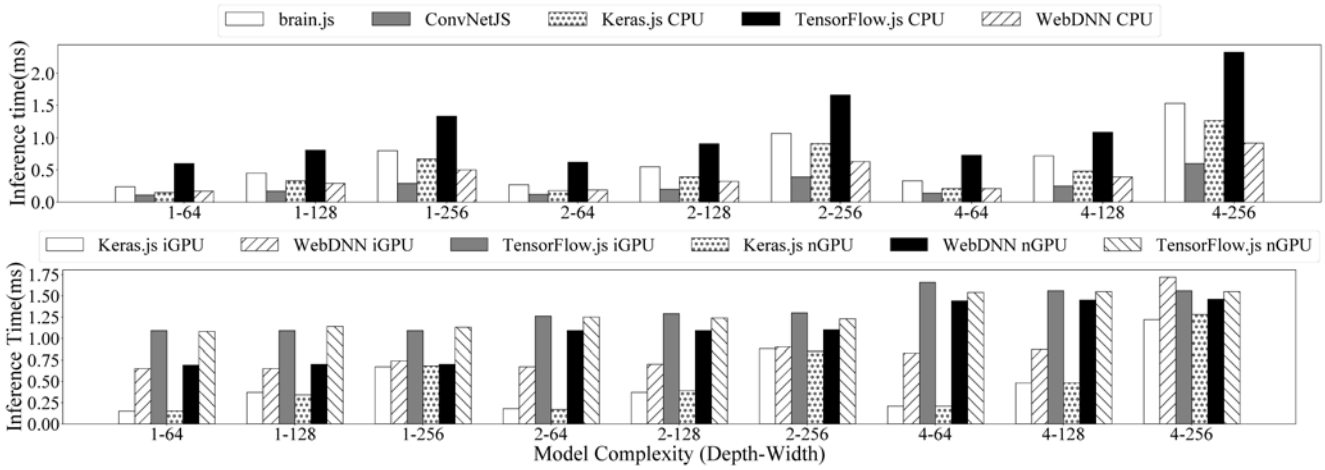

Figure 4: Average inference time (ms) on one sample under different model complexities.

longer than ConvNetJS. The model loading time of TensorFlow.js is almost unchanged regardless of the model size.

The loading time on the GPU backend does not change much under different model complexities. However, the difference is still significant between different frameworks. TensorFlow.js is the fastest. Compared with loading models on the CPU backend, Keras.js speeds up loading large models, but the loading time of WebDNN is longer. In addition, it can be seen that there is no difference in the model loading time between iGPU and nGPU.

Warmup time. Next, we examine the difference of warmup time on the GPU backend. As shown in Figure 3, Keras.js is still far ahead, and can complete the warmup in 3ms on all tasks. Tensorflow.js is the second, and WebDNN is the worst. On the whole, the warmup time on iGPU backend is shorter than that on nGPU.

Inference time. Figure 4 shows the average time of doing inference on one sample. Almost all the inference tasks can finish within 1.5ms (except synaptic, of which the shortest is 6.68ms). In the range of the model sizes we set, the powerful computation capability of GPU does not make a difference. Among all the model sizes, ConvNetJS occupies all the first place, followed by WebDNN on the CPU backend. The inference time of WebDNN on the GPU backend is longer than the inference time on the CPU backend. As for TensorFlow.js, running on the CPU backend is faster for inference on smaller models, while the GPU backend is faster for inference on larger models. Inference times of Keras.js on the CPU and GPU backend are basically the same.

We can observe that for all the frameworks on the CPU backend, the inference time increases when the model becomes complex. In particular, when the width increases, the time increases sharply (about two times as the model width doubles). Similar to the training tasks, such a result also reflects that these frameworks do not optimize the large-scale matrix operations in the process of forward propagation on the CPU backend. TensorFlow.js and WebDNN on the GPU backend do not exhibit this problem, but Keras.js on the GPU still suffers from this problem.

4.4 Takeaway

Based on the above results, we can see that in small-scale fully-connected neural network which the browser is capable of, ConvNetJS performs the best for both training and inference. However, since ConvNetJS is no longer maintained and has fewer functionalities, developers may need to choose some alternatives.

Tensorflow.js is the only framework that can take advantage of GPU to accelerate training processes. It is feature-rich and has comparable performance with ConvNetJS. So TensorFlow.js is a good choice for both training and inference. We do not recommend using GPU as the backend on small models because the advantage of GPU's computation power is not fully exploited.

Finally, we are interested in why ConvNetJS has the best performance for all the tasks among these frameworks. Given the same model of which the process logic is the same, the performance difference is likely to be accounted by the different implementation

details. To this end, we compare the function call stack of ConvNetJS with that of TensorFlow.js when doing the same training task. It is surprising to find that the depth of the call stack of ConvNetJS is only 3 while TensorFlow.js is 48! Such a result suggests that one possible reason for the performance difference among different frameworks is the deep call stack that costs a lot of computation resources.

5 COMPARISON WITH NATIVE FRAMEWORK

In this section, we study the third research question, i.e., how big is the performance gap between running DL in the browser and on the native platform? To this end, we compare the performance of TensorFlow.js and the native TensorFlow in Python, both of which are released and maintained by Google and have similar APIs, making the comparison fair enough.

We study the performance gap from two aspects. On one hand, we leverage well-known pre-trained models to compare the performance when running inference tasks on TensorFlow.js and native TensorFlow. On the other hand, we use decision tree analysis to distinguish the factors contributing to the performance gap. We use the same laptop as the one used in the experiments of the last section. We install the latest TensorFlow in Python (version 1.11.0) on the laptop.

5.1 Inference Based on Pre-Trained Models

We use the pre-trained models officially provided by the Keras to measure the performance of TensorFlow.js and native TensorFlow when doing inference tasks on these classical models.

5.1.1 Limitations of TensorFlow.js and browser constraints. Keras officially provides 11 pre-trained models. Although these models can work using native TensorFlow, we encountered a series of errors when we run them using TensorFlow.js in the browser. These errors imply the limitations of TensorFlow.js itself as well as constraints imposed by the browser.

For the model of NasNet Large, the browser throws out the error message "truncatedNormal is not a valid Distribution". For the model of ResNet V3, the browser throws out the error message "Unknown layer: Lambda". The reason for these two errors is that TensorFlow.js is still under development and so far has offered only a limited number of support for the converted model. Many user-defined operations are not supported by TensorFlow.js, e.g., models with control flow operations in RNNs are not yet supported.

When we try to use VGG16 or VGG19, the browser throws out the error message "GL OUT OF MEMORY", meaning that the GPU memory is overfilled. The reason is that the VGG16 model applies for more than 1GB GPU memory. However, it should not be an issue since the GPU memory of our experiment laptop is 8GB. As a result, such an error is due to the browser constraints.

After trying all the models, we finally have 5 models that can be correctly converted and run on the browser. The information of these models are listed in Table 4. The number of trainable parameters is obtained by the build-in `summary()` method of tensorflow.keras, and the computation complexity (Floating Operations) are obtained by `tensorflow.propfiler.profile()` method.

Table 4: Selected Keras pre-trained models.

Model Name	Pre-trained Model Size	Trainable Parameters	Computation (FLOPs)
MobileNetV2	14MB	3.5M	7.2M
DenseNet121	33MB	8.0M	16.3M
Xception	88MB	22.9M	46.0M
InceptionV3	92MB	23.8M	47.8M
ResNet50	99MB	25.6M	51.4M

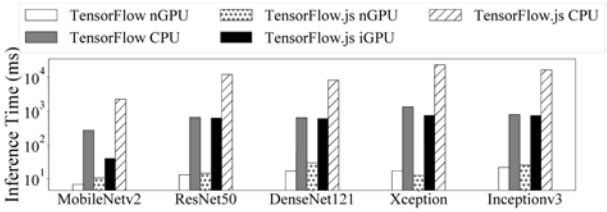

Figure 5: Inference time on pre-trained Keras models. The y-axis is on log scale.

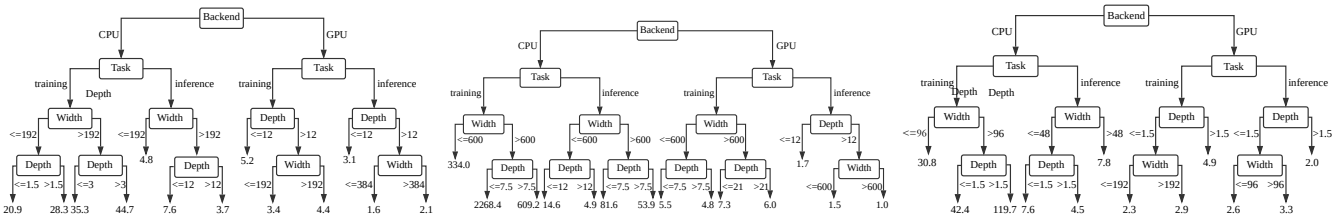

5.1.2 Results. Figure 5 shows the inference time for each model. It can be seen that the inference time of TensorFlow.js on nGPU is comparable (1x-2x slower) to native TensorFlow's. The most encouraging result is that the performance of TensorFlow.js on the iGPU backend is better than that of native TensorFlow on the CPU backend. This result is not surprising considering the computation capability of integrated graphics card and CPU. However, since traditional native DL frameworks do not support integrated graphics card for acceleration, DL tasks can benefit a lot from browsers in such a case with the help of integrated graphics card that is common on current devices.

Under the real-time requirement of client-side DL, if users want to achieve the experience of 10FPS (frame per second), they need to consider using a more powerful standalone graphics card. The Mobile Net model accelerated by iGPU can also meet the requirement. If the requirement is 1FPS, iGPU is also fully capable. But if only CPU can be used, then these common models are too heavy to run in browsers.

5.2 Decision Tree Analysis

In order to deeply reveal how different factors of DL tasks influence the performance gap between DL in browsers and on native frameworks, we build a predictive model based on decision tree analysis to study the factor importance.

5.2.1 Experiment Setup. We consider 4 factors that influence the performance gap between DL in browsers and on native platforms as shown in Table 5, including backend (CPU or GPU), task type (training or inference), as well as depth and width that represent the model complexity. In the DNN and RNN models, width refers to the number of neurons of each layer. In the CNN models, width refers to the number of kernels used in the convolution layer. For each of DNN, CNN and RNN, we choose one model from the Tensorflow.js official examples. The DNN and CNN models are used to recognize handwritten digits on the MNIST dataset, and the RNN model is to perform text generation from Nietzsche's writings. The

(a) DNN (b) CNN (c) RNN

Figure 6: Decision tree to analyze the time ratio of TensorFlow.js over native TensorFlow on DNN, CNN, and RNN Models.

Table 5: Contributing factors to the performance gap.

Network Type	Factor	Range
DNN	Backend	CPU, GPU
	Task Type	training, inference
	Depth	1, 2, 4, 8, 16
	Width	64, 128, 256, 512
CNN	Backend	CPU, GPU
	Task Type	training, inference
	Depth	6, 9, 15, 27
	Width	200, 400, 800
RNN	Backend	CPU, GPU
	Task Type	training, inference
	Depth	1, 2, 3
	Width	4, 8, 16, 32, 64, 256

range of depth and width is selected according to the values set in Tensorflow.js official examples.

In our experiment, we build and run the DNN, CNN and RNN models under different configurations using TensorFlow.js and native TensorFlow, respectively. Each configuration is a combination of values for the factors above. We measure the execution time of each configuration as the average time per batch for training tasks and average time per sample for inference tasks on two platforms. We use the ratio of the execution time on TensorFlow.js over that on native TensorFlow to quantify the performance gap.

5.2.2 Methodology. We run the decision tree algorithm with sklearn [10] to predict the ratio of execution time between TensorFlow.js and native TensorFlow. The decision tree depicts the relative importance of contributing factors. Intuitively, factors close to the root of the decision tree affect the time ratio more than those near the leaves. This is because the decision tree chooses to do the splitting of the nodes according to the Entropy-Information Gain criterion. In other words, the decision tree places the important factors near the root to gain the best prediction of splits.

Based on the results, we first produce a fully grown and unpruned decision tree for all the factors. In this way, each leaf contains only one configuration. Then we set the depth of the tree to the number of factors, in order to prevent using a factor several times on one path. Figure 6 shows the decision trees for DNN, CNN, and RNN.

5.2.3 Results. The execution time of TensorFlow.js is longer than native TensorFlow in almost every configuration.

Backend is the most important factor contributing to the performance gap. The ratio of execution time on the CPU backend is much higher than that on the GPU backend. For example, the ratio decreases from 44.7 to 4.4 for training tasks when the DNN model with depth over 3 and width over 192 runs on the GPU backend instead of on the CPU backend. The extreme case happens on the CNN. On the CPU backend, there is a wide range of the ratio from below 5 to over 2200 (when depth is less than 7.5 and width is over 600). However, when doing inference task on the GPU backend with depth over 12 and width over 600, TensorFlow.js performs as fast as native TensorFlow. This is because CNN makes use of the powerful computation capability of GPU when the model is large enough, yet not exceeding the upper bound of the browser memory.

The second most important factor is task type for all the three models. Performing training tasks exhibits a higher ratio, while the performance gap on inference tasks is small. For example, for the DNN model on the CPU backend, training tasks of TensorFlow.js perform 33.9 times slower than native TensorFlow on average, and inference tasks of TensorFlow.js perform 5.8 times slower than native TensorFlow on average.

The decision trees of DNN and RNN both suggest that the importance of depth and width depends on which backend the task is taken on. On the CPU backend, the importance of width outweighs that of depth, while depth plays a more important role on the GPU backend. However, in the case of CNN, width plays a more important role to the performance gap than depth for training tasks.

6 IMPLICATIONS

Table 6 summarizes the findings and implications of our study. Specifically, we draw implications for three stakeholders of DL in browsers: application developers, DL-framework vendors, and browser vendors. For application developers, we give recommendations on how to choose frameworks for DL in browsers, how to optimize the model, as well as how to select the backend. For DL-framework vendors, we present some advice on encoding of model files and optimizing the call stack. For browser vendors, we suggest on the utilization of system resources.

7 RELATED WORK

To the best of our knowledge, this paper is the first study to characterize the DL in browsers. So we survey related work on general client-side DL and performance measurement of DL systems.

Table 6: Major findings and implications of DL in browsers.

No.	Name	Finding	Implication	Stakeholder
1	Specific DL Tasks Support	Frameworks supporting DL in browsers are emerging and being actively maintained. Most of them are not for general purpose and support only a specific subset of DL tasks.	It is better for developers to use general-purpose DL frameworks like TensorFlow.js to implement their DL-powered Web applications.	Application Developer
2	Model Complexity	The width of DL models dominates the performance variation of both training and inference tasks considering the complexity of DL models.	Developers should pay attention to the width of their models, and balance the width and required performance if possible.	Application Developer
3	Model Loading	For inference tasks, loading and warming up the DL model accounts for much longer time than running the inference task itself. The warmup time on the integrated graphics card is generally shorter than that on the standalone graphics card.	Developers should pre-load and warm up the model before using it for inference.	Application Developer
4	Benefits from GPU	For popular pre-trained models like MobileNet and Inception, TensorFlow.js has comparable performance with native TensorFlow when running inference on the standalone graphics card.	It is possible to develop Web applications rather than native applications for these tasks.	Application Developer
5	Benefits from Integared Graphics Card	TensorFlow.js running on the integrated graphics card works better than native TensorFlow running on CPU backend.	For devices without standalone GPUs, developers can use the browser for DL tasks, leveraging integrated graphics card for acceleration.	Application Developer
6	Model File Encoding and Size	Model file encoded in JSON is much bigger (7x) in size than that encoded in binary, and significantly increases the model loading time.	It is better to encode DL models in binary files.	DL-Framework Vendor
7	Framework Call Stack	The call stack of TensorFlow.js is much deeper than that of ConvNetJS, pulling down the performance.	Framework vendors could leverage compiler optimization techniques to reduce the call stack when the DL models are used in the production environment.	DL-Framework Vendor
8	System Resource Utilization	The capability of multi-core CPU cannot be utilized when running DL tasks on the CPU backend in browsers since the JavaScript program is single-threaded. GPU memory usage is limited in 1GB, failing to load and run larger models.	JavaScript engine should take into account the support of multi-process or scheduling among multi cores for better performance of DL tasks in browsers. The GPU memory should be configurable for DL tasks.	Browser Vendor

7.1 Client-side Deep Learning

With the emphasis on privacy, personalization and timely response, it is a trend to conduct DL directly on the clients where the data is generated, especially on mobile devices. Lane et al. [27] studied the feasibility of using DL for typical mobile sensing tasks, such as activity recognition. Yao et al. [40] proposed DeepSense, a unified DL framework for processing time-series mobile sensing data. Despite of the increasing computation power of mobile devices, typical DL tasks are still of heavy workload for these resource-constraint devices. Several optimization methods were proposed to improve the performance of client-side DL. One line of work focuses on the DL models. Han et al. [22] proposed deep compression to compress the DNN through a three-stage method: pruning, trained quantization and Huffman coding, which showed a considerable reduction in terms of the storage requirements of DNNs. The other line of work leverages the cloud and edge environment to offload the computation-intensive tasks to powerful computation nodes [29]. Kang et al. [26] proposed Neurosurgeon, a lightweight scheduler to automatically partition DNN computation between mobile devices and data centers at the granularity of neural network layers. Wang et al. [39] designed Arden, a cloud-based deep learning framework for mobile devices. The framework partitions the DNN and offloads the resource-hungry training and complex inferences tasks to the cloud.

Anther usage scenario of client-side DL is to support the distributed deep learning. Teerapittayanon et al. [37] proposed distributed deep neural networks (DDNNs) over distributed computing hierarchies, consisting of the cloud, the edge (fog) and end devices. Ichinose et al. [24] proposed a pipelined method for distributed DL processing between mobile devices and the cloud to reduce the amount of data sent to the cloud and protect the privacy of users. Meeds et al. [33] designed MLitB, a prototype DL framework capable of performing large-scale distributed computing with heterogeneous classes of devices using Web browsers.

7.2 Performance Measurement of Deep Learning

In recent years, researchers have conducted studies to measure the performance for various kinds of deep learning tasks. Liu et al. [30] evaluated the performance of leading DL methods for object detection. Guignard et al. [21] presented detailed characterization results of a set of archetypal state-of-the-art DL workloads to identify the performance bottlenecks and to guide the design of prospective acceleration platforms in a more effective manner. Shi et al. [36] evaluated the performance of four state-of-the-art distributed DL frameworks over different GPU hardware environments. They built performance models of standard processes in training DNNs with SGD, and then benchmark the performance of the frameworks with three neural networks (i.e., AlexNet, GoogleNet and ResNet-50). As for DL on mobile devices, Ignatov et al. [25] studied state-of-the-art DL in the Android ecosystem and described available frameworks, programming models and the limitations of running AI on smartphones.

Although many JavaScript-based frameworks have been published to support DL in browsers, there is no comprehensive study to understand their characteristics and performance. Some researchers focus on the possibility of supporting DL in browsers by measuring the low-level browser capabilities. Malle et al. [31] presented a comparison study between native code and different browser-based implementations: JavaScript, ASM.js as well as WebAssembly on a representative mix of algorithms. However, these algorithms are not DL tasks. Their goal is just to show that the browsers performance is now comparable to and even exceeds native binary performance.

8 CONCLUSION

This paper made the first study on understanding the feasibility and performance of deep learning in Web browsers. We chose 7 recently emerging JavaScript-based DL frameworks and comprehensively revealed which type of DL tasks have been supported. We measured the performance of different frameworks when doing different DL tasks in browsers, and compared with the native DL framework to investigate the performance gap. Although the in-browser DL is still at the early stage, some interesting findings, e.g., the comparable performance of JavaScript frameworks to that of native ones on some types of DL tasks and the benefits gained from the integrated graphics card, can be useful and help guide the DL-powered Web applications. Additionally, we have also found that there are some potential space of improvement for currently in-browser DL frameworks, and plan to realize some practical solutions. We believe that our work can shed a light on the future of Web applications in the AI era.

ABSTRACT

Email continues to be one of the most commonly used forms of online communication. As inboxes grow larger, users rely more heavily on email search to effectively find what they are looking for. However, previous studies on email have been exclusive to enterprises with access to large user logs, or limited to small-scale qualitative surveys and analyses on limited public datasets such as Enron[1] and Avocado[2]. In this work, we propose a novel framework that allows for experimentation with *real* email data. In particular, our approach provides a realistic way of simulating email re-finding tasks in a crowdsourcing environment using the workers' personal email data. We use our approach to experiment with various ranking functions and quality degradation to measure how users behave under different conditions, and conduct analysis across various email types and attributes. Our results show that user behavior can be significantly impacted as a result of the quality of the search ranker, but only when differences in quality are very pronounced. Our analysis confirms that time-based ranking begins to fail as email age increases, suggesting that hybrid approaches may help bridge the gap between relevance-based rankers and the traditional time-based ranking approach. Finally, we also found that users typically reformulate search queries by either entirely re-writing the query, or simply appending terms to the query, which may have implications for email query suggestion facilities.

1 INTRODUCTION

For 50 years, email has been the mainstay of online communication. Email continues to be used widely for both business and personal communication, with a projected 4.2 billion worldwide users sending over 330 billion emails *per day* by the year 2022 [25]. As cheaper data storage has resulted in an increase in email storage quotas, users are becoming less inclined to delete email [12]. This has implications on the way in which users interact with their email client; they need to be more persistent in re-finding tasks, especially if the email is ranked by time. To this end, recent work has explored the use of relevance ranking in email search, showing effectiveness improvements with respect to ranking by time [2, 12, 14]. Although this is a promising step towards improving the email search experience, there is still a large gap in understanding how users interact with email search systems, particularly those that use relevance ranking. This is due to the difficult nature of experimenting within this context – email data is highly personal, private, and exclusive to commercial email providers. Additionally, users are often interested in finding a single known message [18].

Based on this knowledge, we propose a novel offline evaluation framework that allows us to examine how users behave on realistic email search tasks using their personal email data. Our approach allows for a vast number of experiments to be conducted across realistic email search scenarios, using real data from real users. For instance, we examine user behavior in email search tasks using both the traditional rank-by-time result presentation, as well as more modern rank-by-relevance and hybrid ranking approaches as illustrated in Figure 1. Our framework also allows us to compute implicit success metrics such as Session Success Rate (SSR), in addition to relevance-based metrics such as Mean Reciprocal Rank (MRR) [46], for different settings. We also compare the query reformulation of users across various experimental settings. We focus on the following research questions:

RQ1: *How does user behavior differ with respect to different email ranking approaches?*

RQ2: *How do the characteristics of email impact re-finding success?*

RQ3: *How does search quality affect user behavior in email re-finding?*

In answering these questions, our main contributions are as follows:

1. We describe a novel approach for simulating email re-finding tasks that can be used for user behavior studies and offline evaluation experimentation in crowdsourcing environments (Section 2), and

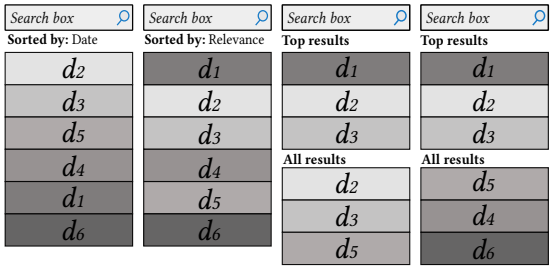

Figure 1: A pictorial example of the four different systems that we compare using the offline evaluation framework introduced in this paper. From left to right: Time (T_0): ranked by time, Rel (T_1): ranked by relevance, HybDup (T_2): hybrid relevance-time with duplicates, and Hyb (T_3): hybrid relevance-time without duplicates. Following the example of Carmel et al. [14], we denote message freshness by the shade of the cell, and we denote the relevance ranking as the document subscript.

2. We leverage this approach to characterize user behavior in email re-finding tasks across a wide range of factors such as ranking quality, SERP format, and email type (Section 4).

The remainder of the article is organized as follows: Section 2 provides some brief background and outlines our novel framework for simulating email re-finding, Section 3 describes the analysis we conduct, Section 4 reports on the experimental results, Section 5 validates our experimental framework, Section 6 outlines related work in user behavior analysis and email ranking, and Section 7 summarizes and concludes this article.

2 SIMULATING EMAIL RE-FINDING

Personal search tasks (e.g. email search) have been very difficult to study in realistic settings due to the nature of the email search process and the limitations on using and sharing email data. Email search is often characterized as a re-finding task [18] where a user is looking for a *specific known message* rather than looking for general information or exploring [4]. Additionally, since email data is highly personal, queries and relevance annotations are not readily available for both learning to rank email and evaluating email search systems. While synthetic approaches for data generation have been explored previously [1], they do not provide a realistic setting since the email data does not belong to the user conducting the search task. Instrumenting email clients was also proposed [20, 22, 30]; while allowing for a realistic setting, this approach provides no control over the experimental system. Hence, it is more suitable for logging user interactions rather than experimentation. This is analogous to using online experimentation and log gathering [12, 14] in large scale search settings, which is not possible without a real system and thousands or millions of users. Here, we introduce a novel approach for simulating email re-finding tasks. Our approach is deployed as crowdsourced *human intelligence tasks* (HITs), making it suitable for academic settings, while also allowing *real* email interaction data to be studied in a realistic and privacy-preserving manner.

2.1 Process

The task is broken into three distinct stages, each shown in Figure 2. First, the user is shown an email message e_t, known as the *target* message, which is sampled from the most recent N emails in their *inbox* folder (we set N to 1000 in our experiments). This screen is shown to the user for t_{read} seconds, in which the user can read the body of the message (Figure 2, left). Based on some preliminary experimentation, we set $t_{read} = 5$ seconds. This provides enough time for the user to 'get the gist' of the target email without learning or memorizing particular phrases from it. After t_{read} seconds have lapsed, the user is then shown a second screen with a questionnaire (see Section 2.2). Although we do not limit the amount of time a user can spend answering the questionnaire, we denote the time they take in this phase as $t_{question}$ (Figure 2, center). In the final stage of the task, the user is presented with a standard email search screen. On the top, a search bar is present, with the search engine results page (SERP) on the left side of the page and the body of the *current* email shown on the right (Figure 2, right). The user may scroll down the SERP and click on any of the emails to make them appear in full on the right pane. Once the user locates and opens the target message, a pop-up message informs the user that they successfully located the message, and the task is ended. For this phase of the task, the user may spend up to t_{search} seconds. If they do not find the target email in this time, then the search task is deemed as failed. We set $t_{search} = 120$ seconds. When showing the SERP, we show 20 documents in total. Although commercial providers generally provide more results to the user (such as the 50 per page[3], or an infinite scroll[4]), serving just 20 results (rather than 50 or more) improves the efficiency of the API calls, minimizing the impact of latency on user behavior [7, 10]. We leave exploration of alternative SERPs as future work. Note that we also allow the user to enter free-form feedback upon the completion or failure of a task if they wish.

2.2 Questionnaire

For completeness, we now outline the questions presented to the users. All questions require *yes* or *no* answers, making them less cognitively expensive than other formats (such as those employing a Likert scale). We asked the worker seven questions in total about aspects of the target message:

- Did you reply to this email?
- Is this the type of email that you would likely search for?
- Was this email a system generated email?
- Was this email important to you?
- Do you get more than 10 emails from this sender in a week?
- Do you remember reading this email before?
- Was the email too long to read?

The aim of this questionnaire, besides offering a momentary distraction from the target email content, is to gain insight into the importance of the target email as perceived by the user. Furthermore, this allows additional quality control of the judges, as answers to some of the questions can be validated using the search API, such as whether the message was read, replied to, marked as important, and so on.

[3]https://mail.google.com/
[4]https://outlook.office.com/owa/

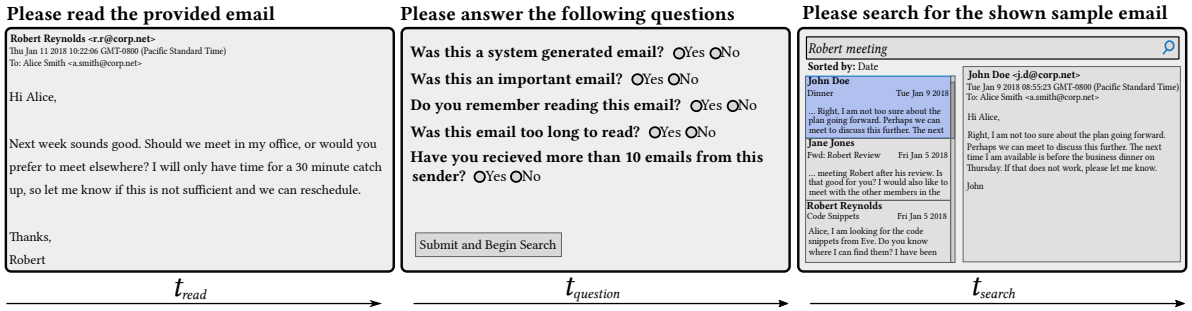

Figure 2: A pictorial example of our experimental framework. First, the user is shown an email sampled from their inbox for t_{read} seconds. Next, they must answer a short questionnaire. Finally, the user is taken to the search window where they have t_{search} seconds to find the email that they were shown. Once the user clicks on the target email, the task is ended, and the user is taken to a new task.

2.3 Metrics

Since we are interested in characterizing user behavior, we employ a range of measurements for comparing behavior across different treatments. Although these types of measurements are quite standard [29, 36, 40], we elucidate them for clarity. We also note that all time-based measures are calculated from the time in which the user enters the *search* phase of the HIT.

Task level interactions.

- *Success rate:* The percentage of successful tasks for the given configuration.
- *Time to success:* The time taken for the user to find the target message.
- *Number of queries:* The total number of issued queries.
- *Rate of abandonment:* The rate of reformulation without any message accesses.

Query level interactions.

- *Query action:* Reformulate/Succeed/Fail.
- *Time per SERP:* Average time spent per SERP.
- *Number of clicks:* The average number of clicks per SERP.
- *Query length:* The length (number of terms) of the submitted query.
- *Rank of clicks:* The average click depth.
- *Lowest ranked click:* The average rank of the lowest document accessed per SERP.
- *Time to first click:* The time taken for the user to click the first accessed document.
- *Time to deepest click:* The time taken for the user to click the deepest accessed document.

These interaction signals can also be regarded as online metrics, which would commonly be collected and analyzed in online systems. One disadvantage in real online systems is that the ground truth is not known, meaning that typical offline effectiveness metrics are not easy to deploy. Since we have access to the ground truth, we can deploy offline effectiveness metrics here. We use *Mean Reciprocal Rank* to measure the performance of the various systems across all provided queries, which is defined as

$$\text{MRR} = \frac{1}{|Q|}\sum_{i=1}^{|Q|}\frac{1}{e_i} \tag{1}$$

where Q is the set of queries, and e_i is the rank of the target email in the SERP for query i. MRR is a suitable metric for a re-finding task as there is only *one* email that the user is looking for.

2.4 Prerequisites

We rely on the Microsoft Graph API[5] as an interface between the workers' mailbox and our task. The API provides all query matching and ranking functionality. Therefore, a crowdworker must have a Microsoft managed email address such as one at `outlook.com`, `live.com`, `hotmail.com`, or `msn.com` to be eligible to enroll in our task. Alternatively, they are provided with an option to import their inbox into an Outlook inbox such that the API is available for use. Other email systems have similar APIs. For example, our system also supports the Gmail API[6], but we only present results based on the Microsoft Graph API here for simplicity.

3 SETTINGS

In the previous section, we described our approach for simulating email re-finding tasks. In this section, we describe the experimental settings for the study we conducted to answer the research questions outlined earlier.

3.1 Search Results Grouping

We explore three ranking conditions that are found in real email systems. The first refers to the traditional approach of ranking all email that matches the query by *time*, the most common technique for ranking email. The second approach refers to ranking email by *relevance*, whereby the results are ranked by their estimated relevance to the user query. Finally, the *hybrid* approach refers to providing the top-3 results according to the relevance model, followed by the standard ranking of matched emails by time [14, 42].

3.2 Search Results Quality

Our experimental framework allows us to purposefully degrade the quality of the search results [27, 45], which is useful for both validation and experimental analysis. Firstly, it allows us to validate that our metrics align with the user experience of the system; when the quality of the results is degraded, we expect to observe the user

[5]https://developer.microsoft.com/en-us/graph/
[6]https://developers.google.com/gmail/api/

taking longer to find the target email, inputting more searches per task, and so on. Secondly, it enables us to add another condition to our study by degrading the quality of the search results and observing how users behave when they are failing. For our system, we employ a very simple quality degradation mechanism. On a per-task basis, we set some probability P that we will remove the target, e_t, from the SERP. Then, on a per-query basis, we remove e_t with probability P. We plan to look at alternative degradation approaches in future work, where the target email can be demoted in various ways [45].

3.3 Search Results Duplication

Since the hybrid ranking uses both relevance and time ranking, it is possible that a document that is surfaced as being in the top-3 most relevant is also present in the most recent documents too. As such, we decided to study another condition to help us understand how duplicating the documents in the hybrid ranking affects user behavior [14, 42]. We instantiate two versions of the hybrid system with respect to the duplication condition: one version allows documents appearing in the "top results" pane to also appear in the "all results" section of the SERP, whereas the other version removes any duplicates found further down the ranking.

Based on the aforementioned conditions, we experiment with four unique systems, as shown in Figure 1. In practice, the two hybrid systems are very similar, though the Hyb system is guaranteed to have the same or better performance as compared to the HybDup system in terms of MRR, given the exclusion of duplicate documents.

Furthermore, note that our systems are similar but not directly comparable to those discussed by Carmel et al. [14], and we refer the interested reader to this work for both textual and graphical explanations of their systems. For our experiments, we treat Time as the control system, and measure differences between Time and all other systems using Dunnett's multiple comparison test [19].

4 EXPERIMENTS

We now employ our experimental approach to gain insight into how various rankings and interfaces impact user behavior and success in email re-finding tasks.

4.1 Users and Data

We employ 53 unique *trained* [28] judges to perform the given tasks; all judges were required to complete a set of *training tasks* before they were enrolled in the data collection tasks. Judges are not paid per HIT, but are paid an hourly rate, which we believe reduces incentive to game the tasks. Each judge could complete up to 90 tasks, and task configuration was randomized between tasks, meaning that each judge was equally likely to see each variation of the system. We also vary the probability of degradation, P, on a per-task basis, with $P \in \{0.0, 0.25, 0.50\}$. The judges completed a total of 3,678 tasks across a two-week period in August, 2018. Table 1 summarizes the data on both a per-judge level, and on a per-task level. Clearly, there is some variance in each measurement, as task difficulty can vary depending on the mailbox of the user, their search strategy, and so on. Although these statistics reflect expectation, we found that the age of the sampled emails is much older than anticipated, with a mean age of 142 days, and a median age of 67 days. Since we sample from the most recent 1,000 emails, this indicates that the judges do not receive a high volume of email (on average) to these personal accounts.

Table 1: Summary statistics on a per-judge level (top) and on a per-task level (bottom) for 53 unique judges across a total of 3,678 records.

	Mean (SD)	Median	Min	Max
Tasks	69.4 (12.8)	67	30	83
No. Successful	61.0 (13.1)	64	22	81
TTS per task	45.4 (11.0)	44.5	22.4	76.9
Queries per task	1.8 (0.4)	1.8	1.1	2.9
Clicks per task	2.6 (2.4)	1.7	0.9	12.9
Age [days]	141.9 (219.0)	64	0	1,911
TTS	45.3 (36.4)	30.4	3.7	120.0
No. queries	1.8 (1.4)	1	1	17
No. clicks	2.4 (4.9)	1	0	100

Table 2: Distribution of the questionnaire data collected from our HITs, shown as percentages. Each question pertains to the target email for the given task.

Email property	Percentage marked true
Machine Generated	72.6
Read [User Response]	9.8
Read [API]	30.6
Replied	4.2
Important	16.3
Popular Sender	30.1
Likely to Search	16.8

Table 2 summarizes the questionnaire data across each HIT. Most emails are classified by users as machine generated [34], which is not surprising since we are using personal web email accounts. Interestingly, users recalled reading around 10% of the sampled messages, whereas the API reported that 31% of these had been read. This can be explained in several ways. Firstly, users may not have perfect recall of whether they read an email or not. This could be related to the importance of the email, receiving a large volume of similar email, etc. Secondly, the API can only tell us if the email is marked as read, not whether the user actually reads the email. Another interesting observation is that only around 4% of the sampled mail was replied to, as contrasted with other studies that report reply rates of around 15% [49] and 20% [38]. Note that these studies were focused on enterprise data, where responses are more likely as compared with personal mail scenarios, where a lower reply rate be explained by the high volume of machine generated messages that saturate the user's inbox [34].

4.2 Ranker Effectiveness

Our first experiment evaluates the effectiveness of the various rankers we deploy. For the first query from each task, we retrieve the ranked list for each ranker, and evaluate the reciprocal rank for that particular ranked list. Figure 3 shows the MRR for each system

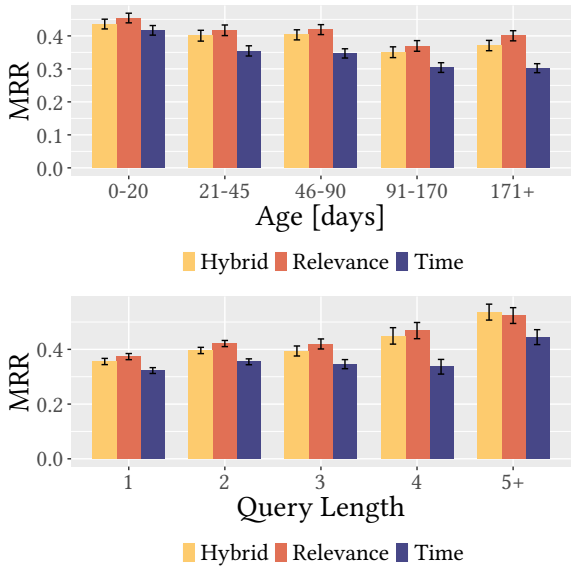

Figure 3: MRR and standard error for each system with respect to email age (top) and query length (bottom). Email ages are grouped such that ≈ 20% of all tasks are shown in each bucket.

for target emails of different ages and different input query lengths. Since we found that both hybrid systems have the same performance across this query set, we show only one *hybrid* bar in this analysis. Relevance based ranking provides the most effective ranking, followed closely by the hybrid ranking. As expected, ranking by time is most effective for new mail, as there is less chance that the ranker will surface matching (but irrelevant) messages. Even so, ranking by time is still inferior to the alternatives, at least with respect to MRR. Additionally, as query length increases, so too does the MRR for each ranker, which confirms the results from Carmel et al. [14]. The reason that longer queries are more effective in the email search paradigm is because email ranking is still based mostly on matching, whereas other applications such as web search rely heavily on click-through data and anchor text which is not readily available for email ranking. Interestingly, we found that most queries submitted in this experiment are either one (36%) or two (36%) terms, with only 15% containing three, 6% containing four, and 7% containing five or more terms, respectively. This supports observations from prior work; even though longer queries result in a better ranking, users opt to submit very short queries [13, 14, 30]. Using a two-tailed t-test with a Bonferroni correction, we find that both the hybrid and the relevance rankers significantly outperform the rank-by-time system ($p < 0.01$).

4.3 Behavior Comparison

We now evaluate the four different systems with respect to the interactions discussed in Section 3, thereby addressing RQ1. For this experiment, we are interested only in evaluating the systems when there is no quality degradation; after filtering out tasks where $P > 0$, we retain approximately 400 tasks per system.

User Behavior. Table 3 summarizes the observations we collected from the search task. Firstly, we observe that the success rates across the systems are very similar, with most tasks being completed successfully, while also aligning with rates observed in prior work [6]. It is also clear that the time to success does not vary widely between the systems, though the standard deviations are quite large. This suggests some variance in the difficulty of the search tasks. Users tend to issue less queries on the HybDup system, although not statistically significantly so. Users also submit less queries per task on systems other than Time, though the difference is small. Interestingly, the rate of abandonment is higher for Time than the other systems, which may suggest that users are more aware of *when* they should abandon and reformulate in a rank-by-time scenario, especially since this is what most users are accustomed to.

Looking more deeply at the query level analysis, we observe that tasks on Rel and Hyb result in statistically significantly shallower clicking on average compared to those on Time. Furthermore, the deepest clicks on Hyb were statistically significantly shallower than those on Time. Intuitively, this makes sense, because the MRR for these systems is significantly higher than on the rank-by-time system (Time). However, it is surprising that the same observation is not true for HybDup. One possibility is that, since HybDup is simply the same as Time with the addition of three 'champions', users can more easily fall back to the same search style they employ for Time, whereas the same notion is not true for Rel and Hyb. To further investigate this phenomenon, we analyze the tasks from HybDup which contain e_t in both the top-3 'champions' section of the ranker, as well as the rank-by-time section. It is expected that users begin at the top-ranked result and work down the ranked list, one document at a time, until they find the target document. However, we found that 6% of the time, users would click the *lower-ranked* instance of e_t, that is, in the rank-by-time part of the SERP. This suggests that some users may occasionally either miss or glance beyond the target document, or may just prefer to not examine the top-results. Although rarely used, this provides evidence of some benefit of duplication of top-results, and helps explain why users preferred duplication in the study from Carmel et al. [14].

In summary, we expected that the relevance and hybrid systems would result in significantly different behavior as compared to the system that ranks documents by time, as they are significantly better rankers based on MRR. However, we found that the ranking employed by the search systems does not largely impact user behavior (RQ1). One explanation for this outcome is that MRR is more sensitive than users are, in the sense that a statistically significant change in MRR does not necessarily mean that a user will notice such change.

Failure Analysis. While it is clear that users are generally quite good at successfully completing the provided task (Table 3), there are a small number of cases where users were unable to do so. To learn more about what caused users to fail, we conducted a failure analysis across these tasks (where $P = 0.0$). We define two types of failure: *Unforced failures* occur when the target document was surfaced on at least one of the SERPs that was viewed by the worker. That is, the user would have been able to successfully complete the task with at least one of the SERPs they were shown. The remainder of the failures are characterized as *forced failures*, where the user had

Table 3: Summary table of user behavior across the four systems using mean and SD. Only tasks with no degradation are considered. The rank of clicks, and deepest clicks, consider only queries in which at least one document was clicked.

Measure	Time (T_0)	Rel (T_1)	HybDup (T_2)	Hyb (T_3)
		Task Level		
Success Rate	93.8	92.2	93.9	92.7
TTS	36.70 (32.08)	36.37 (32.40)	34.15 (29.70)	37.22 (32.12)
Number of queries	1.52 (1.00)	1.50 (1.27)	1.40 (0.98)	1.45 (1.05)
Rate of abandonment	0.17 (0.29)	0.13 (0.26)	0.13 (0.28)	0.14 (0.28)
		Query Level		
Time on SERP	25.42 (18.91)	26.55 (20.72)	26.02 (19.38)	27.56 (21.63)
Number of clicks	1.36 (2.84)	1.60 (3.67)	1.39 (2.24)	1.18 (1.74)
Length of queries	2.28 (1.47)	2.23 (1.46)	2.07 (1.28)†	2.28 (1.39)
Rank of clicks	4.19 (4.19)	3.51 (3.98)†	4.02 (4.38)	3.33 (3.73)‡
Deepest click	4.75 (4.89)	4.16 (4.89)	4.58 (4.99)	3.77 (4.18)‡
Time to first click	11.90 (15.39)	12.24 (14.98)	10.99 (13.54)	13.03 (16.75)
Time to deepest click	12.94 (15.39)	13.25 (14.97)	12.23 (13.90)	13.65 (16.99)

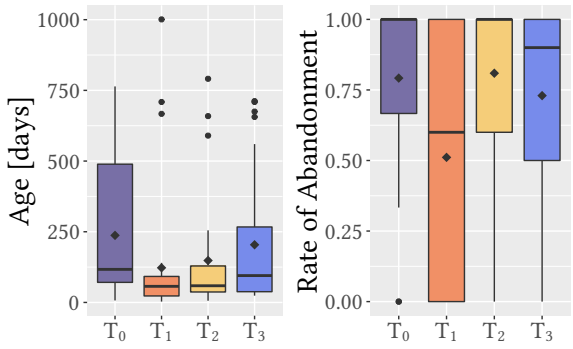

Figure 4: The age of the target email (left), and the abandonment rate within the task (right) for unsuccessful tasks.

no chance of completing the task since their queries never surfaced the target. There were 25, 33, 25, and 29 failed tasks for systems Time, Rel, HybDup, and Hyb, respectively, which represents around a 6–7% rate of failure. Of these, 4, 6, 4, and 0 were unforced, meaning that the majority of failures were due to users not being able to surface the target document at all. Figure 4 (left) shows the age of the target emails from the failed tasks on a per-system basis. Clearly, users struggle to surface older documents on Time. The converse is true for the relevance based ranking in Rel, where most failure cases were emails that were received within the last ≈ 125 days. The two hybrid systems appear somewhere between Time and Hyb. Figure 4 (right) shows the rate of abandonment across the failed tasks. Users abandoned the resultant SERPs at a very high rate, suggesting that they were quite confident that their query had not surfaced the target email, opting to reformulate instead. Interestingly, users were less likely to abandon the relevance based SERP (Rel) than those of the other systems. One explanation is that users have a much stronger intuition for when a time-ranked SERP has not provided the desired result in comparison to a relevance-based SERP.

Table 4: Examples of the different types of reformulation that were observed from our log and the percentage in which they are observed. 0.3% of cases did not fall into any of our categories, and are thus omitted here.

Type	Example	% Obs.
Full reform.	*grammarly* → *writing*	35.7
Partial reform.	*cv attached* → *cv provided*	11.6
Generalize	*out for delivery* → *delivery*	6.9
Specialize	*amazon* → *amazon order number*	23.3
Typo.	*fornt desk* → *front desk*	18.6
Revert	*new account* → *bank* → *new account*	3.6

4.4 Reformulation

Continuing our analysis of user behavior across the varying systems, our next experiment investigates how users reformulate their queries when they cannot find what they are searching for. We refer to a reformulation as the modification of query q which results in the next successive query q'. For this experiment, we consider all tasks where a reformulation was made, irrespective of the ranking system and degradation probability. In total, there were 2,794 reformulations from 1,445 tasks.

Categorizing Reformulations. In order to categorize the reformulation strategies, we first examine the query trace from each task with more than one query to understand what users are doing when they reformulate. Based on this analysis, we came up with six major strategies as defined in Table 4, similar to those defined by Jansen et al. [26] and Hassan [23]. Note that the strategy defined as *partial reformulation* refers to a combination of adding and removing terms where q' contains at least one term from q.

Next, we use a semi-automated process to categorize each subsequent query given all previous queries within the task. This process uses features such as the bag-of-words from each query, the edit distance from q to q', and the term ordering to determine the category of the reformulation. The output was then validated manually.

Table 4 also shows the proportion of the strategies that were employed. The most popular reformulation action is to generate an entirely new query, which occurs around 35% of the time. After further examination, it became clear that these full reformulations often came from users changing their search strategy. For example, many of the full reformulations involved users initially trying to use a keyword oriented query to find relevant results, and then reformulating to use a date instead (eg, *'amazon delivery'* → *'june 2018'*). The next most popular reformulation action is to specialize the previous query. This suggests that users were trying to improve precision. This is also a likely strategy for users of email search systems since queries are generally very short. Another common action was to fix typographical errors, which made up around 19% of all reformulations. It would be interesting to see how the proportion of typographical errors changes if query autosuggestion [13] was made available, but we leave this for future work. We also note that the relative proportions of reformulation strategies did not change with respect to the ranking algorithm used, which indicates that users are not sensitive to the ranker when considering their reformulation approach.

Comparing these findings to web search scenarios, we find that users typically reformulate typographical errors and generalize query terms with similar rates to those seen in web search, but are more likely to construct full reformulations in email r-finding [23]. Additionally, while other works have reported a reasonably large (up to 20%) use of advanced search operators such as '`from:`' or '`to:`' [4, 30], we observed almost no such occurrences (< 1% of submitted queries). We postulate that this is because these studies were from corporate environments, where users may be more accustomed to searching using operators. We must also note that we did not give the users any information on whether or not our system could handle such operators.

Behavior when Reformulating. We also examine the user behavior measures across successive reformulations to see if there is evidence of users becoming frustrated (or of any other changes in behavior). We found that, in general, user behavior did not change markedly across successive reformulations with one exception; as users continue to reformulate, they typically spend less time on the resultant SERP (Figure 5, left). Although we initially believed this to be due to increased time pressure [17], examining the time spent on each SERP reveals that users (generally) have used less than 50% of their allocated time at the time of their final reformulation. Next, we investigated the number of *unseen* documents that are surfaced in the SERP for each subsequent reformulation (Figure 5, right). Evidently, as users continue to reformulate, they are observing fewer new documents, which explains why they spend less time on the SERP. Similar trends were found across all system configurations.

Supplementing the answers to RQ1, our findings show that users typically submit short queries, and prefer to either specialize them, or to write entirely new queries when they cannot locate the target document, irrespective of the ranking quality or system in use. Furthermore, we observed that users tend to spend less time per successive SERP as they reformulate. This is caused by the ranker surfacing many documents the user has already seen, which in turn is caused by the query strategy taken by the user. These findings have implications for ranking in email and personal search; diversification or techniques for re-ranking that account for documents that the user has already seen [44] may be valuable in improving both the user experience and the engagement of the user, especially since it is known that users prefer to submit short queries and specialize as they reformulate.

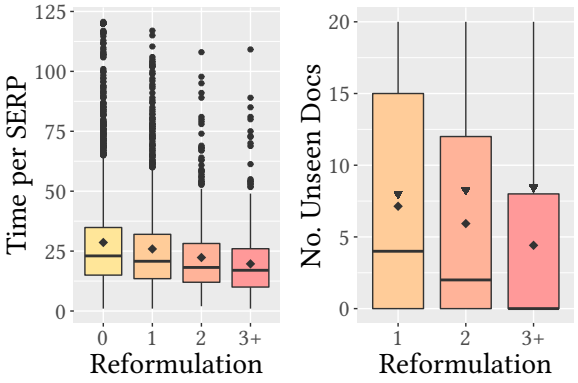

Figure 5: Time per SERP (left) and the number of unseen documents (right) for successive reformulations. On the right plot, the triangles denote the *average rank* of the unseen documents.

4.5 Email Properties and Importance

For our final experiment, we explore whether user behavior changes with respect to the properties of the sample email, thus answering RQ2. We define important emails as those that are marked as important, replied to, read, and those that the user is likely to search for. For each message, we use the sum of these importance criteria to define an overall importance score. For example, a message that was read, replied to, and marked as important would receive an importance score of 3. Figure 6 shows the time to success and the number of submitted queries across these levels of importance. We observe that the more important a message is to a user, the easier they are able to find it, issuing less queries and spending less time to succeed. This is because users are more likely to remember certain aspects of messages that are important to them, the converse being true for unimportant messages.

We were also interested in whether users found machine generated emails harder to search for. Our hypothesis is that since the majority of the mail received by the workers is machine generated, this would make searching for such mail more difficult (due to a high volume of similar messages). Table 5 shows the behavior across tasks, divided by whether the target message was generated by a human or a machine. We observe that users tend to submit shorter queries, click less, but go deeper in the ranking when the email is sent from a human, although none of these observations are statistically significant. Answering RQ2, users are able to find important emails faster and with less effort than those that are less important. Furthermore, whether the email is sent by a machine or by a real user tends to have no impact on the effort or success rate of re-finding, indicating that users are quite capable of searching for machine generated emails.

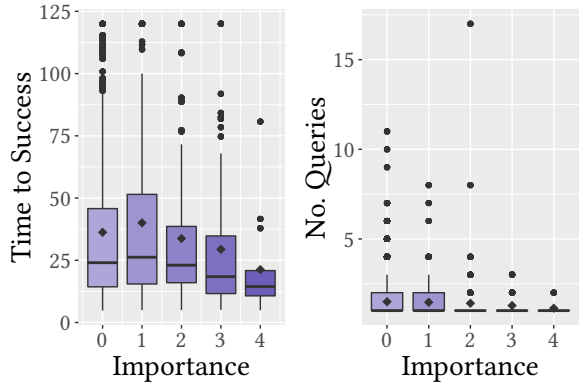

Figure 6: Time to success (left) and number of queries submitted (right) for emails of varying levels of importance.

Table 5: Summary of user behavior measures using mean and SD where the target email was sent by a human, or was an automated email. No significance was detected for any of the metrics shown.

Measure	Machine	Human
Task Level		
Success Rate	92.7	93.4
TTS	36.84 (32.45)	35.71 (31.14)
Number of queries	1.45 (1.07)	1.48 (1.09)
Rate of abandonment	0.14 (0.27)	0.15 (0.28)
Query Level		
Time on SERP	26.76 (22.30)	26.17 (18.94)
Number of clicks	1.47 (2.62)	1.34 (2.80)
Length of queries	2.39 (1.61)	2.14 (1.26)
Rank of clicks	3.51 (4.09)	3.89 (4.08)
Deepest click	4.13 (4.89)	4.41 (4.70)
Time to first click	12.62 (16.78)	11.73 (14.29)
Time to deepest click	13.66 (16.90)	12.68 (14.43)

5 VALIDATION

We now perform some analysis to validate the robustness of our experimental framework and collected data.

5.1 Sampling Target Email

A key aspect of our experimental framework is the way in which we sample the target email. As discussed in Section 2 and 3, we sample a random email from the most recent $N = 1{,}000$ emails in a workers inbox, ensuring an adequate sample size. However, this results in a large proportion of email being categorized as email that is not likely to be searched for by the worker (Table 2). Looking further at Table 2, it is clear that many of the sampled emails are in fact generated automatically by machines. While these emails can be useful and important, such as flight tickets, bills, or order invoices, they can also be general newsletters, repeated notifications, and other possibly annoying or low-utility content [34]. It is also important to consider the context in which the user is viewing the email. While some emails are unlikely to be searched *now*, the very same emails may have been sought by the user previously. One such example is a user who is waiting for a delivery from an e-commerce provider. Before the delivery is received, the user may search for the email to find tracking details, for instance. However, once the delivery is received by the user, they are unlikely to be interested in finding this email again. To ensure that the target email sampling does not bias our results, we compared the user behavior and ranking robustness where users classified emails as being either 'likely' or 'unlikely' to be searched for. We did not find any significant differences in user behavior or the performance of the tested systems. Hence, we believe that although our targets may not represent an email that is likely to be searched *now*, the process of re-finding is not impacted by our sampling method.

5.2 Judge Consistency and Quality Control

An important step in analysis of data collected from users is ensuring the quality of the data. Therefore, we conduct a number of analyses to confirm the data quality. First, we explore the click traces of the workers, looking for specific patterns of gaming (such as users clicking each document down the ranking with minimal time delay between clicks). We found very few instances of such behavior (5 occurrences) and removed them from further analysis. Since the target email was randomized and rotated, there were some occasions where a worker had a repeated task at a different point in time (possibly using a different ranking system). From all tasks that we deployed, 271 (7%) of these were repeated. To analyze the consistency of the judges, we compare the submitted queries for the initial task h with the repeated task h'. Our hypothesis is that if judges are consistent, their queries will be similar for the repeat task(s) as they were to the original task. To this end, we consider a judge to be inconsistent if there is no overlap between the submitted queries in h' as compared to h. We found that of the 271 repeat tasks, 51 were classed as inconsistent. Looking further at the inconsistent tasks themselves, it is clear that these inconsistencies arise from the worker employing a different email re-finding strategy, for example, *'2018 conference tickets'* → *'tentative program schedule'*. Furthermore, we only report analysis using trained judges who are trained to conduct our task. However, we did also experiment with employing workers on a per-HIT basis at 40 cents per task. We found the behavior to be consistent with the findings from the trained judges, except that crowdworkers employed on a per-hit basis were generally faster to succeed, which is intuitive given the difference in incentive.

5.3 Controlled Degradation

As discussed in Section 3, we are able to intentionally degrade the search ranking. When collecting data, we opted to run a few different configurations for result degradation, where we remove the target document with probability $P \in \{0.0, 0.25, 0.50\}$. This experiments allows us to study the impact of lower search quality on user behavior and it allows us to validate that our behavior measures move in the expected directions when the ranking quality changes.

Degradation Analysis. Figure 7 shows some of the key measures for each system as P is increased. As expected, the number of

submitted queries per task, the time to success, and the rate of abandonment increases steadily as the result quality becomes worse. Furthermore, users tend to click deeper as the quality becomes worse. These trends holds across all systems, and are statistically significant under a two-tailed paired t-test with a Bonferroni correction ($p < 0.01$). In addition, the success rates fall across the board as P increases, from around 93% ($P = 0.0$) to 87% ($P = 0.25$) and then to 76% ($P = 0.50$). On the other hand, no statistical significance was measured for the number of clicks, or the time spent on the SERP. This indicates that these metrics are not sensitive to ranking quality, and are unlikely to be informative in the experiments conducted in Section 4. So, in answering RQ3, we have shown that user behavior is correlated with the quality of the search experience, and that a degraded search experience will lead to users taking longer to succeed, searching more often, and abandoning the SERP more often. Contrasting these results to those observed in Section 4 (RQ1) suggests that while users are sensitive to the quality of the search experience, the quality difference (as measured by MRR) must be quite pronounced to observe significantly changed behavior. In any case, the clear correlation between quality and these metrics provides additional evidence supporting the validity of the collected data.

6 RELATED WORK

A multitude of prior work has investigated how users interact with the many aspects of Information Retrieval systems, including presentation, ranking, search task, temporal influences, and many others. Here, we review the relevant studies, including those that focus on user behavior in web search tasks, user behavior and characterization on email tasks, crowdsourcing and gamification, and ranking for email search.

6.1 Understanding User Behavior

Web Search. There are a multitude of studies that focused on web search environments and the many components therein. For example, recent studies have quantified how users behave with respect to the number of documents included in a SERP [29], the information content and length of snippets [36], the difficulty of the querying interface [9], and other aspects of web search such as result presentation, visual interfaces, result coherence, and user typing ability [5, 8, 17, 33, 41]. However, these studies are far less common in personal search environments due to the difficult nature of experimentation on personal data [11]. Our work follows this line of work but focuses on email re-finding tasks.

Email Search. While email use is at an all-time high, email search has not received as much attention from the IR community compared to other areas such as web search. As Carmel et al. [12] pointed out, this is likely due to the lack of publicly available data. While some collections are available, they often have limitations such as using synthetic queries [1], which are not reflective of true user intent on email finding tasks. Most of the prior work on user behavior for email tasks has come from query log analyses, user studies, and surveys. One line of work investigates how users organize their mail and how this impacts their re-finding strategies or actions [4, 6, 21, 38, 47]. Another line of related work explores modeling and predicting various aspects of email search such as

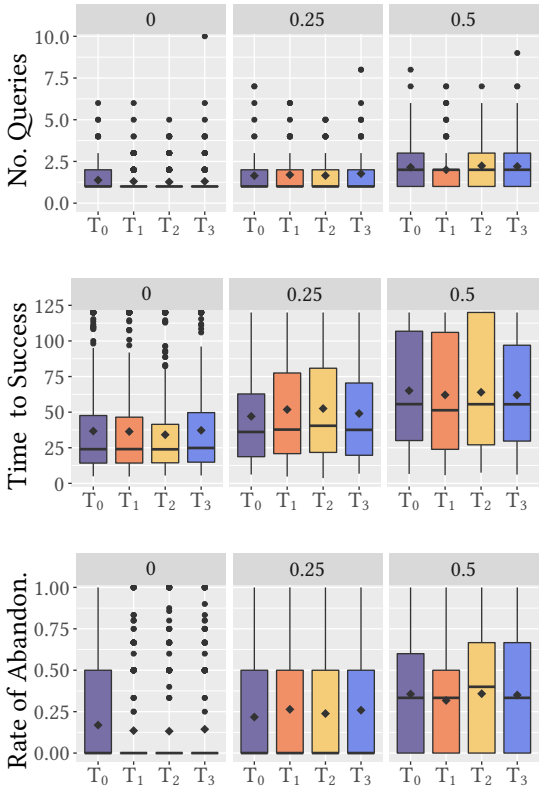

Figure 7: The effect of removing the target email e_t from the SERP with probability P on both the number of submitted queries, the time to success, and the rate of abandonment. Systems are shown in Figure 1. Degradation results in significantly more queries being submitted per task, a significantly longer time to success, and a significantly higher rate of abandonment.

how successful a user will be in their search task [30], how likely user will be to respond to new mail [49], how long a user's reply will be [31], and whether a user will defer an email [43], among many others. Elsweiler et al. [20] studied re-finding behavior by instrumenting the Mozilla Thunderbird[7] email client to capture user behavior. Their study uncovered several interesting findings such as that re-finding is difficult for users, and that users can become disoriented while performing re-finding tasks. Other studies have also observed the use of very short queries in email search [4, 13, 14]. Interestingly, users are generally successful at re-finding mail [6, 15], indicating that users are somewhat comfortable with re-finding even if such tasks are thought to be difficult. Our work addresses some of the major limitations of previous work by proposing an approach for simulating email re-finding tasks using real data in a crowdsourcing environment.

Crowdsourcing and Gamification. Crowdsourcing is a simple and cost effective approach for rapidly collecting data from users [32]. Prior work has involved using crowdsourcing to understand how users interact and behave with search tasks. The most relevant work

[7] https://www.thunderbird.net/

to our approach is that of Ageev et al. [3], who use *gamification* [37] to model user behavior in a crowdsourcing environment. This involves proposing a unique and scalable crowdsourcing task that allows user behavior to be captured across informational search tasks with a *known intent*. Subsequent works have focused on how user behavior can be studied via gamification [24], and the implications that such frameworks have on user behavior. Our approach is influenced from these ideas of leveraging crowdworkers with novel systems and tasks to collect user behavior for further analysis, allowing us to bypass many of the aforementioned issues such as experimentation on personalized data.

6.2 Ranking for Email Search

Some interest has been placed on ranking email results by *relevance* instead of the classic *rank-by-time* approach. Many of these ranking approaches were inspired directly from ad-hoc web search, including the use of language models [39] and BM25F [16]. Macdonald and Ounis [35] studied which combinations of email fields are useful as evidence for email ranking, suggesting that both the body and the subject of emails are crucial for effective retrieval.

Recently, the community has focused on the use of machine learning models for ranking email search, and the implications this has on users. Aberdeen et al. [2] outline the approach that Google uses for ranking email in their *Priority Inbox*. In particular, they focus on ranking documents by the predicted probability that the user will interact with the email within some time threshold after delivery. They make this prediction based on *social, content, label,* and *thread* features. They found that internal users of the priority inbox spent 13% less time reading unimportant mail, helping ease *email overload* [31, 48].

Advocating for rank-by-relevance, Carmel et al. [12] experimented with the implementation and deployment of a two-stage ranking model for effective email ranking, showing that a full relevance ranking significantly increases *Mean Reciprocal Rank (MRR)* as compared to rank-by-time.

Using a similar ranking system as described in [12], Ramarao et al. [42] described a new mail system called *InLook*. However, instead of ranking the entirety of the matched search results, InLook displays an *intent pane* which shows the top-3 most relevant matched emails, followed by the standard rank-by-time list. The authors argue that certain query types cannot be sufficiently matched using just rank-by-time or rank-by-relevance, providing justification for the hybrid ranking. Carmel et al. [14] further investigated hybrid rankings, arguing that users are not accepting rank-by-relevance in email search, likely because their search process is ingrained in the rank-by-time model. They propose a very similar approach to Ramarao et al. [42], where they provide the top-H results by relevance (called 'Heroes') above the remaining top-T by time, and explore a few variants of this hybrid approach. They found that providing the top-3 results based on relevance followed by the standard default time-ordered results, without removing duplicates, provided the best user experience (based on both MRR and a small-scale user study). This ranking, named *Heroes-Dup*, was subsequently deployed in Yahoo corporate and Yahoo web mail A/B testing scenario, significantly improving MRR over the baseline. Our work extended this line of research by exploring the implications that relevance ranking has on user behavior.

7 DISCUSSION AND CONCLUSION

A major contribution of this research is the proposed framework for studying email search using email data from real users in a realistic and privacy-preserving setting. We described an approach that is extensible, and can be modified to study a variety of different aspects of email re-finding, including alternative search interfaces and ranking approaches, among others. We also acknowledge some limitations and opportunities for future work. One interesting capability that was not explored in this work is to control the rank of the target email; since the target is known before the SERP is shown to the user, the target document could be strategically placed *anywhere* in the ranking. While our approach aims to be as realistic as possible, the random sampling of target emails may not truly reflect an email that a user would search for (Section 5). It would be interesting to see if more robust sampling approaches could be used, such as sampling only emails that are marked as important, or come from specific senders. A final aspect of interest is further gamification of the system, whereby the task could be appropriately modified to include additional incentives for crowdworkers. This would ultimately lead to more robust data collection in situations where *untrained* judges are employed, such as in typical crowdsourcing platforms.

Another major contribution of this work is leveraging our email search experimentation framework for analyzing user behavior in email re-finding tasks. Our results confirmed that relevance based ranking significantly outperforms rank-by-time for email search in terms of MRR, and that rank-by-time performs worse for re-finding older emails. We also showed that although both hybrid and relevance ranked systems are significantly better than the rank-by-time system, in terms of MRR, user behavior (in terms of success rate and time to success) does not markedly differ between the systems. This indicates that MRR may not be entirely representative of utility to users in re-finding tasks (RQ1 and RQ3). We also showed that users tend to do better with deciding when they should abandon the SERP and reformulate the query when rank-by-time is used. Another interesting observation was that some users occasionally either miss or glance beyond the target document when shown in the top results list of a hybrid SERP. Alternatively, they may have just preferred to not examine the top-results and skip to the more familiar rank-by-time setup. These observations show the challenges of trying to introduce new features that require users to change existing behavioral patterns and search strategies.

When studying how users reformulate their searches, we found similar behavior to web search but with more full reformulations which usually result from change in strategy (keyword search to time-based search). Finally, we also explored how properties of email impact re-finding success (RQ2). Most notably, users have more success finding emails that are deemed important. We found no evidence that machine-generated emails are more difficult to find. Our findings have several implications on designing email clients and email search systems. Our proposed framework for experimenting with email search could enable additional work to further study and evaluate email search systems by overcoming the

challenges around studying email search interactions in realistic settings.

ABSTRACT

Detecting and understanding implicit measures of user satisfaction are essential for enhancing recommendation quality. When users interact with a recommendation system, they leave behind fine grained traces of interaction signals, which contain valuable information that could help gauging user satisfaction. User interaction with such systems is often motivated by a specific need or intent, often not explicitly specified by the user, but can nevertheless inform on how the user interacts with, and the extent to which the user is satisfied by the recommendations served. In this work, we consider a complex recommendation scenario, called *Slate Recommendation*, wherein a user is presented with an ordered set of collections, called *slates*, in a specific page layout. We focus on the context of music streaming and leverage fine-grained user interaction signals to tackle the problem of predicting user satisfaction.

We hypothesize that user interactions are conditional on the specific intent users have when interacting with a recommendation system, and highlight the need for explicitly considering user intent when interpreting interaction signals. We present diverse approaches to identify user intents (interviews, surveys and a quantitative approach) and identify a set of common intents users have in a music streaming recommendation setting. Additionally, we identify the importance of shared learning across intents and propose a multi-level hierarchical model for user satisfaction prediction that leverages user intent information alongside interaction signals. Our findings from extensive experiments on a large scale real world data demonstrate (i) the utility of considering different interaction signals, (ii) the role of intents in interpreting user interactions and (iii) the interplay between interaction signals and intents in predicting user satisfaction.

1 INTRODUCTION

An increasingly larger proportion of users rely on recommendation systems to pro-actively serve them recommendations based on diverse user needs and expectations. Developing a better understanding of how users interact with such recommender systems is important not only for improving user experience but also for developing satisfaction metrics for effective and efficient optimization of the recommendation algorithm. This is especially true in the case of online streaming services like Pandora, Spotify and Apple Music, wherein the system could gauge user satisfaction and adapt its recommendations to better serve user needs.

Since obtaining explicit feedback from users is prohibitively expensive and challenging to implement in real world systems, commercial systems rely on exploiting *implicit* feedback signals derived from user activity. When users interact with the recommendations served, they leave behind fine-grained traces of interaction patterns, which could be leveraged for predicting how satisfied was their experience, and for developing metrics of user satisfaction.

Prior work have studied implicit feedback signals (e.g., clicks, dwell time, mouse scrolling) in the case of web search, and verified their effectiveness in predicting user satisfaction, both on traditional desktop [9, 11, 26, 27] and mobile setting [17, 39]. Furthermore, past work in web search systems has also highlighted the importance of considering tasks and intents when interpreting implicit feedback signals [14, 38]. On the other hand, the identification and effectiveness of corresponding implicit feedback signals as well as the role of user intents has remained understudied in the context of recommendation systems, especially in the mobile context.

While search systems have access to explicit queries from users, based on which one could extract tasks, and interpret interaction signals, thereby differentiating between success and failure; recommender systems, on the other hand, lack such explicit indicators of user intent and clear indicators of success. Indeed, the interpretation of signals varies with goals; for example, scrolling can indicate negative experience when the goal is to quickly listen to music now, but can also indicate a positive experience when the goal is to browse the diverse collection of music the system has to offer. Furthermore, interpreting interaction signals becomes especially hard in the context of complex recommendation settings, like *Slate recommendations*, a scenario typical to many music streaming services, where users are recommended a set of collections (called *slates*), with different purposes (to explore new music, or quickly jump to recently played music, etc), and heterogeneous content (playlists, artist profiles, other audio content, etc). Thus, there is a need for a

detailed, holistic view of user interactions with such recommender systems, to establish their utility in predicting satisfaction.

In this work, we consider the use case of music streaming via slates of recommendation, and aim at understanding the relationship between interaction signals, user intents and user satisfaction. We consider the case of users interacting with a mobile based music streaming app, Spotify, and investigate the different interaction signals that can be extracted in slate recommendation setting, and how these interaction signals vary across different intents. Since the list of possible intents user might have is hitherto unknown, we adopt a mixed methods approach to understand user intents, and leverage insights from (i) face-to-face interviews, (ii) large scale in-app survey and (iii) non-parametric clustering techniques to identify the list of possible intents. We identify eight user intents and verify their validity using large scale log data.

To predict user satisfaction, we jointly leverage insights from the extracted interaction signals and intents. While interaction signals have been directly used to predict satisfaction in search [9, 24, 27], we instead hypothesize that interpreting interaction signals without factoring in user intent would lead to noisy, unreliable estimates of satisfaction in our context. We demonstrate that traditional approaches of using a single, global model for satisfaction trained on aggregate data without considering intent groups does not perform well in predicting satisfaction. We show that significant performance gains are obtained in switching from a single global prediction model to separate satisfaction models for each intent.

Further, we identify issues with the global and per-intent models. While the former fails to capture intent-specific intricacies, separate per-intent models ignore information and insights from other intents. To address these, we show the importance of shared learning across intents and propose a *multi-level hierarchical model* that allows the estimation of intent-specific effects while at the same time learning from data across all intents, thereby compromising between the overly noisy per-intent model and the oversimplified global model that ignores intent groups. The proposed multi-level model facilitates incorporating both individual session level and intent group level effect on user satisfaction, thereby allowing for variability in user interaction behavior across intents.

Extensive experiments on a real world large scale music streaming data from Spotify highlight the benefit of explicitly considering user intent and demonstrate the effectiveness of different interaction signals in predicting user satisfaction in a slate recommendation setting. We contend that our findings provide a valuable framework for fine-grained analysis of user interaction behavior for developing metrics and gauging user satisfaction. To the best of our knowledge, the present study is among the first to identify the benefit of incorporating user intent information in understanding user interactions and satisfaction in recommendation settings, and to demonstrate the significant gains obtained over the popularly used single global intent-agnostic prediction models.

2 RELATED WORK

The current research builds upon four areas: (i) slate recommendations, (ii) user interactions for satisfaction prediction, (iii) user intent modeling and (iv) mixed methods approach to analysis.

Slate Recommendation. Recommendation of slates is a common problem arising in various contexts including search [33], ads and recommendations [8]. Several approaches have been proposed to generate slates, including List Conditional Variational Auto-Encoders [12] and Slate-MDPs [32]. A different approach [33] investigates the evaluation of policies that recommend slates, and then introduces a pseudo-inverse estimator for off-policy evaluation in combinatorial contextual bandits. Different from proposing a new approach to generate slates, our work is concerned with investigating user interaction and gauging user satisfaction with recommended slates.

Satisfaction & User Interaction Signals. With respect to interaction signals, implicit feedback signals (e.g., clicks, dwell time, mouse scrolling) and their sequences have been extensively studied in web search and their effectiveness in predicting satisfaction [9, 11, 24, 26, 27, 29] has been verified, using techniques such as Markov models or deep neural models. A detailed overview regarding the evaluation of interactive information retrieval systems with users can be found in Kelly *et al.* [13].

Scrolls and cursor movements do not exist in mobile search; however, the swipe interaction performs a similar function. Past work leveraging user interaction on mobile phones have used signals such as swipes, dwell times on landing pages and zooms for detecting search result relevance [10] as well as for gauging user attention and satisfaction [25]. User interactions with touch based devices have also been used to detect good abandonment [39] and user satisfaction with intelligent assistants [17]. Building upon such work, we leverage swipe interactions and some signals that result from swipe activity to predict satisfaction.

In the context of recommendation systems, temporal features, including variants of dwell time have been considered for understanding satisfaction [16] and relevance [41]. Specifically focusing on evaluating recommender systems, past work has investigated preference elicitation [19], explanations [34] and user centric combinations of explicit and implicit preferences [18]. Past work has also investigated the influence of personal and situational characteristics towards explaining user experience with recommender systems [20, 22].

Our work also investigates implicit feedback signals, similarly to those works, but in a less explored context, that of music recommendation. Additionally, we aim to investigate the hypothesis on how the interpretation of such interaction signals and their role in predicting satisfaction changes across different user intents.

User Intent Modeling. Related to our consideration of user intents, the role of query intents and search tasks have been extensively studied in the search community, with past work aimed at leveraging intents in predicting query and task satisfaction [27, 37, 42]. Recent work reported in [1] considers the role of intents in recommendations and propose an intent-aware recommendation model. In music recommendation, recent efforts have been made around initial exploration of music listening intents associated with common activities [35], as well as studies of why and when people of different ages and in different countries listen to music [36]. These investigations suggest that intent modeling can potentially improve recommendation quality.

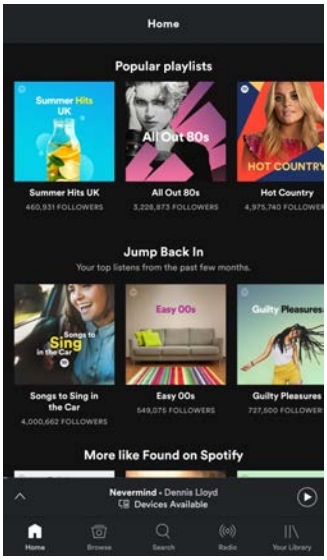

Figure 1: An example homepage of Spotify, a music streaming app.

In web search, tasks have been considered as an analogous abstraction to intents. Prior work has emphasized understanding the role of task level differences while leveraging implicit feedback. Specifically, White *et al.* [38] investigated how individual and task differences impact the effectiveness of algorithms based on implicit relevance feedback. Additionally, Kelly *et al.* [14] considered the effects of task on display time, and quantified the potential impact of this relationship on the effectiveness of display time as implicit feedback.

Mixed methods. Finally, our mixed methods approach of leveraging interviews along with qualitative and quantitative insights follow recent works investigating user expectations, behaviors, and satisfaction in the context of music discovery [5], image [40] and product search [30].

3 PROBLEM FORMULATION

Our goal is to extract and leverage user interaction data to understand and predict user satisfaction in a slate recommendation setting. We consider the Homepage of a major commercial music streaming service, and base our experiments around user interaction with the resulting recommendation page.

3.1 Key concepts

We first define the key concepts used throughout the paper.

- **User Session:** A session is defined as a sequence of user actions with the recommendations rendered, including active browsing of content and passive listening to music. A user session ends when the user has not interacted with or streamed from the Homepage for more than 30 minutes.
- **Slate Recommendation:** A slate is a collection of playlists grouped together under a common theme. Figure 1 shows two slates, *Popular Playlists* and *Jump Back In*, each with 3 playlists. The Slate Recommendation task is to recommend a collection of slates.

Table 1: Description of user interaction signals used.

Signal Type	Signal	Description
Temporal	session length	duration of entire session in seconds
	ms played	total milli-seconds streamed
	dwell time on Homepage	session duration minus downstream time spent streaming content
	avg interaction time	time spent on the Homepage interacting with slates
	time to success	time until first stream
Downstream	songs played	number of songs played
	relationship built	binary signal indicating whether the user saved or downloaded any track or album
	downstream time	total streaming time in any playlist reached via Homepage
Surface Level	no of interactions	total number of clicks on Homepage
	nSlates	no of slates interacted with
	didScroll	binary variable indicating whether or not the user scrolled to view additional recommendations
	max depth	maximum depth reached on the Homepage (number of slates vertically scrolled)
	no of exits	number of exits from Homepage to any playlist
Derivative	avg value of click	total no of clicks / number of stream events
	abandoned	binary feature denoting if the session was abandoned without any interaction
	intentional	binary feature indicating if the user intentionally came to the Homepage from other app feature

- **Homepage:** Also referred to as the home tab, the homepage is the first landing page of the music streaming app, which surfaces a number of playlists, organized as different slates. Figure 1 gives an example of the homepage of Spotify, the music streaming app used in this study.
- **User Satisfaction:** User satisfaction can be viewed as a subjective measure of the utility of recommendations, and we posit that user satisfaction is conditioned not only on the recommendations served, but also on user intent. We rely on implicit signals to derive satisfaction estimates and then use user reported satisfaction scores as gold standard estimate of user satisfaction.

The slate recommendation algorithm aims to find the optimal, ordered subset of items (playlists), a.k.a. slate, given the page layout to serve users recommendations so as to maximize user satisfaction. A Homepage is a collection of such recommended slates, which the user can interact with. Since users come to the app with different goals at different points in time, it becomes important for system designers to understand user interaction to gauge user satisfaction with the slates of recommendations rendered on the app Homepage.

In the rest of this section, we shed light on the different interaction signals we extract from user interaction with the Homepage of Spotify and briefly motivate the need for considering user intent for understanding and predicting user satisfaction in our context.

3.2 Extracting User Interactions Data

The Homepage rendered for a user is rich enough to allow him or her to interact with it in a myriad of ways, including clicking on playlists, scrolling vertically to view more slates, scrolling horizontally to view more playlists in a specific slate, pausing to read and

visually absorb content, clicking and consuming content via streaming, among others. While past work on understanding user interaction in mobile search setting have proposed few signals [17, 39], we additionally propose a number of new signals resulting from the specific *Slate Recommendation* scenario considered in this work.

We use back-end logs of user interactions and extract four different types of interaction signals for each user session:

(1) **Temporal signals**: these focus on the temporal aspects of user interaction, including time spent interacting with the slates, session length, dwell time, etc.
(2) **Surface level signals**: these capture aggregate user interaction on the surface of the Homepage, including total number of clicks, total number of slates the user interacted with, maximum depth the user reached by vertical scrolling, and total number of exits the user had from the Homepage.
(3) **Downstream signals**: these capture downstream user engagement resulting from the Homepage, i.e., user interaction with the playlists, including streaming songs, saving or downloading tracks, viewing Artist profile pages.
(4) **Derivative signals**: these are derived using interaction features like whether the session was abandoned, or whether the session was intentional, with the user going to the Home tab from elsewhere in the app. The average value of click is derived by the considering all clicks in a session and dividing by the total number of streams observed in that session.

Table 1 provides a detailed description of the different interaction signals extracted for each user session.

3.3 Role of User Intent

In the use case of a slate recommendations on a surface like some of the big music streaming apps, users use the Homepage for different needs at different times. With differing needs and intents, users would interact with the app differently, and hence leave different traces of behavioural signals.

Indeed, a user might just want to quickly play some background music, and would not spend much time in finding music to play; on the other hand, a different user might want to carefully find music to save for future listening. In both cases, the way the user interacts with the music app differs, thereby leading to different interaction signals. Since implicit measures of user satisfaction rely heavily on interpreting interaction signals, we hypothesize that understanding and identifying user intent is important to predict user satisfaction in our context, as has been done in other scenarios, particularly in web search [3, 15, 21, 27, 31].

To this end, we discuss different ways of identifying user intents in a recommendation setting in Section 4, and leverage the intents identified along with the extracted interactions signals to predict user satisfaction in Section 5.

4 INTENT IDENTIFICATION

Users use recommendation platforms with different intents. The space of possible intents a user might have is hitherto unknown. In this section, we focus on identifying the different intents users might have when interacting with a music recommendation system.

Table 2: Demographic details of the participants interviewed.

Home Usage	Participant	Gender	Age	Job
Rarely visit Home	Participant 1	Female	31	HR Analyst
	Participant 2	Female	23	Accountant
	Participant 3	Male	20	Student
	Participant 4	Female	27	Construction Manager
	Participant 5	Female	27	Student
	Participant 6	Female	36	Nightlife Manager
Frequently visit Home	Participant 7	Female	28	Student
	Participant 8	Male	31	Finance Manager
	Participant 9	Male	20	Student
	Participant 10	Male	35	Makeup Artist
	Participant 11	Female	32	Attorney
	Participant 12	Male	25	Marketer

4.1 Interviews

To discover and better understand user intents when interacting with the Homepage composed of a set of slate recommendations (playlists), we conducted in-depth 1:1 in-person interviews with users of the streaming app. We describe the interview process and discuss our findings.

Approach. We interviewed 12 users living in the city of New York who were found to have varying degrees of Homepage usage with the Spotify app in the 4 weeks prior to the study. We selected participants from both iOS and Android users with a range of levels of engagement with the app (low, medium, high) and the Homepage (rarely visit, frequently visit), with engagement defined as the number of days they actively used the app in the past month. We emailed a screener survey to a list of Spotify users with these specifications to recruit and schedule the interviews. Table 2 provides a detailed demograpic overview of the participants. With each user, we conducted 1:1 face-to-face interviews spanning 45 minutes each and provided them a $100 gift card upon completion of the interview.

Our goal was to understand and discuss their intents and satisfaction when using the Homepage. We asked them questions around (i) What intents they have when coming to the Homepage; (ii) How satisfied they are with their experience, and (iii) How they behave in relation to intent and satisfaction. The participants were encouraged to provide detailed responses to these questions which were recorded (audio and video).

Findings. We performed a detailed post-hoc analysis of the data from the interviews by going through the video recording of the interviews and the interview transcripts. We grouped together findings that appeared in more than one interview in order to create themes. As per our initial hypothesis, different participants reported to using the Homepage of Spotify for different goals at different times. We were able to categorize user intents into two main themes, Passively Listening, and Actively Listening, and to identify the following overarching intents:

(1) **Theme 1: Passively Listening**
  (a) To find music to play in the background
  (b) To play music that matches their mood or activity
  (c) To quickly access their playlists or saved music

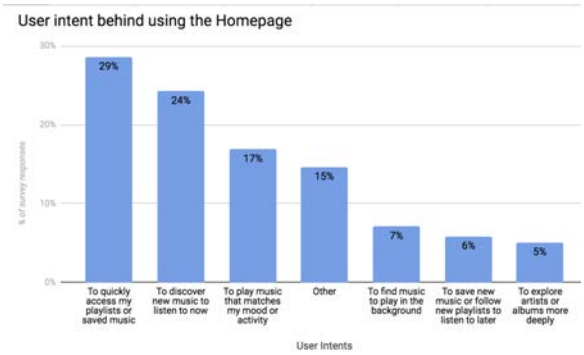

Figure 2: Distribution of user intents.

(2) **Theme 2: Actively Engaging**
   (a) To discover new music to listen to now
   (b) To save new music or follow new playlists to listen to later
   (c) To explore artists or albums more deeply

Additionally, some users pointed out that they use the Homepage because it is the default page that opens upon loading the music app, without having a clear intent when they go on it. We therefore added *Because it is the first screen shown* as an additional intent to the above, thereby making it a total of seven identified intents.

These intents differ from those reported in [36], since they correspond to user intents in using a homepage consisting of slates of recommendations, whereas the intents identified in [36] are user intents for listening to music in general.

Importantly, users often alluded to the fact that their behavior on the Homepage varied with their intent. For example, *scrolling* can be an indicator of exploration, but *scrolling* back and forth can signal a struggle. Not *scrolling* could mean satisfaction with the recommendations presented, but could also indicate dissatisfaction with what was presented. This motivates the need for interpreting interaction signals differently for different intents.

4.2 In-App Survey

Following up on the intents identified from the face-to-face interviews, we performed a large scale survey to validate and understand the prevalence of the intents identified from the interviews. The survey allowed us to collect data from users about their intent and satisfaction during a given session with the Homepage.

Methodology. We selected a random sample of 3 million iPhone users of the Spotify app residing in the US, and presented them with a brief survey at the end of their Homepage session. To not interfere with their natural interaction, and to not bias the user interaction data collected from a session, we trigger the survey only after the user ended their session and moved to another feature of the app (e.g. Search, My Library). To avoid inundating users with the survey repeatedly, the in-app survey is trigged such that each user participates in the survey at most once. Furthermore, we assume that a user has one overarching intent when they begin their Homepage session, an assumption we intend to relax as part of future work.

To gauge user satisfaction we asked the following question: *How satisfied or dissatisfied were you with your experience on the Home screen today?* and presented them with 5 options ranging from *Very satisfied* to *Very Dissatisfied*, along with an additional option of "I wasn't on the Home screen today". Further, to understand their intent behind using the Homepage, we asked them the following question: *Why were you on the Home screen today?* and showed them the six intents identified during the interviews.

As the listed intents may not capture all possible intents users might have, we added *Other* as an option. The *Other* intent option was accompanied by a free text block where users were asked to specify their intent; this allows us to identify any intent not identified during the interviews. Parsing the free flow natural language text and identifying common intents from it is a non-trivial task, which we address in Section 4.3.

Survey Results & Findings. We briefly discuss findings about user intents from the large scale survey, and leave the discussion of findings about user satisfaction for later (Section 6.2). The response rate was 4.5%, with over 116000 users from the 3 million users targeted responding to the survey, which is similar to the response rates we observed in our past surveys.

Figure 3 presents the distribution of intents across user sessions, which indicates how prevalent the intents are. We observe a fairly even distribution of intents across passively listening and actively engaging, which the top two intents: (i) *To quickly access their playlists or saved music* and (ii) *To discover new music to listen to now*, covering 29% and 24% of sessions respectively. A sizeable portion of the sessions involve the user saving music for later consumption or exploring artists in detail, with over 20000 user sessions dedicated to these intents.

Given that the majority of the sessions could be linked to one of the intents identified during interviews, it validates the identified intents. However, since over 15% of users opted for *Other*, indicating that their intent is not covered in the presented list of intents, we further investigate the presence of other intents from the text entered by users. The next section describes a computational approach to analyze the responses to identify new intents.

4.3 Bayesian Non-parametric Model

To ensure that the intents identified sufficiently cover the space of all possible intents users might have when interacting with the Homepage of the Spotify app, we investigate the text entered by the users when they selected the *Other* intent category in the survey responses. Simple clustering on the text is not much useful since the number of possible intents in not known apriori. As a result, we resort to Bayesian nonparametric clustering [7].

The distance dependent Chinese restaurant process (dd-CRP) [2] was recently introduced to model random partitions of data, and is a commonly used method for non-parametric clustering [2, 28]. To extract intents, we consider the dd-CRP model in an embedding-space setting and place a dd-CRP prior over the intents. While a detailed description of non-parametric clustering is beyond the scope of this work, we briefly describe the major steps below. Interested readers are referred to Blei *et al.* [2] who introduce the dd-CRP model, and to Mehrotra *et al.* [28] who apply dd-CRP model to identify query clusters.

Let z_i denote the ith intent assignment, the index of the text with whom the ith text is linked. Let d_{ij} denote the distance measurement between texts i and j, let D denote the set of all distance

measurements between texts, and let f be a decay function. The distance dependent CRP independently draws the text assignments to intent cluster conditioned on the distance measurements,

$$p(z_i = j|D, \alpha) \propto \begin{cases} f(d_{ij}) & \text{if } j \neq i \\ \alpha & \text{if } j = i \end{cases}$$

Here, d_{ij} is an externally specified distance between texts i and j, and α determines the probability that a customer links to themselves rather than another customer. The monotonically decreasing decay function $f(d)$ mediates how the distance between two texts affects their probability of connecting to each other. Cosine similarity between the word2vec embedding representation of two input text describe the distance function (d_{ij}).

Given a decay function f, distances between texts D, scaling parameter α, and an exchangeable Dirichlet distribution with parameter λ, N M-word queries are drawn as follows,

(1) For $i \in [1, N]$, draw $z_i \sim dist - CRP(\alpha, f, D)$.
(2) For $i \in [1, N]$,
   (a) If $z_i \notin R^*_{q_{1:N}}$, set the parameter for the ith text to $\theta_i = \theta_{q_i}$. Otherwise draw the parameter from the base distribution, $\theta_i \sim Dirichlet(\lambda)$.
   (b) Draw the ith terms, $w_i \sim Mult(M, \theta_i)$.

We employ a Gibbs sampler, wherein we iteratively draw from the conditional distribution of each latent variable, given the other latent variables and observations. The Gibbs sampler iteratively draws from

$$p(z_i^{new}|z_{-i}, x) \propto p(z_i^{new}|D, \alpha) \\ p(x|t(z_{-i} \cup z_i^{new}), G_0) \quad (1)$$

The first term is the dd-CRP prior and the second is the likelihood of observations (x) under the partition, and $t(z)$ is the intent-cluster formed from the assignments z. We employ a Dirichlet-Multinomial conjugate distribution to model the likelihood of text terms.

Input texts from users are assigned to intent clusters by considering sets of texts that are reachable from each other through the intent cluster assignments. Notice that many configurations of text assignments might lead to the same intent-cluster assignment. Finally, text assignments can produce a cycle, e.g., text 1 linking with 2 and text 2 linking with 1. This still determines a valid intent-cluster assignment; all texts linked in a cycle are assigned to the same intent cluster.

Upon running the dd-CRP model on the 15% response with user entered text, we obtained 5 different clusters of user responses. We manually investigated these clusters and identified the following intents: (i) To Find X, where X could be any specific playlist a user was trying to find; (ii) To explore or casually browse; (iii) All of the above, wherein the users wanted to select all options presented to them, (iv) I wasn't on Home tab, and (v) Miscellaneous.

Among these five newly identified intents, *I wasn't on Home tab* indicates that the users did not participate in a Homepage session, so we discarded these sessions. Further, Miscellaneous cluster mainly consisted of incoherent text entered by users, thereby rendering it futile. Similarly, we discard sessions tagged with *All of the above* cluster, since it does not present us with new intent and only had few sessions. Finally, the *casually browsing* intent was a very small cluster. In summary, we identified one additional intent: *To Find X* to be added to the pool of the seven intents identified earlier.

Table 3: Final list of user intents identified when interacting with the slated recommended by the Homepage of a music streaming app. Although Intent 1 is not an actual intent, we still refer to it as Intent for ease of writing.

Intent	Definition
Intent 1	Homepage is the first screen shown (i.e. default screen)
Intent 2	To quickly access my playlists or saved music
Intent 3	To discover new music to listen to now
Intent 4	To play music that matches my mood or activity
Intent 5	To Find X
Intent 6	To find music to play in the background
Intent 7	To save new music or follow new playlists to listen to later
Intent 8	To explore artists or albums more deeply.

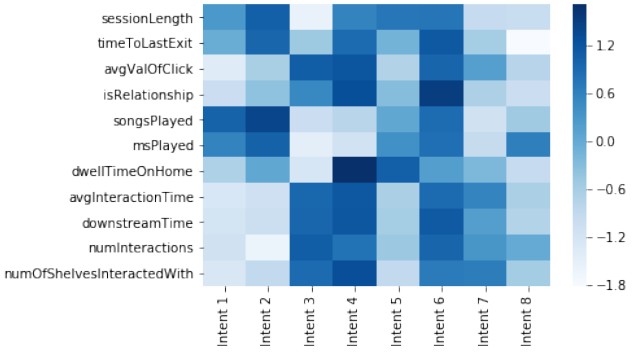

Figure 3: Heatmap of interaction signals across the different user intents. Signals are prevalent to varying extents in different intents, thus highlighting varying user interactions across different intents.

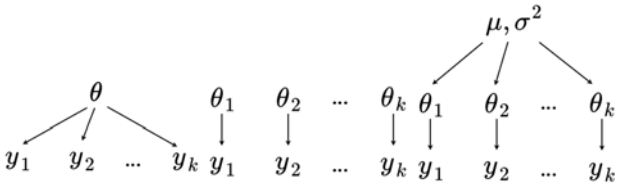

Users often use the Homepage to find something they're looking for, which could be any specific playlist or any specific shelf. The extracted additional intent caters to such search-like use-cases.

Although the rigorous process of non-parametric clustering applied to user entered responses only gives us one new intent, it reaffirms the exhaustiveness and coverage of the six intents identified before.

4.4 Analysis of User Interactions & Intents

Based on the interviews, in-app survey and non-parametric clustering of textual user responses, we end up with eight user intents, as described in Table 3. The diversity of these intents highlights the variety in what users intend to achieve when using the Homepage of the music app.

We hypothesize that the way users interact with the recommended slates of playlists would differ across these intents. Figure 3 presents a heatmap of a subset of interaction signals (see Table 1) with the different intents. We observe that the prominence of interaction signals significantly differs across intents, with certain signals like interaction time on the Homepage significantly lower for intent 2 (to quickly access music). These differences in interaction signals highlight the fact that users indeed behave differently when having different intents. Since implicit measures of satisfaction highly depend on interaction signals, this places

(a) Global Model **(b)** Per-Intent Model **(c)** Multi-level Model

Figure 4: Different modeling assumptions for intent aware SAT prediction model: (a) Global Model for all data across all intents; (b) Per-Intent Model; and (c) Hierarchical Multi-level Model with shared parameters.

special emphasis of explicitly considering intents when predicting satisfaction.

5 PREDICTING SATISFACTION

Our main goal is to understand and predict user satisfaction (SAT) using interaction data. To this end, we extracted detailed user interaction signals, and identified different intents users might have. In this section, we leverage the extracted signals and intents and present techniques to predict user satisfaction using the signals. We present three approaches for satisfaction prediction, covering the spectrum of intent-level granularity, i.e. global model for all intents to a separate model for each intent and a shared model across intents.

5.1 Global Model

We begin by describing the most conventional approach to satisfaction prediction, referred to as *Global Model*. The simplest technique would be to treat all user sessions as a homogeneous collection of data, with the user intent featuring simply as a categorical variable along with user interaction signals. Almost all existing work on predicting user satisfaction from interaction signals [9, 11, 26, 27] have employed such an approach to satisfaction (SAT) prediction.

For the Global prediction model, we perform traditional Logistic Regression and Gradient Boosted Decision Trees classifiers. Given a dataset with n user sessions ($x_i \in X$), each of which is represented by m features, $D = \{(x_i, y_i)\}$ ($|D| = n, x_i \in R^m, y_i \in R$), the logistic regression classifier assigns a probability to each outcome as

$$P(y_i = c|x_i) = logit^{-1}(\theta^T x_i + b) \tag{2}$$

where $c \in \{-1, 1\}$ and is trained with conditional maximum likelihood estimation, wherein we choose θ that maximize the (log) probability of the labels given the observations x_i. Thus, the objective function we aim at maximizing is:

$$L(w) = -\Sigma_{i=1}^{n} \sigma(\theta^T x_i + b)^{y_n} (1 - \sigma(\theta^T x_i + b)^{(1-y_n)} \tag{3}$$

where σ is the sigmoid function. Alternatively, tree boosting type of models (e.g. Gradient Boosted Regression Trees) optimize a tree ensemble model using additive functions to predict the output. We train both Logistic Regression and GBDT models using all the interaction features extracted for each session, along with a categorical variable describing user intent for the current session. As shown in Figure 4 (a), the same parameter is learned and shared across all intents and sessions.

5.2 Per-Intent Model

A key issue with a Global Model is that it ignores the variations in the interaction signals across different intents. Indeed, a user with an intent to quickly access her playlist to play music (Intent 2) would know what she is looking for, and not spend time in detailed exploration, unlike a user interested in exploring an artist more deeply (Intent 8). Whereas the categorical variable for the session intent would slightly help the model account for intent specific traits, a better approach would be to train a separate model for each intent, referred as *Per-Intent Model* illustrated in Figure 4 (b).

Let η_i denote the intent for session i, and $K = 7$ be the total number of intents, i.e. $\eta_i \in [1, K]$. We divide the session data ($D = \{(x_i, y_i)\}$) into K different intent specific groups and train K different SAT prediction models, one for each intent:

$$P(y_i = c|x_i) = logit^{-1}(\theta_k^T x_i + b_k) \tag{4}$$

with (θ_k, b_k) representing the parameters of the k-th intent SAT model.

While the Per-Intent model is able to capture intent specific intricacies of the different interaction signals, it suffers from a few drawbacks. It prohibitively collect data for each intent separately, and there may not be enough data to learn a meaningful model for each intent separately. This problem gets compounded when platform changes encourages users to use the platform for new intents. Furthermore, an intent specific model fails to benefit from shared learning of parameters and hence fails to leverage insights from the interplay between interaction signals and satisfaction data of other intents. We next present a hierarchical multi-level approach to address these shortcomings.

5.3 Multi-level Model

Both the Global and Per-Intent SAT prediction models introduced suffer from various disadvantages. The Per-Intent SAT prediction model works by using just the local intent specific information, and assumes that the data is sampled from separate models for each intent, thereby ignoring information and insights from other intents. Furthermore, it can be rendered futile for intents with small labeled data. At the other extreme, the Global SAT prediction model ignores intent-level variations in the user interaction data and inadvertently suppresses variations that can be important.

To address these issues, we resort to *Multi-level Modeling* [6, 23], which represents a compromise between the two extremes of a single global prediction model and a separate prediction model for each intent. Multi-level models, illustrated in Figure 4 (c), are regression and classification models in which the constituent model parameters are given probability models. This implies that the model parameters are allowed to vary by group. This approach can be used to handle clustered or grouped data (e.g. different user intents), wherein each level is (potentially) a source of unexplained variability. Multi-level modeling provides a coherent model that simultaneously incorporates both individual and group level models.

Benefits of Multi-level Modeling

Modeling the satisfaction prediction model as a multi-level model offers numerous benefits. First, leveraging multilevel models allows us to account for the intent level grouping of the user session.

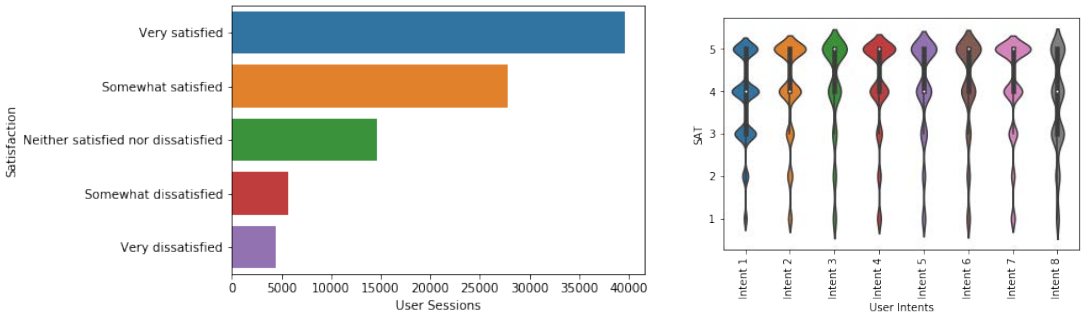

Figure 5: Analysis of user survey responses. Left: Distribution of user satisfaction labels obtained. Right: Distribution of SAT labels across the different user intents. SAT levels 1 to 5 refer to different levels from Very Dissatisfied (1) to Very satisfied (5).

Second, they facilitate incorporating both individual session level as well as intent group level effects on user satisfaction, thereby allowing for variability in user interaction behavior across different intents. Third, by assuming that the intent group level effects come from a common distribution shared across all intents, they facilitate information sharing across different intents. This can help in improving the accuracy and predictive performance for intents with relatively little data.

Intent-aware Multi-level Model

We model the satisfaction prediction problem with a multi-level logistic regression model with the different user intents serving as groups for the hierarchical model. The Multi-level Model can be written as:

$$P(y_i = c|x_i) = logit^{-1}(\theta_{\eta_i}^T x_i + b_{\eta_i}) \tag{5}$$

with η_i denoting the intent group for the i-th user session, and x_i denoting the user interaction signals extracted for the session. In our hierarchical model, parameters are viewed as a sample from a population distribution of parameters.

$$\begin{pmatrix}\theta_\eta \\ b_\eta\end{pmatrix} = \begin{pmatrix}\mu_0 \\ \mu_1\end{pmatrix} + \begin{pmatrix}\gamma_{0,\eta}^{int} \\ \gamma_{1,\eta}^{int}\end{pmatrix} \tag{6}$$

$$\begin{pmatrix}\gamma_{0,k}^{int} \\ \gamma_{1,k}^{int}\end{pmatrix} \sim N\left(\begin{pmatrix}0 \\ 0\end{pmatrix}, \Sigma^{int}\right) for\ k = 1, \ldots, K \tag{7}$$

Thus, we view them as being neither entirely different (as was the case in the Per-Intent model) or exactly the same (as was the case in the Global Model). Figure 4 pictorially depicts the main difference between the parameter sharing across the three different satisfaction prediction models investigated in this work.

6 EXPERIMENTAL EVALUATION

We perform an evaluation to compare the different satisfaction prediction models, consider the role of different interaction features and present results on a large scale real world dataset.

6.1 Dataset

We work with real world user data from Spotify, a large music streaming service, and conduct a large scale in-app survey to collect judgments about intents and user satisfaction. We trigger the in-app survey to a random sample of over 3 million users, and observe a response rate of 4.5%. In total, we received responses from over 116000 users, resulting in over 200K judgments about intents and satisfaction combined. For each session, we collected back-end logs of user interactions with the slates of recommendation and extracted data for all the different interaction signals mentioned in Table 1. For each session, we use the intent selected by the user as the session intent and use the satisfaction prediction label given by the user to train and evaluate our satisfaction prediction models.

Owing to the *response bias*, i.e., the respondents of the survey are likely to be users with a positive bias toward the system, we would end up with a biased dataset for training, which would lead to unreliable prediction estimates. We mitogate this by oversampling the minority class by synthetic minority over-sampling technique [4]. This results in a balanced dataset with a healthy distribution of labels across both satisfaction and dissatisfaction cases.

6.2 Analysis of Survey Results

We begin with an analysis of the survey responses by understanding the degree to which users are satisfied overall, and across different intents. Figure 5 (left) presents the overall distribution of user satisfaction. We observe that most users are either *Very satisfied* or *Somewhat satisfied* with the slates recommended to them in their current session with over 33% user sessions being judged as very satisfying. On the other extreme, over 12000 user sessions were reported to be very or somewhat dissatisfying. A relatively larger number of user sessions were judged as neutral.

To gauge satisfaction for each intent, we plot the satisfaction label distribution separately for each intent in Figure 5 (right). Similar to overall satisfaction, we observe that more user sessions are satisfying than they are dissatisfying. Users with intents 3, 6 and 7 were more satisfied with the slate recommendations shown to them, than users pursuing other goals, which highlights the efficacy of the system in facilitating users to discover new music for now (Intent 3), playing music in background (Intent 6) and saving music for future (Intent 7). However, the distribution of the different levels of satisfaction differs across intents. As can be seen in the violin plot, a substantial number of user sessions were judged as neutral on satisfaction scale for Intent 8, whereas the distribution is skewed more towards the top-most level of satisfaction for Intents 3 and 6.

Considering such differences in distribution of satisfaction across intents helps system designers in identifying those intents where recommendation system under-performs, an insight which instead would have been hidden when considering overall user satisfaction.

Table 4: Comparing satisfaction prediction performances across different prediction models: Global, Per-Intent and Multi-level. * indicates statistical significant ($p \leq 0.05$) using paired t-tests compared to the Global + intent Model.

		Overall			Dissatisfaction			Satisfaction		
Method	**Accuracy**	**Precision**	**Recall**	**F1**	**Precision**	**Recall**	**F1**	**Precision**	**Recall**	**F1**
Global w/o intent	0.55	0.56	0.56	0.56	0.57	0.48	0.53	0.54	0.63	0.59
Global w/ intent	0.57	0.58	0.58	0.57	0.59	0.52	0.55	0.56	0.63	0.60
Intent 1	0.675	0.68	0.68	0.67	0.66	0.73	0.69	0.70	0.62	0.65
Intent 2	0.663	0.67	0.67	0.67	0.66	0.71	0.68	0.68	0.62	0.65
Intent 3	0.672	0.67	0.67	0.67	0.69	0.67	0.68	0.65	0.68	0.67
Intent 4	0.678	0.68	0.68	0.68	0.67	0.71	0.69	0.69	0.64	0.66
Intent 5	**0.814***	**0.81***	0.81	0.81	0.80	0.84	**0.82***	0.83	0.79	0.81
Intent 6	0.760	0.77	0.76	0.76	0.73	0.83	0.77	0.81	0.69	0.75
Intent 7	0.7771	0.77	0.77	0.77	0.75	0.81	0.78	0.79	0.74	0.76
Intent 8	0.769	0.78	0.77	0.77	0.71	**0.87***	0.78	0.85	0.67	0.75
Multi-Level	0.804	0.80	0.79	0.79	0.81	0.79	0.79	0.79	**0.81***	**0.81***

This further motivates the need for incorporating intent information when developing and interpreting user satisfaction metrics.

6.3 Predicting User Satisfaction

We next investigate the extent to which the proposed interaction signals and the predictive models are able to predict user satisfaction. We consider the satisfaction label provided by the user during an in-app survey as ground truth label, and consider a user to be satisfied if their response was either *Very Satisfied* or *Somewhat Satisfied*. In all other cases, the user session was labeled as dissatisfied. Such binarization of user satisfaction isn't ideal, but we contend that it is a good starting point and has been extensively used in prior industrial research on understanding and predicting user satisfaction [17, 27, 39].

In line with prior work on predicting binary user satisfaction, we use four different evaluation metrics: accuracy, precision, recall and F-score. Table 4 presents detailed results comparing the Global, Per-Intent and Multi-level Model on these four metrics. We additionally divide the overall prediction performances and separately consider the performance in predicting satisfaction and dissatisfaction, since understanding them (SAT and DSAT) independently is useful in different use-case scenarios and at different stages of system development.

We observe that the Global Model is not able to predict user satisfaction much better than random, giving an overall accuracy of 57%. The Global Model without intent as a feature (i.e. Global w/o intent) performs worse, which highlights that incorporating intent information is useful in predicting satisfaction. The Per-Intent Model, on the other hand, gives much better prediction results than the Global Model. We observe an increased performance across all eight intents, with performance gains ranging from 10% to 24% for different intents. This confirms the main hypothesis of our work – considering intent information is crucial in accurately understanding and predicting user satisfaction. Since the interaction signals differ across different intents, the Global Model is unable to find a good universal relation between such signals and satisfaction. The Per-Intent Model creates a separate local intent-specific model and is able to capture the interplay between interaction signals and satisfaction to a much better extent.

We observe performance improvements in not just the accuracy, but across all metrics considered for both predicting satisfaction and predicting user dissatisfaction. Furthermore, we observe that the Multi-level Model performs significantly better than the Global Model (with intent) with over 20% improvement in prediction accuracy over the Global Model. Additionally, the Multi-level Model outperforms all but one Per-Intent Model, with performance improvement ranging from 4-14% in terms of prediction accuracy across different intents, while giving comparable performance to the last intent. This shows that the Multi-level Model is able to leverage insights from other intents, which in turn help boost the performance of other intents.

Additionally, we also observe that some intents are easier to predict than others, with intent 1 being the hardest to predict satisfaction for. Indeed, intent 1 sessions are of users who do not particularly have any intent in mind, and had a homepage session because it was the first page shown to them, so they could have any intent while interacting. This makes it harder for the system to predict satisfaction. It is important to note that an intent-specific model works best for certain intents (e.g. Intents 5 & 8) which suggests that the intent specific interaction data is powerful enough in itself, and doesn't gain much from shared learnign across intents. However, the shared learning across intents via the multi-level model is more generally beneficial to most intents and gives improved performance for 7 out of 8 intents. Moreover, maintaining separate intent level models is a demanding engineering task, while the shared multi-level model provides a sweet middle-ground whcih is relatively easier to manage and support from a large scale engineering perspective.

6.4 Importance of Interaction Features

We next investigate the different types of interaction signals considered and analyse their importance in prediction satisfaction. Table 5 presents accuracy results for different groups of interaction signals considered, for all three models. We omit displaying results for the Global - intent Model due to space constraints. We bold the best

Table 5: Comparing the importance of different interaction signals using different satisfaction prediction models using prediction accuracy. * and & indicates statistical significant ($p \leq 0.05$) using paired t-tests compared to Downstream and Temporal baselines respectively.

Interaction Features	Global	Intent 1	Intent 2	Intent 3	Intent 4	Intent 5	Intent 6	Intent 7	Intent 8	Multilevel
Downstreams	0.528	0.556	0.568	0.555	0.525	0.599	0.593	0.641	0.551	0.605
Surface	0.522	0.548	0.546	0.512	0.572	0.550	0.556	0.544	0.595	0.576
Temporal	0.554	0.655	0.639	0.641	0.515	0.756	0.732	0.735	0.754	0.746
Metrics	0.541	0.602	0.593	0.578	0.663	0.711	0.662	0.639	0.712	0.723
Downstreams + Surface	0.523	0.564	0.565	0.560	0.602	0.582	0.586	0.597	0.561	0.598
Downstreams + Temporal	0.560	0.672	0.655	0.649	0.579	0.772	0.746	0.747	0.752	0.781
Temporal + Metrics	0.569	0.660	0.638	0.650	0.668	0.792	0.718	0.725	0.743	0.795
Downstream + Surface + Temporal + Metrics	**0.571**$^{*\&}$	**0.675**$^{*\&}$	**0.666**$^{*\&}$	**0.672**$^{*\&}$	**0.675**$^{*\&}$	**0.811**$^{*\&}$	**0.760**$^{*\&}$	**0.771**$^{*\&}$	**0.769**$^{*\&}$	**0.804**$^{*\&}$

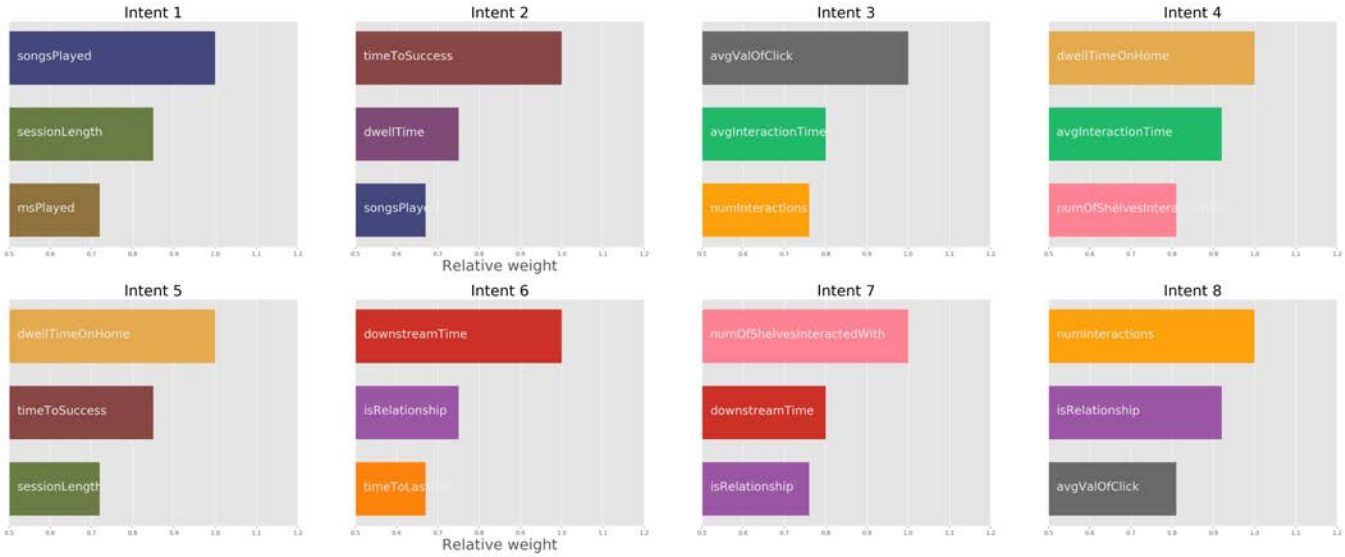

Figure 6: Relative weights of the top 3 predictive features across all eight intents.

performing features for each prediction model. We observe that whereas temporal signals are more important than other types of signals for most intents, surface signals such as number of slates interacted with and depth are important for Intent 4 (play music matching mood). This highlights that different types of signals are important for different intents, which supports the analysis presented in Figure 3 that showed interaction signals to differ based on user intent. Additionally, we observe that the Downstream group of signals performs better for Intent 7 (save new music or follow playlist), than it does for other intents, with 6-10% better predictive performance. Indeed, downstream signals help capture user activity related to saving music and exploring artists in detail, which is what Intent 7 is focusing on.

Finally, we observe a sharp increase in predictive performance when combining downstream and temporal signals, with over 10% performance jumps when compared to any individual signal group. We also observe that even in the case of different signal groups, Per-Intent and Multi-level models performs significantly better than the Global Model. Finally, combining different signals helps in improving satisfaction prediction accuracy by over 10%-15% for most intents.

Importance of signals across intents. To gain insights into which interaction signal is most useful across different intents, we present the top three signals and report their relative feature weight across all eight intents in Figure 6. As expected, we observe that the signals are important to varying degree across different intents. For the case where the user wants to quickly access saved music, signals like time to success and dwell time are most informative, while they are not informative for cases where the user wants to play music in the background. For intents where users wish to explore artists in more detail, signals involving the users building relationships (i.e. saved or downloaded tracks) are shown to be more important.

The variation of the most informative signals across the different intents highlight the fact that different signals are indeed important to different extent for different use cases. These results clearly emphasize the need for modeling intent while interpreting user interactions for predicting user satisfaction.

7 CONCLUSIONS

Given the *query-less paradigm* of slate recommendation, it becomes non-trivial to understand user intents. Based on a mixed-methods approach composed of interviews, in-app survey and non-parametric clustering, we identified eight key user intents, and experimentally demonstrated the importance of explicitly considering these intents when predicting user satisfaction. Our results also indicate that different interaction signals are important to varying extent across intents. Furthermore, the significant improvement in prediction results advocate not only the need for grouping user

sessions into intent groups for predicting satisfaction, but also for shared learning across all intents via the Multi-level Model. We contend that the methodology adopted in this work to identify user intents: interviews, in-app survey and quantitative modeling would provide firm starting grounds for researchers to think about user intents in other recommendation scenarios where it is prohibitively challenging to extract unspecified user intents.

Limitations & Future Work. While our findings are more generally applicable beyond just music streaming domain, a few interesting challenges remain, which serve as useful directions for future work. While we leveraged the intent labels provided by survey responders, these labels are not readily available at run time for user sessions. This motivates the need for developing an intent prediction module to predict the intent for each user session. The current study also operates under the assumption of each session having one intent, which may not always be correct, since user intents might change within a session. Development of intent boundary detection or intent switching prediction modules would help in eliminating this assumption. Additionally, the model would need to cater to intents changing over time, and across contexts. Finally, we did not incorporate user specific intricacies in our formulation, but we believe that user interaction is conditional on user groups, and differ user segments interact differently. Incorporating such user level idiosyncrasies would be a fruitful direction.

ABSTRACT

To provide stable and responsive public SPARQL query services, data providers enforce quotas on server usage. Queries which exceed these quotas are interrupted and deliver partial results. Such interruption is not an issue if it is possible to resume queries execution afterward. Unfortunately, there is no preemption model for the Web that allows for suspending and resuming SPARQL queries. In this paper, we propose SaGe: a SPARQL query engine based on Web preemption. SaGe allows SPARQL queries to be suspended by the Web server after a fixed time quantum and resumed upon client request. Web preemption is tractable only if its cost in time is negligible compared to the time quantum. The challenge is to support the full SPARQL query language while keeping the cost of preemption negligible. Experimental results demonstrate that SaGe outperforms existing SPARQL query processing approaches by several orders of magnitude in term of the average total query execution time and the time for first results.

1 INTRODUCTION

Context and motivation: Following the Linked Open Data principles (LOD), data providers published billions of RDF triples [5, 24]. However, providing a public service that allows anyone to execute any SPARQL query at any time is still an open issue. As public SPARQL query services are exposed to an unpredictable load of arbitrary SPARQL queries, the challenge is to ensure that the service remains *available* despite variation in terms of the arrival rate of queries and *resources* required to process queries.

To overcome this problem, most public LOD providers enforce a fair use service policy based on *quotas* [3]. According to DBpedia administrators:"A Fair Use Policy is in place in order to provide a stable and responsive endpoint for the community."[1] The public DBpedia SPARQL endpoint [2] Fair Use Policy prevents the execution of SPARQL longer than 120 seconds or that return more than 10000 results, with a limit of 50 concurrent connections and 100 requests per second per IP address. Quotas aim to share fairly server resources among Web clients. Quotas on communications limit the arrival rate of queries per IP. Quotas on space prevent one query to consume all the memory of the server. Quotas on time aim to avoid the *convoy phenomenon* [6], *i.e.*, a long-running query will slow down a short-running one, in analogy with a truck on a single-lane road that creates a convoy of cars. The main drawback of quotas is that *interrupted queries can only deliver partial results, as they cannot be resumed.* This is a serious limitation for Linked Data consumers, that want to execute long-running queries [22].

Related works: Existing approaches address this issue by decomposing SPARQL queries into subqueries that can be executed under the quotas and produce complete results [4]. Finding such decomposition is hard in the general case, as quotas can be different from one server to another, both in terms of values and nature [4]. The Linked Data Fragments (LDF) approach [17, 27] tackles this issue by restricting the SPARQL operators supported by the server. For example, in the Triple Pattern Fragments (TPF) approach [27], a TPF server only evaluates triple patterns. However, LDF approaches generate a large number of subqueries and substantial data transfer.

Approach and Contributions: We believe that the issue related to time quotas is not interrupting a query, but the impossibility for the client to *resume* the query execution afterwards. In this paper, we propose SaGe, a SPARQL query engine based on Web preemption. Web preemption is the capacity of a Web server to suspend a running query after a time quantum with the intention to resume it later. When suspended, the state S_i of the query is returned to the Web client. Then, the client can resume query execution by sending S_i back to the Web server.

Web preemption adds an overhead for the Web server to suspend the running query and resume the next waiting query. Consequently, the main scientific challenge here is to keep this overhead marginal whatever the running queries, to ensure good query execution performance. The contributions of this paper are as follows:

- We define and formalize a *Web preemption* model that allows to suspend and resume SPARQL queries.
- We define a set of preemptable query operators for which we bound the complexity of suspending and resuming of these operation, both in time and space. This allows to build a preemptive Web server that supports a large fragment of the SPARQL query language.
- We propose SaGe, a SPARQL query engine, composed of a preemptive Web server and a smart Web client that allows executing full SPARQL queries[3].

- We compare the performance of the SaGe engine with existing approaches used for hosting public SPARQL services. Experimental results demonstrate that SaGe outperforms existing approaches by several orders of magnitude in term of the average total query execution time and the time for first results.

This paper is organized as follows. Section 2 summarizes related works. Section 3 defines the Web preemption execution model and details the SaGe server and the SaGe client. Section 4 presents our experimental results. Finally, conclusions and future work are outlined in Section 5.

2 RELATED WORKS

SPARQL endpoints. SPARQL endpoints follow the SPARQL protocol [4], which "describes a means for conveying SPARQL queries and updates to a SPARQL processing service and returning the results via HTTP to the entity that requested them". Without quotas, SPARQL endpoints execute queries using a First-Come First-Served (FCFS) execution policy [10]. Thus, by design, they can suffer from *convoy effect* [6]: one long-running query occupies the server resources and prevents other queries from executing, leading to long waiting time and degraded average completion time for queries.

To prevent convoy effect and ensure a fair sharing of resources among end-users, most SPARQL endpoints configure quotas on their servers. They mainly restrict the arrival rate per IP address and limit the execution time of queries. Restricting the arrival rate allows end-users to retry later, however, limiting the execution time leads some queries to deliver only partial results. To illustrate, consider the SPARQL query Q_1 of Figure 1. Without any quota, the total number of results of Q_1 is 35 215, however, when executed against the DBpedia SPARQL endpoint, we found only 10 000 results out of 35 215 [5].

Delivering partial results is a serious limitation for a public SPARQL service. In SaGe, we deliver complete results whatever the query. In some way, quotas interrupt queries without giving the possibility to resume their execution. SaGe also interrupts queries, but allows data consumers to resume their execution later on.

Decomposing queries and restricting server interfaces. Evaluation strategies [4] have been studied for federated SPARQL queries evaluated under quotas. Queries are decomposed into a set of subqueries that can be fully executed under quotas. The main drawbacks of these strategies are: (i) They need to know which quotas are configured. Knowing all quotas that a data provider can implement is not always possible. (ii) They can only be applied to a specific class of SPARQL queries, *strongly bounded SPARQL queries*, to ensure complete and correct evaluation results.

The Linked Data Fragments (LDF) [17, 27] restrict the server interface to a fragment of the SPARQL algebra, to reduce the complexity of queries evaluated by the server. LDF servers are no more compliant with the W3C SPARQL protocol, and SPARQL query processing is distributed between smart clients and LDF servers. Hartig et al. [17] formalized this approach using Linked Data Fragment machines (LDFMs). The Triple Pattern Fragments (TPF) approach [27] is one implementation of LDF where the server only evaluates *paginated triple pattern queries*. As paginated triple pattern queries can be evaluated in bounded time [18], the server does not suffer from the convoy effect. However, as joins are performed on the client, the intensive transfer of intermediate results leads to poor SPARQL query execution performance. For example, the evaluation of the query Q_1, of Figure 1, using the TPF approach generates 507156 subqueries and transfers 2Gb of intermediate results in more than 2 hours. The Bindings-Restricted Triple Pattern Fragments (BrTPF) approach [15] improves the TPF approach by using the bind-join algorithm [14] to reduce transferred data but joins still executed by the client. In this paper, we explore how Web preemption allows the server to execute a larger fragment of the SPARQL algebra, including joins, without generating convoy effects. Processing joins on server side allow to drastically reduce transferred data between client and server and improve significantly performance. For example, SaGe executes the query Q_1 of Figure 1 in less than 53s, with 553 requests and 2.1Mb transferred.

Preemption and Web preemption. FCFS scheduling policies and the convoy effect [6] have been heavily studied in operating systems. In a system where the duration of tasks vary, a long-running task can block all other tasks, deteriorating the average completion time for all tasks. The *Round-Robin* (RR) algorithm [19] provides a fair allocation of CPU between tasks, avoids convoy effect, reduces the waiting time and provides good responsiveness. RR runs a task for a given *time quantum*, then suspends it and switches to the next task. It repeatedly does so until all tasks are finished. The value of this time quantum is critical for performance: when too high, RR behaves like FCFS with the same issues, and when its too low, the overhead of context switching dominates the overall performance. The action of suspending a task with the intention of resuming it later is called preemption. In public Web servers, preemption is already provided by the operating systems, but *only between running tasks*, excluding those waiting in the server's queue. If we want to build a fully *preemptive Web server*, we need to consider the queries sent to the server as the tasks and the Web server as the resource that tasks competed to get access to. In this paper, we explore how preemption can be defined at the Web level to execute SPARQL queries.

3 WEB PREEMPTION APPROACH

We define *Web preemption* as the capacity of a Web server to suspend a running query after a fixed quantum of time and resume the next waiting query. When suspended, partial results and the state of the suspended query S_i are returned to the Web client [6]. The client can resume query execution by sending S_i back to the Web server. Compared to a First-Come First-Served (FCFS) scheduling policy,

[4] https://www.w3.org/TR/2013/REC-sparql11-protocol-20130321/

[5] All results were obtained on DBpedia version 2016-04.

[6] S_i can be returned to the client or saved server-side and returned by reference.

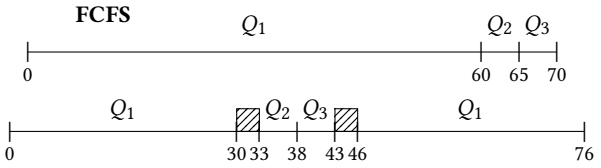

Figure 2: First-Come First-Served (FCFS) policy compared to Web Preemption (time quantum of 30s and overhead of 3s).

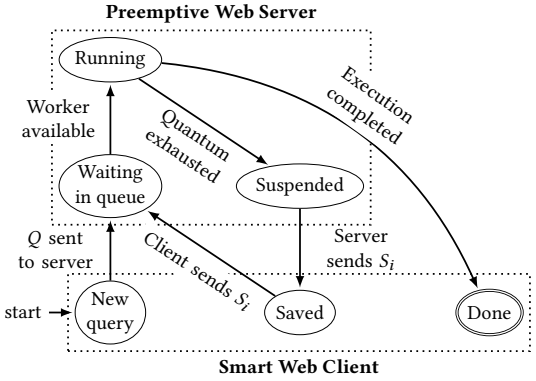

Figure 3: Possible states of a query execution in a preemptive Web Server.

Web preemption provides *a fair allocation of Web server resources across queries, a better average query completion time per query and a better time for first results* [2]. To illustrate, consider three SPARQL queries Q_1, Q_2, and Q_3 submitted concurrently by three different Web clients. Q_1, Q_2, Q_3 execution times are respectively 60s, 5s and 5s. Figure 2 presents a possible execution of these queries with a FCFS policy on the first line. In this case, the throughput of FCFS is $\frac{3}{70} = 0.042$ queries per second, the average completion time per query is $\frac{60+65+70}{3} = 65s$ and the average time for first results is also 65s. The second line describes the execution of $Q_1 - Q_3$ using Web preemption, with a time quantum of 30s. We consider a preemption overhead of 3s (10% of the quantum). In this case, the throughput is $\frac{3}{76} = 0.039$ query per second but the average completion time per query is $\frac{76+38+43}{3} = 52.3s$ and the average time for first results is approximately $\frac{30+38+43}{3} = 37s$. If the quantum is set to 60s, then Web preemption is equivalent to FCFS. If the quantum is too low, then the throughput and the average completion time are deteriorated.

Consequently, the challenges with Web preemption are *to bound the preemption overhead in time and space* and *determine the time quantum* to amortize the overhead.

3.1 Web Preemption Model

We consider a *preemptive Web server*, hosting RDF datasets, and a *smart Web client*, that evaluates SPARQL queries using the server. For the sake of simplicity, we only consider *read-only queries* [7] in this paper. The server has a pool of *server workers* parameterized with a fixed time quantum. Workers are in charge of queries execution. The server has also a *query queue* to store incoming queries when all workers are busy. We consider an *infinite* population of clients, a *finite* server queue and a *finite* number of Web workers.

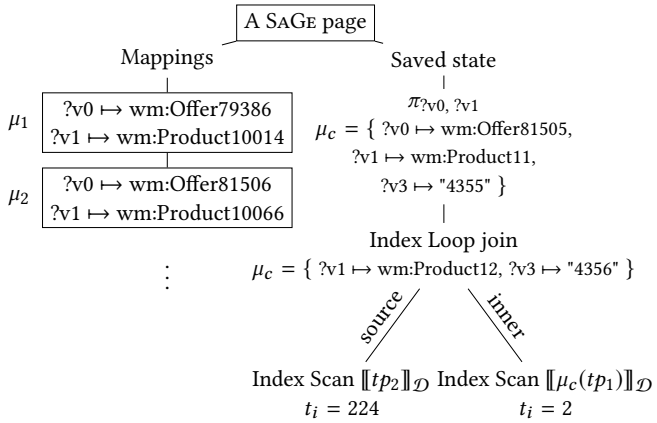
The preemptive Web server suspends and resumes queries after the time quantum. A running query Q_i is represented by its *physical query execution plan*, denoted P_{Q_i}. Suspending the execution of Q_i is an operation applied on P_{Q_i} that produces a *saved state* S_i; $\texttt{Suspend}(P_{Q_i}) = S_i$. Resuming the execution of a query Q_i is the inverse operation, it takes S_i as parameter and restores the physical query execution plan in its suspended state. Therefore, the preemption is correct if $\texttt{Resume}(\texttt{Suspend}(P_{Q_i})) = P_{Q_i}$.

Figure 3 presents possible states of a query. The transitions are executed either by the Web server or by the client.

The Web server accepts, in its waiting queue, Web requests containing either SPARQL queries Q_i, or suspended queries S_i. If a worker is available, it picks a query in the waiting queue. For Q_i, the worker produces a physical query execution plan P_{Q_i} using the *optimize-then-execute* [12] paradigm and starts its execution for the time quantum. For S_i, the server resumes the execution of Q_i. The time to produce or resume the physical query execution plan for a query is not deducted from the quantum.

If a query terminates before the time quantum, then results are returned to the Web client. If the time quantum is exhausted and the query is still running, then the Suspend operation is triggered, producing a state S_i which is returned to the Web client with partial results. The time to suspend the query is not deducted from the quantum. Finally, the Web client is free to continue the query execution by sending S_i back to the Web server.

The main source of overhead in this model is the time and space complexity of the Suspend and Resume operations, *i.e.*, time to stop and save the running query followed by the time to resume the next waiting query. Our objective is to bound these complexities such that they depend only on the *query complexity*, *i.e.*, the number of operations in the query plan. Consequently, *the problem is to determine which physical query plans P_{Q_i} have a preemption overhead bounded in $O(|Q|)$*, where $|Q|$ denotes the number of operators in the expression tree of P_{Q_i}.



3.2 Suspending and Resuming Physical Query Execution Plans

The Suspend operation is applied to a running physical query execution plan P_{Q_i}. It is obtained from the logical query execution plan of Q_i by selecting physical operators that implement operators in the logical plan [11]. A running P_{Q_i} can be represented as an expression tree of physical operators where each physical operator has a state, *i.e.*, all internal data structures allocated by the operator. Suspending a plan P_{Q_i} requires to traverse the expression tree of the plan and save the state of each physical operator. To illustrate, consider the execution of query Q_2 in Figure **??**. The state of P_{Q_2} can be saved as described in Figure **??**: the state of the Scan operator is represented by the *id* of the last triple read t_i, the state of the Index Loop Join operator is represented by mappings pulled from the previous operator and the state of the inner scan of tp_1.

[7] Preemption and concurrent updates raise issues on correctness of results.

```

 ?v1 schema:contentSize ?v3. # tp2
}
```

(a) SPARQL query Q_2, from the Waterloo SPARQL Diversity Test suite benchmark [1]

(b) One page returned by the SaGe server during Q_2 evaluation.

Figure 4: A tree representation of a page returned by the SaGe server when executing SPARQL query Q_2 with the saved plan passed by value.

Suspending and resuming a physical query execution plan raise several major issues.

Suspending physical operators in constant time. Bounding the time complexity of $Suspend(P_{Q_i})$ to $O(|Q_i|)$ requires to save the state of all physical operators in constant time. However, *some physical operators need to materialize data*, *i.e.*, build collections of mappings collected from other operators to perform their actions. We call these operators *full-mappings* operators, in opposition to *mapping-at-a-time* operators that only need to consume one mapping at a time from child operators[8]. Saving the state of full-mappings operators cannot be done in constant time. To overcome this problem, we distribute operators between a SaGe server and a SaGe smart client as follows:

- *Mapping-at-a-time* operators are suitable for Web preemption, so they are supported by the SaGe server. These operators are a subset of CoreSPARQL [17], composed of Triple Patterns, AND, UNION, FILTER and SELECT. We explain how to implement these operators server-side in Section 3.3.
- *Full-mappings* operators do not support Web preemption, so they are implemented in the SaGe smart client. These operators are: OPTIONAL, SERVICE, ORDER BY, GROUP BY, DISTINCT, MINUS, FILTER EXIST and aggregations (COUNT, AVG, SUM, MIN, MAX). We explain how to implement these operators in the smart client in Section 3.4.

[8]This is a clear reference to *full-relation* and *tuple-at-a-time* operators in database systems [11][Chapter 15.2]

As proposed in LDF [17, 27], the collaboration of the SaGe smart client and the SaGe server allows to support full SPARQL queries.

Communication between operators. Bounding the time complexity of $Suspend(P_{Q_i})$ to $O(|Q_i|)$ requires to avoid materialization of intermediate results when physical operators communicate. This only concerns operators of the SaGe server. To solve this issue, we follow *the iterator model* [12, 13]. In this model, operators are connected in a *pipeline*, where they are chained together in a *pull-fashion*, such as one iterator pulls solution mappings from its predecessor(s) to produce results.

Saving consistent states of the physical query plan. Some physical query operators have critical sections and cannot be interrupted until exiting those sections. Saving the physical plan in an inconsistent state leads to incorrect preemption. In other words, we could have $Resume(Suspend(P_{Q_i})) \neq P_{Q_i}$. To solve this issue, we have to detail, for each physical operator supported by the SaGe server, where are located critical sections and estimate if the waiting time for exiting the critical section is acceptable.

Resuming physical operators in constant time. Reading a saved plan as the one presented in Figure **??** should be in $O(|Q|)$. The *Index Scan* $[\![tp_2]\!]_{\mathcal{D}}$ has been suspended after reading the triple with $id = 224$. Resuming the scan requires that the access to the triple with $id \geq 224$ is in constant time. This can be achieved with adequate indexes. To solve this issue, we have to define clearly for each physical operator what are the requirements on backend to bound the overhead of resuming.

3.3 The SaGe Preemptable Server

The SaGe server supports Triple Patterns, AND, UNION, FILTER and SELECT operators. The logical and physical query plans are builds thanks to the *optimize-then-execute* [12] paradigm. The main issues here are the cost of the `Suspend` and `Resume` operations on the physical plan and how to interrupt physical operators.

To support preemption, we extend classical iterators to *preemptable iterators*, formalized in Definition 3.1. As iterators are connected in a pipeline, we consider that each iterator is also responsible for recursively stopping, saving and resuming its predecessors.

Definition 3.1 (Preemptable iterator). A *preemptable iterator* is an iterator that supports, in addition to the classic `Open`, `GetNext` and `Close` methods [13], the following methods:

- `Stop`: interrupts the iterator and its predecessor(s). `Stop` waits for all non interruptible sections to complete.
- `Save`: serializes the current state of the iterator and its predecessor(s) to produce a *saved state*.
- `Load`: reloads the iterator and its predecessor(s) from a saved state.

Algorithm 1 presents the implementation of the `Suspend` and `Resume` functions for a pipeline of preemptable query iterators. `Suspend` simply stops and saves recursively each iterator in the pipeline and `Resume` reloads the pipeline in the suspended state using a serialized state. To illustrate, consider the SaGe page of Figure **??**. This page contains the plan that evaluates the SPARQL query Q_2 of size $|Q_2| = 4$, using *index loop joins* [12]. The evaluation of tp_2 has been preempted after scanning 224 solution mappings.

Algorithm 1: Implementation of the `Suspend` and `Resume` functions following the iterator model

Require: $\mathcal{I}$: pipeline of iterators, S: serialized pipeline state (as generated by `Suspend`)

```
1 Function Suspend(I):
2     let root←first iterator in I
3     Call root.Stop()
4     return root.Save()
5 Function Resume(I, S):
6     let root←first iterator in I
7     Call root.Load(S)
8     return I
```

Table 1: Complexities of preemption of physical query iterators. $|id|$ and $|tp|$ denote the size of encoding an index key and a triple pattern, respectively.

Preemptable iterator	Space complexity of local state	Time complexity of loading local state	Remarks
$\pi_{v_1,\ldots,v_k}(P)$	$O(k + \|var(P)\|)$	$O(1)$	
Index Scan tp	$O(\|tp\| + \|id\|)$	$O(\log_b(\|\mathcal{D}\|))$	Require indexes on all kinds of triple patterns
Merge Join $P_1 \bowtie P_2$	$O(\|var(P_1)\| + \|var(P_2)\|)$	$O(1)$	
Index Loop Join $P \bowtie tp$	$O(\|var(P)\| + \|tp\| + \|id\|)$	$O(\log_b(\|\mathcal{D}\|))$	
P_1 UNION P_2	$O(1)$	$O(1)$	Multi-set Union
P Filter $\mathcal{R}$	$O(\|var(P)\| + \|\mathcal{R}\|)$	$O(1)$	Pure logical expression only
Server physical plan	$O(\|Q\| \times \log_2(\|\mathcal{D}\|)$	$O(\|Q\| \times \log_b(\|\mathcal{D}\|))$	

The index loop join with tp_1 has been preempted after scanning two triples from the inner loop.

In the following, we review SPARQL operators implemented by the SaGe server as preemptable query iterators. We modify the regular implementations of these operators to include non interruptible section when needed. Operations left unchanged are not detailed. Table 1 resumes the complexities related to the preemption of server operators, where $var(P)$ denotes the set of variables in P as defined in [21].

Algorithm 2: A *Preemptable Select Iterator*

Require: $V = \{v_1, \ldots, v_k\}$: projection variables, $\mathcal{I}$: predecessor in the pipeline

Data: $\mu \leftarrow nil$

```
1 Function GetNext():
2     if μ = nil then
3         μ ← I.GetNext()
4     non interruptible
5         let μ' ← Proj(μ, V)
6         μ ← nil
7         return μ'
8 Function Save():
9     return μ
10 Function Load(μ'):
11    μ ← μ'
```

SELECT operator. : The projection operator $\pi_V(P)$ [25], also called SELECT, performs the projection of mappings obtained from its predecessor P according to a set of projection variables $V = \{v_1, \ldots, v_k\}$. Algorithm 2 gives the implementation of this iterator. In this algorithm, Lines 4-7 are non-interruptible. This is necessary to ensure that the operator does not discard mappings without applying projection to them. Consequently, after the termination of $Suspend(P)$, $\pi_V(P)$ can be suspended in $O(k + |var(P)|)$ in space. The projection iterator reloads its local state in $O(1)$.

Triple Pattern: The evaluation of a triple pattern tp over D $[\![tp]\!]_{\mathcal{D}}$ [21] is the set of solution mappings of tp. μ is a solution mapping if $\mu(tp) = t$ where t is the triple obtained by replacing the variables in tp according to μ, such that $t \in \mathcal{D}$. The evaluation of $[\![tp]\!]_{\mathcal{D}}$ requires to read $\mathcal{D}$ and produce the corresponding set of solutions mappings.

The triple pattern operator supposes that data are accessed using *index scans* and a clustered index [11]. Algorithm 3 gives the implementation of a preemptable index scan for evaluating a triple pattern. We omitted the `Stop()` operation, as the iterator does not need to do any action to stop. The `Save()` operation stores the triple pattern tp and the index's $id(t)$ of the last triple t read. Thus, suspending an index scan is done in constant time and the size of the operator state is in $O(|tp| + |id(t)|)$.

The `Load()` operation uses the saved index's $id(t)$ on tp to find the last matching RDF triple read. The time complexity of this operation predominates the time complexity of `Resume`. This complexity depends on the type of index used. With a B+-tree [7], the time complexity of resuming is bound to $O(\log_b(|\mathcal{D}|))$. B+-tree indexes are offered by many RDF data storage systems [8, 20, 28].

Algorithm 3: A *Preemptable Index Scan Iterator*, evaluating a triple pattern tp using an index

Require: tp: triple pattern, $\mathcal{D}$: RDF dataset queried, $\mathcal{I}_{tp}$: clustered index over tp

Data: t: last matching RDF triple read

```
1 Function GetNext():
2     non interruptible
3         t ← next RDF triple matching tp in D
4         let μ ← set of solutions mappings such as μ(t) = tp
5         return μ
6 Function Save():
7     return ⟨tp, id(t)⟩
8 Function Load(id):
9     t ← I_tp.Locate(id)  // Locate the last triple read
```

Basic Graph patterns (AND):. A Basic Graph pattern (BGP) evaluation corresponds to the natural join of a set of triple patterns. Join operators fall into three categories [11]: (1) Hash-based joins *e.g.*, Symmetric Hash join or XJoin, (2) Sort-based joins, *e.g.*, (Sort) Merge join, (3) Loop joins, *e.g.*, index loop or nested loop joins.

Hash-based joins [12, 29] operators are not suitable for preemption. As they build an in-memory hash table on one or more inputs to evaluate the join, they are considered as full-mappings operators. The sort-based joins and loop joins are mapping-at-a-time operators; consequently, they could be preempted with low overhead. However, for sort-based joins, we can only consider merge joins, *i.e.*, joins inputs are already sorted on the join attribute. Otherwise, this will require to perform an in-memory sort on the inputs. In the

following, we present algorithms for building preemptable Merge join and preemptable Index Loop join operators:

Algorithm 4: A *Preemptable Merge Join Iterator* I, joining the output of two iterators I_{left} and I_{right}.

Require: I_{left}: the outer join input, I_{right}: the inner join input, μ_l: the last element read from I_{left}, μ_r: the last element read from I_{right}, $\mathcal{D}$: RDF dataset queried

Function *Stop()*:
  I_{left}.Stop()
  I_{right}.Stop()
Function *Save()*:
  let $s_l \leftarrow I_{\text{left}}$.Save()
  let $s_r \leftarrow I_{\text{right}}$.Save()
  return $\langle s_l, s_r, \mu_l, \mu_r \rangle$
Function *Load*(s_l, s_r, μ'_l, μ'_r):
  I_{left}.Load(s_l)
  I_{right}.Load(s_r)
  $\mu_l \leftarrow \mu'_l$
  $\mu_r \leftarrow \mu'_r$

Algorithm 5: A *Preemptable Index Join Iterator* I_i: a preemptable join operator used by SaGe for BGP evaluation

Require: I_{left}: the iterator responsible for the evaluation of the outer join input, tp_r: the inner join input, $\mathcal{D}$: RDF dataset queried.

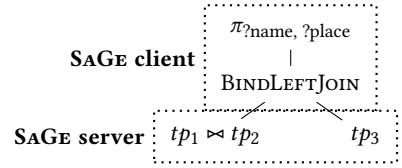
Function *Open()*:
  I_{left}.*Open*()
  $\mu_c \leftarrow nil$
  $I_{\text{find}} \leftarrow$ a *PreemptableIndexScanIterator* over $\emptyset$
Function *GetNext()*:
  while $\neg I_{find}.HasNext()$ **do**
    $\mu_c \leftarrow I_{\text{left}}.GetNext()$
    if $\mu_c = nil$ **then**
      return *nil*
    $I_{\text{find}} \leftarrow$ *PreemptableIndexScanIterator* over $[\![\mu_c(tp_r)]\!]_{\mathcal{D}}$
  non interruptible
    let $\mu \leftarrow I_{\text{find}}.GetNext()$
    return $\mu \cup \mu_c$
Function *Load*(tp', μ', t):
  $tp_r \leftarrow tp'$
  if $\mu' \neq nil$ **then**
    $\mu_c \leftarrow \mu'$
    $I_{\text{find}} \leftarrow$ *PreemptableIndexScanIterator* over $[\![\mu_c(tp_i)]\!]_{\mathcal{D}}$
    I_{find}.Load(t);
Function *Save()*:
  let $t \leftarrow$ the last triple read by I_{find}
  return $\langle tp_r, \mu_c, t \rangle$
Function *Stop()*:
  $I_{\text{left}}.Stop()$
  $I_{\text{find}}.Stop()$

Preemptable merge join: The Merge join algorithm merges the solutions mappings from two join inputs, *i.e.*, others operators sorted on the join attribute. SaGe extends the classic merge join [12] to the *Preemptable Merge join* iterator as shown in Algorithm 4. Basically, its `Stop`, `Save` and `Load` functions recursively stop, save or load the joins inputs, respectively. Thus, the only internal data structures holds by the join operator are the two inputs and the last sets of solution mappings read from them. As described in Table 1, the local state of a merge join is resumable in constant time, while its space complexity depends on the size of two sets of solution mappings saved.

Preemptable Index Loop join: The Index Loop join algorithm [12] exploits indexes on the inner triple pattern for efficient join processing. This algorithm has already been used for evaluating BGPs in [16]. SaGe extends the classic Index Loop joins to a *Preemptable Index join Iterator* (PIJ-Iterator) presented in Algorithm 5. To produce solutions, the iterator executes the same steps repeatedly until all solutions are produced: (1) It pulls solutions mappings μ_c from its predecessor. (2) It applies μ_c to tp_i to generate a *bound pattern* $b = \mu_c(tp_i)$. (3) If b has no solution mappings in $\mathcal{D}$, it tries to read again from its predecessor (jump back to Step 1). (4) Otherwise, it reads triple matching b in $\mathcal{D}$, produces the associated set of solution mappings and then goes back to Step 1.

A *PIJ-Iterator* supports preemption through the `Stop`, `Save` and `Load` functions. The non-interruptible section of `GetNext()` only concerns a scan in the dataset. Therefore, in the worse case, the iterator has to wait for one index scan to complete before being interruptible. As with the merge join, the `Save` and `Load` functions needs to stop and resume the left join input. The latter also needs to resume an Index Scan, which can be resumed in $O(\log_b(|\mathcal{D}|)$.

Regarding the saved state, the iterator saves the triple pattern joined with the last set of solution mappings pulled from the predecessor and an index scan. For instance, in Figure **??**, the saved state of the join of tp_2 and tp_1 is μ_c = {`?v1` ↦ `wm:Product12, ?v3` ↦ `"4356"`}.



UNION fragment: The UNION fragment is defined as the union of solution mappings from two graph patterns. We consider a *multi-set union* semantic, as set unions require to save intermediate results to remove duplicates and thus cannot be implemented as mapping-at-a-time operators. The set semantic can be restored by the smart Web client using the DISTINCT modifier on client-side. Evaluating a multi-set union is equivalent to the *sequential evaluation* of all graph patterns in the union. When preemption occurs, all graph patterns in the union are saved recursively. So the union has no local state on its own. Similarly, to resume an union evaluation, each graph pattern is reloaded recursively.

FILTER fragment: A SPARQL FILTER is denoted $F = \sigma_{\mathcal{R}}(P)$, where P is a graph pattern and $\mathcal{R}$ is a built-in filter condition. The evaluation of F yields the solutions mappings of P that verify $\mathcal{R}$. Some filter conditions require collection of mappings to be evaluated, like the EXISTS filter which requires the evaluation of a graph pattern. Consequently, we limit the filter condition to *pure logical expressions* (=, <, ≥, ∧, etc) as defined in [21, 25]. The preemption of a FILTER is similar to those of a projection. We only need to suspend or resume P, respectively. For the local state, we need to save the last solution mappings pulled from P and $\mathcal{R}$.

Table 1 summarizes the complexities of `Suspend` and `Resume` in time and space. The space complexity to `Save` a physical plan is established to $O(|Q| \times \log_2(|\mathcal{D}|))$. We supposed that $|var(P)|$ and the number of $|tp|$ to save are close to $|Q|$. However, the size of index

```

 ?actor rdfs:label ?name . # tp2
 OPTIONAL { ?actor dbo:birthPlace ?place . # tp3 }
}
```

(a) SPARQL query Q_3: finds all actors with their names and their birth places, if they exist.

(b) Client-side physical query execution plan.

Figure 5: Physical query execution plan used by the SaGe smart Web client for the query Q_3.

IDs are integers that can be as big as the number of RDF triples in $\mathcal{D}$. Hence, they can be encoded in at most $\log_2(|\mathcal{D}|)$ bits. The time complexity to `Resume` a physical plan is $O(|Q| \times \log_b(|\mathcal{D}|))$. It is higher than the time complexity of `Suspend`, as resuming index scans can be costly. Overall, the complexity of Web preemption is higher than the initial $O(|Q|)$ stated in Section 3.1. However, we demonstrate empirically in Section 4 that time and space complexity can be kept under a few milliseconds and kilobytes, respectively.

3.4 SaGe smart Web client

The SaGe approach requires a *smart Web client* for processing SPARQL queries for two reasons. First, the smart Web client must be able to continue query execution after receiving a saved plan from the server. Second, as the preemptable server only implements a fragment of SPARQL, the smart Web client has to implement the missing operators to support full SPARQL queries. It includes SERVICE, ORDER BY, GROUP BY, DISTINCT, MINUS, FILTER EXIST and aggregations (COUNT, AVG, SUM, MIN, MAX), but also $\bowtie$, $\cup$, $⟕$ and π to be able to recombine results obtained from the SaGe server. Consequently, the SaGe smart client is a *SPARQL query engine* that accesses RDF datasets through the SaGe server. Given a SPARQL query, the SaGe client parses it into a logical query execution plan, optimizes it and then builds its own physical query execution. The leafs of the plan must correspond to subqueries evaluable by a SaGe server. Figure **??** shows the execution plan build by the SaGe client for executing query Q_3, from Figure **??**.

Compared to a SPARQL endpoint, processing SPARQL queries with the SaGe smart client has an overhead in terms of the number of request sent to the server and transferred data[9]. With a SPARQL endpoint, a web client executes a query by sending a single web request and receives only query results. The smart client overhead for executing the same query is the additional number of request and data transfered to obtain the same results. Consequently, the client overhead has two components:

Number of requests: To execute a SPARQL query, a SaGe client needs $n \geq 1$ requests. We can distinguish two cases: (1) The query is fully supported by the SaGe server, so n is equal to the number of time quantum required to process the query. Notice that the client needs to pay the network latency twice per request. (2) The query is not fully supported by the SaGe server. Then, the client decomposes the query into a set of subqueries supported by the server, evaluate each subquery as in the first case, and recombine intermediate results to produce query results.

Data transfer:) We also distinguish two cases: (1) If the query is fully supported by the SaGe server, the only overhead is the size of the saved plan S_i multiplied by the number of requests. Notice that the saved plan S_i can be returned by reference or by value, *i.e.*, saved server-side or client-side. (2) If the query is not fully supported by the SaGe server, then the client decomposes the query and recombine results of subqueries. Among these results, some are intermediate results and part of the client overhead.

Consequently, the challenge for the smart client is to *minimize the overhead in terms of the number of requests and transferred data.* The data transfer could be reduced by saving the plans server-side rather than returning it to clients[10]. However, the main source of client overhead comes from the decomposition made to support full SPARQL queries, as these queries increase the number of requests sent to the server. Some decompositions are more costly than others. To illustrate, consider the evaluation of (P_1 OPTIONAL P_2) where P_1 and P_2 are expressions supported by the SaGe server. A possible approach is to evaluate $[\![P_1]\!]_{\mathcal{D}}$ and $[\![P_2]\!]_{\mathcal{D}}$ on the server, and then perform the left outer join on the client. This strategy generates only two subqueries but materializes $[\![P_2]\!]_{\mathcal{D}}$ on client. If there is no join results, $[\![P_2]\!]_{\mathcal{D}}$ are just useless intermediate results.

Another approach is to rely on a *nested loop join approach*: evaluates $[\![P_1]\!]_{\mathcal{D}}$ and for each $\mu_1 \in [\![P_1]\!]_{\mathcal{D}}$, if $\mu_2 \in [\![\mu_1(P2)]\!]_{\mathcal{D}}$ then $\{\mu_1 \cup \mu_2\}$ are solutions to $P_1 ⟕ P_2$. Otherwise, only μ_1 is a solution to the left-join. This approach sends *at least* as many subqueries to the server than there is solutions to $[\![P_1]\!]_{\mathcal{D}}$.

To reduce the communication, the SaGe client implements BindLeftJoins to process local join in a block fashion, by sending unions of BGPs to the server. This technique is already used in federated SPARQL query processing [26] with bound joins and in BrTPF [15]. Consequently, the number of request to the SaGe server is reduced by a factor equivalent to the size of a block of mappings. However, the number of requests sent still depends on the cardinality of P_1.

Consequently, we propose a new technique, called OptJoin, for optimizing the evaluation of a subclass of left-joins. The approach relies on the fact that:

$$[\![P_1 ⟕ P_2]\!]_{\mathcal{D}} = [\![P_1 \bowtie P_2]\!]_{\mathcal{D}} \cup ([\![P_1]\!]_{\mathcal{D}} \setminus [\![\pi_{var(P_1)}(P_1 \bowtie P_2)]\!]_{\mathcal{D}})$$

So we can deduce that: $[\![P_1 ⟕ P_2]\!]_{\mathcal{D}} \subseteq [\![(P_1 \bowtie P_2) \cup P_1]\!]_{\mathcal{D}}$. If both P_1 and P_2 are evaluable by the SaGe server, then the smart client computes the left-join as follows. First, it sends the query $(P_1 \bowtie P_2) \cup P_1$ to the server. Then, for each mapping μ received, it builds local materialized views for $[\![P_1 \bowtie P_2]\!]_{\mathcal{D}}$ and $[\![P_1]\!]_{\mathcal{D}}$. The client knows that $\mu \in [\![P_1 \bowtie P_2]\!]_{\mathcal{D}}$ if $dom(\mu) \subset var(P_1 \bowtie P_2)$, otherwise $\mu \in [\![P_1]\!]_{\mathcal{D}}$. Finally, the client uses the views to process the left-join locally. With this technique, the client only use one

[9] The client overhead should not be confused with the server overhead.

[10] In our implementation, we choose to save plans client-side to tolerate server failures.

subquery to evaluate the left-join and, in the worst case, it transfers $[\![P_1 \bowtie P_2]\!]_{\mathcal{D}}$ as additional intermediate results.

To illustrate, consider query Q_3 from Figure **??**. Q_3, with 88334 solutions. The cardinality of $tp_1 \bowtie tp_2$ is also of 88334, as every actor has a birth place. This is the worse case for a BindLeftJoin, which will require $\frac{88334}{Blocksize}$ additional requests to evaluate the left join. However, with an OptJoin, the client is able to evaluate Q_3 in approximately 500 requests.

We implement both BindLeftJoin and OptJoin as physical operators to evaluate OPTIONALs, depending on the query. We also implement regular BindJoin for processing SERVICE queries.

4 EXPERIMENTAL STUDY

We want to empirically answer the following questions: What is the overhead of Web preemption in time and space? Does Web preemption improves the average workload completion time? Does Web preemption improves the time for first results? What are the client overheads in terms of numbers of requests and data transfer? We use Virtuoso as the baseline for comparing with SPARQL endpoints, with TPF and BrTPF as the baselines for LDF approaches.

We implemented the SaGe client in Java, using Apache Jena[11]. As an extension of Jena, SaGe is just as compliant with SPARQL 1.1. The SaGe server is implemented as a Python Web service and uses HDT [9] (v1.3.2) for storing data. Notice that the current implementation of HDT cannot ensure $log_b(n)$ access time for all triple patterns, like (?s p ?o). This impacts negatively the performance of SaGe when resuming some queries. The code and the experimental setup are available on the companion website[12].

4.1 Experimental setup

Dataset and Queries: We use the Waterloo SPARQL Diversity Benchmark (WatDiv[13]) [1]. We re-use the RDF dataset and the SPARQL queries from the BrTPF [15] experimental study[14]. The dataset contains 10^7 triples and queries are arranged in 50 workloads of 193 queries each. They are SPARQL conjunctive queries with STAR, PATH and SNOWFLAKE shapes. They vary in complexity, up to 10 joins per query with very high and very low selectivity. 20% of queries require more than $\approx 30s$ to be executed using the virtuoso server. All workloads follow nearly the same distribution of query execution times as presented in Figure 6. The execution times are measured for one workload of 193 queries with SaGe and an infinite time quantum.

Approaches: We compare the following approaches:

- SaGe: We run the SaGe query engine with various time quantum: 75ms and 1s, denoted SaGe-75ms and SaGe-1s respectively. HDT indexes are loaded in memory while HDT data is stored on disk.
- *Virtuoso:* We run the Virtuoso SPARQL endpoint [8] (v7.2.4), *without any quotas or limitations* .
- *TPF:* We run the standard TPF client (v2.0.5) and TPF server (v2.2.3) with HDT files as backend (same settings as SaGe).

- *BrTPF:* We run the BrTPF client and server used in [15], with HDT files as backend (same settings as SaGe). BrTPF is currently the LDF approach with the lowest data transfer [15].

Servers configurations: We run all the servers on a machine with Intel(R) Xeon(R) CPU E7-8870@2.10GHz and 1.5TB RAM.

Clients configurations: In order to generate load over servers, we rely on 50 clients, each one executing a different workload of queries. All clients start executing their workload simultaneously. The clients access servers through HTTP proxies to ensure that client-server latency is kept around 50ms.

Evaluation Metrics: Presented results correspond to the average obtained of three successive execution of the queries workloads. (1) *Workload completion time (WCT)*: is the total time taken by a client to evaluate a set of SPARQL queries, measured as the time between the first query starting and the last query completing. (2) *Time for first results (TFR)* for a query: is the time between the query starting and the production of the first query's results. (3) *Time preemption overhead*: is the total time taken by the server's `Suspend` and `Resume` operations. (4) *Number of HTTP requests and data transfer*: is the total number of HTTP requests sent by a client to a server and the number of transferred data when executing a SPARQL query.

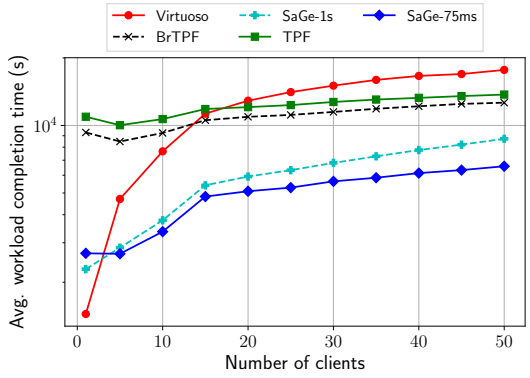

Figure 8: Average workload completion time per client, with up to 50 concurrent clients (logarithmic scale).

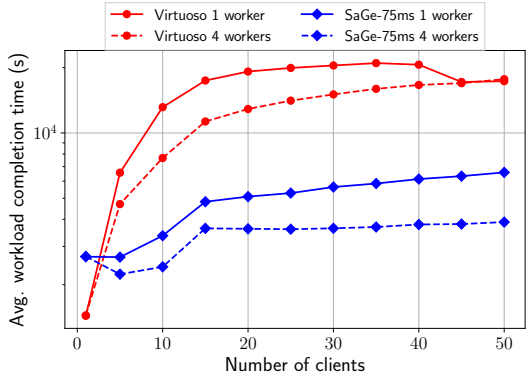

Figure 9: Average workload completion time per client, with 4 workers (logarithmic scale).

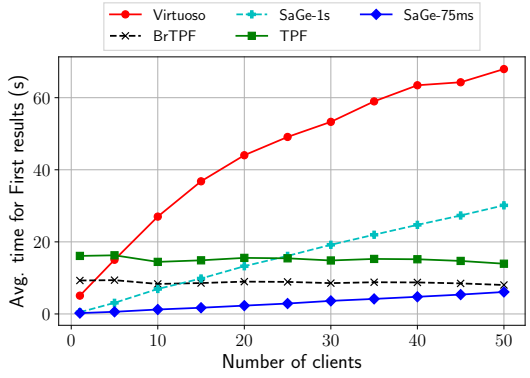

Figure 10: Average time for first results (over all queries), with up to 50 concurrent clients (linear scale).

4.2 Experimental results

We first ensure that the SaGe approach yield complete results. We run both Virtuoso and SaGe and verify that, for each query, SaGe delivers complete results using Virtuoso results as ground truth.

What is the overhead in time of Web preemption? The overhead in time of Web preemption is the time spent by the Web server for suspending a running query and the time spent for resuming the next waiting query. To measure the overhead, we run one workload of queries using SaGe-75ms and measure time elapsed for the `Suspend` and `Resume` operations. Figure 7 shows the overhead in time for SaGe `Suspend` and `Resume` operations using different sizes of the WatDiv dataset. Generally, the size of the dataset does not impact the overhead, which is around 1*ms* for `Suspend` and 1.5*ms* for `Resume`. As expected, the overhead of the `Resume` operation is greater than the one of the `Suspend` operation, due to the cost of resuming the Index scans in the plan. With a quantum of 75ms, the overhead is $\approx$ 3% of the quantum, which is negligible.

What is the overhead in space of Web preemption? The overhead in space of the Web preemption is the size of saved plans produced by the `Suspend` operation. According to Section 3.3, we determined that the SaGe physical query plans can be saved in $O(|Q|)$. To measure the overhead, we run a workload of queries using SaGe-75ms and measure the size of saved plans. Saved plans are compressed using Google Protocol Buffers [15]. Table 2 shows the overhead in space for SaGe. As we can see the size of a saved plan remains very small, with no more than 6 kb for a query with ten joins. Hence, this space is indeed proportional to the size of the plan suspended.

Does Web preemption improve the average workload completion time? To enable Web preemption, the SaGe server has a restricted choice of physical query operators, thus physical query execution plans generated by the SaGe server should be less performant than those generated by Virtuoso. This tradeoff only make sense if the Web preemption compensates the loss in performance. Compensation is possible only if the workload alternates long-running and short running queries. In the setup, each client runs a different workload of 193 queries that vary from 30s to 0.22s, following an exponential distribution. All clients execute their workload concurrently and start simultaneously. We experiment up to 50 concurrent clients by step of 5 clients. As there is only one worker on the Web server, and queries execution time vary, this setup is the worst case for Virtuoso.

Figure 8 shows the average workload completion time obtained for all approaches, *with a logarithmic scale*. As expected, Virtuoso is significantly impacted by the convoy effect and delivers the worse WTC after 20 concurrent clients. TPF and BrTPF avoid the convoy and behave similarly. BrTPF is more performant thanks to its bind-join technique that group requests to the server. SaGe-75ms and SaGe-1s avoid the convoy effect and delivers better WTC than TPF and BrTPF. As expected, increasing the time quantum also increases the probability of convoy effect and, globally, SaGe-75ms offers the best WTC. We rerun the same experiment with 4 workers for SaGe-75ms and Virtuoso. Figure 9 shows the average workload completion time obtained for both approaches. As we can see, both approaches benefit of the four workers. However, Virtuoso still suffers from the convoy effect.

Does Web preemption improve the time for the first results? The Time for first results (TFR) for a query is the time between the query starting and the production of the first query's results. Web

Table 3: Average number of HTTP requests sent to server

preemption should provides better time for first results. Avoiding convoy effect allows to start queries earlier and then get results earlier. We rerun the same setup as in the previous section and measure the time for first results (TFR). Figure 10 shows the results *with a linear scale*. As expected, Virtuoso suffers from the convoy effect that degrades significantly the TFR when the concurrency increases. TPF and BrTPF do not suffer from the convoy effect and TFR is clearly stable over concurrency. The main reason is that delivering a page of result for a single triple pattern takes $\approx$ 5ms in our experiment, so the waiting time on the TPF server grows very slowly. BrTPF is better than TPF due to its bind-join technique. The TFR for SaGe-75ms and SaGe-1s increases with the number of clients and the slope seems proportional to the quantum. This is normal because the waiting time on the server increases with the number of clients, as seen previously. Reducing the quantum improves the TFR, but increases the number of requests and thus deteriorates the WTC.

What are the client overheads in terms of number of requests and data transfer? The client overhead in requests is the number of requests that the smart client sent to the server to get complete results minus one, as Virtuoso executes all queries in one request. As WatDiv queries are pure conjunctive queries and supported by the SaGe server, the number of requests to the server is the number of time quantum required to evaluate the whole workload. We measure the number of requests sent to servers with one workload for all approaches, with results shown in Table 3 (a). As expected, Virtuoso just send 193 requests to the server. SaGe-75ms send 4082 requests to the server, while TPF send 2.55×10^5 requests to the TPF server. We can see also that increasing the time quantum significantly reduces the number of requests; SaGe-1s send only 645 requests. However, this seriously deteriorates the average WCT and TFR as presented before. To compute the overhead in data transfer of SaGe, we just need to multiply the number of requests by the average size of saved plans; for SaGe-75ms, the client overhead in data transfer is $4082 \times 1,3$ kb = 5.45 Mo. As the total size of results is 51Mo, the client overhead in data transfer is $\approx$ 10%. For TPF, the average size of a page is 7ko; $2.5 \cdot 10^5 \times 7k = 1.78$ Go, so the data transfer overhead is $\approx$ 340% for TPF.

What are the client overheads in terms of numbers of requests and data transfer for more complex queries? The WatDiv benchmark does not generate queries with OPTIONAL or FILTER operators. If some filters are supported by the SaGe server, the OPTIONAL operator and other filters clearly impact the number of requests sent to the SaGe server, as explained in Section 3.4. First, we run an experiment to measure the number of requests for queries with OPTIONAL. We generate new WatDiv queries from one set of 193 queries, using the following protocol. For each query $Q = \{tp_1, \ldots, tp_n\}$, we select $tp_k \in Q$ with the highest cardinality, then we generate $Q' = tp_k \bowtie (Q \setminus tp_k)$. Such queries verify conditions for using BindLeftJoin and OptJoin. They are challenging for the BindLeftJoin as they generate many mappings; they are also challenging for the OptJoin as all joins yield results. Table 3(b) shows the results when evaluating OPTIONAL queries with OptJoin and BindLeftJoin approaches. We observe that, in general, OptJoin outperforms BindLeftJoin. Furthermore, OptJoin is improved when using a higher quantum, as the single subquery sent is evaluated more quickly. This is not the case for BindLeftJoin, as the number of requests still depends on the number of intermediate results.

Finally, we re-use 166 SELECT queries from Feasible [23] with the DBpedia 3.5.1 dataset, which were generated from real-users queries. We excluded queries that time-out, identified in [23], and measure the number of requests sent to the server. Table 3(a) shows the results. Of course, Virtuoso just send 166 requests to the server. As we can see the ratio of requests between SaGe-75 and TPF is nearly the same as the previous experiment. However, the difference between SaGe-1s and SaGe-75ms has clearly decreased, because most requests sent are produced by the decomposition of OPTIONAL and FILTER and not by the evaluation of BGPs.

5 CONCLUSION AND FUTURE WORKS

In this paper, we demonstrated how Web preemption allows not only to suspend SPARQL queries, but also to resume them. This opens the possibility to efficiently execute long-running queries with complete results. The scientific challenge was to keep the Web preemption overhead as low as possible; we demonstrated that the overhead of large a fragment of SPARQL can be kept under 2ms.

Compared to SPARQL endpoint approaches without quotas, SaGe avoids the convoy effect and is a winning bet as soon as the queries of the workload vary in execution time. Compared to LDF approaches, SaGe offers a more expressive server interface with joins, union and filter evaluated server side. Consequently, this considerably reduces data transfer and the communication cost, improving the execution time of SPARQL queries.

SaGe opens several perspectives. First, for the sake of simplicity, we made the hypothesis of read-only datasets in this paper. If we allow concurrent updates, then a query can be suspended with a version of a RDF dataset and resumed with another version. The main challenge is then to determine which consistency criteria can be ensured by the preemptive Web server. As SaGe only accesses the RDF dataset when scanning triple patterns, it could be possible to compensate concurrent updates and deliver, at least, eventual consistency for query results. Second, we aim to explore how the interface of the server can be extended to support named graphs and how the optimizer of the smart client can be tuned to produce better query decompositions, especially in the case of federated SPARQL query processing. Third, we plan to explore if more elaborated scheduling policies could increase performance. Finally, the Web preemption model is not restricted to SPARQL. An interesting perspective is to design a similar approach for SQL or GraphQL.

ABSTRACT

Email accounts represent an enticing target for attackers, both for the information they contain and the root of trust they provide to other connected web services. While defense-in-depth approaches such as phishing detection, risk analysis, and two-factor authentication help to stem large-scale hijackings, targeted attacks remain a potent threat due to the customization and effort involved. In this paper, we study a segment of targeted attackers known as "hack for hire" services to understand the playbook that attackers use to gain access to victim accounts. Posing as buyers, we interacted with 27 English, Russian, and Chinese blackmarket services, only five of which succeeded in attacking synthetic (though realistic) identities we controlled. Attackers primarily relied on tailored phishing messages, with enough sophistication to bypass SMS two-factor authentication. However, despite the ability to successfully deliver account access, the market exhibited low volume, poor customer service, and had multiple scammers. As such, we surmise that retail email hijacking has yet to mature to the level of other criminal market segments.

1 INTRODUCTION

It has long been understood that email accounts are the cornerstone upon which much of online identity is built. They implicitly provide a root of trust when registering for new services and serve as the backstop when the passwords for those services must be reset. As such, the theft of email credentials can have an outsized impact—exposing their owners to fraud across a panoply of online accounts.

Unsurprisingly, attackers have developed (and sell) a broad range of techniques for compromising email credentials, including exploiting password reuse, access token theft, password reset fraud and phishing among others. While most of these attacks have a low success rate, when applied automatically and at scale, they can be quite effective in harvesting thousands if not millions of accounts [27]. In turn, email providers now deploy a broad range of defenses to address such threats—including challenge questions to protect password reset actions, mail scanning to filter out clear phishing lures, and two-factor authentication mechanisms to protect accounts against password theft [7–9]. Indeed, while few would claim that email account theft is a solved problem, modern defenses have dramatically increased the costs incurred by attackers and thus reduce the scale of such attacks.

However, while these defenses have been particularly valuable against large-scale attacks, targeted attacks remain a more potent problem. Whereas attackers operating at scale expect to extract small amounts of value from each of a large number of accounts, targeted attackers expect to extract large amounts of value from a small number of accounts. This shift in economics in turn drives an entirely different set of operational dynamics. Since targeted attackers focus on specific email accounts, they can curate their attacks accordingly to be uniquely effective against those individuals. Moreover, since such attackers are unconcerned with scale, they can afford to be far nimbler in adapting to and evading the defenses used by a particular target. Indeed, targeted email attacks—including via spear-phishing and malware—have been implicated in a wide variety of high-profile data breaches against government, industry, NGOs and universities alike [10, 12, 13, 31].

While such targeted attacks are typically regarded as the domain of sophisticated adversaries with significant resources (e.g., state actors, or well-organized criminal groups with specific domain knowledge), it is unclear whether that still remains the case. There is a long history of new attack components being developed as vertically integrated capabilities within individual groups and then evolving into commoditized retail service offerings over time (e.g., malware authoring and distribution, bulk account registration, AV testing, etc. [27]). This transition to commoditization is commonly driven by both a broad demand for a given capability and the ability for specialists to reduce the costs in offering it at scale.

In this paper, we present the first characterization of the *retail* email account hacking market. We identified dozens of underground "hack for hire" services offered online (with prices ranging from $100 to $500 per account) that purport to provide targeted attacks to all buyers on a retail basis. Using unique online buyer personas, we engaged directly with 27 such account hacking service providers and tasked them with compromising victim accounts of our choosing. These victims in turn were "honey pot" Gmail accounts, operated in coordination with Google, and allowed us to record key interactions with the victim as well as with other fabricated aspects of their online persona that we created (e.g., business web servers, email addresses of friends or partner). Along with longitudinal pricing data, our study provides a broad picture of how such services operate—both in their interactions with buyers and the mechanisms they use (and do not use) to compromise victims.

We confirm that such hack for hire services predominantly rely on social engineering via targeted phishing email messages, though one service attempted to deploy a remote access trojan. The attackers customized their phishing lures to incorporate details of our fabricated business entities and associates, which they acquired either by scraping our victim persona's website or by requesting the details during negotiations with our buyer persona. We also found evidence of re-usable email templates that spoofed sources of authority (Google, government agencies, banks) to create a sense of urgency and to engage victims. To bypass two-factor authentication, the most sophisticated attackers redirected our victim personas to a spoofed Google login page that harvested both passwords as well as SMS codes, checking the validity of both in real time. However, we found that two-factor authentication still proved an obstacle: attackers doubled their price upon learning an account had 2FA enabled. Increasing protections also appear to present a deterrent, with prices for Gmail accounts at one service steadily increasing from $125 in 2017 to $400 today.

As a whole, however, we find that the commercialized account hijacking ecosystem is far from mature. Just five of the services we contacted delivered on their promise to attack our victim personas. The others declined, saying they could not cover Gmail, or were outright scams. We frequently encountered poor customer service, slow responses, and inaccurate advertisements for pricing. Further, the current techniques for bypassing 2FA can be mitigated with the adoption of U2F security keys. We surmise from our findings, including evidence about the volume of real targets, that the commercial account hijacking market remains quite small and niche. With prices commonly in excess of $300, it does not yet threaten to make targeted attacks a mass market threat.

2 METHODOLOGY

In this section we describe our methodology for creating realistic, but synthetic, victims to use as targets, the infrastructure we used to monitor attacker activity, and the services we engaged with to hack into our victim email accounts. We also discuss the associated legal and ethical issues and how we addressed them in our work.

2.1 Victims

We created a unique victim persona to serve as the target of each negotiation with a hack for hire service. We never re-used victim personas among services, allowing us to attribute any attacks deployed against the persona back to the service we hired. In creating victim personas, we spent considerable effort to achieve three goals:

- *Victim verisimilitude.* We created synthetic victims that appeared sufficiently real that the hacking services we hired would treat them no differently from other accounts that they are typically hired to hack into.
- *Account non-attributability.* We took explicit steps to prevent attackers from learning our identities while we engaged with them as buyers, when they interacted with us as victims, and even if they successfully gained access to a victim email account.
- *Range of attacker options.* We did not know a priori what methods the hacking services would use to gain access to victim email accounts. Since there are many possibilities, including brute-force password attacks, phishing attacks on the victim, and malware-based attacks on the victim's computers, we created a sufficiently rich online presence to give attackers the opportunity to employ a variety of different approaches.

The remainder of this section details the steps we took to achieve these goals when creating fictitious victims, the monitoring infrastructure we used to capture interactions with our fake personas, and the selection of "hack for hire" services we engaged with.

Victim Identities. Each victim profile consisted of an email address, a strong randomly-generated password, and a name. While each of our victims 'lived' in the United States, in most cases we chose popular first and last names for them in the native language of the hacking service, such as "Natasha Belkin" when hiring a Russian-language service.[1] The email address for the victim was always a Gmail address related to the victim name to further reinforce that the email account was related to the victim (e.g., `natasha.r.belkin@gmail.com`). We loaded each email account with a subset of messages from the Enron email corpus to give the impression that the email accounts were in use [5]. We changed names and domains in the Enron messages to match those of our victim and the victim's web site domain (described below), and also changed the dates of the email messages to be in this year.

Each victim Gmail account used SMS-based 2-Factor Authentication (2FA) linked to a unique phone number.[2] As Gmail encourages users to enable some form of 2FA, and SMS-based 2FA is the most utilized form, configuring the accounts accordingly enabled us to explore whether SMS-based 2FA was an obstacle for retail attackers who advertise on underground markets [1] (in short, yes, as discussed in detail in Section 3.4).

Online Presence. For each victim, we created a unique web site to enhance the fidelity of their online identity. These sites also provided an opportunity for attackers to attempt to compromise the web server as a component of targeting the associated victim (server attacks did not take place). Each victim's web site represented either a fictitious small business, a non-governmental organization (NGO), or a blog. The sites included content appropriate for its purported function, but also explicitly provided contact information (name and email address) of the victim and their associates (described

[1] These example profile details are from a profile that we created, but in the end did not need to use in the study.
[2] These phone numbers, acquired via prepaid SIM cards for AT&T's cellular service, were also non-attributable and included numbers in a range of California area codes.

shortly). We hosted each site on its own server (hosted via third-party service providers unaffiliated with our group) named via a unique domain name. We purchased these domain names at auction to ensure that each had an established registration history (at least one year old) and the registration was privacy-protected to prevent post-sale attribution to us (privacy protection is a common practice; one recent study showed that 20% of .com domains are registered in this fashion [17]). The sites were configured to allow third-party crawling, and we validated that their content had been incorporated into popular search engine indexes before we contracted for any hacking services. Finally, we also established a passive Facebook profile for each victim in roughly the style of Cristofaro et al. [3]. These profiles were marked 'private' except for the "About Me" section, which contained a link to the victim's web site.[3]

Associate Identity. In addition to the victim identity, we also created a unique identity of an associate to the victim such as a spouse or co-worker. The goal with creating an associate was to determine whether the hacking services would impersonate the associate when attacking the victim (and some did, as detailed in Section 3.2) or whether they would use the associate email account as a stepping stone for compromising the victim email account (they did not). Similar to victim names, we chose common first and last names in the native language of the hacking service. Each victim's web site also listed the name and a Gmail address of the associate so that attackers could readily discover the associate's identity and email address if they tried (interestingly, most did not try as discussed in Section 3.2). Finally, if the victim owned their company, we also included a company email address on the site (only one attack used the company email address in a phishing lure).

Buyer Identity. We interacted anonymously with each hack for hire service using a unique buyer persona. When hiring the same service more than once for different victims, we used distinct buyer personas so that each interaction started from scratch and was completely independent. In this role, we solely interacted with the hacking services via email (exclusively using Gmail), translating our messages into the native languages of the service when necessary.

Many hacking services requested additional information about the victim from our buyers, such as names of associates, to be able to complete the contract. Since we made this information available on the victim web sites, we resisted any additional requests for information to see if the services would make the effort to discover this information themselves, or if services would be unable to complete the contract without it (Section 3.1).

2.2 Monitoring Infrastructure

Email Monitoring. For each Gmail account, we monitored activity on the account by using a modified version of a custom Apps Script shared by Onaolapo et al. [23]. This script logged any activity that occurs within the account, such as sending or deleting email messages, changing account settings, and so on (Section 3.6 details what attackers did after gaining access to accounts). The script then uploaded all logged activity to a service running in Google's public cloud service (Google App Engine) as another level-of-indirection to hide our infrastructure from potential exposure to attackers. Since the script runs from within the Gmail account, it is possible in principle for an attacker to discover the script and learn where the script is reporting activity to, though only after a successful attack. We found no evidence that our scripts were detected.

Login Monitoring. In addition to monitoring activity from within the accounts, the accounts were also monitored for login activity

[3]None of the service providers we contracted with appeared to take advantage of the Facebook profile, either by visiting the victim's web site via this link or communicating with the victim via their Facebook page.

Table 1: We contacted 27 hacking services attempting to hire them to hack 34 different victim Gmail accounts. We communicated with the services in the language in which they advertised, translating when necessary. The prices were advertised in their native currency, and we normalized them to USD for ease of comparison. (Yes†: for first-time customers.)

Figure 1: An online advertisement for Gmail hacking services. We remove any identifiable information and translate the page from Russian to English.

by Google's system-wide logging mechanisms. Google's monitoring, shared with us, reported on login attempts and whether they were successful, when attackers were presented with a 2FA challenge, and whether they were able to successfully respond to the challenge (Section 3.4). These monitoring logs also include the infrastructure and devices used to make login attempts, which Google used to identify other Gmail accounts attacked by these services (Section 4.1).

Phone Monitoring. As described earlier, each victim account was associated with a unique cell number (used only for this purpose) which was configured in Gmail to be the contact number for SMS-based 2FA. To capture attacks against these phone numbers or notifications from Google (e.g., for 2FA challenges or notification of account resets) we logged each SMS message or phone call received.

Web Site Monitoring. To monitor activity on the web sites associated with the victims, we recorded HTTP access logs (which included timestamp, client IP, user agent, referrer information, and path requested). For completeness, we also recorded full packet traces of all incoming traffic to the target server machines in case there was evidence of attacker activity outside of HTTP (e.g., attempts to compromise the site via SSH). Overall, we found no evidence of attackers targeting our web sites.

2.3 Hacking Services

Recruitment. We identified hacking services through several mechanisms: browsing popular underground forums, searching for hacking services using Google search, and contacting the abuse teams of several large Internet companies. We looked for services that specifically advertised the ability to hack into Gmail accounts. While we preferred services that explicitly promised the passwords of targeted accounts, we also engaged with services that could instead provide an archive of the victim's account. Figure 1 shows an example service advertisement (one we did not purchase from).

When hiring these services, we followed their instructions for how to contact them. Typically, interactions with the services consisted of a negotiation period, focused on a discussion of what they would provide, their price, and a method of payment. The majority of the services were non-English speaking. In these cases, we used a native speaker as a translator when needed. We always asked whether they could obtain the password of the account in question as the objective, and always offered to pay in Bitcoin. If the sellers did not want to use Bitcoin, we used online conversion services to convert into their desired currency (the minority of cases). Interestingly, only a handful of services advertised Bitcoin as a possible payment vector, though many services were generally receptive towards using Bitcoin when we mentioned it.

Table 1 summarizes the characteristics of all services that we contacted, which we anonymize so that our work does not advertise merchants or serve as a performance benchmark. In total, we reached out to 27 different services and attempted to hire them to hack 34 unique victim Gmail accounts. When a service successfully hacked into an account, we later hired them again (via another unique buyer persona) with a different victim to see if their methods changed over time (we denote different purchases from the same service by appending a number after the letter used to name the service).

Service reliability. Of the twenty-seven services engaged, ten refused to respond to our inquiries. Another twelve responded to our initial request, but the interactions did not lead to any attempt on the victim account. Of these twelve, nine refused up front to take the contract for various reasons, such as claiming that they no longer hacked Gmail accounts contrary to their contemporary advertisements. The remaining three appear to be pure scams (i.e., they were happy to take payment, but did not perform any service in return). One service provided a web-based interface for entering the target email address, which triggered an obviously fake progress bar followed by a request for payment.[4] Another service advertised payment on delivery, but after our initial inquiry, explained that they required full prepayment for first-time customers. After payment, they responded saying that they had attempted to get into the account but could not bypass the 2FA SMS code without further payment. They suggested that they could break into the mobile carrier, intercept the SMS code, and thus break into the Gmail account. We paid them, and, after following up a few times, heard nothing further from them. During this entire exchange, we did not see a single login attempt on the victim's Gmail account from the hacking service. The third site similarly required pre-payment and performed no actions that we could discern.

Finally, five of the services made clear attempts (some successful, some unsuccessful) to hack into eleven victim accounts. We focus on these services going forwards.

Pricing. The cost for hiring the hacking services often varied significantly between the advertised price and the final amount we paid. Table 2 shows a breakdown of the price differences during engagement with the hacking services we successfully hired. The table shows the service, the purported price for that service from their online advertisement, the initially agreed upon price for their services, and then any price increase that may have incurred during the attack period. When services failed to hack into the account, they did not request payment. Several factors influenced the changes in prices, in particular the use of 2FA on the accounts (Section 6).

[4] We did not pay them since we would learn nothing more by paying.

Service	Advertised	Discussed	Final
A.1	$230	$230	$307
A.2	$230	$230 - $307	Failed
A.3	$460	$460	$460
B.1	$383	$383	Failed
B.2	$383	$383	$383
C.1	$92	$102	$100
C.2	$92	–	Failed
D.1	$77	$184	Failed
D.2	$77	$184	Failed
E.1	$123	$383 - $690	$383
E.2	$123	$690	Failed

Table 2: The changes in negotiated prices when advertised, when initially hired, and when finally successful at hacking into victim Gmail accounts. All prices were originally in rubles, but are converted to USD for easier comparison.

As a rule, we always paid the services, even when they requested additional money, and even when we strongly suspected that they might not be able to deliver when they asked for payment up front.[5] Our goal was to ultimately discover what each service would actually do when paid.

2.4 Legal and Ethical Issues

Any methodology involving direct engagement with criminal entities is potentially fraught with sensitivities, both legal and ethical. We discuss both here and how we addressed them.

There are two legal issues at hand in this study: unauthorized access and the terms of service for account creation and use. Obtaining unauthorized access to third-party email accounts is unlawful activity in most countries and in the United States is covered under 18 USC 1030, the Computer Fraud and Abuse Act (CFAA). Contracting for such services, as we did in this study, could constitute aiding and abetting or conspiracy if the access was, in fact, unauthorized. However, in this study, the email accounts in question are directly under our control (i.e., we registered them), and since we are acting in coordination with the account provider (Google), our involvement in any accesses was explicitly authorized. The other potential legal issue is that this research could violate Google's terms of service in a number of ways (e.g., creating fake Gmail accounts). We addressed this issue by performing our study with Google's explicit permission (including a written agreement). Both our institution's general counsel and Google's legal staff were appraised of the study, its goals, and the methods employed before the research began.

This study is not considered human subjects research by our Institutional Review Board because, among other factors, it focuses on measuring organizational behaviors and not those of individuals. Nevertheless, outside traditional human subjects protections, there are other ethical considerations that informed our approach. First, by strictly using fictitious victims, associates and web sites, we minimized the risk to any real person resulting from the account hacking contracted for in this study. Second, to avoid indirect harms resulting from implicitly advertising for such services (at least the effective ones), we made the choice to anonymize the names of each service. Finally, to minimize our financial contributions to a potentially criminal ecosystem, we limited the number of purchases to those needed to establish that a service "worked" and, if so, that its modus operandi was consistent over time.

[5]The one exception to this rule is the aforementioned service whose automated web site immediately told us they had hacked the site when all evidence was to the contrary.

3 HACK FOR HIRE PLAYBOOK

Our study characterizes the operational methods that hack for hire services employ when making a credible attempt to hijack our victim personas. We limit our analysis exclusively to the five services where the attackers made a detectable attempt to gain access to our victim account. We note that the ultimate "success" of these attacks is partially dependent on our experimental protocol: in some cases, we supplied 2FA SMS codes to phishing attacks or installed a provided executable, while in other cases, we avoided such actions to see if the attackers would adapt.

3.1 Attacks Overview

We present a high-level breakdown of each hack for hire service's playbook in Table 3. Four of the five services relied on phishing, while just one relied on malware. In all cases, attacks began with an email message to our victim persona's Gmail address. We never observed brute force login attempts, communication with a victim's Facebook account, or communication to our associate personas of any kind.[6] On average, attackers would send roughly 10 email messages over the course of 1 to 25 days—effectively a persistent attack until success. All of the services but one were able to bypass Gmail spam filtering (though to varying degrees of success) until at least one of their messages appeared in our victim's inbox. However, this outcome is expected: since these are targeted attackers with more focused motivation, they have strong incentives to adapt to phishing and spam defenses to ensure that their messages arrive in the victim's inbox. For example, attackers can create honeypot accounts of their own to test and modify their techniques, thereby ensuring a higher success rate; unlike their high-volume counterparts, targeted attackers only produce a modest number of examples and thus may pass "under the radar" of defenses designed to recognize and adapt to new large-scale attacks.

3.2 Email Lures

Each email message contained a lure impersonating a trusted associate or other source of authority to coerce prospective victims into clicking on a link. We observed five types of lures: those impersonating an associate persona, a stranger, a bank, Google, or a government authority. The associate lures tempted the user to click on an "image" for the victim's associate (using the personal connection as a sense of safety), while the Google, bank, and government lures conveyed a sense of urgency to induce a user to click on the link. Figure 2 shows a sample Google lure that mimics a real warning used by Google about new device sign-ins. Such lures highlight the challenge of distinguishing authentic communication from service providers, whereby attackers repurpose potentially common experiences to deceive victims into taking an unsafe action.

Attackers cycled through multiple lures over time in an apparent attempt to find any message that would entice a victim into clicking

[6]In practice, a victim's password may be exposed in a third-party data breach. Our use of synthetic identities prevents this as a potential attack vector.

Service	Method	Lure	Inbox or Spam	Promised goods	Requested	Success
A.1	Phishing	A, G, S	Inbox	Archive	–	Y
A.2	Phishing	A, G, S	Inbox	Archive	Victim and associate name, phone number	N
A.3	Phishing	A, G, S	Inbox	Archive	Victim and associate name, phone number	Y
B.1	Phishing	B	Inbox, Spam	Password	–	N
B.2	Phishing	A, G, V	Inbox, Spam	Password	Victim name, associate name/email, phone number*	Y
C.1	Phishing	G	Inbox	Password	–	Y
C.2	Phishing	G	Inbox, Spam	Password	–	N
D.1	Malware	V	Spam	Password	Victim name and occupation	N
E.1	Phishing	G, V	Inbox, Spam	Password	–	Y

Table 3: Overview of attack scenarios per service. Lure emails include impersonating an associate (A), bank (B), Google (G), government (V), or a stranger (S). In the event a service indicated they could not succeed without additional information, we indicate what details they requested. In one case (marked *), this was only for the second attempt.

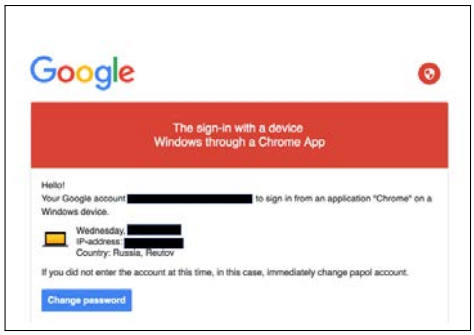

Figure 2: An example Google lure mimicking a real warning that Gmail will send to users. Identifying information removed and translated to English.

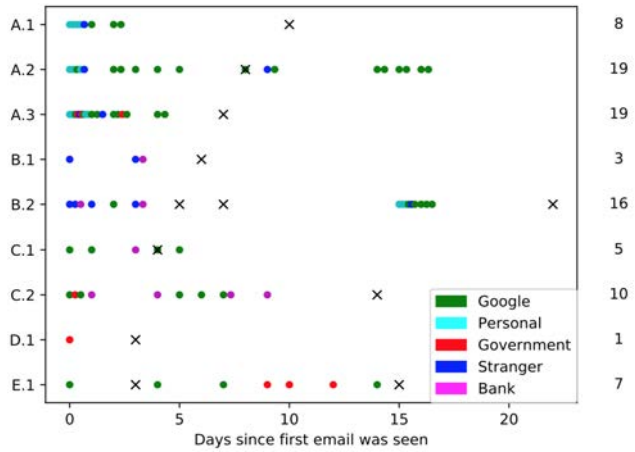

Figure 3: Different types of lures used by services that attempted to access a victim account. An 'X' marks when we clicked on a link in a message sent to a victim. Numbers on the right denote the total number of emails sent by a service.

on a link. Figure 3 shows the elapsed time since attackers sent their first email message to our victim account, the type of lure they used for each message, and when we clicked on the lure acting as a victim (potentially halting further attempts). Each row corresponds to one attack on a victim, and the x-axis counts the number of days since the service sent their first message to the victim. The numbers on the right y-axis show the number of messages sent by the service to the victim. The most popular lure mimicked Google, followed by associates and then lures from strangers.

Of the five services, two relied on personalized messages when communicating with four victim personas. In three of these cases, the service asked for additional details upfront about the victim persona during negotiation. Only service A.1 was able to construct personal lures without requesting assistance from the buyer, finding the details from the victim persona's website. The extent of personalization was limited, though, consisting either of mimicking the victim persona's company or their associate's personal email address. No additional branding was lifted from our web sites.

3.3 Phishing Landing Pages

All services but one relied on phishing as their attack vector. Once we clicked on the links sent to the victim personas, we were redirected to a spoofed Google login page that requested the credentials from the victim. Table 4 lists the different attack attempts and the degree to which attackers tried to spoof a Google domain, use HTTPS, or mask URLs from a crawler via multiple redirects. All services but one used "combo" domain name squatting [14] with the keyword 'google' in the URL, presumably to trick the victim into thinking that the URL was a real Google subdomain. Services A.2 and B.2 used the same fully qualified domain name for the phishing landing page, suggesting that they share a business relationship (i.e., they may both be value-added resellers for the same phishing page service). Long-lived, reused domains suggest that they are valuable and perhaps relatively costly to acquire.

All but one service tried to obscure the URL to their phishing page with at least one layer of redirection. (The exception was the link in the phishing message from C.2, which redirected to an error page on a Russian hosting service indicating that the page had been taken down.) The redirection URLs seemed to be one-time use URLs, since we were not able to visit them after the attack executed and did not see repeat redirection URLs in any of the attacks. One-time use URLs are attractive for attackers because they can greatly

Service	'google' in URL?	HTTPS	# redirects to phishing page
A.1	Yes	Yes	2
A.2	Yes	Yes	2
A.3	Yes	Yes	2
B.1	Yes	No	1
B.2.1	Yes	No	1
B.2.2	Yes	No	1
B.2.3	Yes	Yes	2
C.1	No	No	0
C.2	NA	NA	NA
D.1	NA	NA	NA
E.1.1	Yes	Yes	1
E.1.2	Yes	Yes	2

Table 4: For services that attempted to hack a victim account, we show whether Google was used in the phishing URL, whether the phishing page used HTTPS, and the number of redirects to the phishing page. We include separate rows for the services that sent multiple messages (services B and E).

complicate investigating attacks after the fact or sharing attack information among organizations.

Figure 4 shows an example page flow used by one hacking service. We always entered the Gmail credentials of the victim to see how the hacking attempt would progress. After collecting the password, all but one of the hacking services would redirect to a new screen which asked for the 2FA code that the victim had just received on their phone from Google.

Six of the nine hacking attempts captured the password from the phishing page and then immediately tried to use it to login to the victim's account (as verified with our Gmail access logging). Due to the similar behavior and speed at which these logins occurred, we believe that most of these services used an automated tool, similar to Evilginx [6], for this step.

Moreover, three of five of these attacks captured the necessary information in one session visiting the phishing pages. This sophistication suggests that attackers can readily adapt any additional information requested by Google as a secondary factor. Since our study, Google launched additional protections at login to prevent automated access attempts [26]. However, hardware security keys remain the best protection mechanism against phishing for users.

3.4 Live Adaptation

Services B.2 and E.1 exhibited phishing attacks that adapted over time to overcome obstacles. These services, once realizing that the account used 2FA, sent new phishing email messages with a different structure than the ones they sent previously. Service E.1, for example, initially used a phishing attack that only captured the Gmail password. When the service attempted to login, they were blocked by the 2FA prompt. The service then contacted our buyer persona asking for the victim's phone number. The victim's email account subsequently received more phishing messages in their inbox. Clicking on the link in the phishing messages led to a page that requested the 2FA code that was sent to the victim's phone. When we entered the 2FA code into the phishing page, the service was able to successfully login. This behavior indicates live testing

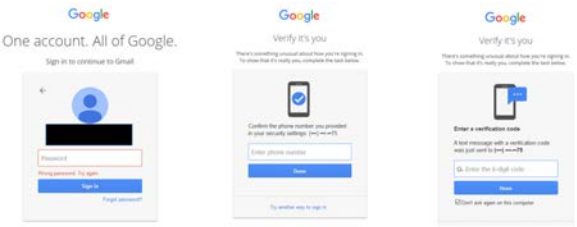

Figure 4: A service phishing flow, with identifiable information redacted. The flow is purposefully designed to mimic Gmail to trick the user into trusting the site.

of password validity, as the attackers were able to determine if the account had 2FA.

Service B.2 was similar to service E.1, but when they were blocked by the 2FA challenge they switched to phishing messages that looked exactly like the messages from service A. Upon collecting the password and the 2FA code that was sent to the phone number for the victim, the service was able to login.

3.5 Malware Attachments

Service D was the only service that attempted to hijack our victim account using malware. The attacker in this case sent just one email message to our victim persona—flagged as spam—that contained a link to a `rar` archive download (Gmail forbids executable attachments). The archive contained a sole executable file. We unpacked and ran the executable in an isolated environment, but to no effect. According to VirusTotal [32], it is a variant of TeamViewer (a commercial tool for remote system access) which would have enabled the attacker to hijack any existing web browsing sessions.

After no further visible activity, the service eventually contacted our buyer persona to say that they could not gain access to our victim account. We decided to hire them again via a different contract (and different buyer and victim personas) to see if the seller would adapt to Gmail's defenses. However, we observed no email messages from the attacker the second time around, even in our spam folder. The seller eventually responded stating that they could not gain access to our second persona's account. While this malware vector proved unsuccessful, the presence of remote access tools poses a significant risk for adaptation, as session hijacking would enable an attacker to bypass any form of two-factor authentication.

3.6 Post Compromise

For those services that did obtain our victims' credentials and 2FA codes, the attackers proceeded to sign in to each account and immediately removed all Google email notifications (both from the inbox and then trash) related to a new device sign-in. None changed the account password. We also observed that services A, B, and E removed the 2FA authentication and the recovery number from our victim accounts as well. Presumably they took these steps to regain access to the account at a later time without having to phish an SMS code again, but we did not see any service log back into the accounts after their initial login. However, these changes to the account settings could alert a real victim that their account had been hijacked, a discovery which the attackers are willing to risk.

Once accessed, all but one of the services abused a portability feature in Google services (Takeout) to download our victim account's email content and then provided this parcel to our buyer persona. One advantage of this approach is that it acquires the contracted deliverable in one step, thus removing risks associated with subsequent credentials changes, improvements in defenses, or buyer repudiation. Only service C avoided logging into our victim account and only provided the buyer persona with a password.[7] These findings highlight an emerging risk with data portability and regulations around streamlining access to user data. While intended for users, such capabilities also increase the ease with which a single account hijacking incident can expose all of a user's data to attackers. Since our study, Google has added additional step-up verification on sensitive account actions.

4 REAL VICTIMS & MARKET ACTIVITY

Based on our findings from the hack for hire process, we returned to the forums of the most successful attackers to understand their pricing for other services and how they attract buyers. Additionally, we present an estimate of the number of real victims affected by these services based on login traces from Google. Our findings suggest that the hack for hire market is quite niche, with few merchants providing hijacking capabilities beyond a handful of providers.

4.1 Victims Over Time

Of the 27 initial services we contacted, only three—services A, E, and B—could successfully login to our honeypot accounts. Google examined metadata associated with each login attempt and found that all three services rely on an *identical* automation process for determining password validity, bypassing any security check such as producing an SMS challenge, and downloading our honey account's email history. Whereas the email messages from the services had varied senders and delivery paths for each contracted campaign, this automation infrastructure remained stable despite eight months between our successive purchases. This stability in turn allowed Google to develop a signature allowing the retrospective analysis of all such login attempts from the three services in aggregate.

Over a seven-month period from March 16 to October 15, 2018, Google identified 372 accounts targeted by services A, B, and E. Figure 5 shows a weekly breakdown of activity. On an average week, these services attacked 13 targets, peaking at 35 distinct accounts per week. We caution these estimates are likely only lower bounds on compromise *attempts* as we cannot observe users who received a phishing URL, but did not click it (or otherwise did not enter their password on the landing page). Despite these limitations, the volume of activity from these hack for hire services is quite limited when compared to off-the-shelf phishing kits which impact over 12 million users a year [29]. Thus, we surmise that the targeted account hacking market is likely small when compared to other hacking markets, e.g., for malware distribution [11]. While the damage from these commercialized hacking services may be more potent, they are only attractive to attackers with particular needs.

Apart from the volume of these attacks, we also examine the sophistication involved. As part of its authentication process, Google

[7]The service demanded additional payment to defeat the 2FA, which we paid, at which point they stopped responding to our requests.

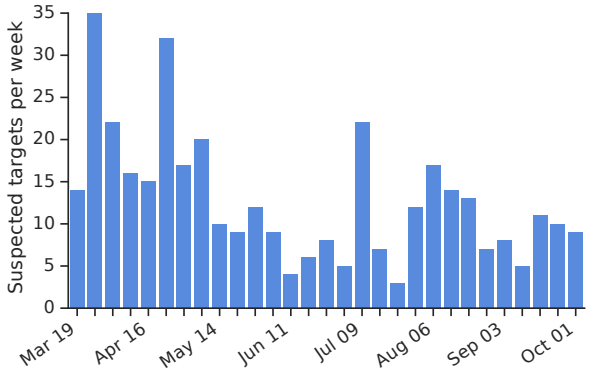

Figure 5: Weekly target accounts retroactively associated with hack for hire services.

may trigger a "challenge" for sign-in attempts from previously unseen devices or network addresses [20]. All of the hack for hire attempts triggered this detection. In 68% of cases, the attacker was forced to solve an SMS challenge, while in 19% of cases the attacker only had to supply a victim's phone number. The remaining 13% involved a scattering of other secondary forms of authentication. This layered authentication approach provides better security when compared to passwords alone, with attackers only correctly producing a valid SMS code for 34% of accounts and a valid phone number in 52% of cases. These rates take into consideration repeated attacks: Google observed that attackers would attempt to access each account a median of seven times before they either succeeded or abandoned their efforts. As such, even though these attacks may be targeted, Google's existing account protections can still slow and sometimes stop attackers from gaining access to victim accounts.

4.2 Alternate Services and Pricing

While our investigation focused on Google—due in large part to our ethical constraints and abiding by Terms of Service requirements—the hack for hire services we engaged with also purport to break into multiple mail providers (Yahoo, Mail.ru, Yandex), social networks (Facebook, Instagram), and messaging apps (WhatsApp, ICQ, Viber). To provide a price comparison between offerings, in preparation for our study we performed a weekly crawl of the forum page or dedicated web site advertising each service starting in January 1, 2017. However, as detailed previously in Section 3, only a fraction of the services are authentic, and just three—services A, B, and C—had online prices that matched (or were close) to the final price we paid. We treat these as trusted sources of pricing information. We also include services E and D, but note their prices were higher than advertised. We exclude all other services as they failed to attack any of our victim personas.

We present a breakdown of pricing information as of October 10, 2018 in Table 5 for the five services that executed an attempt to access the accounts. Across all five services, Russian mail provider hacking (i.e., Mail.ru, Rambler and Yandex) was the cheapest, while other mail providers such as Gmail and Yahoo were more expensive. The cost of hacking a social media account falls in the middle of these two extremes.

Target	Service A	Service B	Service C	Service D*	Service E*
Mail.ru	$77	$77	$62	$54	$77
Rambler	$152	$108	$77	$77	$108
Yandex	$106	$108	$77	$77	$108
Gmail	$384	$385	$92	$77	Negotiable
Yahoo	$384	$231	$92	–	–
Facebook	$306	–	–	–	–
Instagram	$306	–	–	–	$231

Table 5: Purported prices to access various accounts, based on an October 10, 2018 snapshot. All prices USD, converted from rubles. An '*' indicates the service's advertised price was lower than the final payout requested.

Some services increased their prices over time. For services B and C, prices on the forums they advertise have been stable since we first began our monitoring. Only service A provided dynamic pricing, with rates increasing as shown in Figure 6. Since 2017, Gmail prices have steadily increased from $123 to $384, briefly peaking at $461 in February 2018. The advertised rates for targeting Yahoo accounts has largely tracked this same rate, while Facebook and Instagram were initially priced higher before settling at $307. We hypothesize that the price differences between services and the change in prices for a service over time are likely driven by both operational and economic factors. Thus, prices will naturally increase as the market for a specific service shrinks (reducing the ability to amortize sunk costs on back-end infrastructure for evading platform defenses) and also as specific services introduce more, or more effective, protection mechanisms that need to be bypassed (increasing the transactional cost for each hacking attempt).

4.3 Advertising & Other Buyers

As a final measure, we examined the forum advertisements each service used to attract buyers. Here, we limit our analysis to the five successful hack for hire services. Across seven underground forums, we identified two types of advertisements—pinned posts and banner ads—which require paying forum operators. Services A, B, and E, the three services that were able to bypass two-factor authentication, all had pinned posts on forums where this option was available. Only service A paid for banner advertisements on all of these forums. Together, this suggests that the services are profitable enough to continue advertising via multiple outlets. Additionally, these three services had verified accounts, indicating that a forum moderator had vetted the service stated. Further, services A, B, D, and E all stated they could work with a "guarantor", an escrow service proxying for payment between service and buyer to avoid fraud risks. Generally, feedback on the forum was positive, though we caution this may be biased due to the ability to delete posts and the difficulty in distinguishing between legitimate customers and virtual "shills". We avoid using forum posts as a count of purchases as most negotiation activity occurs via private messaging.

In addition to this qualitative search, we received an email advertisement from one of the services for upcoming changes to the service, which was sent to 44 other buyers as well (exposing their clientele's email addresses). The message was an announcement that the service now had a Telegram channel that was available

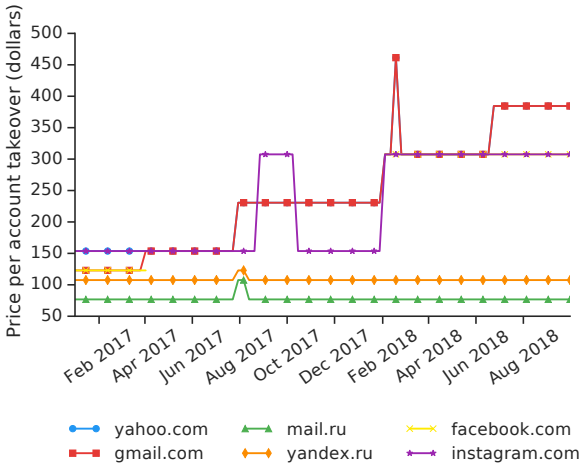

Figure 6: Monthly price that Service A charges across email and social network account providers. Over two years, the price per Gmail account increased from $123 to $384.

(with a link to the channel), and to join the channel to keep up to date with relevant news. The only response to that initial email message was another customer exclaiming their excitement for this new development. Of the 44 email addresses that were leaked, 23 were accounts with `mail.ru` or `yandex.ru`, 9 were Gmail addresses, and the rest were various other providers, like Tutanota, Protonmail, or iCloud. We were unable to find these buyers online, which indicates that they did not engage in forum postings, or used a burner (one-purpose use) email address. However, the concentration of Russian mail providers suggests that interest in the market may largely be geographically limited, potentially due to language barriers or culturally-biased demands for account hacking.

5 RELATED WORK

Phishing is a well studied, yet continuing concern in the security community. Sheng et al. studied the demographic of people who are susceptible to phishing attacks, and found that users 18–25 years of age are most likely to click on phishing messages [24]. Egleman et al. studied the effectiveness of phishing warnings and found they can be successful in preventing account hijacking [4]. Following this mode of thought, there are a variety of studies on effective anti-phishing training as well as the creation of a content-based approach to detect phishing sites [15, 25, 33]; in all of these studies, the percentage of users' susceptible to phishing emails dropped. Similarly, Zhang et al. evaluted anti-phishing tools, and found that many of them are not effective on new URLs and have exploits of their own. Oest et al. also studied the phishing ecosystem via an analysis of phishing kits, and developed a URL-based scheme to detect phishing URLs [22].

Account hijacking threats represent a spectrum that ranges from financially motivated, large-scale attacks to highly-targeted incidents motivated by political, personal, or financial incentives. Thomas et al. identified billions of credentials stolen via data breaches and millions of credentials stolen by phishing kits and keyloggers, with phishing posing the largest hijacking risk [29]. Once an account was accessed, hijackers searched for financial records or used

the account as a stepping stone to control connected online identities [2, 23]. While techniques such as risk-aware authentication [20] or two-factor authentication help protect against unsophisticated bulk attacks, the hack for hire outfits we studied were more dedicated, with attackers stealing SMS two-factor codes as part of their phishing pages to bypass the additional layers of security. Security keys would prevent this attack vector.

At the other end of the spectrum, Marczak et al. investigated government actors targeting political dissidents [19]. The hijackers in these cases relied on exploits or social engineering to have victims install commercial or off-the-shelf spyware to enable long-term monitoring of the victim's activities. Email was a common delivery mechanism, where attackers customized their lures to the NGOs where employees worked or to the human rights topics they were involved with [12, 16]. Given the risks involved here, researchers have focused on how to improve the security posture of at-risk users [18]. Compared to our work, we found more generalized lures that can work for any target (e.g., your account is running out of storage space or there was a security incident), while phishing was the most popular technique for gaining one-off access to a victim's account. Pressure on the hack for hire playbook, or wider-scale adoption of security keys, may cause them to move towards malware and thus mirror government attackers.

6 DISCUSSION AND CONCLUSION

When starting this study, we had very little knowledge of what to expect in terms of attacker methods, behaviors, and ability. At a high level, we find that the commercial account hijacking ecosystem is far from mature. When such attackers are successful, they can be potentially devastating to individuals. Yet, as an overall market it is not poised to cause widespread harm.

Retail account hijacking is a niche market. Many aspects of engaging with account hijackers strongly indicate that these services are a fledgling market:

- Most telling is that only five of the 27 services we contacted were willing to take our business, a third never responded to repeated requests as buyers, and some were outright fraudulent.
- Services have inconsistent and poor customer service. For example, three of the services charged significantly higher prices than their advertised price, and two services changed their initial prices while they were executing the hack. Moreover, customer service is slow and inconsistent in their communication with the buyer, sometimes taking more than a day to respond.
- Attackers showed little initiative. Most attacks made no effort to gather information independently about their victims. Of the nine attempts, only services A.1 and A.2 discovered additional information about the victim on their web sites, such as the name of their associate. The others, including different contracts within service A, would not attempt hacking the account without explicitly requesting additional information from the buyer.

In contrast, studies on markets for CAPTCHA solving [21], Twitter spam [30], and Google phone verified accounts [28] show that those services are quick to respond, and stable in their services and pricing. This differentiation between other underground service offerings and the retail hacking market suggests that account hacking may not be the main focus of these attackers, and may simply be a "side hustle" — a method to gain opportunistic income in addition to other activities they are more fully engaged in.

Services predominantly mount social engineering attacks using targeted phishing email messages. All but one of the nine attacks used targeted email phishing to hack into our Gmail accounts. The attackers customized their phishing messages using details that we made available about the businesses and associates of our fictitious victims. To prompt engagement with a victim, the phishing messages created a sense of urgency by spoofing sources of authority.

These methods are a subset of those used in other targeted attack ecosystems. In particular, in *addition* to targeted phishing (frequently much more tailored than any attacks mounted by the services we studied), government-targeted attackers use malware and long-term monitoring of victim behavior to gain access to the account, requiring much more overhead than phishing alone [19]. Indeed, although these two classes of attackers are superficially similar in focusing on individual users, they are distinct in most other respects including the nature of the populations they target, their resource investment per target, their goals upon compromising an account, and a far greater requirement for covert operations.

Two-factor authentication creates friction. Even though phishing can still be successful with 2FA enabled, our results demonstrate that 2FA adds friction to attacks. Various services said that they could not hack into the account without the victim's phone number, had to adapt to 2FA challenges by sending new phishing messages to bypass them, and one renegotiated their price (from $307 to $690) when they discovered that the account had 2FA protection. Based on these results, we recommend major providers encourage or require their user base to use a 2FA physical token

Minimal service differentiation. Even with a variety of services advertising in the account hijacking market, they have remarkably little differentiation in their methods and infrastructure. Four services sent very similar re-usable phishing email messages to their respective victims, and all services that successfully hacked our accounts used identical automation tools for determining password validity, bypassing security checks, and downloading victim data.

Gmail as a vantage point. Overall, our study indicates that the attack space against Gmail is quite limited. Since we focused on hiring services to hack solely into Gmail accounts, it is possible that the landscape of the commercialized hacking market would look much different when deployed against native email services such as `mail.ru` or `yandex.ru`.

ACKNOWLEDGEMENTS

We would like to thank Mikhail Kolomogorov for his help in translating emails, as well as Kirill Levchenko, Vector Guo Li, and Ivan Mikhailin. Our thanks also to Shawn Loveland who provided data that expanded the set of underground hack for hire services that we considered. We also thank Elie Bursztein, Angelika Moscicki, Tadek Pietraszek, and Kashyap Puranik for their feedback on our study. We are also grateful to our anonymous reviewers for their insightful feedback and suggestions. This work was supported in part by NSF grants CNS-1629973 and CNS-1705050, DHS grant AFRL-FA8750-18-2-0087, and by generous research, operational and/or in-kind support from Google.

ABSTRACT

In this work, we propose a new, fast and scalable method for anomaly detection in large time-evolving graphs. It may be a static graph with dynamic node attributes (e.g. time-series), or a graph evolving in time, such as a temporal network. We define an anomaly as a localized increase in temporal activity in a cluster of nodes. The algorithm is unsupervised. It is able to detect and track anomalous activity in a dynamic network despite the noise from multiple interfering sources.

We use the Hopfield network model of memory to combine the graph and time information. We show that anomalies can be spotted with good precision using a memory network. The presented approach is scalable and we provide a distributed implementation of the algorithm.

To demonstrate its efficiency, we apply it to two datasets: Enron Email dataset and Wikipedia page views. We show that the anomalous spikes are triggered by the real-world events that impact the network dynamics. Besides, the structure of the clusters and the analysis of the time evolution associated with the detected events reveals interesting facts on how humans interact, exchange and search for information, opening the door to new quantitative studies on collective and social behavior on large and dynamic datasets.

1 INTRODUCTION

In recent years, the Web has significantly affected the way people learn, interact in social groups, store and share information. Apart from being an essential part of modern life, social networks, online services, and knowledge bases generate a massive amount of logs containing traces of global online activity on the Web. Most of this data is related to the standard activity of the users. However, the larger these logs become, the harder it is to detect deviations from normal behavior in the network. Localization of these anomalies becomes even more difficult because of the continuous expansion and dynamic nature of these networks. Hence, in recent years, anomaly detection has become an important field of research focusing on this problem [8], [33].

In this paper, we present a scalable anomaly detection approach for spatio-temporal datasets such as user activity logs of web and social networks. The approach focuses on anomaly detection in the collective behavior of users in such networks. Our approach introduces the following novelties that distinguish it from the state-of-the-art.

1) The method bridges the gap between graph anomaly detection [1, 2, 33] and spatio-temporal data mining [3]. It uses the formalism of anomaly detection and extends it to spatio-temporal event analysis. Here, the *spatial component* is a graph of interconnected entities (e.g. web pages, users or documents), and the *temporal component* is the activity logs of these entities. A spatio-temporal event is a set of nodes that have an abnormal behavior during a period of time. Importantly, the nodes may not undergo a change at the same time. There can be a complex interaction between the nodes during an event when a change in one node can trigger changes in others. This complex spatio-temporal evolution is not covered in anomaly detection literature.

2) For each event or anomaly detected using our method, the model produces a rich set of spatio-temporal indicators rather than a single label or a probability of being an anomaly. In this sense, it is closer to the spatio-temporal data mining [3], where the purpose is to extract the anomalous events and keep as much information about them as possible for the sake of interpretability. Providing the description of detected anomalies to domain experts is a powerful feature of our data mining process. Our approach provides insights on the collective behavior in web and social networks, how the visitor activity evolves and propagates over the network. We illustrate that in the Experiment section and reveal new insights on the collective behavior of Wikipedia visitors.

3) We define the concept of *potential anomaly* that introduces a prior on the presence of an anomaly and enhances the scalability of the method. Indeed, in many anomaly detection applications and thanks to expert knowledge, the data can be separated into 2 parts;

one part contains potential anomalies, while the other contains non-anomalous samples. Our concept defines the separation in a rigorous manner and allows discarding non-anomalous samples. This step significantly reduces the amount of data to process. The concept of *potential anomaly* is general and can be used for other methods and applications.

Our approach can be applied to the data that has a structure depicted in Fig. 1. It consists in an attributed graph where the attributes of the nodes are time-series signals. It leverages the network structure of the given data to detect dynamic events or anomalies in collective behavior.

In the experiments, we use two spatio-temporal datasets. First, we build a network of Wikipedia articles and use visitor activity of each article, i.e. the number of visits per article per hour, as a node attribute. The static underlying network is the Wikipedia hyperlinks network. Two pages are connected if there is at least one hyperlink reference between them. Second, we transform the Enron email dataset into a temporal network where nodes correspond to email addresses of employees and edges reflect an email exchange between a couple of employees. The temporal activity attributes of the nodes is the number of emails sent per day by an employee.

In the results of our experiments, we demonstrate that we can extract anomalous patterns in collective behavior of users in web and social networks. The anomalies correspond to subgraphs containing nodes whose behavior deviates from the norm. For the Enron email dataset, these subgraphs are groups of employees having an increase in their email exchange during a short period of time corresponding to major events in the corporation. For the Wikipedia data, the subgraphs contain linked pages closely related to an event that triggered a sudden increase of visits during a short period of time. These clusters of anomalous nodes can then be used for more detailed investigation, as shown in Section 5.

The strength of our approach is that it provides a comprehensive description of detected anomalies. As a result, we are able to perform a thorough qualitative evaluation of our results. Although, it turns into a difficulty when a quantitative evaluation of the method is needed. It is not as straightforward as computing the accuracy of a classification. Therefore, we use alternative methods for validating of the results. First, we use Google Trends as a ground truth indicator of the anomalous activity of the visitors on the Web. We verify the detected anomalous events using the trending topics extracted from Google Trends. In the second case, the Enron email dataset contains ground truth, hence we use it to validate the detected anomalies.

2 RELATED WORK

Anomaly detection. A recent review of the emerging field of spatio-temporal data mining highlights the importance of anomaly detection techniques for the dynamic networks domain [3]. Due to the complex nature of the data, most existing approaches treat spatial and temporal components of the data independently [10, 25, 36]. There are several application-specific approaches for anomaly detection in video streams that use spatial and temporal information jointly [22, 24]. Lappas et al. [23] presented an approach for bursts identification in Twitter using spatial and temporal aspects of the data, although did not use the formalism of anomaly detection.

When dealing with the data from social networks, event detection is closely related to anomaly detection, therefore there exists a number of approaches that use spatio-temporal features of these datasets for collective behavior analysis. The category of Event detection in [33, Type 4] covers the case where all nodes of a subgraph contribute to the creation of an event at the same time. This is also the case in [2, Def. 4], where the authors defined it as a problem of the dynamic-graph anomaly detection. In addition, these reviews as well as [1], focus on dynamic graphs, where the graph structure evolves over time, whereas in our case, the structure of the graph is static.

Our method is developed for static graphs with a dynamic evolution of node attributes (time-series). Our definition of an anomaly is more general since we track a heterogeneous spatio-temporal pattern that can emerge in situations when the anomaly spread or propagate over the network. It can not be captured by a single subgraph. Within our framework, an anomaly is described by two components. First, *a graph pattern* that involves multiple nodes, possibly anomalous at different time steps. Second, *a temporal pattern*, a set of time-series, that reflects the anomaly evolution on each node. Tracking these types of patterns has a number of applications [3, 5, 16], although they have not yet been linked to the field of anomaly detection.

Enron email dataset. Several studies have investigated the Enron email dataset using different approaches. While many of them focus on email contents and perform analysis using natural language processing techniques, others focus on the network structure and anomaly detection. In [9], the authors explore the email communication network of the corporation. Wang et al. [35] adopt an anomaly detection framework to spot remarkable events. We compare our results to this latter reference to validate the accuracy of our detection.

Wikipedia dataset. There is a large number of studies on mining the visitor or editor activity on Wikipedia that are aimed at getting better insights on collective behavior and social interactions [34], [14], [20]. However, due to a large amount of data, the aforementioned studies are restricted to particular topics of interest and subsets of selected Wikipedia articles. For instance, only traumatic events such as attacks and bombings have been investigated in [12], [11] based on the Wikipedia edit activity data. Analyzing Wikipedia daily page views, Kanhabua et al. [20] investigated 5500 events from 11 categories such as aviation accidents, earthquakes, hurricanes, or terrorist attacks. Wikipedia hourly visits on the pages of celebrities were used to investigate the fame levels of tennis players [39]. These studies point out the high interest in this dataset and the increasing need for more systematic detection methods.

Mongiovi et al. [31, 32] provided the first investigation from an anomaly detection point of view, where the Wikipedia page counts data are combined with the graph of hyperlinks. However, they apply their method to a pre-selected subset of Wikipedia.

Due to the introduced concept of potential anomaly and the distributed implementation, our method can handle the full Wikipedia network and long-term visitor activity records.

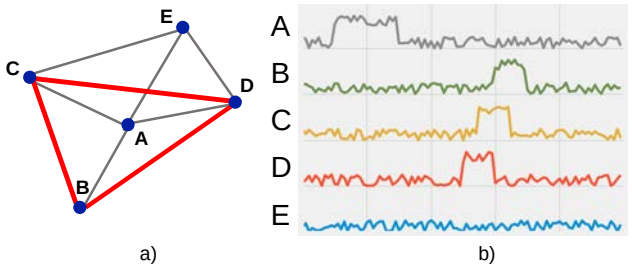

Figure 1: Spatio-temporal data structure combining a graph topology and time-series. a) Graph topology. Edges highlighted in red depict the spatial component of an anomalous spatio-temporal pattern. b) Time-series signals residing on the vertices of the graph. Signals associated to nodes B, C and D are correlated: an anomalous process is propagating from node D to B through C. This is an abstract illustration of a dynamic anomaly detected by our method.

3 METHOD

Anomaly detection in dynamic networks generally contains two stages [33]. The first stage is usually responsible for feature extraction from the domain-specific data. The second stage applies the anomaly detection algorithm to the extracted features and reports the detected anomalies.

We build our method upon this scheme in the following way. Firstly, we add to the Stage 1 a filtering step that keeps only potentially anomalous signals. It allows reducing the amount of data that is processed in Stage 2 by discarding obviously non-anomalous cases. Secondly, in Stage 2, our model contains a learning step that enhances the interpretability of the detected anomalies. It provides a complete and detailed spatio-temporal description of the detected anomaly, rather than the classification *anomalous/non-anomalous* commonly seen in anomaly detection. This description is a group of interconnected nodes (spatial information), where every node has a time-series attribute (temporal information) that indicates the time when the anomaly occurred.

The learning step is inspired by the model of a memory neural network, the Hopfield network with the Hebbian learning rule. In our model, we adapt the learning rule to fit our spatio-temporal data structure in the following way. An edge weight is reinforced when two neighbors are active together during the same time slice. This particular network design shares similarities with the Hotspot anomaly detection for graph streams [38], however, the authors use it for feature engineering (Stage 1 of the processing), while in our approach this update is a part of Stage 2, the learning and classification stage.

The Hopfield network approach learns a memory network, where the nodes correspond to the ones of the initial graph. During the learning process, edges between the nodes will be either strengthened or removed depending on the temporal behavior of each node. As a result of learning, nodes with similar behavior are connected by strong links and clustered together in the memory network. These clusters contain groups of nodes with common abnormal behavior.

Stage 1: Feature extraction and filtering. This stage highlights anomalies and extracts features from the raw data. We introduce a notion of *potential anomaly* and we filter out the nodes that are not potentially anomalous. Let V be the set of vertices of graph G and $x_i[t] \in \mathbb{R}$ be the value associated to vertex $v_i \in V$ at the time $t \in [0, T-1]$. The time-series have a length of T samples.

Definition 3.1 (Single vertex potential anomaly). Given a score function $f_i : \mathbb{R} \to \mathbb{R}$ for each vertex v_i and a threshold value $c_0 \geq 0$, a vertex $v_i \in V$ is said to have a potential anomaly at time t when its time series value is such that $|f_i(x_i[t])| > c_0$.

Note that the potential anomaly is local on the graph, i.e. it depends only on the time-series attribute of a considered vertex. If the score function is such that $f_i = f - \hat{f}(v_i)$, for some function f and $\hat{f}(v_i)$ a summary statistics of the scores $f(v_i[t])$, our definition corresponds to the definition of the anomaly in [33]. A basic example of a potential anomaly is the time-series values exceeding a fixed threshold c_0. In that case, f_i is the identity.

In this work, potential anomalies have to satisfy the following requirement. A potentially anomalous node must have a sufficient number of bursts in their time-series attribute. Unless this requirement holds, we discard the node. To define a burst of activity we compute the mean μ_i and the standard deviation σ_i of x_i over time. We normalize the time-series by defining the score function $f_i^b(x_i[t]) = (x_i[t] - \mu_i)/\sigma_i$. We select values that are above c_0^b, the activity rate parameter ($c_0^b = 5$ for Wikipedia, $c_0^b = 3$ for Enron). The *burstiness* b_i of a signal x_i of a node i is

$$b_i = \sum_{t=0}^{T-1} k_i[t], \qquad k_i[t] = \begin{cases} 1, & \text{if } |f_i^b(x_i[t])| > c_0^b, \\ 0, & \text{otherwise.} \end{cases} \tag{1}$$

The minimal number of bursts (potential anomalies) per vertex in Wikipedia is $b_i = 5$ while in the email dataset it is $b_i = 2$.

The general definition of the potential anomaly allows for other score functions, such as a moving average or ARMA filter prior to the thresholding, a short time Fourier transform or a wavelet transform. This depends on the dataset and should be chosen carefully to make a compromise between efficiency and scalability.

Applying f_i to the time-series gives us 1) features reflecting an anomaly and 2) an initial indication of anomalous behavior. In practice, removing nodes with no potential anomaly reduces the amount of data by an order of magnitude without losing relevant information that is required for the anomaly detection.

Stage 2: Hopfield network learning. The presented anomaly detection approach is aimed at detecting groups of vertices that have a similar, abnormal behavior. The learning stage is intended to make this coherent behavior apparent in the memory network.

Our approach is based on the Hopfield model of artificial memory [18]. It is an unsupervised learning method. To implement it, we use a synaptic-plasticity-inspired computational model, the Hebbian learning rule [17]. The main idea of this model of brain memory is that a co-activation of two neurons results in the reinforcement of a connection (synapse) between them. Although, contrary to the original learning rule, in our model, we do not take causality of activations into account.

In our case, the Hopfield network has N nodes. These nodes correspond to the ones given in the dataset, after the reduction performed at Stage 1 (only the nodes containing potential anomalies).

The learning process is as follows. We use the initial structure of the given network. For two initially connected nodes i and j of the Hopfield network, at time t, we update the weight of an edge e_{ij} between them according to the similarity measure $\mathrm{Sim}\{i, j, t\}$. Note that we only perform this step for the nodes that are initially connected and do not compare every possible pair of nodes. This is crucial for the tractability of the method in cases when we deal with large networks. For each time step t, the edge weight w_{ij} between i and j is updated as follows:

$$\Delta w_{ij} = \begin{cases} +Sim\{i,j\}, & \text{if } Sim\{i,j\} > \lambda, \\ -\alpha Sim\{i,j\}, & \text{otherwise,} \end{cases} \tag{2}$$

where $\lambda \geq 0$ is the *sparsity parameter*. Similarly to firing neurons, nodes expressing similar behavior have their connection weight increased. When $\alpha > 0$, the weight decreases allowing older events to be forgotten in order to keep only the latest anomalies. In our experiments, we set $\alpha = 0$, as we want to keep all the anomalies. We also fix $\lambda = 0.5$. The value of λ influences the sparsity of the final network. Increasing λ reduces the number of edges in the resulting memory network. One should increase the value of λ, when looking for the most outstanding anomalies and decrease it, when a higher sensitivity is required.

Before describing the similarity function, let us introduce the activity function y_i at a node v_i:

$$y_i[t] = x_i[t] \times k_i[t]. \tag{3}$$

Note that the activity function can also be defined from the features calculated at Stage 1, $y_i[t] = f_i(x_i[t]) \times k_i[t]$. In the present work, we use the definition (3).

Different similarity measures can be defined. A first example is the following:

$$\mathrm{Sim}\{i, j, t\} = y_i[t] y_j[t]. \tag{4}$$

When y_i and y_j are normalized, this measure gives the Pearson correlation between the nodes (if $\lambda = 0$ and $\alpha = 1$). The L^2 distance with a Gaussian kernel $\mathrm{Sim}\{i, j, t\} = \exp(-|y_i[t] - y_j[t]|^2)$ can also be a good candidate. Another measure, restricted to the interval $[0, 1]$ and that worked well in our applications, is defined as follows: $\mathrm{Sim}\{i, j, t\} = 0$ if $y_i[t] = y_j[t] = 0$ and otherwise,

$$\mathrm{Sim}\{i, j, t\} = \frac{\min(y_i[t], y_j[t])}{\max(y_i[t], y_j[t])} \in [0, 1]. \tag{5}$$

Recalling process. Starting from an initial partial memory pattern $P_0 \in \mathbb{R}^{N \times T}$, the recall of a learned pattern is done by the following iterative computation:

$$P_{j+1} = h_\theta(W P_j), \tag{6}$$

where $W \in \mathbb{R}^{N \times N}$ is the weight matrix of the Hopfield network. The function $h_\theta : \mathbb{R}^{N \times T} \to \mathbb{R}^{N \times T}$ is a nonlinear thresholding function (step function giving values $\{-1, 1\}$) that binarize the vector entries. The value θ is the threshold (same for all entries). In our case, we build a network per month so W is associated to a particular month. For each $j \geq 0$, P_j is a matrix of binarized time-series where each row is associated to a node of the network and each column corresponds to a time step of the month considered. We stop the iteration when the iterative process has converged to a stable solution ($\|P_{j+1} - P_j\| \leq \varepsilon$, where ε is small, the norm is the Frobenius norm). The initial pattern P_0 is a binary matrix, where the rows have all values set to -1 (inactivity) except the ones associated to the partial memory pattern obtained from the time-series using the expression of k_i defined in Eq. (1). The computation of the iterative process is efficient as the matrices are sparse and in practice, it converges after a reasonable number of steps.

Graph visualization and community detection. Since the connections between nodes with similar activity are reinforced during the learning process, after we prune low-weight edges, each Hopfield network transforms into a modular graph structure with strongly connected clusters of nodes having a similar activity. These groups can be either isolated connected components or communities within the largest connected component. The analysis of the Hopfield networks and their communities provides a good way to spot, analyze, and interpret the anomalies in the dynamics as we will see in the next section. To find communities, we use the Louvain method [7] and to represent the graph in 2D space for visualization, we use a force-directed layout [19]. Additional and more interactive visualizations are available online [28].

Storing memories of detected anomalies. The number of anomalies that can be memorized by a single network is limited [26]. Indeed, without the forgetting parameter α, the clusters of nodes will accumulate inside the graph, eventually overlapping and forming larger clusters of unrelated anomalies. To avoid this but still keep track of older events, we create snapshots of memories by slicing the time-series into time-windows of the finite duration. The time-window size depends on the application. For example, in the analysis of Wikipedia data, we use time-windows of one-month length.

Complexity. The computations are tractable because 1) they are local on the graph, i.e. weight updates depend on a node and its one-hop neighbors, 2) weight updates are iterative, and 3) a weight update occurs only between initially connected nodes and not among all possible combinations of nodes. These three facts allow us to build a distributed model to speed up computations. For this purpose, we use a graph-parallel Pregel-like abstraction, implemented in the GraphX framework [15], [37].

Stage 1 has complexity $O(NT)$ where N is the number of nodes and T the number of time steps. Stage 2 has a complexity of $O(ET)$, where E is the number of edges. The recall process involves a multiplication by a sparse matrix with $2E$ non-zero entries, hence the complexity is $O(ET)$. It is important to point out that the number of nodes and edges in the computations are not necessarily the numbers found in the dataset: Stage 1 may discard a large number of inactive nodes (containing no potential anomaly), Stage 2 sparsifies the time series as Eq. (3) may set to zero a large number of values.

4 DATASETS

Wikipedia dataset. We use the dataset described in [6]. This dataset is based on two Wikipedia SQL dumps: English language articles and user visit counts per page per hour. The original datasets are publicly available on the Wikimedia website [13].

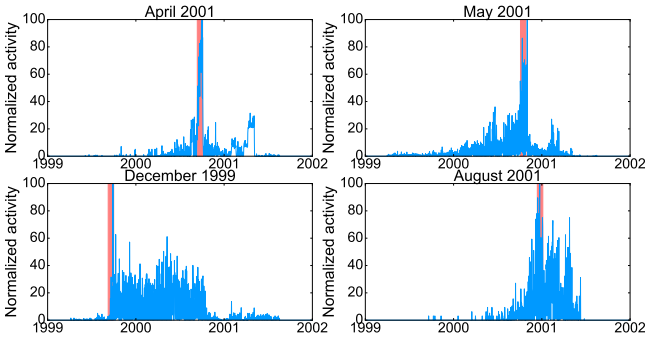

Figure 2: Anomaly detection in Enron email network. Red areas highlight the month periods previously reported as anomalies (ground truth supported by the real world events). Blue lines reflect the normalized (scale 0-100) overall activity level in the network computed by the proposed algorithm. We can see that the algorithm detects anomalies in all reported cases.

The Wikipedia network of pages is first constructed using the data from article dumps that contain information about the references (edges) between the pages (nodes)[1]. Time-series are then associated to each node (Fig. 1), corresponding to the visits history from 02:00, 23 September 2014 to 23:00, 30 April 2015. The time-series have a length of $T = 5278$ hours.

Enron dataset. We use Enron email dataset[2]. It contains 614586 emails sent over the period from 6 January 1998 until 4 February 2004. We remove the periods of low activity and keep the emails from 1 January 1999 until 31 July 2002 which is 1448 days of email records in total. We remove inactive email addresses that sent less than three emails over that period. In total, the Enron email network contains 6 600 nodes and 50 897 edges.

5 EXPERIMENTS AND RESULTS

In this section, we present our results of the anomaly detection experiments. We apply the proposed algorithm to the two datasets. The results obtained from the Enron one serve mainly to validate the method so we do not describe the analysis of the data. We dedicate more space to the detailed inspection of the Wikipedia dataset, which is a larger and more informative dataset allowing us to demonstrate the scalability of our method and to provide the detailed interpretation of the results.

Enron email dataset. In order to apply our anomaly detection algorithm to this dataset, we represent the data as a time-series graph data structure, which is depicted in Fig. 1. The static graph is the network of email communications: the nodes are email addresses and they are connected if they have exchanged at least one email over the 5 years. It is an undirected, unweighted graph. Time-series associated to the nodes are captured from the email activity; each temporal value is the number of emails sent from the associated address during one day. Here, the connection between email addresses is reinforced if a similar amount of emails have been sent by both of them over the same hour. Note that the graph and time-series design could have been more complex with directed edges or time-series associated to the edges. However, in order to stay as general as possible, we decided to strictly follow the steps described in Sec. 3.

In this case, an anomaly is a sudden increase in email communications among a group of employees of the corporation. After learning a Hopfield network for every month, we investigate their structure. We select four months where the results can be compared to the literature. The authors of [35] observe four anomalous periods and relate them to the specific news reports involving Enron. We use these events as a ground truth. These are the months of December 1999, April, May and August 2001. For each month, we select the largest connected component of the learned graph. We sum up the activity of its nodes to get a single time-series representative of the group activity. We show this normalized activity on Figure 2. We define an anomaly to be a spike of overall activity in a cluster of email addresses that we detect after learning. All the four curves have a larger activity during the chosen month than in the rest of the time span. For April and May 2001, it is more than twice the maximal activity for the rest of the months, showing the evidence of an anomaly. December 1999 and August 2001 increases in activity have a longer trace after the main anomaly has been detected but still, the high activity does not spread for more than one year. Concerning the monthly components of active nodes for the 4 chosen months, it involves 29, 25, 126, 28 nodes respectively for December 1999, April, May and August 2001. Almost all of them correspond to addresses of Enron employees. Except for the May event, the activity involves less than 30 persons. In May, it involves 100 employees out of the 158, showing an event that impacted the whole company.

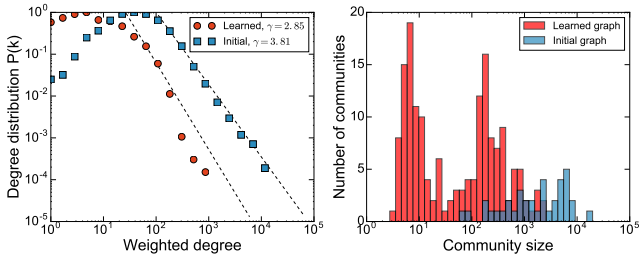
The application of our method to the Enron dataset allows detecting all the anomalies presented in the state-of-the-art literature. It reveals the days of the peak activities, the duration of the events, and the persons involved, which makes more detailed investigation possible in the future. Besides, our approach can detect periodic or recurrent anomalies due to associative nature of the Hopfield network. This feature will be demonstrated in the following experiments on the Wikipedia data.

Wikipedia dataset. We conduct more detailed experiments on the Wikipedia web network and use Google Trends data as a ground truth to verify the accuracy of our findings. An anomaly, in this case, is a sudden increase in visitor activity in a small, local part of the web network. We start by analyzing the initial graph of Wikipedia web pages connected with hyperlinks. In this experiment, the time-series attributes of the nodes correspond to the viewership statistics of the associated web pages, described in Section 4.

To learn the global anomalies that occurred in the long-term dynamics of the Wikipedia web network, we build the Hopfield network of the 7-month period. After the learning, only 275 498 edges have strictly positive weights (4.2% of the initial graph). We remove the disconnected nodes and preserve only the largest connected component of the graph. The number of remaining nodes is 35 839 (31% of the initial number).

[1]Note that Wikipedia is continuously updating. Some links that existed at the moment we made the dump may have been removed from current versions of the pages. To check consistency with past versions, one can use the dedicated search tool at http://wikipedia.ramselehof.de/wikiblame.php.

[2]https://www.kaggle.com/wcukierski/enron-email-dataset



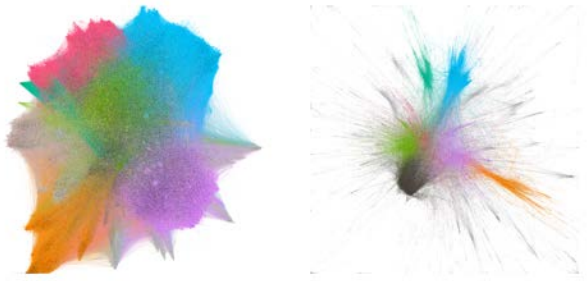


Figure 3: *Left.* Weighted degree distribution in log-log scale for the Wikipedia graph and Hopfield network learned over the entire 7 months time span. Linearity in log-log scale corresponds to power-law behavior $P(k) \sim k^{-\gamma}$. The learned graph preserves a similar scale-free behavior, but is less connected and has fewer hubs than the initial graph. *Right.* Community size distribution of the initial Wikipedia graph of hyperlinks (blue) and the learned Hopfield network (red). The total number of communities: 32 for the initial graph, 172 for the learned one.

(a) Initial (b) Learned

Figure 4: Wikipedia graph of hyperlinks (left) and learned Hopfield network (right). Colors correspond to the detected communities. The learned graph is much more modular than the initial one, with a larger number of smaller communities. The layout is force-directed.

The analysis of the static underlying graphs shows that both (the initial and learned) Wikipedia graphs have statistically heterogeneous connectivity (Fig. 3). However, the initial Wikipedia graph is dominated by large hubs that attract most of the connections to numerous low-degree neighbors. These hubs correspond to general topics in the Wikipedia network. They often link broad topics such as, for instance, the "United States" page, with a large number of hyperlinks pointing to it from highly diverse subjects. If we look at the viewership statistics, the activity of the visitors in these large clusters is uniform and does not expose any anomalies over time. We aim at extracting smaller communities that correspond to localized anomalies in the dynamics of the network. This is why we need the learned graph.

The visualizations of the initial and learned graphs using a force layout algorithm show striking differences (Fig. 4). The initial Wikipedia graph is dense and cluttered with a significant number of unused references, while the learned graph reveals smaller and more separated communities. This is also confirmed by the numerical measures such as the community size and degree distributions of the graphs (Fig. 3, right). The number of communities and their size change after learning. Initially, the small number of large communities dominate the graph (blue), while after the learning (red) we see a five times increase in the number of communities. Moreover, as a result of the learning, the size of the communities decreases by one order of magnitude. The modularity of the learned graph is 25% higher, strengthening the evidence of the creation of associative structures. These measures indicate that as a result of learning, we obtain a graph structure with small strongly connected clusters that correspond to a summary of anomalies in the network dynamics. We provide detailed examples of such anomalies in the following experiments.

The analysis of each community of nodes in the learned graph gives a glimpse of the events that occurred during the 7-month period and caused the anomalous behavior of visitors during that period of time. Each cluster is a group of pages related to a common topic such as a championship, a tournament, an awards ceremony, a world-level contest, an attack, an incident, or popular festive events such as Halloween or Christmas.

Before going deeper into the clusters analysis and the corresponding anomalies in the network dynamics, we investigate the evolution of the graph structure over time with an emblematic example.

Monthly networks. As stated in Sec. 3, we split the dataset into one-month periods. These periods are longer than the duration of an average event attracting the attention of Wikipedia users, that usually lasts no longer than two weeks. This means that we are going to detect multiple anomalies at once. Monthly graphs are smaller, compared to the 7-months graph, and contain 10 000 nodes on average. However, the properties and distributions of monthly graphs are similar to the 7-months one, described above.

To give an example of a detected event and the associated anomalous behavior of the Wikipedia users, we discuss the cluster of the USA National Football League championship, spotted in and extracted from the Hopfield network during several months between 2014 and 2015 (Fig. 5).

NFL is one of the most popular sports leagues in the USA and it triggers a lot of interest to the related articles on Wikipedia. Due to the high number of visits on this topic we were able to localize a cluster related to the NFL on each of the monthly graphs. Figure 5 shows the detailed information about the NFL clusters. The top part of the figure contains the learned graphs for each month, where the NFL cluster is highlighted in red.

The final game of the 2014 season, Super Bowl XLIX, had been played on February 1, 2015. This explains the continuous expansion of the cluster until February where its size reaches the maximum. The activity collapses right after this event and the cluster disappears.

For the sake of figure interpretability, we extracted 30 NFL team pages from the original cluster (485 pages) to show the details of the evolution in time as a table on Fig. 5. This fraction of the nodes reflects overall dynamics in the entire cluster. Each row describes the hourly activity of a page, while the columns split the plot into

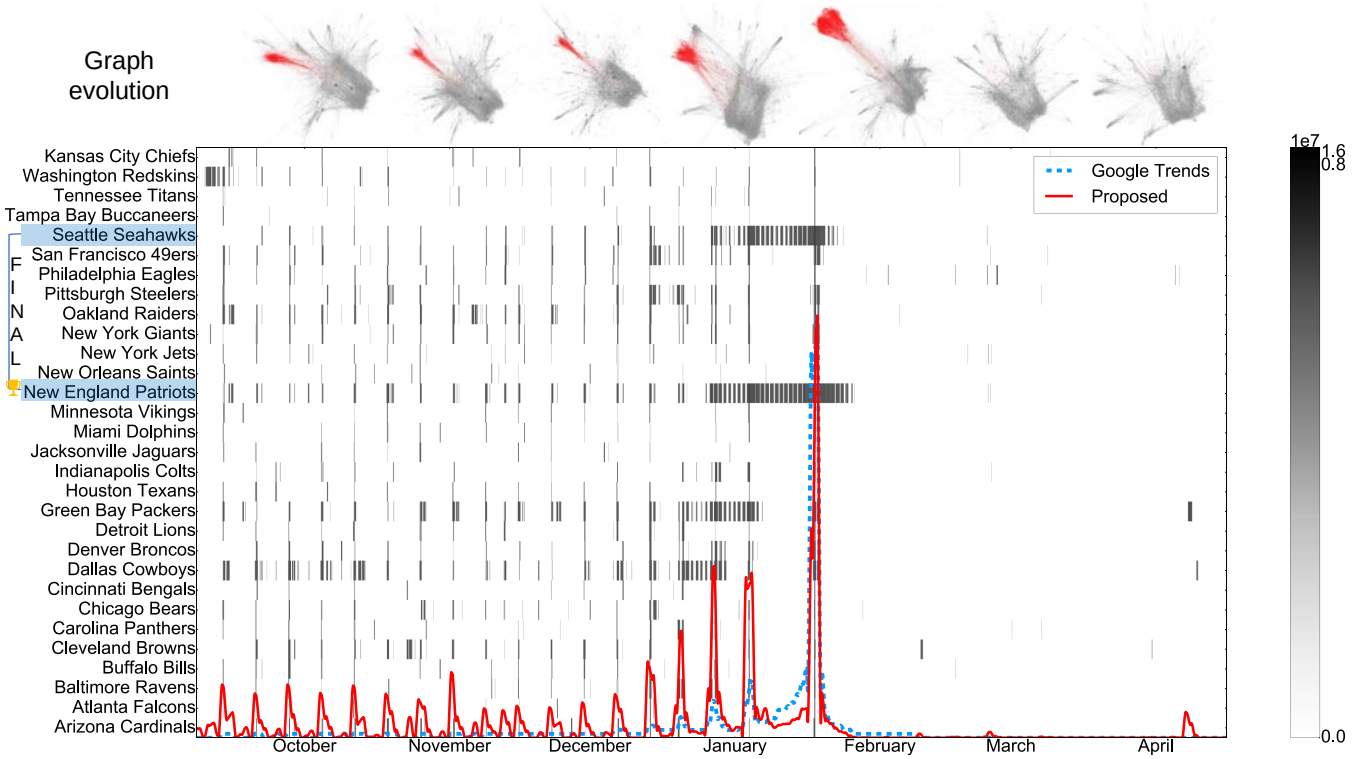

Figure 5: Evolution of the National Football League 2014-2015 championship cluster and visits on its articles. We show 30 NFL teams from the main cluster. Top: the 7 monthly learned graphs in gray, with the NFL cluster highlighted in red. The month is displayed on the bottom of the figure. Middle table: visitors activity per hour on the NFL teams' Wikipedia pages in greyscale (the more visits, the darker). Bottom: the red and blue curves are the total number of visits in the articles of the clusters over time (normalized) and the Google Trends curve for the keyword "Super Bowl", respectively.

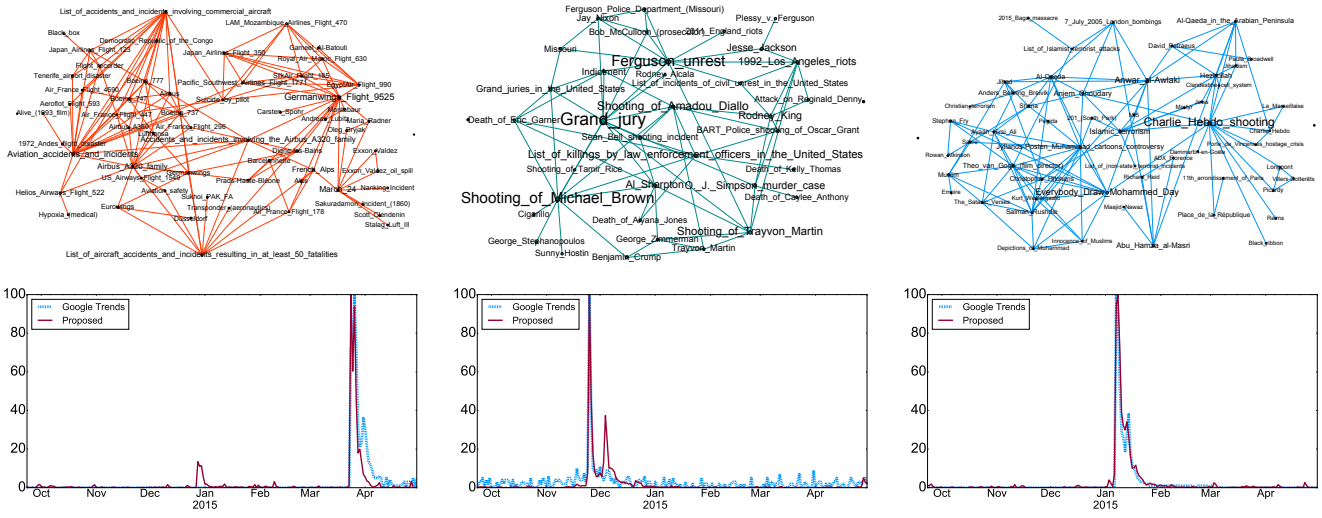
months. The sum of visits for the selected pages is plotted as a red line in the bottom.

The dynamics of the detected cluster reflects the real timeline of the NFL championship. The spiking nature of the overall activity corresponds to weekends when most of the games were played. Closer to the end of the championship, the peaks become stronger, following the increasing interest of fans. We see the highest splash of the activity on 1 February, when the final game was played.



We want to emphasize that this cluster, as well as all the others, was obtained in a completely unsupervised manner. The football teams pages were automatically connected together in a cluster having "Super Bowl" as a common topic. Moreover, the cluster is not formed by one Wikipedia page and its direct neighbors, it involves many pages with distances of several hops in the graph.

The NFL championship case is an example of a periodic (yearly) event. The interest increases over the months until the expected final event, which causes an anomaly in the network dynamics. Accidents and incidents are the events of a different nature as they appear suddenly, without prior activity. The proposed learning method allows detecting this kind of events and the related anomalies as well. We provide examples of three accidents to demonstrate the ability of our method to detect anomalous behavior in the network in case of an unexpected event.

We pick three core events among 172 detected and discuss them to show the details of our anomaly detection approach. Figure 6 shows the extracted clusters from the learned graph (top) and the overall timeline of the clusters' activity (bottom). We evaluate the accuracy of the anomaly detection using Google Trends history records.

Charlie Hebdo shooting. 7 January 2015. This terrorist attack is an example of an unexpected event. The cluster emerged over a period of 72 hours, following the attack. All pages in the cluster are related to the core event. Strikingly, a look at the title of the pages is sufficient to get a precise summary of what the event is about. There is a sharp peak of activity on the first day of the attack, slowly decaying over the following week.

Germanwings flight 9525 crash. 24 March 2015. This cluster not only involves pages describing the crash or providing more information about it, but also the pages of similar events that happened in the past. It includes, for example, a page enumerating airlane crashes and the page of a previous crash that happened in December 2014, the Indonesia AirAsia Flight 8501 crash. As a result, the time activity of the event is connected to the one of the Flight 8501 crash, that is why we can see an increase in visits in December. This is an example where our approach captures two relevant events and

(a) Germanwings 9525 crash (b) Ferguson unrest (c) Charlie Hebdo attack

Figure 6: Graphs and activity timelines of the 3 events that triggered anomalies in the network dynamics. Top: Clusters of pages grouped after learning in the Hopfield network. Bottom: A normalized sum of all visits of the articles of each cluster over time (in red). The Google Trends curve for the keywords "Germanwings 9525 crash" (a), "Ferguson unrest" (b) and "Charlie Hebdo attack" (c) is displayed in blue.

groups them together in one cluster allowing to detect a secondary anomaly that is only implicitly related to the main one.

Ferguson unrest. Second wave. November 24, 2014 – December 2, 2014. This is an example of an event that has the official beginning and end dates. A sharp increase in the activity at the beginning of protests highlights the main event. This moment triggers the core cluster emergence. We also see that the cluster becomes active once again at the end of the unrest allowing to record the two related anomalies in the visitor activity.

Finally, in Table 1, we summarize our exploration of the clusters of the learned graphs by providing a list of handpicked page titles inside each cluster that refer to previous events and related subjects. The connected events occurred outside of the 7-months period we analyze. This illustrates the associative property of our the anomalies we detect. Firstly, pages are grouped by events with the help of visitors activity. Secondly, the events themselves are connected together by this activity. An anomaly is characterized by a group of connected concepts and these groups are in turn connected together through concepts they share. This feature makes it easy to interpret the cause of the detected anomaly.

Google Trends Evaluation. For each of the events presented before, we have compared the total number of visits in the clusters with Google Trends curves reflecting anomalous search activity of internet users. There is a striking correspondence between the detected anomalies and Google Trends, as we can see in Fig. 5 and 6. In all 4 examples, the anomalous activity and Google Trends curves reach their maximum at the same time and have a very similar shape. The differences that appear during the months prior to the Super Bowl date are explained by the fact that our "Super Bowl" cluster contains articles about Football teams and other topics related to the Super Bowl. Due to the associative nature of the detected anomalies, this example has a higher accuracy of detection than Google Trends.

As discussed previously, the periodic spikes in the visitor activity take place during the weekends when football matches are played. We observe the same phenomenon in the case of the Germanwings crash, where we observe a small peak of activity in December. This peak is the result of the prior activity on the pages related to another airplane crash that happened in December 2014. Again, this demonstrates the richness of the obtained clusters: they describe a group of events that caused an anomaly in visitor activity, as confirmed by Google Trends but represent more than a single keyword since the detected anomaly is a result of multiple real-world events.

Recalling memories. In this last experiment, our goal is to test the hypothesis that the proposed method, as a memory, allows recalling or recovering events from partial information. We emulate recall processes using the Hopfield network approach, described in Section 3. We show that the learned graph structure can recover a full event (cluster of pages and its activations) from an incomplete input.

We create incomplete patterns for the Hopfield network by selecting randomly a few pages contained in a chosen cluster. We built the input matrix P_0 setting to (-1) (inactive state) all the time-series except for the few pages selected. We then apply iteratively Eq. (6).

We present only one example of the recall, to demonstrate the recall ability of the network but also to illustrate its complexity, on Fig. 7. From the cluster associated to the Charlie Hebdo Attack and we choose a subset of the list of articles, here 80%. We apply the learned graph for the month of January when the memory was detected. After the recall, we can remark two important facts. First, if we focus on the short time span when the event occurs (within

Table 1: Examples of Wikipedia article titles contained in the clusters associated to the events presented.

Charlie Hebdo attack	Germanwings 9525 crash	Ferguson unrest
Porte de Vincennes hostage crisis	Inex-Adria Aviopromet Flight 1308	Shooting of Tamir Rice
Al-Qaeda	Pacific Southwest Airlines Flight 1771	Shooting of Amadou Diallo
Islamic terrorism	SilkAir Flight 185	Sean Bell Shooting Incident
Hezbollah	Suicide by pilot	Shooting of Oscar Grant
2005 London bombings	Aviation safety	1992 Los Angeles riots
Anders Behring Breivik	Air France Flight 296	O.J. Simpson murder case
Jihadism	Air France Flight 447	Shooting of Trayvon Martin
2015 Baga massacre	Airbus	Attack on Reginald Denny

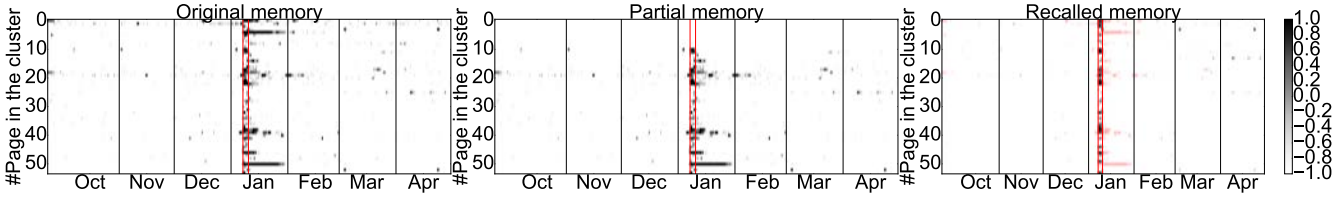


Figure 7: Recall of an event from a partial pattern (Charlie Hebdo attack). The red vertical lines define the start of the event and its most active part, ending 72 hours from the start. Left: full activity over time of the pages in the cluster. Middle: pattern with 20% of nodes set inactive (top lines). Right: the result of the recall using the Hopfield network model. In light red are shown the difference with the original pattern (the forgotten activity).

the red vertical lines), most of the cluster is recovered. Second, the model forgets a part of the activity, plotted in light red, outside of the event bounds. This missing part is made of pages that are active outside of the time of the event, giving the evidence that they are not directly related (or weakly related) to the event.

The results of this experiments show that our method can be used to recover the signals related to the detected anomalies given a noisy or incomplete input. For instance, this feature can be helpful in cases when the data required for anomaly interpretation is destroyed by some intruders that are interested in hiding traces after an attack on the network.

6 CONCLUSIONS AND FUTURE WORK

In this paper, we presented a new unsupervised graph algorithm that allows detecting anomalies in large datasets with dynamic activity records. We showed that this approach allows analyzing the root causes of detected anomalies. Beyond the presentation of the method, we also provided new insights on collective behavior of Wikipedia users.

This approach is promising. We noted experimentally a high robustness of the method to the tuning of the parameters. We also plan to go deeper into the analysis of the recalling process.

This work opens new avenues for dynamic graph-structured data analysis. For example, the proposed approach could be used in a framework for automated event detection, monitoring, and recording. However, to cover these use cases, the method should be able to process streams of data as they are recorded. An online version of the method is not straightforward and will be the object of future work.

The artificial memory model used in the method suggests an interesting connection between the detection of anomalies and the functioning of the memory. This insight is more apparent in the experiments related to Wikipedia. Events and abnormal activity in the data trigger the recording process of the collective associative memory. The Hopfield network trained on Wikipedia articles transforms into a set of interconnected concepts or topics that have interested people at some point in the past. It resembles an artificial collective memory. This is fascinating and deserves further research in this direction related to social sciences.

7 TOOLS, IMPLEMENTATION, CODE AND ONLINE VISUALIZATIONS

All learned Wikipedia graphs (overall September-April, monthly activity, and localized events) are available online [28] to foster further exploration and analysis. For graph visualization we used the open source software package Gephi [4] and layout ForceAtlas2 [19]. We used Apache Spark GraphX [37], [15] for graph learning implementation and graph analysis. The presented results can be reproduced using the code, written in Scala and Python [27], [29]. Both datasets are available on Zenodo [21], [30].

ACKNOWLEDGMENTS

We would like to thank Michaël Defferrard and Andreas Loukas for fruitful discussions and useful suggestions. Also, we would like to thank anonymous reviewers for their constructive criticism and recommendations that helped improve this paper.

The research leading to these results has received funding from the European Union's H2020 Framework Programme (H2020-MSCA-ITN-2014) under grant agreement n^{o} 642685 MacSeNet.

ABSTRACT

The goal of Information Retrieval (IR) systems is to satisfy searchers' Information Need (IN). Our research focuses on next-generation IR engines, which can proactively detect, identify, and serve INs without receiving explicit queries. It is essential, therefore, to be able to detect when INs occur. Previous research has established that a realisation of INs physically manifests itself with specific brain activity. With this work we take the next step, showing that monitoring brain activity can lead to accurate predictions of a realisation of IN occurrence. We have conducted experiments whereby twenty-four participants performed a Q/A Task, while their brain activity was being monitored using functional Magnetic Resonance Imaging (fMRI) technology. The questions were selected and developed from the TREC-8 and TREC 2001 Q/A Tracks. We present two methods for predicting the realisation of an IN, i.e. Generalised method (GM) and Personalised method (PM). GM is based on the collective brain activity of all twenty-four participants in a predetermined set of brain regions known to be involved in representing a realisation of INs. PM is unique to each individual and employs a 'Searchlight' analysis to locate brain regions informative for distinguishing when a "specific" user realises an information need. The results of our study show that both methods were able to predict a realisation of an IN (statistically) significantly better than chance. Our results also show that PM (statistically) significantly outperformed GM in terms of prediction accuracy. These encouraging findings make the first fundamental step towards proactive IR engines based on brain signals.

1 INTRODUCTION

Information need (IN) is an essential concept and plays a core and fundamental role in the information seeking and retrieval process. Over the last several decades, much research has been dedicated to better understand IN to most effectively satisfy it with information retrieval engines, e.g. [8, 12, 23, 32, 58]. In general, satisfying INs is a formidable challenge due to the inherent complexity and ambiguity associated with the IN concept. That is, expressing an IN using a set of query keywords is an uncertain and noisy process [53], as keywords can only vaguely approximate the actual IN [51]. The problem becomes even more pronounced when an IN is *ill-defined*: i.e., when the searcher only knows "fringes of a gap in [his/her] knowledge" [12] making it extremely difficult for the searcher to identify and describe the IN precisely with keywords [6, 8, 11]. Therefore, it is possible that a given query may not sufficiently define the characteristics of relevant documents, or even any relevant information since a searcher cannot form an appropriate initial state from which to form a query [13].

To close this gap, IR systems have been relying on techniques such as relevance feedback including explicit [29], implicit [57], and/or affective feedback [2] to better understand and satisfy users' information needs. Despite their invaluable contributions, these techniques lead to systems that are reactive in nature, being engaged in response to an input query issued by a user. Given the aforementioned problematic nature of users' queries (in terms of expressing searchers' real INs), recently, there is an increased interest in the research community in developing zero-query (or proactive) IR systems that aim to not only better understand, but even anticipate users' INs [9, 49]. These approaches mainly consider the contextual or behavioural information of users to predict their IN. While this is intuitively a promising approach, such proactive IR systems could potentially create an information overload situation for users, in particular, if users are not experiencing an IN when the information is presented to them. Therefore, being able to predict *when* an IN occurs is of high importance to better satisfying it. With this work, we make the first positive step in this direction.

Recently Moshfeghi et al. [42] have shown that there are clear, detectable, physical manifestations (i.e. neural correlates) of INs in human brains which can be identified in an early stage of an information seeking and retrieval process and also specific brain

regions where INs manifest themselves. However, two fundamental research questions remain unanswered:

- **RQ1:** "Is it possible to predict a realisation of an IN using brain signals?";
- **RQ2:** "Can we rely on a common set of predefined brain regions to predict a realisation of an IN or is there a unique set of regions for every individual?"

An answer to these questions will play a key role in opening new doors to the design and implementations of novel IR systems, which will be enabled to better and in particular proactively satisfies searchers' IN. To do so, we aim to train a classification model on brain activity to be able to discriminate between an IN realisation vs memory retrieval, within an IR process performed by participants engaged in a Question Answering (Q/A) retrieval task. In particular, in this paper, we are focusing on the period in which the brain exhibits complex activity with regards to the process analysing a question, from the moment of observing the question to the point in time when they either recognise an "Anomalous State of Knowledge" (ASK) [7, 8], or they have a successful memory retrieval. We then aim (i) to build a model that predicts a realisation of IN (in its earliest possible state) from the signals of the brain regions that have been associated with an IN realisation and (ii) contrast its prediction accuracy with the accuracy of a prediction model that considers the signals of the whole brain regions, in a Q/A task. Our positive results can be the basis for next-generation proactive IR systems based on brain signals.

The remainder of the paper is organised as follows: Section 2 presents related work and the background. Section 3 discusses at length the experimental methodology. Section 4 presents and analyses our results. Finally, Section 5 presents our key conclusions.

2 RELATED WORK

2.1 From Reactive to Proactive IR

A well-known issue in IR research is that INs are inherently complex and ambiguous in that, typically, users may not know beforehand exactly what they are looking for, or, in other words, what are the set of documents/information that would satisfy their need [12]. Given this, formulating queries (i.e., mapping INs to a set of keywords) is inherently an imperfect process [7, 8, 12, 22, 51]. The formulated query is unavoidably therefore not guaranteed to be an accurate representation of the users' IN, and thus brings about the question whether the retrieved documents are relevant [55].

IR systems have addressed this issue using mechanisms based on relevance feedback. In short, relevance feedback is an iterative process whereby the system receives cues from users as to the relevance of presented results so far, improving the relevance of results presented in the next step in the process. Such cues from users come in many forms and types. As mentioned in Section 1, relevance feedback can be categorised as being explicit [29], implicit [57], and/or affective [2]. The most robust method to improve retrieval effectiveness is explicit feedback [29]. However, it places a large cognitive burden on users [56]. Implicit feedback avoids this pitfall. In implicit feedback, relevance is indirectly inferred from the interactional data without users' additional input [24]. Researchers, for example, have tried to infer relevance by understanding how task [57] dwell time [28] and click-through [24] relate to relevance. However, this is not a panacea. Kelly and Belkin [27] have shown that implicit feedback can be unreliable and difficult to interpret, limiting its usefulness. Affective feedback, on the other hand, [2] relies on different types of feedback data, such as facial expressions [5], eye tracking [36], and physiological signals [3, 38] (such as skin temperature) and uses them as implicit relevance judgements. Nonetheless, affective feedback on its own is not yet considered to be very effective. More recently, Arapakis et al. used emotions in the process of information retrieval [2, 4] and later showed that emotions can be used for building implicit feedback systems [4], and to personalise search [2]. Going a step further, the work by Moshfeghi et al. used, in addition to emotions, [39], physiological features both for modelling relevance and for predicting task types [38]. However, these approaches are reactive in nature, being engaged in response to an input query issued by a user. In this work, we aim to predict a realisation of IN before a user has issued a query.

Similar research efforts in the community have begun to explore and stimulate discussion about systems that can proactively anticipate and fulfil the information needs of users [10]. In addition to the works published in [10], additional research in this domain of proactive IR is emerging. A recent example is the work by Song et al. [49] where a query-less search and recommendation engine was proposed. The engine predicts when and what types of tasks users will issue in the near future by considering the time dimension. They also considered a personalised approach for predictive IR by performing model adaptation by learning individual deep learning models for each user task. However, their proactive model is based on strong user behaviour repetition in search engine logs and even stronger repetition on mobile devices. An even more recent example is the work by Benetka et al. [9] which addresses the problem of identifying, ranking, and anticipating a user's information need, based on users' last activity. This work develops a method that gathers and ranks information needs relevant to an activity using a limited amount of query suggestions from a search engine. However, in this study, INs are inferred from users' check-in records on a location-based social network.

Our paper blends well with the above research efforts. By predicting a realisation of IN from brain signals, IR system could be in stronger position to disambiguate and understand INs, e.g. by taking into account contextual information/data around the time an IN was realised. It also could alleviate information overload scenario. That is, a proactive IR system could make a better decision as to provide any information to users, based on their prediction of a realisation of IN from their brain signals.

2.2 Advances in Neuroscience & IR

There is growing research literature using modern techniques of brain imaging to explore the user perspective of IR. The two topics which have received attention include relevance and information need (IN), though other research has begun to investigate the effect of task and specificity of search results [43]. Research into the topic of relevance has been performed using the brain imaging techniques of Electroencephalography (EEG), magnetoencephalography (MEG) and fMRI. Results of Moshfeghi et al. [40] used fMRI to identify brain regions activated by the process of judging the relevance of an

image. They contrasted brain activity from the viewing of relevant images to non-relevant images. Brain regions with higher activity when viewing relevant items included the inferior parietal lobe, inferior temporal gyrus and superior frontal gyrus. While these results were interpreted as representing the activity of visuospatial working memory on relevant items, the prefrontal cortex has also been shown to be activated in judging the relevance of written items [44] and thus this region could be involved in aspects of general task control and decision making.

Another study into relevance was conducted by Eugster et al. [17] that used EEG to show that the frequency content of the EEG signal as well as Event Related Potentials (ERPs) can be used effectively as a set of features to decode the relevance of a text. This work was later extended [16] to show that methods of automatic classification applied to single trials could be used to classify individual words being read as relevant or non-relevant successfully. Likewise, Kauppi et al. [25] showed using MEG that the frequency content of the MEG signal, along with eye movement data can be used for decoding the relevance of images. These results are consistent with the findings of Allegretti et al. [1] who reported on EEG results that indicated that within 500 ms EEG signals begin to appear that differentiate between viewing a relevant and a non-relevant image. These studies with fMRI, EEG and MEG have used the relative strength of the different measurement techniques to make great progress and to indicate where in the brain relevance judgments are happening and what the time course is of these neural processes that determine relevance.

Expanding upon work on relevance, research by Moshfeghi et al. [42] used fMRI to examine the neural processes involved in how IN emerges. In this study, they compared two tasks where participants read a question and were provided with responses that included the possibility of answering the question or asking for additional information (acknowledging an information need). In the first task, participants went on to the next trial regardless of their response, but in the second task they went on to an information retrieval dialogue if they stated an information need. Brain imaging results revealed the posterior cingulate as a region common to both tasks. However the posterior cingulate can be divided into different regions, and activity in different regions was found for the two tasks that reflect the role of the posterior cingulate in switching between internal (e.g. memory) and external (e.g. sensory) sources of information.

How the neural correlates of IN fit into the larger context of a search was explored by Moshfeghi and Pollick [41] who investigated search as a process of transitions between neural states. To achieve this, they defined the time periods corresponding to five different aspects of search (realisation of Information Need, Query Formulation, Query Submission, Relevance Judgment and Satisfaction Judgment) and the brain activity was contrasted between these different periods. Results showed how the cognitive demands of the different search periods involved various large-scale brain networks including perception, cognition and executive control that reflected task demands. For example, the transition between IN and Query Formulation revealed extensive changes consistent with what would be expected from the dynamic restructuring of neural resources to attempt to answer the query. Motivated by these results, this paper indicates that the period of IN involves complex patterns of brain activity and by application of more sensitive data analyses, reliable fine patterns of brain activity that are consistent with being in a state of IN can be revealed.

3 EXPERIMENTAL METHODOLOGY

To investigate our research questions mentioned in Section 1, an information need scenario was created where participants were asked a multiple-choice question, and if they did not know the answer, they engaged in a search process. Before describing the experimental methodology in detail, we would like to point out several practical constraints on the design and analysis of fMRI experiments that are critical to consider [15, 40]. Firstly, the fMRI scanning environment is restrictive in that a participant is placed in the central bore of the scanner and must lay supine with their head kept still. Moreover, only limited response/interactive devices can be placed in this scanning environment without causing signal or safety issues. This constraint led to the use of multiple choice questions for a task since it was possible to provide a response using an MRI-compatible button box. Another constraint is that although fMRI provides a spatial resolution of brain activity to within a few millimetres, it does not have a fine temporal resolution. This is because the time taken to achieve one measurement of the entire brain takes approximately 2 seconds. This relatively slow rate of data acquisition is compounded by the fact that the Blood Oxygenation Level Dependent (BOLD) signal measured is related to the underlying neural signal in a complex way that introduces further delays [19]. As a consequence of these temporal factors, it was necessary to time the events happening in the experiment at a rate that was compatible with our fMRI measurements. To achieve a suitable design for our questions about IN we were guided by the methods used by Moshfeghi et al. [42] who explored the neural correlates of IN. These methods themselves had been adapted from research into problem-solving [59] that examined neural correlates of insight by comparing brain activity when a multiple choice response showed insight, to brain activity when a multiple choice response did not show insight. A final practical constraint is that running fMRI experiments are costly at £500 per hour which would limit the number of our participants.

3.1 Participants

Participants consisted of twenty-four healthy individuals with 11 males and 13 females. The participants were under the age of 44, with the largest group between the ages of 18-23 (54.1%) followed by a group between the ages of 30-35 (20.8%). The handedness survey indicated that 79.1% were right-handed, 12.5% were left-handed, and 8.33% were mixed-handed. Participants tended to have a postgraduate degree (20.8%), bachelors (33.33%) or other qualifications (45.8%). They were primarily students (54.1%), though there were a number of individuals who were self-employed (20.8%), not employed (4.16%) or employed by a company or organisation (20.8%). Participants were primarily native speakers (79.1%) or had an advanced level of English (20.8%). They all had experience in searching, with an average of 11.66 years (SD of 3.58) experience.

3.2 Design

We used a within-subject design for this study. The independent variable was the realisation of information need, with two levels: an information need was realised (IN), and no information need was realised (no-IN), which was controlled by responding to questions viewed on the screen. The set of questions were designed so that averaged across all participants there would be an equal number of responses expressing an answer and expressing a need for search. The dependent variable was brain activity revealed by the BOLD signal. From this BOLD signal, we estimate the accuracy of different prediction methods of a realisation of an IN.

3.3 Task

The entire experimental procedure is explained in the following section, and here we explain the task performed by participants in an experimental trial while being scanned. Participants first were presented with a question for 4 seconds, then for 4 seconds, four possible responses were provided while the question remained on the screen. Participants were not able to make a response until after the 4 seconds of observing the possible responses. The reason for this was so that brain activity related to the motor response of pressing the button would not be contained in the target pattern of brain activity, which only included these first 8 seconds. After the 8 seconds, participants were able to respond. Of the four possible responses, one was always the correct answer, and one of them was always "need to search". If participants chose that they needed to search then, this trial was labelled as a "IN", and otherwise, the trial was labelled as "no-IN". The position of the four alternatives was randomised for each trial and the response provided by pressing one of the four buttons available on the button box that each participant had in their right hand. The time to respond was left free so that participants were not under time pressure to respond. The order of the questions was randomised for each participant. If the answer "need to search" was provided then they entered an additional stage where they formulated a search query (and submitted it verbally into a noise-cancelling microphone), received a document and evaluated this document. In the present study, we do not investigate brain activity during the search and document evaluation periods. Instead, we focus only on the brain activity in response to the presentation of the question and the possible responses.

3.4 Question Answering Dataset

To perform the task scenario mentioned in Section 3.3, we created a Question Answering dataset[1]. To develop this standard set of questions, we used previous runs of TREC Q/A Track, in particular, we carefully selected a set of 80 questions from the TREC-8 and TREC-2001 Question Answering Tracks - Main Task[2]. We chose these two Tracks since they were the first and last tracks where the questions presented there were (i) independent from one another, in contrast to other Tracks that share a relationship, and (ii) they also provided the correct answer to the questions.

[1]The Question Answering dataset is available upon request.
[2]For more information, please visit http://trec.nist.gov/data/qa/t8_qadata.html and http://trec.nist.gov/data/qa/2001_qadata/main_task.html

We then manually examined all the questions presented in these two tracks and selected a subset of questions that (i) was not longer than one line, and (ii) the correct answer to the question was not longer than five words. This constraint is due to the limitation of presenting the questions and options to the participants in an fMRI setting. An additional constraint was that there were at least two relevant and non-relevant answers in their QRel. We then removed the questions that were ambiguous or were time dependent, e.g. *"Who is the president of Stanford University?"* (TREC-8, Topic 51), making the answers provided in the Track not appropriate. The answers of all these questions were then checked by current search engines to make sure that the answers are still valid and correct. We also created two wrong answers for each question that were in the domain of the question. For example, for question *"What is supernova?"* (TREC- 2001, Topic 1067) the correct answer is *"An exploding star"* and we created two other wrong answers i.e. *"A newborn star"* and *"A dead star"*. We also made sure that the questions covered a wide range of topics, e.g. history, politics, science, etc. this was done to reduce any bias that might occur from an emphasis of a particular type of question.

Over this set of questions, two annotators separately judged the difficulty of the questions (i.e. hard or easy) and then selected a subset of questions where both annotators agreed upon their difficulties. For our task, 40 questions were randomly selected where 20 were easy, and 20 were hard questions. Since the fMRI data acquisition for these 40 questions was divided into two runs, additional care was made to further divide the questions across the runs so that they both had 10 easy and 10 hard questions covering a variety of topics. The goal of this procedure was to control the set of questions such that on average there was an equal chance of experiencing ASK [7, 8] and knowing the answer.

Another extra step was to prepare the documents that were shown to the subjects once they engaged in a search process. This took the form of simulating a snippet answer that is returned by a current search engine such as Google when a question is submitted. For this purpose, we selected two relevant and two non-relevant documents from QRel. The length of the answers provided in TREC-8 and TREC 2001 were incompatible. To keep the size of the results consistent, for those answers that were too short, we found the original source file and selected sentences around the answer so that all snippets had the same length. The average length of the answers shown to the participants for the first and second run were 39.47 words (SD of 3.33) and 39.65 words (SD of 3.285) respectively. This was done to reduce any potential confounding effect of snippet size on the brain activity results.

3.5 Procedure

This section outlines the flow of the study, from beginning to end. Ethical permission for the study was obtained from the Ethics Committee of the College of Science and Engineering, University of Glasgow. Participants were recruited from the participant database at the Centre for Cognitive Neuroimaging, University of Glasgow. Participants were instructed that the experiment would take approximately one hour in total and would include performing tasks while being scanned, as well as a 10 minute period where the anatomical data were obtained, and they need only stay still. They were

informed that they could leave at any point in time during the experiment and would still receive payment (the payment rate was £6/hr). They were then asked to sign a consent form. Before participating, participants underwent a safety check to guarantee that they did not possess any metal items inside or outside of their body, or any other contraindications for scanning, such as certain tattoo inks. They were then provided with clothes (similar to a training suit) to wear for the duration of the experiment as a precaution to avoid interference with the fMRI signal from any metal objects in their clothes.

Next, to provide training before entering the scanner, participants were given an example task and a corresponding set of example questions to familiarise themselves with the procedure. Once they had successfully completed their training task, participants entered the fMRI machine, and the experimenter adjusted the settings of the machine to maximise their comfort and vision. While being scanned, each participant participated in two separate runs of our task, with each run comprised of 20 questions. A short rest break given between the two runs was chosen to give the participants a break to relax during the scanning and to prevent fatigue. After the functional runs were complete, the anatomical data of each participant were obtained.

After completion of scanning, participants were asked to fill out an *exit questionnaire*. The purpose of this questionnaire was to obtain demographic and background information about the participants. This included familiarity with related fMRI and user studies as well as questions addressed at understanding the participants' subjective experience about how they found the experiment. They also filled out the Edinburgh handedness questionnaire [45], which provides the evaluation of whether the participant was right-, left- or mixed-handed. Handedness information was obtained since lateralisation of brain function is influenced by handedness, and we wished to ensure that our sample of participants approximated the general population.

3.6 Apparatus

Visual presentation of the questions, answers and search results to participants was obtained using Presentation® software[3] to control projection on a LCD projector that projected onto a translucent screen, which was visible to participants in an angled mirror while they lay in the bore of the MRI scanner.

3.7 fMRI Data Acquisition and Preprocessing

A 3T Tim Trio Siemens MRI scanner, including a 32-channel head coil, was used to obtain all brain imaging data. This scanner is located on-site at the Centre for Cognitive Neuroimaging, University of Glasgow. Functional data included two T2*-weighted runs of our task with parameters: TR 2000ms; TE 30ms; 32 Slices; $3mm^3$ voxel; FOV of 210, imaging matrix of 70×70. An anatomical scan was performed at the end of the scanning session that comprised a high-resolution T1-weighted anatomical scan using a 3D magnetisation prepared rapid acquisition gradient echo (ADNI- MPRAGE) T1-weighted sequence (192 slices; $1mm^3$ voxel; Sagittal Slice; TR = 1900ms; TE = 2.52; 256×256 image resolution).

[3]Presentation® software (Neurobehavioral systems, Inc.), http://www.neurobs.com.

The fMRI data were preprocessed using Brain Voyager QX. A standard pipeline of pre-processing of the data was performed for each participant [20]. This involved slice scan time correction using trilinear interpolation based on information about the TR and the order of slice scanning. Three-dimensional motion correction was performed to detect and correct for small head movements by spatial alignment of all the volumes of a participant to their first volume by rigid body transformations. Also, linear trends in the data were removed, and high pass filtering with a cutoff of 0.0025 Hz performed to reduce artefact from low frequency physiological noise. The functional data were then coregistered with the anatomic data and spatially normalised into the common Talairach space [50]. Finally, the functional data of each individual underwent spatial smoothing using a Gaussian kernel of 6mm.

3.8 Pilot Studies

Before commencing the main study, we performed a pilot study with two participants to verify the procedure worked appropriately. The results of the pilot study verified the accurate logging of both behavioural and brain imaging data and generally confirmed the effectiveness of our procedure. However, it also revealed some aspects that could be improved, and we changed the procedure accordingly.

3.9 Multi-voxel Pattern Analysis (MVPA)

The technique of Multi-voxel Pattern Analysis (MVPA) is increasingly used to analyse fMRI data, aiming to identify patterns from brain activity and enabling sensitive identification of the information encoded by brain activity. Most early fMRI studies investigating perception and cognition employed a General Linear Model (GLM) and aimed to localise brain regions by employing a univariate analysis at every voxel to contrast the magnitude of the brain response to different stimuli conditions. In contrast, MVPA employs a multivariate analysis that can examine the spatial encoding of information in a set of voxels. Increased performance over the univariate GLM approach is obtained since brain activity related to a mental process can be distributed across multiple brain areas [33], and MVPA is sensitive to these differences.

3.10 IN Prediction Methods using MVPA

For prediction of IN realisation, we have a binomial classification problem where the classes are "+1" (IN) and "-1" (no-IN). Therefore, we used ROI[4]-SVM, an implementation of SVM for MVPA in Brain Voyager QX[5] to discriminate between the two classes explained above. We trained our models using a linear kernel which outperformed other SVM kernels (e.g. polynomial and RBF) based on our analysis, not presented due to the space limits.[6] Using the settings described above, we devised two prediction methods, a Generalised and a Personalised.

[4]ROI refers to a region of interest which is a subset of brain voxels that are considered as a region to serve a particular purpose.

[5]http://www.BrainVoyager.com

[6]It has been shown that the linear kernel is a special case of RBF [26] where the linear kernel with a penalty parameter C has the same performance as the RBF kernel with some parameters (C, γ) [54]. But when the number of features is very large, which is the case for brain signals, RBF kernel is known to be not suitable and the linear kernel is the one that should be used [54].

Generalised Method (GM): The Generalised method follows the hypothesis that there is a common ROI for all participants that represents an IN realisation. We created this ROI by including spheres of radius 5mm centred around each of the Talairach coordinates of peak activation reported by [42] in their GLM analyses contrasting IN versus no-IN. All reported regions were selected regardless of whether they showed greater activity for IN or no-IN for comprehensiveness.

Personalised Method (PM): In contrast, the Personalised method follows the hypothesis that there is a unique ROI for each individual that represents an IN realisation as revealed by the Searchlight analysis [30, 31]. The Searchlight analysis uses MVPA and addresses the issue that the entire collection of brain voxels forms a high dimensional space. To reduce dimensionality and establish a reduced set of feature voxels it works by moving a small predefined volume (three voxels in our case) throughout the entire brain and creates a map based on the prediction accuracy obtained at the centre of the volume. From this map, it is possible to find all voxels with performance above a criterion value to define a personalised ROI that can then be used to test the prediction accuracy.

Baseline (BL): Our baseline represents an untrained model where all its predictions are based on a random choice, i.e. where its accuracy is set to 50%.

4 RESULTS

4.1 Task Perception

In this section, we investigate participants' evaluation of the task they had performed in terms of the judged difficulty of the task, the familiarity of the participant with the task and the degree to which they found their performance of the task to be stressful, clear, successful, and satisfactory. Namely, participants were given the following questions *"The tasks we asked you to perform were [easy/stressful/familiar/clear/Satisfactory] (answer: 1: "Strongly Disagree", 2: "Disagree", 3: "Neutral", 4: "Agree", 5: "Strongly Agree")"*. Descriptive statistics of these responses are shown by box plots in Figure 1, which show five key statistics: the minimum, first, second (median), third, and maximum quartiles.[7]. These results indicate that participants found the tasks difficult (not easy) and stressful, familiar, clear, successful, and satisfactory.

4.2 Log Analysis

The fMRI analysis relied upon a participant's response to the question to code whether a trial was IN or No-IN. This raised the consideration that for analysis of the brain data to have the maximum power it is important to have approximately an equal response rate for IN and No-IN responses. Thus, it was important to examine the average response rates for whether the number of IN and no-IN responses were approximately balanced. The average number of IN responses was 17.5 (SD of 5.91), and the average number of No-IN responses was 22.5 (SD of 5.91). A paired t-test revealed a marginal difference between the type of responses (p-value = 0.05).

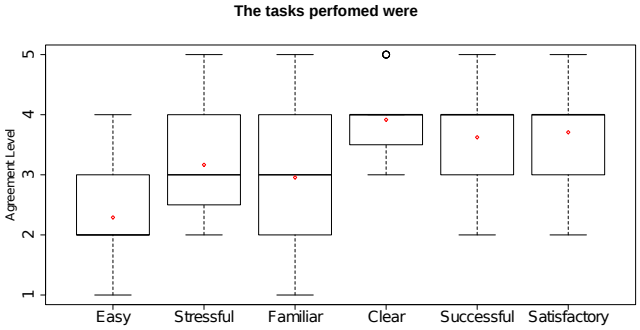

Figure 1: Box plot of the task perception based on the information gathered from the questionnaires of twenty-four participants. The red diamond represents the mean value.

4.3 Comparison of Brain Regions Associated with GM and PM

Before examining the performance of the MVPA approach in classification accuracy of discriminating between IN and no-IN states, it is instructive to examine the brain areas used by the two approaches. The GM technique restricted the analysis to the same feature set of voxels for all participants while the PM used a unique feature set of voxels for each individual as revealed by the Searchlight procedure. Given the bespoke nature of PM, where a unique feature set of voxels was derived for each participant, comparison of the regions used in PM to those used in GM is not straightforward. To address this issue, we created a probability map of the individual PM results that allowed us to visualise how many of the twenty-four participants had the same voxel present from the Searchlight procedure. To achieve this, we first defined 70% as a common threshold of prediction performance for the Searchlight procedure in discriminating IN versus no-IN.

This probability map included 87.9% of all voxels in the brain volume if we examined the probability that a voxel would be found in any one of the participants. Since this map contains almost all voxels in the brain volume, we aimed to identify a more specific subset of voxels by increasing the criterion in the probability map to 0.35, corresponding approximately to a voxel being found in 8 of the 24 participants. This resulted in a map with 0.6% of all voxels in the brain volume. This map is shown in Figure 2, along with the regions used for the GM analysis. Details of the voxels identified in our probability map are provided in Table 1. As can be seen, the probability map revealed ten areas that are distributed across the brain, in many cases bilaterally, and concentrated mostly in frontal and occipital regions.

Additionally, except for the inferior frontal gyrus, there is little overlap between the GM regions and the PM regions. An essential point here is that the current results used a Multi-Voxel Pattern Analysis (MVPA) while the previous experiment used a General Linear Model (GLM) analysis. MVPA uses the pattern of activation of a group of voxels to classify brain activity and is sensitive to the spatial pattern of information encoded in brain activity. However, GLM analysis focuses on brain activity that occurs per each

[7]Further information can be found in [37].

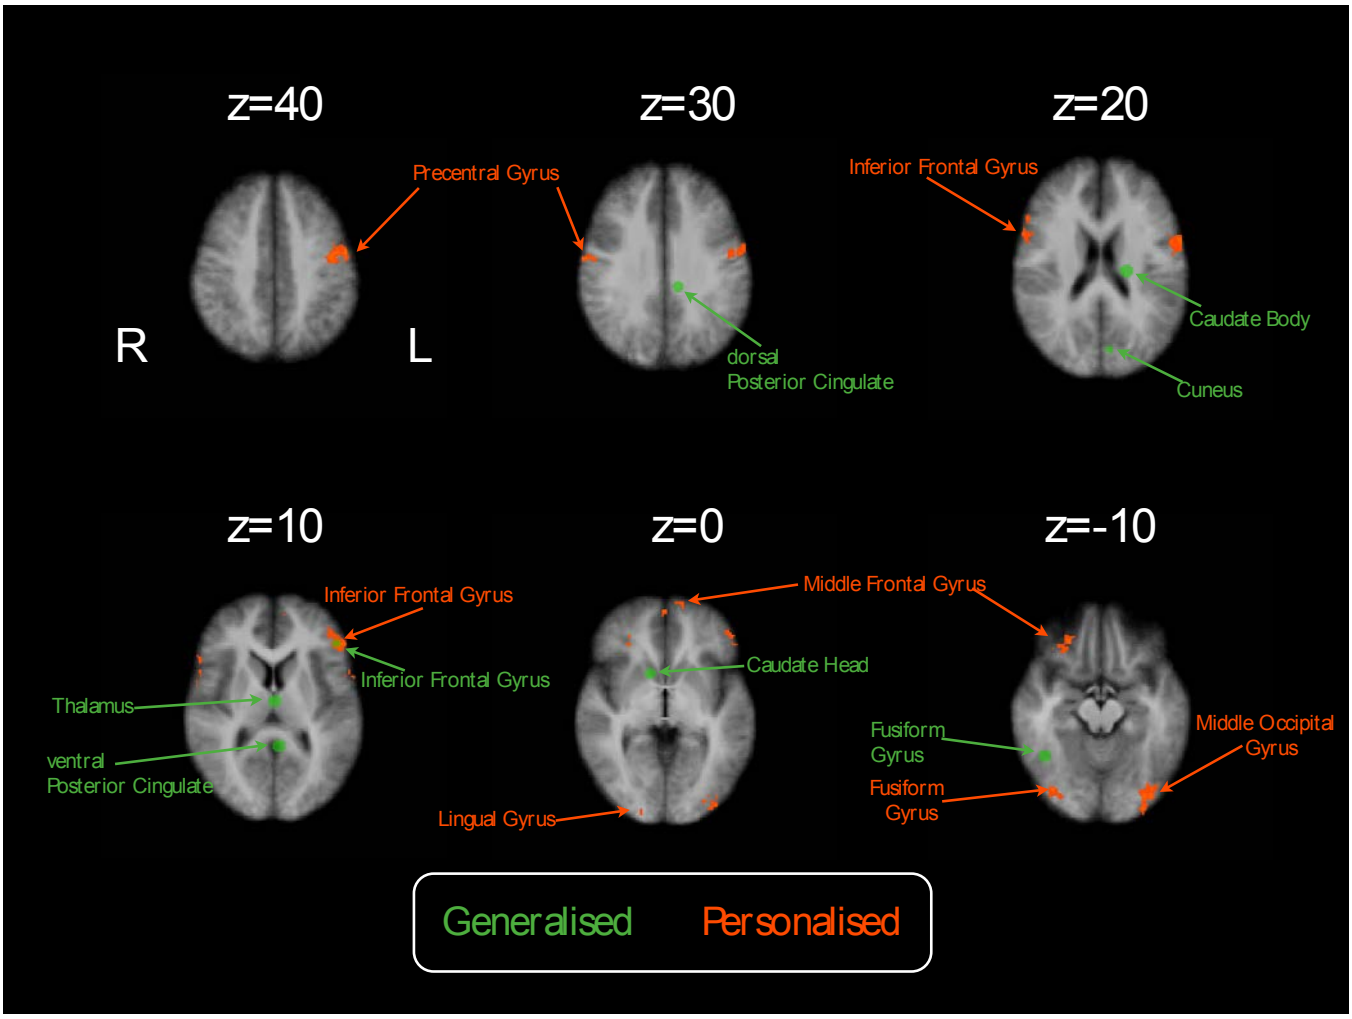

Figure 2: Comparison of brain regions in PM with probability greater than 0.35 to results from GM based on regions found in [42] PM and GM regions are shown in orange and green respectively.

Table 1: Details of probability map of PM results, including their anatomic label, location, Brodmann Area (BA), effect size and volume.

		Talairach Coordinates				Peak Probability	Number of voxels
Brain Area	Hemisphere	X	Y	Z	BA	value	mm^3
Precentral Gyrus	Right	60	-7	31	6	47.6%	230
Inferior Frontal Gyrus	Right	57	5	16	44	52.4%	1253
Fusiform Gyrus	Right	36	-73	-8	19	57.1%	558
Middle Frontal Gyrus	Right	24	35	-11	11	52.4%	756
Lingual Gyrus	Right	18	-88	-2	17	47.6%	130
Medial Frontal Gyrus	Left	-9	53	7	10	47.6%	203
Medial Frontal Gyrus	Left	-3	63	7	10	47.6%	230
Middle Occipital Gyrus	Left	-36	-79	-8	18	57.1%	1839
Precentral Gyrus	Left	-51	-6	40	6	52.4%	3444
Inferior Frontal Gyrus	Left	-45	29	10	46	57.1%	1127

voxel and is sensitive to differences in mean activation [14, 21, 52]. Therefore, MVPA and GLM analysis are different in nature, and it is not entirely expected that they would yield identical results. Since MVPA considers multiple voxels at the same time, it can lead to the identification of additional regions that collectively have a discriminative power but not individually (which is the case for GLM). Thus, the areas reported by Moshfeghi et al. [42] but not found in our PM results would be those with significant differences in mean activation and not necessarily where the spatial pattern of activation could be decoded. However, one region was highlighted in both studies, i.e. the left inferior frontal gyrus region, which indicates that this region both changes its mean activation and its spatial distribution of activity with IN. Future research can examine this property more closely.

With this in mind, we now describe the voxels presented in Table 1. The ten areas presented in Table 1 are commonly related to the domains of text/semantic processing (precentral gyrus, right inferior frontal gyrus), vision (middle occipital gyrus, lingual gyrus, fusiform gyrus), complex cognition (medial frontal gyrus), executive function (left inferior frontal gyrus) and reward (middle frontal gyrus). The finding of areas involved in complex cognition suggests that a realisation of an IN involves high-level cognition [23]. For example, the medial frontal cortex (Brodmann Area 10) is at the most anterior section of the frontal cortex. Models of branching control of cognition suggest this area serves at the top of a processing hierarchy to assemble information across different processing strands. Similarly, the executive function includes processes such as working memory and keeping track of task rules. Thus the region of left inferior frontal gyrus, known as the dorsolateral prefrontal cortex, suggests that there is a difference in executive function depending upon whether there is an IN or no-IN. However, an unexpected finding is that a realisation of an IN need appears to be encoded in visual and textual processing areas. While these areas are consistent with performing the required tasks of reading questions and answers, It is not clear why it should encode a realisation of an IN. We would like to investigate this in the future. In summary, it would seem that these ten regions are distributed across the brain and involve both (i) high-level cognition, which could represent the concept of IN per se, and (ii) low level perceptual and textual processing where the decoding results from differences in the depth of processing IN vs no-IN items.

4.4 Prediction Accuracy of IN Realisation

Table 2 shows the classification performance averaged over the twenty-four participants of the study for both the GM condition when a common feature set of voxels was used across all participants and for the PM condition when a unique feature set of voxels was obtained for each participant. The table reports the accuracy of the model (i.e. the fraction of items in the test set for which the models' predictions were correct) using 10-fold cross-validation. We also performed a paired Wilcoxon test between the predictions obtained for each model to check the significance of the difference with its baseline. We use (**) and (††) to denote the fact that a model trained on a set of features had results different from that of "BL" and "GM" with the confidence level ($p < 0.01$) respectively.

Table 2: This table shows the prediction accuracy of our methods (presented as columns). The percentage of improvement over the baseline is presented in the parenthesis. The best performing model is highlighted in bold.

Method	*BL*	*GM*	*PM*
Accuracy	50%	67.54%**	**79.68%**** ††

The key findings arising from our study are that brain activity could be used to predict whether participants were realising an IN (addressing RQ1). If the brain activity of a set of common regions to all participants was used (i.e. GM) then performance was (statistically) significantly above chance. In addition, the prediction accuracy (statistically) significantly improved over both chance and GM when the brain activity of a set of unique regions to each participant was used (i.e. PM) (addressing RQ2). Our findings are encouraging and indicate that it is possible to build proactive IR systems in which the IN realisation can be detected from brain signals.

5 DISCUSSION AND CONCLUSION

The main goal of Information Retrieval (IR) systems is to satisfy searchers' Information Needs (IN). However, satisfying INs is a formidable challenge, due to the inherent complexity and ambiguity associated with the IN concept. As a result of this, searchers' queries (i.e. searchers' representation of their IN) may not sufficiently define the characteristics of relevant documents or even any relevant information [13]. Recently, there is an increased interest in the research community in developing zero-query (or proactive) IR systems aiming to not only better understand, but even anticipate users' INs [9, 49]. However, current approaches mainly consider the contextual or behavioural information of users to predict their IN. While this is intuitively a promising approach, it could potentially create an information overload situation for users, in particular, if users are not experiencing an IN when the information is presented to them. It is essential, therefore, to be able to detect when INs occur.

In this paper, we investigated the possibility of predicting a realisation of an IN from brain signals. Previous research has established that INs physically manifest themselves with specific brain activity. With this work we take the next step, showing that monitoring brain activity can lead to accurate predictions of IN occurrence. We have conducted a "within-subjects" design experiment where we measured the brain activity of twenty-four participants while they performed a Question Answering (Q/A) Task. The independent variable was the realisation of an information need, with two levels: an information need was realised (IN), and no information need was realised (no-IN), and the dependent variable was the BOLD signal. From the TREC-8 and TREC 2001 Q/A Tracks, a set of questions was carefully designed so that we obtained an equal number of responses for expressing an answer to the question and expressing a need to search for more information to answer the question. We then test two methods for predicting a realisation of an information need. A Generalised method (GM) that uses a predefined set of

brain regions for all participants as well as a Personalised method (PM) that uses a unique set of brain regions for each participant.

Given that PM provided a unique ROI for each individual, we then investigated the probability that the ROIs obtained for each individual were overlapping, presented as a probability map. When we used a criterion that a voxel can enter the map if at least one participant obtained this voxel, 87.9% of all voxels in the brain volume were included in the map. This is consistent with previous studies suggesting that representational and memory systems are widely distributed in the brain [48]. When we increased the criterion to 0.35 to examine highly overlapping regions, 0.6% of all voxels in the brain volume were included in the map, revealing ten regions. An analysis of these ten regions suggested that these regions are distributed across the brain and involve both (i) high-level cognition, which could represent the concept of IN per se, and (ii) low level perceptual and textual processing where the decoding results from differences in the depth of processing IN vs no-IN items. Such a finding is consistent with theoretical views that information processing in the brain involves extensive feedforward and feedback between brain regions [18].

Our findings show that brain activity could be used to predict whether participants were in a state of information need (addressing RQ1). The prediction accuracy depended upon the choice of brain regions used to learn the model. If the brain activity of a set of common regions to all participants was used (i.e. GM) then performance was (statistically) significantly above chance. Also, the prediction accuracy (statistically) significantly improved over both chance and GM when the brain activity of a set of unique regions to each participant was used (i.e. PM) (addressing RQ2). This result shows the benefit of PM for the prediction of a realisation of IN from brain activity.

The model proposed by Moshfeghi et al. [42] postulated that activation in the dorsal posterior cingulate cortex (PCC) represented a switch to broad attention directed to the external world [35] and this was an important neural correlate of a realisation of an IN. The current results advance our understanding of this model. Firstly, functional connectivity exists between the PCC to the inferior frontal gyrus (dorsolateral prefrontal cortex) [34], and anatomical connectivity exists between the PCC and the medial frontal cortex [46, 47]. Thus, the encoding of a realisation of an IN in these highly cognitive regions can be regulated by activity in the PCC. In addition, the current finding that visual and textual regions encode a realisation of an IN are consistent with the modulatory activity of the PCC in exerting top-down influences on perception through the regulation of extended brain networks.

In conclusion, the results of our experiment not only show that we can predict a realisation of an IN from brain activity but also substantially advance our understanding of the neural mechanisms involved in such a phenomenon. The encouraging results obtained from GM and especially PM in predicting a realisation of an IN provides an essential and fundamental step towards the next-generation of proactive IR systems based on brain signals. These results point to the beneficial use of fMRI to examine activity within the entire brain with high spatial resolution to reveal areas involved in a realisation of an IN. Given that this paper is the first attempt to predict a realisation of an IN from brain signals, such a high spatial resolution was crucial to investigate our hypotheses thoroughly.

Our findings also inform what other neuroimaging techniques might be effective for further study of a realisation of an IN. This is because brain imaging technologies have varied effectiveness in revealing activity at different depth levels in the brain. For example, the left dorsolateral prefrontal cortex, revealed in the present study, is a brain region that is relatively superficial and thus amenable to study with a variety of other brain imaging technologies. In future work, we want to continue to advance our understanding of brain activity for a realisation of an IN across other IR scenarios. Further, we would like to translate our current findings to mobile brain imaging technologies, such as EEG or functional Near-Infrared Spectroscopy (fNIRS) and possibly build proactive search engines that use brain activity for realising the occurrence of an IN.

ABSTRACT

Social influence plays a vital role in shaping a user's behavior in online communities dealing with items of fine taste like movies, food, and beer. For online recommendation, this implies that users' preferences and ratings are influenced due to other individuals. Given only time-stamped reviews of users, can we find out who-influences-whom, and characteristics of the underlying influence network? Can we use this network to improve recommendation?

While prior works in social-aware recommendation have leveraged social interaction by considering the *observed* social network of users, many communities like Amazon, Beeradvocate, and Ratebeer *do not have explicit user-user links*. Therefore, we propose GhostLink, an unsupervised probabilistic graphical model, to automatically *learn* the latent influence network underlying a review community – given only the temporal traces (timestamps) of users' posts and their content. Based on extensive experiments with four real-world datasets with 13 million reviews, we show that GhostLink improves item recommendation by around 23% over state-of-the-art methods that do not consider this influence. As additional use-cases, we show that GhostLink can be used to differentiate between users' latent preferences and influenced ones, as well as to detect influential users based on the learned influence graph.

CCS CONCEPTS

• **Information systems → Social recommendation**; *Collaborative filtering*; • **Computing methodologies → Topic modeling**.

1 INTRODUCTION

Traditional works in recommender systems that build upon collaborative filtering [19] exploit that similar users have similar rating behavior and facet preferences. Recent works use review content [25, 28, 37] and temporal patterns [11, 12, 29] to extract further cues. All of these works assume the users to behave independently of each other. In a social community, however, users are often influenced by the activities of their friends and peers. How can we detect this influence in online communities?

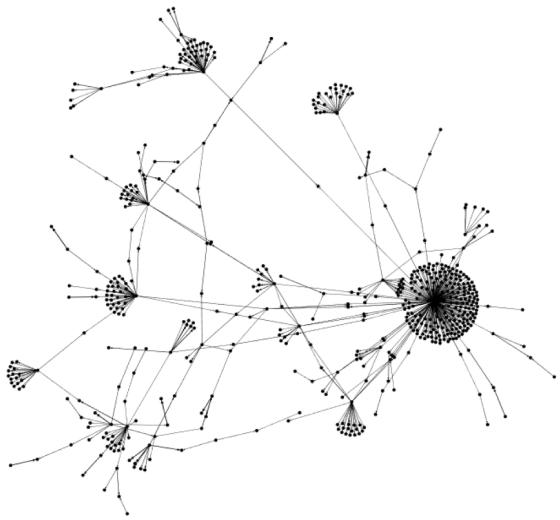

Figure 1: Given only timestamped reviews of users in the Beeradvocate community without any explicit user-user link/interaction, GhostLink extracts this latent influence network (of top K influencers) based on opinion conformity. This is compactly represented by a Maximum Weighted Spanning Forest (MWSF) preserving 99.4% of the influence mass from 73.4% of the edges of the inferred influence network depicting a tree-like structure of influence.

One way to answer this question is to exploit the *observed* social network or interaction of users — like friend circles in Facebook, the follow graph in Twitter, and trust relations in Epinion. Recent works [5, 14, 16, 20, 22, 27, 33, 34, 41, 42] leverage such *explicit* user-user relations or the observed social circle to propose social-network based recommendation. Similarly, in the field of citation networks, [2] attempt to extract citation influence given the *explicit network* of who-cited-whom.

However, there is one big catch: many online review communities like Amazon or Beeradvocate do *not* have any explicit social network – thus, making the above methods not applicable. Can we infer the influence network based on other signals in the data?

Amazon Movies
U1: style intense pretentious non-linear narrative rapid editing
U2: non-linear narrative crazy flashback scene randomly interspersed
Beeradvocate
U1: cloudy reddish amber color huge frothy head aroma spicy
U2: hazy golden amber dissipating head earthy aroma pepper clove

Table 1: Sample (influenced) review snippets extracted by GhostLink from two communities: user U1's review is influenced by U2.

While some recent works [13, 21, 23, 24] model implicit relationships, they are limited to the historical rating behavior of users, ignoring the textual information. Similarly, works in information diffusion over latent networks model temporal traces ignoring the textual information [6, 7, 9, 30] and make some strong assumptions like a homogeneous network with static transmission rates. These techniques being agnostic of the context fail to capture complex interactions resulting in sparse networks. Some recent works on text-based diffusion [4, 15, 36] model context. However, they also make some strong assumptions regarding the topics of diffusion being known apriori and the network being explicit. Most importantly, none of these works are geared for item recommendation, nor do they study the characteristics of review communities.

In contrast, in this work, we leverage opinion conformity based on writing style as an indication of influence: where a user echoes/copies facet descriptions from peers (called influencers) across multiple items. This is a common setting for communities dealing with items of fine taste like movies, beer, food and fine arts where users often co-review multiple items. Our informal goals are:

Informal Problem 1. *Given only timestamped reviews of users in online communities,* ***extract*** *the underlying influence network of who-influences-whom based on opinion conformity, and* ***analyze*** *the characteristics of this influence network.*

Informal Problem 2. ***Leverage*** *the implicit social influence (network) to improve item rating prediction based on peer activities.*

To answer these questions, we propose GhostLink, an unsupervised probabilistic graphical model, that automatically extracts the (latent) influence graph underlying a review community.

Key idea and approach: Consider two users reviewing a movie in a review community. The first user expressed fascination for the movie's 'non-linear narrative style', 'structural complexity', and 'cinematography' as outlined in the content of her review. Later, following this review, a second user also echoed similar concepts such as 'seamless narrative', 'style', and 'matured cinematography'. That is, the second review closely resembles the first one *conceptually* in terms of *facet descriptions* – not simply by using the same words. While for a *single* item this could be simply due to chance, *a repeated occurrence of this pattern across multiple items* – where the second user reviewed an item some time *after* the first user echoing *similar facet descriptions* – gives an indication of influence. A user could be influenced by several users for different facets in her review. GhostLink models this notion of multiple influence common in communities dealing with items of fine taste like movies, food and beer where users often co-review multiple items. Table 1 shows a snapshot of (influenced) review snippets extracted by GhostLink.

Based on this idea, we propose a probabilistic model that exploits the facet descriptions and preferences of users — based on principles similar to Latent Dirichlet Allocation — to learn an influence graph. Since the influencers for a given user and facets are unobserved, all these aspects are learned solely based on their review content and their temporal footprints (timestamps).

Figure 1 shows such an influence graph extracted by GhostLink from the Beeradvocate data. Analyzing these graphs gives interesting insights: There are only a few users who influence most of the others, and the distribution of influencers vs. influencees follows a power-law like distribution. Furthermore, most of the mass of this influence graph is concentrated in giant tree-like component(s). We use such influence graphs to perform influence-aware item recommendation; and we show that GhostLink outperforms state-of-the-art baselines that do not consider latent influence. Moreover, we use the influence graph to find influential users and to distinguish between users' latent facet preferences from that of induced/influenced ones. Overall, our contributions are:

- **Model:** We propose an unsupervised probabilistic generative model GhostLink based on Latent Dirichlet Allocation to learn a latent influence graph in online communities without requiring explicit user-user links or a social network. This is the first work that solely relies on timestamped review data.
- **Algorithm:** We propose an efficient algorithm based on Gibbs sampling [10] to estimate the hidden parameters in GhostLink that empirically demonstrates fast convergence.
- **Experiments:** We perform large-scale experiments in four communities with 13 million reviews, 0.5 mil. items, and 1 mil. users where we show improved recommendation for item rating prediction by around 23% over state-of-the-art methods. Moreover, we analyze the properties of the influence graph and use it for use-cases like finding influential members in the community.

2 GHOSTLINK: INFLUENCE-FACET MODEL

Our goal is to learn an influence graph between users based on their review content (specifically, overlap of their facet preferences) and timestamps only. The underlying assumption is that when a user u is influenced by a user v, u's facet preferences are influenced by the ones of v. Since the only signal is the textual information of the reviews – and their inferred latent facet distributions (also known as topic distributions in the context of LDA) – we argue that influence is reflected by the used/echoed words and facets.

While classical user topic models assume that each word of a document is associated with a topic/facet that follows the user's preference, we assume that the topic/facet of each word might be based on the preferences of *other* users as well – the influencers. Inspired by this idea, we first describe the generative process of GhostLink followed by the explanation of the inference procedure.

Generative Process. Consider a corpus D of reviews written by a set of users U at timestamps T on a set of items I. The subset of reviews for item $i \in I$ is denoted with $D_i \subseteq D$. Let $d \in D_i$ be a review on item $i \in I$, we denote with u_d the user and with t_d the timestamp of the review. All the reviews on an item i are assumed to be ordered by timestamps. Each review d consists of a sequence of N_d words denoted by $d = \{w_1, \ldots, w_{N_d}\}$, where each word is drawn from a vocabulary W having unique words indexed by $\{1, \ldots, W\}$. The number of latent facets/topics corresponds to K.

In most review communities, a user browses through other reviews on an item before making a decision (say) at time t. Therefore,

the set of users and corresponding reviews that could potentially influence the given user's perspective on an item i consists of all the reviews d' written at time $t_{d'} < t$. We call the corresponding set of users – the potential influence set $IS_{u,i} = \{u' \in U \mid \exists d, d' \in D_i : u = u_d \wedge u' = u_{d'} \wedge t_{d'} < t_d\}$ for user u and item i.

In our model, each user is equipped with a latent facet preference distribution θ_u, whose elements $\theta_{u,k}$ denote the preference of user u for facet $k \in K$. That is, θ_u is a K-dimensional categorical distribution; we draw it according to $\theta_u \sim Dirichlet_K(\alpha)$ with concentration parameter α. These distributions later govern the generation of the review text (similar to LDA).

Furthermore, for each user an influence distribution ψ_u is considered, whose elements $\psi_{u,v}$ depict the influence of user v on user u. That is ψ_u represents a U-dimensional categorical distribution – *and all ψ_* together build the influence graph we aim to learn* (see also Sec. 3.4). Similar to above we define $\psi_u \sim Dirichlet_U(\rho)$.

When writing a review, a user u can decide to write an original review based on her latent preferences θ_u — or be influenced by someone's perspective from her influence set for the given item; that is, using the preferences of θ_v for some $v \in IS_{u,i}$. Since a user might not be completely influenced by other users, we allow each word of the review to be either original or based on other influencers. More precise: For each word of the review, we consider a random variable $s \sim Bernoulli(\pi_u)$ that denotes whether it is original or based on influence, where π_u intuitively denotes the 'vulnerability' of the user u to get influenced by others.

If $s = 0$ the user uses her own latent facet preferences. That is, following the idea of standard topic models, the latent facet for this word is drawn according to $z \sim Categorical(\theta_u)$. If $s = 1$, user u writes under influence. In this case, the user chooses potential influencer(s) v according to the strength of influence given by ψ_u. Since for a specific item i, the user u can only be influenced by users in $IS_{u,i}$ who have written a review *before* her, we write $v \sim Categorical(\psi_u \cap IS_{u,i})$ to denote restriction of the domain of ψ_u to the currently considered influence set.

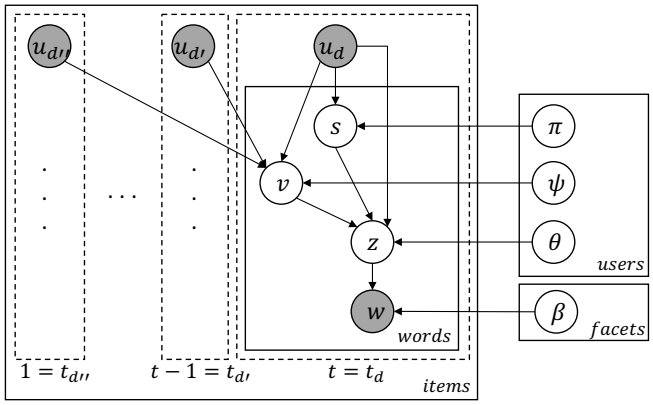

Figure 2: Plate diagram for the generative process. Each dashed box indicates a single review.

Given the sampled user v, the latent facet for this word should be drawn according to v's preferences. Now, we are faced with a modeling choice. We can use the influencer's overall facet distribution θ_v (as is used in citation-network based topic models). However,

Algorithm 1: Generative process for influence – facet model.

1. Draw $\theta_u \sim \text{Dirichlet}_K(\alpha)$ // latent facet preference of each user
2. Draw $\psi_u \sim \text{Dirichlet}_U(\rho)$ // influencer distribution of each user
3. Draw $\pi_u \sim \text{Beta}(\eta)$ // vulnerability of each user to be influenced
4. Draw $\beta_k \sim \text{Dirichlet}_W(\gamma)$ // word distribution of each facet

for *each item $i \in I$* **do**
  for *each review $d \in D_i$ on i at time t by user u* **do**
    for *each word w in d* **do**
      5. Draw $s \sim \text{Bernoulli}(\pi_u)$
      if $s = 0$ **then**
        6. $\theta' = \theta_u$ // use latent facet preference of user
      if $s = 1$ **then**
        7. Draw $v \sim \text{Categorical}(\psi_u \cap IS_{u,i})$
        8. $\theta' = \tilde{\theta}_v^{d'}$ // use the influencer's facet preference
        /* where $\tilde{\theta}_v^{d'}$ is the facet distribution *used* by v for review d' written at time $t' < t$ */
      9. Draw $z \sim \text{Categorical}(\theta')$
      10. Draw $w \sim \text{Categorical}(\beta_z)$

by using θ_v, one considers v's *generic* facet distribution – which might be very unrelated to the item under consideration. That is, while v might prefer specific facets, in his actual review d' about item i these facets might have not been used. And accordingly, since the user u only sees the observed review d' – and not the latent facet distribution of v – the user u cannot be influenced by facets which have not been considered. Thus, in our model, instead of considering the influencer's (generic) facet distribution θ_v, we consider the facet distribution that the influencer has actually *used* for writing his review d' for the given item i. Since the review of the user v has already been generated (otherwise the user would not be in $IS_{u,i}$), the used facets z for each word of his review are known. Thus, instead of considering θ_v, we consider the 'observed' facet distribution based on the actual review, denoted with $\tilde{\theta}_v^{d'}$. Given this distribution, we sample $z \sim Categorical(\tilde{\theta}_v^{d'})$. Since the model samples an influencer for each facet, a user can have *multiple influencers* corresponding to multiple facets in his review.

In summary, in the above process, the user u either draws the facet z from θ_u (if $s = 0$) or $\tilde{\theta}_v^{d'}$ (if $s = 1$). Given facet z, we draw the actual word $w \sim Categorical(\beta_z)$ following the generative process of Latent Dirichlet Allocation [1]. As usual, $\beta_z \sim Dirichlet_W(\gamma)$ denotes corresponding per-facet word distributions.

Overall, the user's review can be regarded as being generated by a *mixture* of her latent preferences and preferences of her influencers. Algorithm 1 summarizes the generative process, and the graphical model is illustrated in Figure 2, where we indicated with u_d the (observed) user for each review.

3 JOINT PROBABILISTIC INFERENCE

We now describe the inference procedure for GhostLink. That is, given the set of all reviews (and their timestamps), we aim to infer the latent variables. To not clutter notation, we drop the indices of variables when it is clear from context (e.g. θ_u is abbreviated as θ).

Let S, V, Z be the set of all latent variables corresponding to the influence variables s, influencers v, and facets z. Let W' denote the set of latent variables corresponding to the observed words, and

U' the set of latent variables corresponding to the observed users[1]. The joint probability distribution of our model is:

$$P(S, V, Z, W', \theta, \beta, \psi, \pi | U'; \alpha, \gamma, \rho, \eta) \propto \prod_{u \in U} \Big(P(\pi; \eta) \cdot P(\psi; \rho) \cdot P(\theta; \alpha) \Big) \cdot \prod_{k \in K} P(\beta_k; \gamma) \cdot \prod_{i \in I} \prod_{d \in D_i} \Big(\prod_{s \in S} P(s | \pi_{u_d}) \cdot \prod_{v \in V} P(v | \psi_{u_d})^{\mathbb{I}(s=1)} \cdot \prod_{z \in Z} \Big(P(z | \theta_{u_d})^{\mathbb{I}(s=0)} \cdot P(z | \tilde{\theta}_v^{d'})^{\mathbb{I}(s=1)} \Big) \cdot \prod_{w \in W'} P(w | \beta_z) \Big) \quad (1)$$

Since exact inference is intractable, we have to resort to approximate inference. For this purpose, we perform Collapsed Gibbs Sampling [10]. In Gibbs sampling, the conditional distribution for each hidden variable is computed based on the current assignment of the other hidden variables. The values for the latent variables are sampled repeatedly from this conditional distribution until convergence. In our problem setting we have three sets of latent variables corresponding to S, V and Z respectively – the remaining variables θ, β, ψ, π are marginalized out (collapsed).

Given the current assignment of random variables, we use the shortcuts: $n(u, s)$ denotes the count of words written by u with influence variable $s \in \{0, 1\}$. $n(u, v, s = 1)$ denotes the count of words written by u under influence from v (i.e. $s = 1$) in the community across all items and facets. $n(u, z, s = 0)$ denotes the number of times u wrote facet z for any word based on her latent preferences (i.e. $s = 0$). $n(v_{d'}, z)$ denotes the count of facet z in review $v_{d'}$, and $n(z, w)$ denotes the number of times word w is used with facet z.

Collapsing. We first marginalize out the remaining variables as mentioned above. Exploiting conjugacy of the Categorical and Dirichlet distributions, we can integrate out π, ψ, θ, and β from the above distribution to obtain the four posterior distributions

$$P(S|U'; \eta) = \frac{\Gamma(\sum_s \eta) \prod_s \Gamma(n(u, s) + \eta)}{\prod_s \Gamma(\eta) \sum_s \Gamma(n(u, s) + 2 \cdot \eta)}$$

$$P(V|U', S; \rho) = \frac{\Gamma(\sum_v \rho) \prod_v \Gamma(n(u, v, s = 1) + \rho)}{\prod_v \Gamma(\rho) \sum_v \Gamma(n(u, v, s = 1) + U \cdot \rho)}$$

$$P(Z|U', S, V; \alpha) = \frac{\Gamma(\sum_z \alpha) \prod_z \Gamma(n(u, z, s = 0) + \alpha)}{\prod_z \Gamma(\alpha) \sum_z \Gamma(n(u, z, s = 0) + K \cdot \alpha)}$$

$$P(W'|Z; \gamma) = \frac{\Gamma(\sum_w \gamma) \prod_w \Gamma(n(z, w) + \gamma)}{\prod_w \Gamma(\gamma) \sum_w \Gamma(n(z, w) + W \cdot \gamma)}$$

where Γ denotes the Gamma function[2].

Gibbs sampling. Given the above, the joint probability distribution with conditional independence assumptions is:

$$P(S, V, Z|U', W') \propto P(S|U') \cdot P(V|S, U') \cdot P(Z|V, S, U') \cdot P(W'|Z)$$

The factors on the right-hand side capture (in order): vulnerability of the user being influenced, potential influencers given the user, facet distribution to be used (latent or influenced), and subsequent words to be used according to the facet distribution chosen. We infer all the distributions using Gibbs sampling.

[1]Note that U' refers to the latent variable attached to each review that 'stores' the user information. Thus, a user might appear multiple times in U' since she might have written reviews on multiple items. Similar for W'.

[2]The derivation of the following equations — for integrating out latent variables from the joint distribution exploiting Multinomial-Dirichlet conjugacy and Gibbs Sampling updates — follow from the standard principles of Latent Dirichlet Allocation, and, therefore, details have been omitted for space.

Let the subscript $-j$ denote the value of a variable excluding the data at the j^{th} position. The conditional distributions for Gibbs sampling for updating the latent variable S — that models whether the user is going to write on her own or under influence — is:

$$P(s_j = 0 | u_d, z, s_{-j}) \propto \frac{n(u_d, s_j = 0) + \eta}{\sum_s n(u_d, s) + 2 \cdot \eta} \cdot \frac{n(u_d, z, s_j = 0) + \alpha}{\sum_z n(u_d, z, s_j = 0) + K \cdot \alpha} \quad (2)$$

$$\tilde{P}(s_j = 1 | u_d, v_{d'}, z, s_{-j}) \propto \frac{n(u_d, s_j = 1) + \eta}{\sum_s n(u_d, s) + 2 \cdot \eta} \cdot \frac{n(v_{d'}, z) + \alpha}{\sum_z n(v_{d'}, z) + K \cdot \alpha} \quad (3)$$

$$P(s_j = 1 | u_d, z, s_{-j}) \propto max_{v_{d'} \in D_i : t_{d'} < t_d} \tilde{P}(s_j = 1 | u_d, v_{d'}, z, d, s_{-j}) \quad (4)$$

The first factor in Equation 2 and 3 above models the probability of the user being influenced: as a fraction of how many facets the user wrote under influence ($s = 1$), or otherwise ($s = 0$), out of the total number of facets written. The second factor in Equation 2 models the user's propensity of using a particular facet based on her latent preferences (when $s = 0$); whereas the second factor in Equation 3 models the probability of the user writing about a facet under influence (when $s = 1$) from an earlier review on the given item. Note that in this case — as the user is influenced by another user's review that appeared earlier in her timeline — she adopted her influencer's *used facet distribution* to write about the given facet instead of her own latent facet preference distribution.

Note that in the above question, we did not assume the influencers v'_d to be given since this would lead to a very restrictive Gibbs sampling step. Instead, as shown in Equation 4, we sample the best possible influencer for a given facet to determine the probability for $s = 1$. Accordingly, the influencer for a given user and word, when writing under influence, is updated as

$$v_{d'j} | u_d, s = 1, z, v_{d'-j} = argmax_{v_{d'} \in D_i : t_{d'} < t_d} \Big(\frac{n(u_d, v_{d'}, s = 1) + \rho}{\sum_v n(u_d, v, s = 1) + U \cdot \rho} \cdot \frac{n(v_{d'}, z) + \alpha}{\sum_z n(v_{d'}, z) + K \cdot \alpha} \Big) \quad (5)$$

The first factor above counts how many times u has been influenced by v on writing about any facet — out of the total number of times u has been influenced by any other member in the community. The second factor is the facet distribution *used* by v in the review that influenced u's current facet description.

Instead of computing Equations 4 and 5 separately, we perform the update of both — s_j and $v_{d'j} | s_j = 1$ — *jointly*, thereby, reducing the computation time significantly.

The conditional distribution for sampling the latent facet z is:

$$P(z_j | u_d, s = 0, z_{-j}) \propto \frac{n(u_d, z_j, s = 0) + \alpha}{\sum_z n(u_d, z, s = 0) + K \cdot \alpha} \cdot \frac{n(z_j, w) + \gamma}{\sum_w n(z_j, w) + W \cdot \gamma} \quad (6)$$

$$P(z_j | u_d, v_{d'}, s = 1, z_{-j}) \propto \frac{n(v_{d'}, z_j) + \alpha}{\sum_z n(v_{d'}, z) + K \cdot \alpha} \cdot \frac{n(z_j, w) + \gamma}{\sum_w n(z_j, w) + W \cdot \gamma} \quad (7)$$

The first factor in the above equations models the probability of using the facet z under the user's (own) latent preference distribution (Equation 6), or adopting the influencer's used facet distribution (Equation 7). The second factor counts the number of times facet z is used with word w — out of the total number of times it is used with any other word.

3.1 Overall Processing Scheme

Exploiting the above results, the overall inference is an iterative process consisting of the following steps. We sort all reviews on an item by timestamps. For *each word* in each review on an item:

(1) Estimate whether the word has been written under influence, i.e. compute s using Equations 2 - 4 keeping all facet assignments fixed from earlier iterations.
(2) In case of influence (i.e. $s = 1$), an influencer v is jointly sampled from the previous step.
(3) Sample a facet for the word using Equations 6 and 7 keeping all influencers and influence variables fixed.

The process is repeated until convergence of the Gibbs sampling process (i.e. the log-likelihood of the data stabilizes).

3.2 Example

Consider a set of reviews written by three users in the following time order: first Adam, then Bob, then Sam (see Table 2). The table also shows the *current* assignment of the latent variables z and s. The goal is to *re-sample* the influence variables. For ease of explanation, we ignore the concentration parameters of the Dirichlet distribution in the example and we ignore the subscript $-j$ from the variables. That is, we do not exclude the current state of the own random variable as in Gibbs sampling.

Similar to before, let $n(u, s)$ be the number of tokens written by u with influence variable as s, $n(d, z)$ be the total number of tokens with topic as z in document d, $n(d)$ be the number of tokens in document d, and $n(u)$ be the total number of tokens written by u.

For Adam we have $s = 0$ for each word. As he is the first reviewer, he has no influencers. For Bob, the influence variable s w.r.t. the word 'non-linear' is based on:

$$P(s_{\text{'non-lin'}}=0|u=Bob,\, z=z_2) \propto \frac{n(u=Bob,\, s=0)}{n(u=Bob)} \cdot \frac{n(u=Bob,\, z=z_2,\, s=0)}{n(u=Bob,\, s=0)}$$
$$= \frac{1}{2} \cdot \frac{0}{1} = 0$$
$$P(s_{\text{'non-lin'}}=1|u=Bob,\, v=Adam,\, z=z_2,\, v_d=d_1)$$
$$\propto \frac{n(u=Bob,\, s=1)}{n(u=Bob)} \cdot \frac{n(z=z_2,\, v_d=d_1)}{n(v_d=d_1)} = \frac{1}{2} \cdot \frac{2}{3} = \frac{1}{3}$$

Therefore, Bob is more likely to write 'non-linear' being influenced by Adam's review than on his own. Similarly, for Sam:

$$P(s_{\text{'non-lin'}}=0|u=Sam,\, z=z_2) \propto \frac{1}{2} \cdot 1 = \frac{1}{2}$$

Note the higher probability compared to the one of Bob since Sam uses further terms (i.e. 'thriller') which also belong to facet z_2 that he wrote uninfluenced. For the case $s = 1$, we would obtain:

$$P(s_{\text{'non-lin'}}=1|u=Sam,\, v=Adam,\, z=z_2,\, v_d=d_1) \propto \frac{1}{2} \cdot \frac{2}{3} = \frac{1}{3}$$
$$P(s_{\text{'non-lin'}}=1|u=Sam,\, v=Bob,\, z=z_2,\, v_d=d_2) \propto \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{4}$$

As seen, Sam is more likely influenced by Adam's review, rather than by Bob's, when considering facet z_2, since d_1 has a higher concentration of z_2. It is worth noting that the probability of the influence variable s depends only on the facet, and not the exact words. Our model captures semantic or facet influence rather than just capturing lexical match. Overall, however, Sam is likely to write 'non-linear' on his own rather than being influenced by someone else since $P(s_{\text{'non-lin'}}=0|\ldots)$ is larger.

Reviewer	Document	time	Word	Facet	Influence (s=)
Adam	d_1	0	action	z_1	0
			non-linear	z_2	0
			narrative	z_2	0
Bob	d_2	1	action	z_1	0
			non-linear	z_2	1
Sam	d_3	2	non-linear	z_2	1
			thriller	z_2	0

Table 2: Example to illustrate our method.

While the above example considers a single item, in a community setting — especially for communities dealing with items of fine taste like movies, food and beer where users co-review multiple items — such statistics are aggregated over several other items. This provides a stronger signal for influence when *a user copies/echoes similar facet descriptions from a particular user across several items.* Our algorithm, therefore, relies on three main factors to model influence and influencer in the community:

a) The vulnerability of a user u in getting influenced, modeled by π and captured in the counts of $n(u, s)$.
b) The textual focus of the influencing review v_d by v on the specific facet (z), modeled by θ and captured in the counts of $n(v_d, z)$; as well as how many times the influencer v influenced u, modeled by ψ and captured in counts of $n(u, v, s = 1)$ — aggregated over all facets and items they co-reviewed.
c) The latent preference of u for z, modeled by θ_u and captured in the counts of $n(u, z, s = 0)$.

3.3 Fast Implementation

In the above generative process, we sample a facet for *each token/word* in a given review. Thus, we may sample different facets for the same word present multiple times in a review. While this makes sense for long documents where a word can belong to multiple topics, for short reviews it is unlikely that the same word is used to represent different facets. Therefore, we reduce the time complexity by sampling a facet for *each unique token* present in a review. We modify our sampling equations to reflect this change.

In the original sampling equations, we let *each token* contribute 1 unit to the counts of the distribution for estimation. Now, *each unique token* contributes c units corresponding to c copies of the token in the review. As we sample a value for a random variable during Gibbs sampling, ignoring its current state, we also need to discount c units for the token (instead of 1) to preserve the overall counts. All the sampling equations are modified accordingly.

3.4 Constructing the Influence Network

Our inference procedure computes values for the latent variables S, V, Z, and corresponding distributions. Using these, our objective is to construct the influence network given by ψ:

$$\psi_{u,v} = \frac{n(u, v, s = 1) + \rho}{\sum_v n(u, v, s = 1) + U \cdot \rho}$$

The above counts the number of facet descriptions $n(u, v, s = 1)$ that are copied by u from v (with $s = 1$ depicting influence) out of the ones copied by u from anyone else. Given ψ, we can construct a directed, weighted influence network $G = (U, E)$, where each user $u \in U$ is a node, and the edgeset E is given by:

$$E = \left\{ \{v, u\} \mid \psi_{u,v} > 0, u \in U, v \in U \right\} \quad (8)$$

That is, there exists an edge from v to u, if v positively influences u with the edge weight being $\psi_{u,v}$.

Furthermore, GhostLink can distinguish between different facet preference distributions of each user. The *observed* facet preference distribution θ_u^{obs} of u is given by:

$$\theta_{u,z}^{obs} = \frac{n(u, z) + \alpha}{\sum_z n(u, z) + K \cdot \alpha}$$

This counts the proportion of times u wrote about facet z out of the total number of times she wrote about any facet — with or without influence. This distribution represents essentially the preferences as it is captured by a standard author-topic model [32], user-facet model [25], and most of the other works using generative processes to model users/authors.

With GhostLink, however, we can derive even more informative distributions:

$$\theta_{u,z}^{latent} = \frac{n(u, z, s = 0) + \alpha}{\sum_z n(u, z, s = 0) + K \cdot \alpha}$$

$$\theta_{u,z}^{infl} = \frac{n(v = u, z, s = 1) + \alpha}{\sum_z n(v = u, z, s = 1) + K \cdot \alpha}$$

The distribution θ_u^{latent} intuitively represents a user's latent facet preference when *not being influenced* from the community (i.e. $s = 0$). In contrast, θ_u^{infl} captures the facet distribution of u as an influencer, i.e. that she used to influence someone else. That is, the latter one counts the proportion of times u was chosen as the influencer (i.e. $v = u$, $s = 1$) by another user in the community; or in other words when some other user copied from u.

4 ITEM RATING PREDICTION USING INFLUENCE NETWORKS

Our proposed method learns an influence network ψ from the review data. We hypothesize that using this network helps to improve rating prediction. That is, our objective is to predict the rating $y'_{u,i,t}$ that user u would assign to an item i at time t exploiting her latent social neighborhood given by ψ_u. Since we know the actual ground ratings $y_{u,i,t}$, the performance for this task can be measured by the mean squared error: MSE = $\frac{1}{|U,I|} \sum_{u,i} (y_{u,i,t} - y'_{u,i,t})^2$. Note that we use the rating data only for the task of rating prediction – it has *not been used* to extract the influence graph.

In the following, we describe the features we will create for each review for the prediction task. We will analyze and compare their effects in our experimental study. Recap that each review d consists of a sequence of words $\{w\}$ by u on item i at time t.

F1. Language model features based on the review text: Using the learned language model β, we construct $\langle F_w = log(max_z \beta_{z,w}) \rangle$ of dimension W (size of the vocabulary). That is, for each word w in the review, we consider the value of β corresponding to the best facet z that can be assigned to the word. We take the log-transformation of β which empirically gives better results.

F2. Rating bias features: Similar to [19, 25], we consider: (i) Global rating bias γ_g: Average rating $avg(\langle y \rangle)$ assigned by all users to all items. (ii) User rating bias γ_u: Average rating $avg(\langle y_{u,.,.} \rangle)$ assigned by u to all items. (iii) Item rating bias γ_i: Average rating $avg(\langle y_{.,i,.} \rangle)$ assigned by all users to item i.

F3. Temporal influence features: Finally, we exploit the temporal and influence information we have learned with our model. (i) Temporal rating bias γ_r: Average rating $avg(\langle y_{.,i,t} \rangle)$ assigned by all users to item i *before* time t. This baseline considers the temporal trend in the rating pattern. (ii) Temporal influence from rating γ_d: Let $\langle d_t \rangle$ be the set of reviews written by users $\langle v_{d_t} \rangle$ before time t on the item i. Consider the influence of $v_{d'}$ on u, i.e. the variable $\psi_{u,v_{d'}}$, as learned by our model. The feature $avg(\langle \psi_{u,v_{d_t}} \cdot y_{v_{d_t},i,t} \rangle)$ aggregates the rating of each previous user and her influence on the current user for item i at time t to model the influence of previous users' ratings on the current user's rating. This baseline combines the temporal trend and the social influence of earlier users' rating. (iii) Temporal influence from context γ_{dc}: Consider the review d with the sequence of words $\langle w \rangle$. Let $s_w \in \{0, 1\}$ be the influence variable sampled for a word w, and v_w be the influencer sampled for the word when $s_w = 1$, as inferred from our model. Also, let y_{v_w} be the rating assigned by v_w to the current item at time $t' < t$. Consider $\mathbb{I}(.)$ be an indicator function that is 1 when its argument is true, and 0 otherwise. We use:

$$\gamma_{dc} = \frac{1}{|d|} \sum_{w \in d} \left(\mathbb{I}(s_w = 1) \cdot \left(\psi_{u,v_w} \cdot y_{v_w} \right) + \mathbb{I}(s_w = 0) \cdot \gamma_u \right)$$

For each word w in the review d, if the word is written under influence ($s_w = 1$), we consider the influencer's rating and her influence on the current user given by $\psi_{u,v_w} \cdot y_{v_w}$. Otherwise ($s_w = 0$), we consider the user's self rating bias γ_u. This is aggregated over all the words in the review. This baseline combines the temporal trend and context-specific social influence of earlier users' rating.

Using different combinations of these features (see Sec. 5), we use Support Vector Regression [3] from LibLinear with default parameters to predict the item ratings $y'_{u,i,t}$, using ten-fold cross-validation (https://www.csie.ntu. edu.tw/ cjlin/liblinear/).

Dataset	#Users	#Items	#Reviews	#Years
Beer (BeerAdvocate)	33,387	66,051	1,586,259	16

5 EXPERIMENTS

We empirically analyze various aspects of GhostLink, using four online communities in different domains: BeerAdvocate (`beeradvocate.com`) and RateBeer (`ratebeer.com`) for *beer* reviews. Amazon (`amazon.com`) for *movie* and *food* reviews. Table 3 gives an overview. All datasets are publicly available at `http://snap.stanford.edu`. We have a total of 13 million reviews from 1 million users over 16 years

	Beer advocate	Rate beer	Amazon Foods	Amazon Movies
GhostLink: Fast Implementation	1.8	1.6	0.08	1.9
GhostLink: Basic	6	2.2	0.14	3.1

Table 4: Run time comparison (in hours) till convergence between different versions of GhostLink.

from all of the four communities combined. From each community, we extract the following quintuple for GhostLink <$userId, itemId, timestamp, rating, review$>. We set the number of latent facets $K = 20$ for all datasets. The symmetric Dirichlet concentration parameters are set as: $\alpha = \frac{1}{K}, \eta = \frac{1}{2}, \rho = \frac{1}{U}, \gamma = 0.01$.[3]

Performance improvements of GhostLink over baseline methods are statistically significant at 99% level of confidence determined by *paired sample t-test.*

5.1 Likelihood, Smoothness, Fast Convergence

There are multiple sets of latent variables in GhostLink that need to be inferred during Gibbs sampling. Therefore, it is imperative to show the resultant model is not only stable, but also improves log-likelihood of the data. A higher likelihood indicates a better model. There are several measures to evaluate the quality of facet models; we use here the one from [35]: $LL = \sum_d \sum_{j=1}^{N_d} log\ P(w_{d,j}|\beta; \alpha)$.

Figure 3 shows the log-likelihood of the data per iteration for the Beeradvocate and Amazon Foods data. The plots for the other datasets are similar. We find that the learning is stable and has a *smooth* increase in the data log-likelihood *per iteration.* Empirically GhostLink also shows a fast convergence in around 10 iterations.

Table 4 shows the run time comparison to convergence between the basic and fast implementation of GhostLink[4]. The fast version uses two tricks: (i) instead of computing Equations 4 and 5 separately, it estimates — s_j and $v_{d',j}|s_j = 1$ — *jointly*, and (ii) it estimates facets for each *unique* token *once* as in Section 3.3.

We also compare the log-likelihood of our model to another generative model that is closest to our work namely, the Author-Topic Model [32]. This work models documents (reviews) to have a distribution over authors, authors to have a distribution over topics, and topics to have a distribution over words. This model is easy to mimic in our setting by ignoring the notion of influence (i.e. setting $s = 0$ as constant for all authors/users). Figure 3 shows the stark difference in log-likelihood of the two models where GhostLink considering influence ($s \in \{0, 1\}$) performs much better than the baseline that ignores the effect of temporal influence ($s \in \{0\}$).

[3]We did not fine-tune hyper-parameter K. It is possible to improve performance by considering the value of K that gives the best model perplexity. Similarly, we consider symmetric Dirichlet priors for a simplistic model with less hyper-parameters to tune.
[4]Experiments are performed in: Intel(R) Xeon(R) CPU E5-2667 v3 @ 3.20GHz. Note that our Gibbs sampling based inference process is sequential and not distributed.

Figure 3: Log-likelihood of GhostLink and Author-Topic Model [32] per-iteration in Beeradvocate & Amazon Foods.

5.2 Influence-aware Item Rating Prediction

Next, we show the effectiveness of GhostLink for item rating prediction. In Section 4 we described the set of features and evaluation measure for this task. Table 5 compares the mean-squared error of GhostLink with all the baselines with *ten-fold cross validation* — where we use 90% of the data for training and 10% for test with results averaged over 10 such splits.

We divide our baselines into four main categories. For each category, we chose the state-of-the-art system as a baseline that is the most representative of that category with all the features as applicable. Unavailability of explicit user-user links in our data renders many of the related works inapplicable to our setting.

(A) Rating and Time-aware Latent Factor Models: These baselines model users, items, ratings and their temporal dynamics but ignore the text or content of the reviews. For most of these baselines, we used the code repository from http://cseweb.ucsd.edu/ jmcauley/code/. Note that these models use the rating bias features (F2) from Section 4. Since they do not model text or influence network, the other features are not applicable.

(a) LFM: This is the classical latent factor model based on collaborative filtering with temporal dynamics [18] that considers ratings, latent facets, and time.

(b) Community at uniform rate: This set of models [26, 39, 40] consider users and products in a community to evolve using a single global clock with the different stages of community evolution appearing at uniform time intervals. So the preference for items evolves over time.

(c) Community at learned rate: This extends (b) by learning the rate at which the community evolves with time [26].

(d) User at uniform rate: This extends (b) to consider individual users and modeling users' progression based on their maturity and preferences evolving over time. The model assumes a uniform rate for evolution [26].

(e) User at learned rate: This extends (d) by allowing each user to evolve on their individual clock, so that the time to attain maturity varies for different users [26].

(B) Text-aware Latent Factor Model: Unlike the previous baselines, this model [25] considers text of the reviews along with the latent factor models using collaborative filtering for item rating prediction. The authors learn topic/facet distributions from text using a generative model based on Latent Dirichlet Allocation, and tie them to the latent facet distributions learned from the collaborative filtering model based on users and ratings. All of these are jointly learned to minimize the mean squared error for item rating prediction. This is the strongest baseline for our work but ignores the notion of network influence. Note that this baseline uses the rating bias features (F2) and language model (F1) from Section 4. The network influence features are not applicable.[5]. Also, note that the generative process in this work is similar to the Author Topic Model [32] with the main difference of the former being tailored for item rating prediction.

[5]We used their code publicly available at http://cseweb.ucsd.edu/ jmcauley/code/

Models	Beer advocate	Rate beer	Amazon Foods	Amazon Movies
(D) GhostLink (Rating + Network + Time + Text)	**0.282**	**0.250**	**0.711**	**0.646**

User at learned rate [26]	0.610	0.797	1.007	0.891

Table 5: Mean squared error for rating prediction (lower is better). GhostLink outperforms competing methods.

(C) Network-aware Models: We also experiment with two information diffusion based baselines [7, 9]. Both models infer the latent influence network underlying a community based on only the temporal traces of activities (e.g., timestamps of users *posting* reviews, nodes *adopting* or becoming infected with information); they *ignore the review text.*

(f) NetInfluence: This model [9] learns the probability of one node influencing another based on logs of their past propagation (*action logs*). The model assumes that when a user u in a network is influenced to perform an action, it may be influenced by its neighbors (Ψ_u in our setting) who have performed the action before. Therefore, each of these predecessors share the "credit" for influencing u to perform that action. In order to adapt their model to our setting, we consider the event of writing a review on an item i to be an *action* at a given timestamp. Therefore input is the set of actions $\langle u, i, t\rangle$ and $\langle u, v\rangle$. Although the authors do not perform recommendation, we use their estimated "influence" scores to construct Ψ (refer to Equation 8).[6]. This allows us to use all the features (F3) in Section 4 derived from the influence network in addition to the rating bias features (F1). Since they do not model text, the language model features are not applicable.

(D) GhostLink: We evaluate GhostLink with various combinations of the feature sets. In particular, we consider: (a) rating bias (F2, F3.i), (b) network influence (F3), (c) combining rating and network influence (F2, F3), (d) language model (F1), and the full model (F1, F2, F3).

Results: Table 5 shows the results. Standard latent factor collaborative filtering models and most of its temporal variations (Models: A) that leverage rating and temporal dynamics but ignore text and network influence perform the worse. We observe that the network diffusion based model that incorporates the latent influence network from temporal traces in addition to the rating information (Models: C) perform much better than the previous models not considering the network information. However, these too ignored the textual signals. Finally, we observe that contextual information harnessed from the review content in addition to rating information (Models: B) outperforms all of the previous models.

From the variations of Ghostlink (using only language model), we observe that textual features alone are not helpful. GhostLink progressively improves as we incorporate more influence-specific features. Finally, the joint model leveraging all of context, rating, temporal and influence features incurs the least error. Comparison with the best performing baseline models shows the power of combined contextual and influence features over only context (Models: B) or only network influence (Models: C).

Additional Network-aware models: We also explored NetInf [7] for tracing paths of diffusion and influence through networks. Given the times when nodes adopt pieces of information or become infected, NetInf identifies the optimal network that best explains the observed infection times. To adapt NetInf to our setting, we consider all the reviews on an item to form a cascade — with the total number of cascades equal to the number of items. For each cascade (item), the input is the set of reviews on the item by users u at timestamps t. However, NetInf yielded extremely sparse networks on our datasets — suffering from multiple modeling assumptions like a single influence point for a node in a cascade, static propagation and fixed transmission rates for all the nodes. For example, in BeerAdvocate it extracted only 5 pairs of influenced interactions. In contrast, both our model as well as NetInfluence, the influence probability $\Psi_{u,v}$ varies for every pair of nodes.

[6]We used their code available at http://www.cs.ubc.ca/ goyal/code-release.php/

Table 6: Facet preference divergence between distributions.

5.3 Facet Preference Divergence

In this study, we want to examine if there is any difference between the latent facet preference of users, as opposed to their *observed* preference, and their preference when acting as an influencer (see Sec. 3.4 for the definition of these preference distributions).

We compute the Jensen-Shannon Divergence (JSD) between the different distributions $\theta_u^{infl}, \theta_u^{latent}, \theta_u^{obs}$ to observe their difference. JSD is a symmetrized form of Kullback-Leibler divergence that is normalized between 0 - 1 with 0 indicating identical distributions. We compute the JSD results averaged over all the users u in the community, i.e. $\frac{1}{|U|}\sum_u JSD(\theta_u^x \,||\, \theta_u^y)$ with the corresponding $x, y \in \{latent, infl, obs\}$. Table 6 shows the results.

We observe (statistically) significant difference between the latent facet preferences of users from that observed/acquired in a community (C1). This result indicates the strong occurrence of social influence on user preferences in online communities. We also find that users are more likely to use their original latent preferences to influence others in the community, rather than their acquired

Dataset	Model	Pearson Correlation
Beeradvocate	**GhostLink**	**0.708**

Amazon Movies	589K	145.4K	476K	80.81%	145K	99.72%

Table 8: Structure of the latent influence networks: The Influence Graph (IG) is well represented by a Maximum Weighted Spanning Forest (MWSF)

ones. That is, the JSD between the influencer and latent facet preference distribution (C2) is always significantly smaller than the JSD between the observed and the influencer distribution (C3).

5.4 Finding Influential Members

GhostLink generates a directed, weighted influence network $G = (U, E)$ using the user-influencer distribution Ψ. Given such a network, we can find influential nodes in the network. We used several algorithms to measure authority like Pagerank, HITS, degree centrality etc. out of which eigenvector centrality performed the best[7]. The basic idea behind eigenvector centrality is that a node is considered influential, not just if it connects to many nodes (as in simple degree centrality) but if it connects to high-scoring nodes in the network. Given the eigenvector centrality score x_v for each node v, we can compute a ranked list of users.

Comparison: An obvious question is whether this ranking based on the influence graph Ψ is really helpful? Or put differently: Does this perform better compared to a simpler graph-based influence measure? A natural choice, for example, would be the temporal co-reviewing behavior of users. To construct such a graph, we can connect two users u and v with a directed edge if u writes a review following v. The weight of this edge corresponds to all such reviews (following the above temporal order) aggregated across all the items. Therefore, v acts as an influencer if u closely follows his reviews. We choose a cut-off threshold of at least 5 reviews. Also for this graph, we can compute eigenvector centrality scores, and obtain a ranked list of users as described above.

The task: We want to find which of the above graphs gives a better ranking of users. We perform this experiment in the Beeradvocate and Ratebeer communities. In these communities, users are awarded points based on factors like: their community engagement, how other users find their reviews helpful and rate them, as well as their expertise on beers. This is moderated by the community administrators. For instance, in Beeradvocate users are awarded Karma points[8]. The exact algorithm for calculation of these points is not made public to users as it can be game to manipulation – and of course, these scores are also not used in GhostLink.

We used these points as a proxy for user authority, and rank the users. This ranked list is used as a reference list (ground-truth) for comparison. That is, we use the ranked list of users based on eigenvector centrality scores from our influence graph, and compute Pearson correlation with the reference list[9]. A correlation score of 1 indicates complete agreement, whereas −1 indicates complete disagreement. We can also do the same for the ranked list of users based on their co-reviewing behavior. As another strong baseline, we also consider the influence scores for the users as generated by NetInfluence [9]. Table 7 shows the results.

We observe that the ranking computed with our influence graph performs much better (higher correlation with ground-truth) than the temporal co-reviewing baseline. Thus, the learned influence network indeed captures more information than simple co-reviewing behavior and even the more advanced diffusion based NetInfluence model, and enables us to find influential users better. Note again, that the point-based scores used for the ground-truth ranking have *not been used* in GhostLink.

5.5 Structure of the Influence Network

Last, we analyze the structure of the influence network Ψ. Our first research question is: How is the mass (sum of influence/edge weights) distributed in the network? Is it randomly spread out, or do we observe any particular structure (e.g., resembling a tree-like structure). For this, we computed a Maximum Weighted Spanning Tree from the graph (or spanning forest as the graph is not connected) and computed the sum of its edge-weights, i.e. its mass.

Table 8 shows the statistics of the constructed MWSF over different datasets and compares it with the (original) influence graph (IG). We observe that *the majority of mass of the influence graph is concentrated in giant tree-components*. For example, in Beeradvocate, 99.37% of the mass of the influence graph is concentrated in the MWSF. The forest accounts for 73.40% of the edges in the influence graph. Thus, the remaining 26.6% of the edges contribute only marginally, and can be pruned out. This tree-like influence matches intuition: a user often influences many other users, while she herself gets primarily influenced by a few – surprisingly, in the majority of cases only by a single other user – as indicated by the good approximation of the graph via a tree (preservation of mass). Figure 5 shows the MWSF for a representative facet "yuengling", and its giant component.

The tree structure in Figure 5 shows another characteristics: only a few users seem to influence many others (it resembles a snowflake) in the community. This brings us to our second research question: Do we observe — similar to real-world networks — specific power-law behaviors? For example, are the majority of nodes 'influencees', and only a few nodes are 'influencers'?

Figure 4 analyzes this aspect. Here we illustrate the distribution of nodes with weighted degree, hub & authority, and eigen vector centrality scores for our influence graph plotted in *log-scale*. These statistics are for the Beeradvocate community. The statistics for

[7]Note that these baselines already subsume simpler activity based ranking (e.g., based on number of reviews written).
[8]https://www.beeradvocate.com/community/threads/beer-karma-explained.184895/
[9]Other ranking measures (Kendall-Tau, Spearman Rho) yield similar improvements.

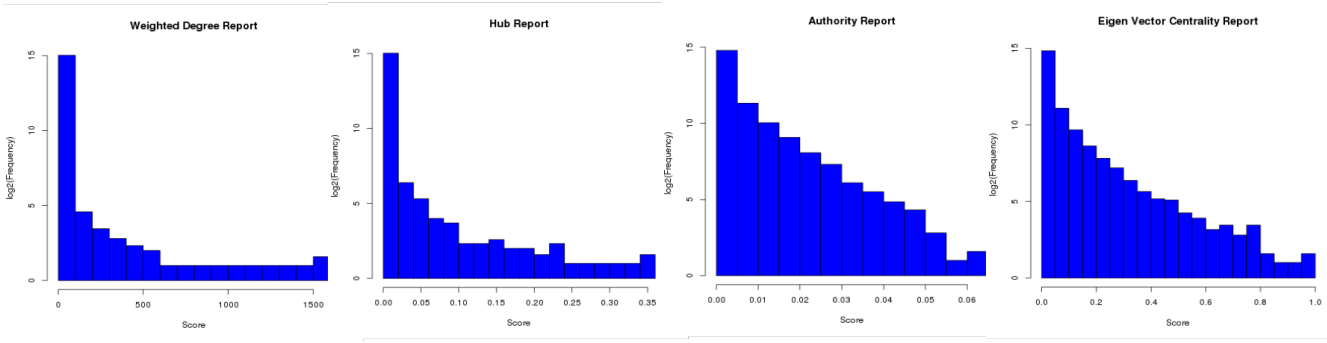

Figure 4: Distribution of nodes with scores (weighted degree, hubs, authorities, and eigen vector centralities in order from left to right) in log-scale for the extracted influence graph (note the change in scale of scores for each figure) in Beeradvocate data.

other communities are similar. Indeed, we observe power-law like distributions with many influencees and a few influencers.

For the HITS algorithm, a hub — with a lot of outgoing edges — is a user who influences a lot of other users; whereas an authority — with a lot of incoming edges — is the one getting influenced by other influential users. Note that each node can be a hub and an authority with different scores simultaneously. We observe that there are a lot of hubs (influencers) with very low influence scores, and only few with very high influence. From the authority report, we see that there are less number of incoming edges to nodes (note the really small range of authority scores of nodes). This indicates that users generally get influenced by only a few users in the community — confirming the tree-like structure of the influence graph.

6 RELATED WORK

State-of-the-art recommender systems exploit user-user and item-item similarities using latent factor models [17, 19]. Temporal patterns in ratings such as bursts, bias, and anomalies are studied in [12, 18, 38]. Recent works [25, 28, 37] have further considered review texts for content-aware recommender systems. However, all of these works assume that users participate independently in the community which is rarely the case.

Social-aware recommender systems [5, 14, 16, 20, 22, 27, 33, 34, 41, 42] exploit peers and friends of users to extract more insights from their activities, likes, and content sharing patterns using homophily. In absence of explicit social networks in many communities, some works [13, 21, 23, 24] exploit collaborative filtering to extract implicit social relationships based on the historical rating behavior. Some of these works also leverage signals like pre-defined trust metrics, and partial or explicit social links. [21, 43] use time as an additional dimension along with ratings.

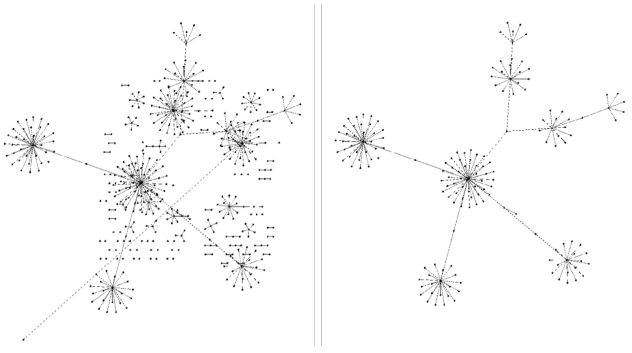

Figure 5: Maximum Weighted Spanning Forest corresponding to a representative facet (left); and its giant component (right).

Information diffusion based works [6, 7, 9, 30] that model underlying *latent* influence or diffusion networks do not consider text. Some of them have strong assumptions in terms of known transmission rates, static and homogeneous transmission etc. Recent works on text-based diffusion [4, 15, 36] alleviate some of these assumptions. However, they also make some assumptions regarding topics of diffusion being known, network being explicit etc. Most importantly, none of these works are geared for item recommendation and do not study the characteristics of review communities.

Works in modeling influence in heterogeneous networks [22] and citations networks [2] assume the presence of explicit user-user links. Prior works on modeling influence propagation and cascades [31] also consider a given network to propagate influence scores. Learning a latent influence network has been possible in the field of information propagation when observing cascades of events [8, 43]. However, these works have not considered the setting where only review text is available, and no explicit networks.

In contrast to prior works, GhostLink learns the latent influence network solely from timestamped user reviews, without requiring any explicit user-user link/rating information. It uses this network to improve item rating prediction considering implicit social influence.

7 CONCLUSION

We presented GhostLink, an unsupervised generative model to extract the underlying influence graph in online communities dealing with items of fine taste like movies, food and beer without requiring any explicit user-user links or ratings. Given only timestamped reviews of users, we leverage opinion conformity from overlapping facet descriptions in co-reviewed content and their temporal traces to extract this graph. Furthermore, we use this influence network to improve item rating prediction by 23% over state-of-the-art methods by capturing implicit social influence. We show in large-scale experiments in four real-life communities with 13 million reviews that GhostLink outperforms several state-of-the-art baselines for tasks like recommendation and identifying influential users.

ABSTRACT

Measuring similarities between vertices is an important task in network analysis, which has numerous applications. One major approach to define a similarity between vertices is by accumulating weights of walks between them that encompasses personalized PageRank (PPR) and Katz similarity. Although many effective methods for PPR based on efficient simulation of random walks have been proposed, these techniques cannot be applied to other walk-based similarity notions because the random walk interpretation is only valid for PPR.

In this paper, we propose a *random-walk reduction* method that reduces the computation of any walk-based similarity to the computation of a stationary distribution of a random walk. With this reduction, we can exploit techniques for PPR to compute other walk-based similarities. As a concrete application, we design an indexing method for walk-based similarities with which we can quickly estimate the similarity value of queried pairs of vertices, and theoretically analyze its approximation error. Our experimental results demonstrate that the instantiation of our method for Katz similarity is two orders of magnitude faster than existing methods on large real networks, without any deterioration in solution quality.

1 INTRODUCTION

In network analysis, measuring similarities between vertices is an important task that has numerous applications such as recommendation [12, 15] and link prediction [20, 25].

One major class of similarity measures is *walk-based similarities* [14]. Here, we first define the weight of a walk. Then, we define the similarity value between two vertices as the sum of the weights of all the walks connecting them. By changing the definition of the weight of a walk, we can express various similarity notions, including personalized PageRank (PPR) [22], Katz similarity [13], and adsorption [3]. Among those, PPR has drawn much attention and several efficient methods have been proposed [1, 2, 4, 10, 17, 18, 24]. In contrast, there are only a few efficient methods that can be applied to *general* walk-based similarities [14, 30], even though they include other practically important similarity notions.

In this paper, we propose a *random-walk reduction* method to address the issue above. Given any walk-based similarity notion, this method constructs a weighted graph on which we can perform a random walk. Then, the original similarity values can be easily recovered from the stationary distribution of a random walk on the weighted graph. With this reduction, we can apply any algorithm that was originally designed to compute PPR (such as the Monte Carlo method [10], FAST-PPR [18] and BiPPR [17]) to any other walk-based similarity notion.

As an application of our random-walk reduction, for any walk-based similarity, we transform BiPPR [17], originally designed to compute the PPR of a target vertex from a source vertex, to a method for the similarity. We also provide a theoretical analysis on its approximation error. The experiment shows that the transformed method instantiated by Katz similarity is two orders of magnitude faster than existing methods without deteriorating the solution quality.

This paper is structured as follows. Section 2 gives an overview of related works. Section 3 provides a basic explanation of our problem. Section 4 explains previous methods that we rely on and outlines our method. We present our method in detail in Sections 5 and 6. We theoretically guarantee the approximation error of our method in Section 7. In Section 8, we present experimental results on one-to-one Katz similarity estimation and show that our method is two orders of magnitude faster than existing methods on large real networks.

2 RELATED WORK

Considering the importance of vertex similarities, several walk-based similarity metrics have been proposed, including PPR [22], Katz similarity [13], and adsorption [3].

Although they are all computable by solving certain linear equations, this approach is time-consuming. To address this issue, various other methods have been proposed to approximately compute the values of these metrics and to compute *top-k* vertices from a given vertex with regard to the given metric.

PPR has been intensively studied in the literature. Monte Carlo approximation algorithms were proposed in [10]. Andersen *et al.* [1, 2] proposed algorithms that iteratively update the estimated value by checking the local neighborhood of each vertex. Lofgren *et al.* [18] proposed bidirectional algorithms for PPR. Their algorithms combine Monte Carlo simulation (*forward work*) and backward local push algorithm (*backward work*) to obtain better estimations in shorter time. For any *threshold* $\delta > 0$, their algorithm for one-to-one similarity estimation can estimate PPR values larger than δ with a theoretical guarantee in average $O(\sqrt{\bar{d}/\delta})$ time, where $\bar{d}$ is the average degree of the graph. These algorithms were later simplified and improved in [17]. Their works are also extended to estimation of probabilities in Markov models [4] and single element of linear systems of form $A^\ell \boldsymbol{z}$ [24].

Esfandiar *et al.* [9] proposed algorithms for approximating Katz similarities and for computing the top-k vertices from the given vertex with theoretical guarantees.

However, there are few methods that can handle *general* walk-based similarity metrics. The only works we are aware of are [14] and [30]. Both methods considered computing top-k vertices by locally updating estimated values and maintaining their upper and lower bounds, which cannot efficiently handle one-to-one similarity estimation.

3 PRELIMINARIES

For a positive integer $n \in \mathbb{N}$, let $[n]$ denote the set $\{1, 2, \ldots, n\}$. We denote by $\langle \cdot, \cdot \rangle$ the standard inner product.

Let $G = (V, E)$ be a directed graph with n vertices and m edges. For a vertex $v \in V$, let $N^+(v)$ denote the set of out-neighbors of $v \in V$ and $d^+(v) := |N^+(v)|$ denote the out-degree of v. Similarly, we define $N^-(v)$ and $d^-(v)$ for in-neighbors.. For a vertex $v \in V$, let $\boldsymbol{e}_v \in \mathbb{R}^V$ be the indicator vector of v, that is, the all-zero vector except the v-th element being one.

3.1 Walk-based similarity

Let $G = (V, E)$ be a directed graph. A *walk* on G is a sequence $(v_0, v_1, \ldots, v_\ell)$ of vertices such that $v_{i-1}v_i \in E$ for every $i \in [\ell]$. We note that $v_0, v_1, \ldots, v_\ell$ are not necessarily distinct; when they are distinct, it is called a *path*.

A *walk-based similarity* [14] is parameterized by a weight function $w \colon E \to \mathbb{R}_+$ on edges and $c \in \mathbb{R}_+$. For a walk $W = (v_0, v_1 \ldots, v_\ell)$ of length ℓ, we define its weight $w_c(W)$ as

$$w_c(W) = c \prod_{i=1}^{\ell} w(v_{i-1}v_i)$$

For two vertices $s, t \in V$, let walk(s, t) be the (infinite) set of walks from s to t. When $s = t$, we include the path of length 0, which consists only of s, to walk(s, s).

The similarity $\sigma_{c,w}(s, t)$ from a vertex $s \in V$ to another vertex $t \in V$ is defined as

$$\sigma_{c,w}(s, t) = \sum_{W \in \mathrm{walk}(s,t)} w_c(W),$$

when the sum converges. We omit the subscripts c and w when they are clear from the context.

Although it is difficult to compute $\sigma_{c,w}(s, t)$ based on the definition, we can rephrase it in linear algebraic terms [14]. We define the *transition weight matrix* $H \in \mathbb{R}^{V \times V}$ as $H_{uv} = w(uv)$. If $\sigma_{c,w}(u, v)$ is well-defined for every $(u, v) \in V^2$, then the spectral radius $\rho(H)$ of H must be less than one and $\sigma_{c,w}(s, t)$ can be represented as

$$\sigma_{c,w}(s, t) = \left\langle \boldsymbol{e}_s, c \sum_{\ell=0}^{\infty} H^\ell \boldsymbol{e}_t \right\rangle,$$

where $\sum_{\ell=0}^{\infty} H^\ell = (I - H)^{-1}$ [8]. Because every component of H is nonnegative, it is guaranteed that $\rho(H)$ equals the largest real eigenvalue of H by the Perron-Frobenius theorem.

By changing the weight function $w \colon E \to \mathbb{R}_+$ and the scalar coefficient $c \in \mathbb{R}_+$, we can express various similarity notions.

Example 3.1 (Personalized Pagerank [22]). *Let $T = AD^{-1}$ be the transition matrix, where $A \in \mathbb{R}^{V \times V}$ is the adjacency matrix of G and $D \in \mathbb{R}^{V \times V}$ is the diagonal matrix such that $D_{vv} = d^+(v)$ for every $v \in V$. For $\alpha \in (0, 1)$, the personalized PageRank $\sigma_{\mathrm{PPR}}(s, t)$ from a vertex $s \in V$ to another vertex $t \in V$ is*

$$\sigma_{\mathrm{PPR}}(s, t) = \left\langle \boldsymbol{e}_s, \alpha \sum_{\ell=0}^{\infty} (1 - \alpha)^\ell T^\ell \boldsymbol{e}_t \right\rangle,$$

which equals the probability of staying at t in the stationary distribution of the following random walk process: Starting with s, we move to a random neighbor of the current vertex with probability $1 - \alpha$ and jump back to s with the complement probability α. We can easily check that σ_{PPR} is the walk-based similarity with $c = \alpha$ and $w(uv) = 1/d^+(u)$.

Example 3.2 (Katz Similarity [13]). *For $\beta \in (0, 1)$, the Katz similarity from a source vertex $s \in V$ to another vertex $t \in V$ is*

$$\sigma_{\mathrm{Katz}}(s, t) = \left\langle \boldsymbol{e}_s, \sum_{\ell=0}^{\infty} \beta^\ell A^\ell \boldsymbol{e}_t \right\rangle,$$

where $A \in \mathbb{R}^{V \times V}$ is the adjacency matrix. The sum converges when β is smaller than the reciprocal of the largest eigenvalue of A. Here, too, we can confirm that σ_{Katz} is the walk-based similarity with $c = 1$ and $w(uv) = \beta$.

We note that any walk-based similarity can be seen as a Katz similarity on a weighted graph, that is, $A \in \mathbb{R}^{V \times V}$ is a general non-negative matrix.

In this work, we primarily consider the following *one-to-one* similarity estimation problem:

Definition 3.3 (One-to-one similarity estimation problem). *The one-to-one similarity estimation problem is specified by a graph $G = (V, E)$ with a weight function $w \colon E \to \mathbb{R}_+$ on edges and a scalar coefficient $c \in \mathbb{R}_+$. The goal is to construct an index with which, given a pair of vertices $(s, t) \in V^2$, a threshold $\delta \in (0, 1)$, an accuracy parameter $\epsilon \in (0, 1)$, and a failure probability $p \in (0, 1)$ as a query,*

we can compute $\hat{\sigma}(s,t)$ such that $|\hat{\sigma}(s,t) - \sigma_{c,w}(s,t)| < \epsilon \cdot \sigma_{c,w}(s,t)$ with probability at least $1-p$ if $\sigma_{c,w}(s,t) \geq \delta$. If $\hat{\sigma}(s,t)$ satisfies this, we call $\hat{\sigma}(s,t)$ an (ϵ, δ, p)-estimation of $\sigma_{c,w}(s,t)$.

Because approximating small $\sigma_{c,w}(s,t)$ is quite difficult [18], introducing the threshold parameter δ is crucial.

4 PREVIOUS METHODS AND OVERVIEW OF OUR METHOD

4.1 Previous methods

In this section, we review previous methods used for the one-to-one similarity estimation problem.

Iterative method. Iterative method is a basic approach for solving linear systems of the form $A\boldsymbol{x} = \boldsymbol{b}$, where $A \in \mathbb{R}^{n \times n}$ is a matrix with $\rho(I - A) < 1$ and $\boldsymbol{b} \in \mathbb{R}^n$ is a vector. The Jacobi method is a popular method that iteratively computes

$$\boldsymbol{x}_0 = 0, \quad \text{and} \quad \boldsymbol{x}_i = (I - A)\boldsymbol{x}_{i-1} + \boldsymbol{b} \ (i \geq 1).$$

Then, $\boldsymbol{x}_i$ converges to $\boldsymbol{x} = A^{-1}\boldsymbol{b}$ (Note that A is nonsingular from the assumption $\rho(I-A) < 1$). This method can be directly applied to compute walk-based similarity vector from a vertex $s \in V$ by setting $A = I - H$ (from the convergence condition, $\rho(I - A) = \rho(H) < 1$ is guaranteed) and $\boldsymbol{b} = \boldsymbol{e}_t$.

The time complexity of this algorithm is $O(m \cdot i)$, where i is the number of iterations. Moreover, the error decreases as $O(\rho(I - A)^i)$ [21]. This algorithm can compute similarity values from all the vertices to a target vertex simultaneously. (Note that we can also compute similarity values from a source vertex to all the vertices at once by setting $A = I - H^\top, \boldsymbol{b} = \boldsymbol{e}_s$.) However, this method can be rather inefficient to solve the one-to-one similarity estimation problem because the target vertex (or the source vertex) varies with queries.

Forward and backward push methods. The forward push method was proposed in [2] to compute PPR and then was applied to compute Katz similarities [9]. The forward push method approximates the similarity values from a source vertex $s \in V$ by maintaining two vectors; the *reserve vector* $\boldsymbol{p}_s \in \mathbb{R}^V$ and the *residue vector* $\boldsymbol{r}_s \in \mathbb{R}^V$. Initially, we set $\boldsymbol{p}_s = 0$ and $\boldsymbol{r}_s(v) = \boldsymbol{e}_s$. Then, these vectors are updated so that the following invariant is maintained:

$$\sigma_{c,w}(s,v) = p_s(v) + \sum_{u \in V} r_s(u)\sigma_{c,w}(u,v). \tag{1}$$

A pseudocode of this method is given in Algorithm 1.

To the extent of our knowledge, there is no approximation guarantee for the forward push method. As for time complexity, Andersen *et al.* [2] showed that Algorithm 1 runs in $O\left(\frac{1}{\alpha\delta}\right)$ time for PPR if we use the termination condition $\max_{v \in V} \frac{r_s(v)}{d^+(v)} < \delta$ instead of $r_s(u) > \delta$.

The backward push method [1] is similar to the forward push method, except that it maintains a *reverse similarity vector* $\boldsymbol{q}_t \in \mathbb{R}^V$ for which $q_t(v)$ is supposed to approximate $\sigma_{c,w}(v,t)$. The backward push method also maintains a residue vector $\boldsymbol{r}_t \in \mathbb{R}^V$. The invariant for this method is the following:

$$\sigma_{c,w}(v,t) = q_t(v) + \sum_{u \in V} \sigma_{c,w}(v,u) r_t(u). \tag{2}$$

A pseudocode of this method is given in Algorithm 2.

Algorithm 1 Forward push

Input: source vertex $s \in V$, threshold $\delta > 0$

$p_s(u) \leftarrow 0 \ (u \in V), r_s(s) \leftarrow 1, r_s(u) \leftarrow 0 \ (u \in V \setminus \{s\})$
while $\exists u \in V, r_s(u) > \delta$ **do**
  for $v \in N^+(u)$ **do**
    $r_s(v) \leftarrow r_s(v) + w(uv) r_s(u)$.
  end for
  $p_s(u) \leftarrow p_s(u) + r_s(u), r_s(u) \leftarrow 0$.
end while

Algorithm 2 Backward push

Input: target vertex $t \in V$, threshold $\delta > 0$

$q_t(u) \leftarrow 0 \ (u \in V), r_t(t) \leftarrow 1, r_t(u) \leftarrow 0 \ (u \in V \setminus \{t\})$.
while $\exists v, r_t(v) > \delta$ **do**
  for $u \in N^-(v)$ **do**
    $r_t(u) \leftarrow r_t(v) + w(uv) r_t(v)$.
  end for
  $q_t(v) \leftarrow q_t(v) + r_t(v), r_t(v) \leftarrow 0$.
end while

As opposed to the forward push method, the backward push method on PPR has an approximation guarantee. Andersen *et al.* [1] showed that Algorithm 2 returns a reverse similarity vector $\boldsymbol{q}_t$ such that $|q_t(v) - \sigma_{\mathrm{PPR}}(v,t)| \leq \delta$ for every $v \in V$. Lofgren and Goel [19] showed that, for uniformly chosen target vertex $t \in V$, Algorithm 2 runs in expected $O\left(\frac{1}{\alpha\delta} \cdot \frac{|E|}{|V|}\right)$ time.

Monte Carlo method. Since the PPR of a vertex indicate the probability of staying at the vertex in the stationary distribution of a random walk, it can be approximated with a Monte Carlo method [10]. It should be noted that this approach is directly applicable only to PPR, because the transition weight matrix H is not a stochastic matrix for other similarity notions (even $\|H\|_\infty := \max_{\boldsymbol{v}} \|H\boldsymbol{v}\|_\infty / \|\boldsymbol{v}\|_\infty > 1$ may hold). An extension of the Monte Carlo method to general similarity notions and its shortcomings are discussed later.

The Monte Carlo method for PPR first generates N random walks starting from the source vertex $s \in V$ and then, for each $v \in V$, computes the number of random walks N_v that terminate at v. Then, the similarity $\sigma_{\mathrm{PPR}}(s,v)$ is estimated as $\frac{N_v}{N}$. Since the probability that a random walk terminates at $v \in V$ equals $\sigma_{\mathrm{PPR}}(s,v)$, this estimator is unbiased.

Bidirectional methods. The first bidirectional algorithm for computing the PPR between two vertices, called *FAST-PPR*, was proposed in [18] and then its improved version, called *BiPPR*, was proposed in [17]. We describe the latter in detail since our method is built on it.

BiPPR carefully combines the Monte Carlo method and the backward push method. Suppose that we have performed backward pushes to obtain the reverse similarity vector $\boldsymbol{q}_t \in \mathbb{R}^V$ and the residue vector $\boldsymbol{r}_t \in \mathbb{R}^V$ for the target vertex t. From (2), if we have

estimates $\hat{\sigma}_{c,w}(s,v)$ of $\sigma_{c,w}(s,v)$ for each $v \in V$, we can approximate $\sigma_{c,w}(s,t)$ by

$$\hat{\sigma}'_{c,w}(s,t) := q_t(s) + \sum_{v \in V} \hat{\sigma}_{c,w}(s,v) r_t(v).$$

Now, we use the Monte Carlo method to obtain $\hat{\sigma}_{c,w}(s,v)$. It is reported in [17] that BiPPR is significantly faster than both the Monte Carlo method and the backward push method.

4.2 Limitation of Monte Carlo based methods on general similarity notions

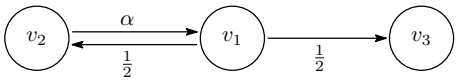

Figure 1: A weighted directed graph for which the variance of the naive Monte Carlo estimator may be infinity

As explained before, the Monte Carlo method cannot be directly used to compute general similarity notions. However, with a slight modification to the Monte Carlo method, we can construct an unbiased estimator for any similarity notion. Unfortunately, its performance is not generally good: The variance of the estimator can be infinite. Below, we explain how we can construct an unbiased estimator and its performance limitation more in detail.

In the case of the PPR, the matrix H itself was used as a transition matrix of a random walk. For a general simliarity notion, we introduce a transition probability matrix P and generate random walks based on P, where P satisfies $\|P\|_\infty \leq 1$ and $P(u,v) > 0$ if and only if $uv \in E$ [7, 23, 29]. Using P, A random walk $W = (v_0, v_1, \ldots, v_\ell)$ starting at vertex u is generated as follows:

(1) $\ell \leftarrow 0, v_0 \leftarrow u$.
(2) Repeat the following:
   - With probability $1 - \sum_{w \in V} P(v_\ell, w)$, terminate the repetition. For every $w \in V$, with probability $P(v_\ell, w)$, $\ell \leftarrow \ell + 1$ and $v_\ell \leftarrow w$.

In general, the distribution of w_ℓ generated this way is not equal to $\sigma_{c,w}(s,v)$. To address this issue, we define *correction weight* $\gamma(W)$ for each walk $W = (v_0, v_1, \ldots, v_\ell)$ as

$$\gamma(W) = \prod_{i=1}^{\ell} \frac{w(v_{i-1}v_i)}{P(v_{i-1}, v_i)}. \tag{3}$$

Suppose that we have generated N walks $W_1, \ldots, W_N$ all starting at s. Then, the Monte Carlo estimation of $\sigma_{c,w}(s,v)$ for every $v \in V$ is given by

$$\hat{\sigma}_{c,w}(s,v) = \frac{1}{N} \sum_{i \in \{1,\ldots,N\}: W_i \text{ ends at } v} \gamma(W_i).$$

We can check that $\hat{\sigma}_{c,w}(s,v)$ is an unbiased estimator of $\hat{\sigma}_{c,w}(s,v)$ regardless of the choice of P.

To use this algorithm, we need to choose P. A naive approach will be to set $P(u,v)$ as the *row-normalized* value of $w(uv)$, that is:

$$P(u,v) = \frac{w(uv)}{c + \sum_{v' \in V, uv' \in E} w(uv')}.$$

However, the variance of the estimator by the Monte Carlo method with this P can be infinite. To see this, we consider the weighted directed graph shown in Figure 1. In Figure 1, the value near the edge from v_i to v_j corresponds to $w(v_iv_j)$. If $\alpha < 2$, the similarity $\sigma_{c,w}(v_1, v_3)$ is well-defined and $\sigma_{c,w}(v_1, v_3) = \frac{c}{2-\alpha}$. We can also see $\hat{\sigma}_{c,w}(v_1, v_3) = \frac{c}{2-\alpha}$. However, $\mathrm{E}[\sigma_{c,w}(v_1, v_3)^2]$ on $N = 1$ is $\mathrm{E}[\sigma_{c,w}(v_1, v_3)^2] = \sum_{i=0}^{\infty} \left(\frac{\alpha(1+c)(\alpha+c)}{2}\right)^i \cdot \frac{(1+c)c^2}{2}$, where i corresponds to the number of visits of a walk to v_2. If $\alpha > \sqrt{2}$, this does not converge regardless of the value of $c > 0$. This also implies that the variance of $\sigma_{c,w}(v_1, v_3)$ is infinite, and the estimation quality cannot be improved by increasing N. Thus, we cannot rely on this estimator for the Monte Carlo estimation of similarity values.

4.3 Overview of our method

Our goal in this study is to obtain efficient methods for the one-to-one similarity estimation problem. To this end, we extend BiPPR [17] to general walk-based similarity notions. As explained, BiPPR combines the Monte Carlo method and the backward push method. Although the backward push method is applicable to general walk-based similarities, the Monte Carlo method cannot be directly applied to general similarities because it relies on the fact that the weights of edges form a transition matrix of a random walk.

To address this problem, we first generalize our definition of walk-based similarities so that different vertices can have different *termination weight*. Then, we introduce a *random-walk reduction* method: From any weight function $w : E \to \mathbb{R}_+$ and scalar coefficient $c \in \mathbb{R}$, this method constructs a pair of a weight function $w' : E \to \mathbb{R}_+$ and a *termination function* $\tau' : V \to \mathbb{R}_+$. The pair (τ', w') is designed so that (i) it forms a transition matrix of a random walk, and (ii) we can easily recover the original similarity value $\sigma_{c,w}(u,v)$ from the similarity value $\sigma_{\tau',w'}(u,v)$ defined by (τ', w').

This reduction method enables us to sample a vertex v with probability proportional to $\sigma_{c,w}(s,v)$ for the source vertex $s \in V$. Thus, we can replace random walks in the Monte Carlo part of BiPPR with this sampling method. Formally, the ability of our reduction method can be stated as follows:

Theorem 4.1. *Let (c,w) be a walk-based similarity on a graph $G = (V,E)$. Then, after preprocessing in $O(m \cdot i)$ time, we can construct an oracle of $O(m)$ space with which, for any given vertex $u \in V$, we can sample a vertex $v \in V$ with probability* almost *proportional to $\sigma_{c,w}(u,v)$. Here, i is the number of iterations in power iteration. The probability with which v is sampled can be made arbitrarily close to $\frac{\sigma_{c,w}(u,v)}{\sum_{v' \in V} \sigma_{c,w}(u,v')}$ by taking a sufficiently large i.*

The idea of buliding an oracle for Monte Carlo estimation of the solution of a linear system $(I - H)\boldsymbol{x} = \boldsymbol{b}$ with $\rho(H) < 1$ but $\|H\|_\infty > 1$ resembles [29]. The algorithm in [29] maintains multiple probability distributions for random walks, while ours require just one. Also, while the algorithm in [29] assigns non-uniform correction weights (similar to (3)), ours enables us to sample walks with probability (almost) proportional to their weights. Thus we can expect that ours have a wider range of applications.

In Section 5, we discuss how to construct (τ', w') from (c,w), and in Section 6, we give a detailed explanation of our algorithm.

5 REDUCTION TO RANDOM WALK

In this section, we describe our generic method that reduces the computation of walk-based similarities to the computation of the stationary distribution of a random walk.

To this end, we slightly generalize the notion of walk-based similarity. For a termination function $\tau\colon V \to \mathbb{R}_+$ and a weight function $w\colon E \to \mathbb{R}_+$, we define the weight of a walk $W = (v_0, \dots, v_\ell)$ as

$$w_\tau(W) = \tau(v_\ell) \prod_{i=1}^{\ell} w(v_{i-1}v_i).$$

Then, we define the similarity $\sigma_{\tau,w}(s,t)$ from a vertex $s \in V$ to a vertex $t \in V$ as

$$\sigma_{\tau,w}(s,t) = \sum_{W \in \mathrm{walk}(s,t)} w_\tau(W).$$

Note that we no longer use the scalar coefficient $c \in \mathbb{R}_+$ because it can be included in τ.

Our goal is to construct other termination function $\tau'\colon V \to \mathbb{R}_+$ and weight function $w'\colon E \to \mathbb{R}_+$ such that

(i) $\sigma_{\tau',w'}(s,\cdot)$ is given by a stationary distribution of a random walk from $s \in V$.
(ii) We can efficiently compute $\sigma_{\tau,w}$ from $\sigma_{\tau',w'}$.

To satisfy (i), τ' and w' must define a transition of a random walk. We first ask for the following condition:

Definition 5.1 (Random walkability). *For functions $\tau\colon V \to \mathbb{R}_+$ and $w\colon E \to \mathbb{R}_+$, we call the pair (τ, w)* randomly walkable *if*

- $\tau(v) \in [0,1]$ *for every* $v \in V$,
- $w(uv) \in [0,1]$ *for every* $uv \in E$, *and*
- $\tau(u) + \sum_{v \in N^+(u)} w(uv) = 1$ *for every* $u \in V$.

Now we discuss (ii). Note that sometimes it is impossible to satisfy $\sigma_{\tau,w}(u,v) = \sigma_{\tau',w'}(u,v)$: If it were possible, then we have $\sum_{v\in V} \sigma_{\tau,w}(u,v) = \sum_{v\in V} \sigma_{\tau',w'}(u,v) = 1$, where the last equality holds because $\sigma_{\tau',w'}$ is given by a stationary distribution of a random walk. However, we may not have $\sum_{v\in V} \sigma_{\tau,w}(u,v) = 1$.

To address the issue above, we consider the following unary quantity

$$c_{\tau,w}(u) = \sum_{v \in V} \sigma_{\tau,w}(u,v), \tag{4}$$

which can be seen as the closeness centrality [5, 6] defined via $\sigma_{\tau,w}$, and we impose the following relaxed condition:

Definition 5.2 (Recoverability). *We say that a pair (τ', w')* recovers *a pair (τ, w) if*

$$\sigma_{\tau',w'}(u,v) = \frac{\sigma_{\tau,w}(u,v)}{c_{\tau,w}(u)} \tag{5}$$

holds for every $u, v \in V$.

The main theorem of this section is as follows:

Theorem 5.3. *For any pair (τ, w), there exists a random-walkable pair (τ', w') that recovers (τ, w).*

We note that, to recover $\sigma_{\tau,w}(u,v)$, we need $c_{\tau,w}(u)$ along with $\sigma_{\tau',w'}(u,v)$. However, computing (an approximation to) $c_{\tau,w}(u)$ is an easier task than directly computing $\sigma_{\tau,w}(u,v)$. We discuss this issue in further detail in Section 6.

Next, for notational simplicity, we write $\sigma(u,v)$ and $\sigma'(u,v)$ to denote $\sigma_{\tau,w}(u,v)$ and $\sigma_{\tau',w'}(u,v)$, respectively. Similarly, we write $c(u)$ and $c'(u)$ to denote $c_{\tau,w}(u)$ and $c_{\tau',w'}(u)$, respectively. The following lemma is useful to guarantee recoverability.

Lemma 5.4. *Suppose that a pair (τ', w') satisfies*

$$w'(W) = \frac{w(W)}{c(u)} \tag{6}$$

for any $u \in V$ and any walk W starting from u. Then, (τ', w') recovers (τ, w).

Proof. The claim holds because

$$\sigma'(u,v) = \sum_{W \in \mathrm{walk}(u,v)} w'(W) = \sum_{W \in \mathrm{walk}(u,v)} \frac{w(W)}{c(u)} = \frac{\sigma(u,v)}{c(u)}.$$

□

Now, we derive the exact form of τ' and w' from the recoverability condition. Considering a walk W consisting of a single vertex $u \in V$, we must have

$$\tau'(u) = \frac{w(W)}{c(u)} = \frac{\tau(u)}{c(u)} \tag{7}$$

Considering walks $W = (v_0, v_1, \dots, v_\ell)$ and $W' = (v_1, \dots, v_\ell)$, we must have

$$w'(v_0v_1) = \frac{w'(W)}{w'(W')} = \frac{w(W)}{c(v_0)} \cdot \frac{c(v_1)}{w(W')} = w(v_0v_1) \cdot \frac{c(v_1)}{c(v_0)} \tag{8}$$

We now show that the pair (τ', w') satisfies the desired conditions.

Lemma 5.5. *The pair (τ', w') satisfies random walkability.*

Proof. We have

$$\tau'(u) + \sum_{v \in N^+(u)} w'(uv) = \frac{\tau(u) + \sum_{v\in N^+(u)} w(uv)c(v)}{c(u)} = 1$$

for every $u \in V$. As $\tau'(u) \geq 0$ and $w'(uv) \geq 0$, it is clear that $\tau'(u) \in [0,1]$ and $w'(uv) \in [0,1]$ hold. □

Lemma 5.6. *The pair (τ', w') recovers (τ, w).*

Proof. By Lemma 5.4, it suffices to check the condition (6). Let $W = (v_0, \dots, v_\ell)$ be an arbitrary walk. Then, we have

$$w'(W) = \prod_{i=1}^{\ell} \left(w(v_{i-1}v_i) \cdot \frac{c(v_i)}{c(v_{i-1})} \right) \cdot \frac{\tau(v_\ell)}{c(v_\ell)} = \frac{w(W)}{c(v_0)}.$$

□

Theorem 5.3 is established by combining Lemmas 5.5 and 5.6.

6 ALGORITHMS

In Section 5, we have seen that computing walk-based similarities can be reduced to computing the stationary distribution of a random walk. To perform random walk, we need to be able to quickly sample random neighbors of a vertex in the weighted graph obtained by the reduction. In Section 6.1, we explain how to implement an oracle with which we can randomly sample neighbors of a vertex, given that we can afford to compute the exact values of $c_{\tau,w}(u)$ (Refer to (4) for the definition). In Section 6.2, we discuss how to implement the oracle when we only have approximations to $c_{\tau,w}(u)$. Finally, in Section 6.3, we describe our algorithm for the one-to-one similarity estimation problem. As in Section 5, we use symbols $\sigma(u,v)$, $\sigma'(u,v)$, $c(u)$, and $c'(u)$ for notational simplicity.

6.1 Random neighbor oracle

In this section, we present the following:

Theorem 6.1. *Let (τ', w') be the pair given in Theorem 5.3. Then, after preprocessing in $O(|V|^3 + |E|)$ time, we can provide an oracle such that, given a query vertex $u \in V$, it returns in $O(1)$ time*

- *a special symbol $\perp$ with probability $\tau'(u)$, and*
- *a vertex $v \in N^+(u)$ with probability $w'(uv)$.*

With the oracle provided in Theorem 6.1, we can perform random walk with respect to the pair (τ', w').

Proof. To obtain (τ', w'), we need to compute $c(u)$ for every $u \in V$. Because the similarity $\sigma(u, v)$ is defined as

$$\sigma(u,v) = \left\langle \boldsymbol{e}_u, \sum_{\ell=0}^{\infty} H^\ell \tau(v) \boldsymbol{e}_v \right\rangle = \left\langle \boldsymbol{e}_u, (I-H)^{-1}\tau(v)\boldsymbol{e}_v \right\rangle,$$

where H is the transition weight matrix defined in Section 3.1. (note that $\sum_{\ell=0}^{\infty} H^\ell \tau(v)\boldsymbol{e}_v$ converges if $\sigma_{\tau,w}(u,v)$ is well defined for every $(u,v) \in V^2$), $c(u)$ can be rephrased as

$$\begin{aligned} c(u) &= \sum_{v \in V} \left\langle \boldsymbol{e}_u, (I-H)^{-1}\tau(v)\boldsymbol{e}_v \right\rangle \\ &= \left\langle \boldsymbol{e}_u, (I-H)^{-1} \sum_{v \in V} \tau(v)\boldsymbol{e}_v \right\rangle = \left\langle \boldsymbol{e}_u, (I-H)^{-1}\boldsymbol{\tau} \right\rangle, \end{aligned}$$

where $\boldsymbol{\tau} \in \mathbb{R}^V$ is a vector with the v-th element being $\tau(v)$. Hence, we can compute $c(u)$ for every $u \in V$ in $O(|V|^3)$ time. Then, we can compute τ' and w' in $O(|V| + |E|)$ time.

Now, we can use Walker's alias method [26] to provide the desired oracle. We need $O(d^+(u))$ time to preprocess each vertex $u \in V$. Hence, the total preprocessing time is $O(|V|^3 + |E|)$. □

6.2 Random neighbor oracle with inexact centrality values

In Section 6.1, we have seen that we can implement a random neighbor oracle by computing $c(u)$. However, this requires $O(|V|^3)$ preprocessing time, which is impractical. To reduce the preprocessing time, in this section, we consider how to implement the random neighbor oracle using approximations $\hat{c}(u)$ to $c(u)$, computed by, for example, the power iteration method.

Considering the proof of Lemma 5.5, the following property was crucial to guarantee for (τ', w') satisfying random walkability:

$$c(u) = \tau(u) + \sum_{v \in N^+(u)} w(uv)c(v) \quad (u \in V). \tag{9}$$

This indicates that we cannot guarantee random walkability if we use approximations $\hat{c}$, instead of c, to define the pair (τ', w').

Therefore, we define another random-walkable pair $(\hat{\tau}', \hat{w}')$ using $\hat{c}$ by slightly changing the recovery condition. First, we define $\hat{c}_R(u)$ by

$$\hat{c}_R(u) = \tau(u) + \sum_{v \in N^+(u)} w(uv)\hat{c}(v) \quad (u \in V).$$

Using this quantity, we define a pair $(\hat{\tau}', \hat{w}')$ as

$$\hat{\tau}'(u) = \frac{\tau(u)}{\hat{c}_R(u)} \quad \text{and} \quad \hat{w}'(uv) = w(uv) \cdot \frac{\hat{c}(v)}{\hat{c}_R(u)}. \tag{10}$$

We can easily confirm the following:

Algorithm 3 Oracle construction

Input: weight function w, termination function τ

1: Compute $\hat{c}$, an approximation of $(I-H)^{-1}\boldsymbol{\tau}$
2: **for** $u \in V$ **do**
3: $\quad \hat{c}_R(u) \leftarrow \tau(u) + \sum_{v \in N^+(u)} w(uv)\hat{c}(u)$
4: $\quad f_u \leftarrow \left\{ \left(v, \frac{w(uv)\hat{c}(v)}{\hat{c}_R(v)} \right) \mid v \in N(u) \right\} \cup \left\{ \left(\perp, \frac{\tau(u)}{\hat{c}_R(v)} \right) \right\}$
5: $\quad \Omega_u \leftarrow$ random sampler that returns v with probability p for every $(v,p) \in f_u$
6: **end for**
7: Return $(\hat{c}, \{\Omega_u\}_{u \in V})$

Algorithm 4 Sampling using the oracle by Algorithm 3

Input: source vertex u, $(\hat{c}, \{\Omega_u\}_{u \in V})$ given by Algorithm 3

1: **loop**
2: $\quad v \leftarrow$ return value of an oracle call to Ω_u
3: $\quad$ Return u if $v = \perp$. Otherwise, $u \leftarrow v$.
4: **end loop**

Proposition 6.2. *The pair $(\hat{\tau}', \hat{w}')$ satisfies random walkability.*

Following the proof of Theorem 6.1, we obtain the following:

Theorem 6.3. *Suppose that we are given a vector $\hat{\boldsymbol{c}} \in \mathbb{R}^V$. Let $(\hat{\tau}', \hat{w}')$ be the pair given by (10). Then, after preprocessing in $O(|V| + |E|)$ time, we can provide an oracle such that, given a query vertex $u \in V$, it returns in $O(1)$ time*

- *a special symbol $\perp$ with probability $\hat{\tau}'(u)$, and*
- *a vertex $v \in N^+(u)$ with probability $\hat{w}'(uv)$.*

The pseudocode of the modified oracle is given in Algorithm 3. The procedure for sampling vertices using the random neighbor oracle is shown in Algorithm 4. It is guaranteed that Algorithm 4 returns a vertex $v \in V$ with probability $\hat{\sigma}'(u,v)$, where $\hat{\sigma}'(u,v) = \sigma_{\hat{\tau}', \hat{w}'}(u,v)$. In Section 7, we discuss the error in using $\hat{\sigma}'(u,v)$ to approximate $\sigma(u,v)$.

6.3 Similarity estimation

We can estimate walk-based similarities by simulating the Monte Carlo part of BiPPR [17] using the random neighbor oracle described in Sections 6.1 and 6.2. However, the transition weights produced by our reduction have different properties from that of PPR:

- Monte Carlo itself only estimates $\hat{\sigma}'(u,v)$. We need to multiply this value by $\hat{c}(u)$ in order to get an estimate of $\sigma(u,v)$, but this may affect the accuracy of the estimation.
- Termination probabilities may be different among vertices. Therefore, the efficiency of push algorithms largely depends on the source vertex.

Hence, we modify the original BiPPR as follows:

Threshold depending on $\hat{c}(u)$. As we see later in Theorem 7.1, $\hat{\sigma}'(u,v)\hat{c}(u)$ is a good approximation to $\sigma(u,v)$. Assume that the difference between $\hat{\sigma}'(u,v)\hat{c}(u)$ and $\sigma(u,v)$ is small enough to be ignored. Then, if $\hat{\sigma}'(u,v)$ is an (ϵ, δ', p)-estimation of $\sigma'(u,v)$, then $\hat{\sigma}'(u,v)\hat{c}(u)$ will be an $(\epsilon, \delta'\hat{c}(u), p)$-estimation of $\sigma(u,v)$. Therefore, if we want to have an (ϵ, δ, p)-estimation of $\sigma_{\tau,w}(u,v)$, we

should set $\delta' = \frac{\delta}{\hat{c}(u)}$. We will use $\frac{\delta}{\hat{c}(u)}$ as the threshold for estimation of $\hat{\sigma}'(u, v)$.

Adaptive thresholding. As indicated in [17, 18], we can dynamically change the threshold for terminating backward pushes. We take a balance between the running time of the backward push part and that of the Monte Carlo part. This technique is especially important for the walk-based similarity estimation, because the cost of backward pushes is difficult to predict and may largely depend on the target vertex. We can estimate the (average) running time of the Monte Carlo part as the product of the average walk time and the number of required walks.

We note that the average walk length may vary depending on the starting vertex. Therefore, we computed the average walk time (using Monte Carlo sampling) from the source vertex at the beginning of each query computation. We also note that the walks obtained in this step can be reused in later steps.

Integrating forward push into Monte Carlo. Instead of generating walks from the source vertex, we can perform forward pushes and then generate walks from each vertex with positive residuals [28].

Suppose we want to generate N walks in the Monte Carlo part for estimation of $\hat{\sigma}'$. Let $\boldsymbol{p}_s$ and $\boldsymbol{r}_s$ be the reserve and residue vectors after running forward push algorithm, respectively. From the invariant of forward push (1), if we have unbiased estimations of $\hat{\sigma}'(u, v)$ for every $u \in V$, then $\hat{\sigma}(s, v)$ defined by the following formula is also an unbiased estimation of $\hat{\sigma}'(s, v)$:

$$\hat{\sigma}(s, v) = p_s(v) + \sum_{u \in V} r_s(u)\hat{\sigma}'(u, v).$$

Here, $\hat{\sigma}'(u, v)$ can be obtained by Monte Carlo estimation from vertex u. If we use at least $\lceil r_s(u)N \rceil$ walks for this estimation for every $u \in V$, we can show that the variance of $\hat{\sigma}(s, v)$ defined above is at most that of the estimator by naive Monte Carlo with N walks. With this technique, we can reduce the cost of tracking many identical walks in the Monte Carlo part.

Final algorithm. Combining the techniques discussed above, we obtain the final algorithm for similarity estimation. This algorithm is shown in Algorithm 5. Here γ is a parameter for controlling accuracy and ι is the number of trials of generating walks for estimating the walk time. Note that this requires the random neighbor oracle generated by Algorithm 3. We can precompute this oracle and use it for answering each query to reduce the computation cost.

In Algorithm 5, we used the terminate condition $N_0 \max_u r_s(u) < 1$. This means that we terminate when the number of walks to be generated from every vertex is less than 1. As this condition may cause too many forward pushes, in Section 8, we also consider a heuristic that uses a terminate condition depending on $\hat{c}(s)$.

As with the original BiPPR [17], we can expect that Algorithm 5 significantly improves the efficiency of similarity estimation. However, as we are considering general walk-based similarity, it is difficult to give upper bounds for running time of this algorithm. Analyzing the time complexity will be a future work.

Algorithm 5 Similarity estimation

Input: source vertex s, target vertex t, threshold δ, parameter γ and ι, $(\hat{c}, \{\Omega_u\}_{u \in V})$ given by Algorithm 3

$\delta' \leftarrow \frac{\delta}{\hat{c}(s)}$
$\tau_{\mathrm{walk}} \leftarrow$ (Time to generate ι walks from s)$/\iota$
Perform Algorithm 2 with the following terminate condition:
  Let τ_{push} be the time required for backward push so far. Terminate if $\frac{\gamma \max_v r_t(v)}{\delta'} \cdot \tau_{\mathrm{walk}} < \tau_{\mathrm{push}}$
$N_0 \leftarrow \lceil \frac{\gamma \max_v r_t(v)}{\delta'} \rceil$
$\hat{\sigma} \leftarrow q_t(s)$
Perform Algorithm 1 using r'_s instead of r_s with the terminate condition of $N_0 \max_u r'_s(u) < 1$
for $u \in V, p_s(u) > 0$ **do**
  $\hat{\sigma} \leftarrow \hat{\sigma} + p_s(u) r_t(u)$
end for
for $u \in V, r'_s(u) > 0$ **do**
  $\omega \leftarrow \frac{\hat{c}(u)}{\hat{c}(s)} N_0 r'_s(u),\ N \leftarrow \lceil \omega \rceil$
  for $i = 1, 2, \ldots, N$ **do**
    $v \leftarrow$ vertex returned by a call to Algorithm 4 with source s and oracle $(\hat{c}, \{\Omega_u\}_{u \in V})$
    $\hat{\sigma} \leftarrow \hat{\sigma} + \frac{\omega}{N} \cdot \frac{1}{N_0} \hat{c}(s) r_t(v)$
  end for
end for
Return $\hat{\sigma}$ as an estimation of $\sigma_{\tau, w}(s, t)$

7 ERROR ANALYSIS

In this section, we provide theoretical guarantees of our algorithm.

First, we analyze the approximation error caused by using the inexact random neighbor oracle given in Section 6.2. We borrow notations from Section 6. Then, we show that $\hat{\sigma}'(u, v)$ and $\sigma(u, v)$ are close:

Theorem 7.1. *Suppose that*

$$\frac{1}{1+\kappa} \hat{c}(u) \le \hat{c}_R(u) \le (1+\kappa)\hat{c}(u) \quad (u \in V) \tag{11}$$

holds for some $\kappa \in (0, 1)$ *and that* $\lambda := \min_{u \in V}(1 - \hat{\tau}'(u)) < \frac{1}{1+\kappa}$ *holds. Then, we have*

$$\underline{\alpha}(\sigma(u, v))^{1+\beta} \le \hat{\sigma}'(u, v)\hat{c}(u) \le \overline{\alpha}(\sigma(u, v))^{1-\beta}$$

where
