$$\underline{\alpha} = \frac{(1-\lambda)^{1+\beta}}{(1+\kappa) - \lambda},\ \overline{\alpha} = \frac{(1-\lambda)^{1-\beta}}{(1+\kappa)^{-1} - \lambda},\ \textit{and } \beta = \log_{\frac{1}{\lambda}}(1+\kappa).$$

Before proving Theorem 7.1, we discuss its implication. Theorem 7.1 claims that the relative error of $s_{\hat{\tau}', \hat{w}'}(u, v)\hat{c}_R(u)$ is controlled by κ. The following proposition states that we can make κ arbitrarily small if we use the power iteration method to compute $\hat{c}_R(u)$.

Proposition 7.2. *Let* $\boldsymbol{x}_0, \boldsymbol{x}_1, \ldots$ *be a sequence that converges to* $\boldsymbol{x} = (I - H)^{-1}\boldsymbol{\tau}$, *where* $H \in \mathbb{R}^{V \times V}$ *is a transition weight matrix with* $\rho(H) < 1$. *Then, for any* $\kappa > 0$, *there exists* i *such that*

$$\frac{1}{1+\kappa} x_i(u) \le \tau(u) + \sum_v H(u, v) x_i(v) \le (1+\kappa) x_i(u) \tag{12}$$

holds for every $u \in V$ *with* $x(u) > 0$.

Proof. Let $\mu = \min\{x(u) \mid u \in V,\ x(u) \neq 0\}$. From the convergence of $\boldsymbol{x}_0, \boldsymbol{x}_1, \ldots$, there exists i such that $\|\boldsymbol{x}_i - \boldsymbol{x}\|_\infty < \delta'$ where $\delta' = \frac{\delta\mu}{2(1+\|H\|_\infty)}$. Then, for $u \in V$ with $x(u) > 0$, we have

$$\begin{aligned}
&\tau(u) + \sum_v H(u,v)x_i(v) \\
&= \tau(u) + \sum_v H(u,v)x(v) + \sum_v H(u,v)(x_i(v) - x(v)) \\
&\geq x(u) - \|H\|_\infty\delta' \geq x_i(u) - (1 + \|H\|_\infty)\delta' \\
&\geq \frac{1}{1+\delta}x_i(u)
\end{aligned}$$

as desired. The second inequality of (12) follows analogously. □

If $\boldsymbol{x}_i$ satisfies (12) and we choose $\hat{\boldsymbol{c}} = \boldsymbol{x}_i$, then (11) is satisfied and the approximation guarantee given in Theorem 7.1 follows. Hence, we can use (12) as a terminate condition in the power iteration.

To prove Theorem 7.1, we need the following technical lemma, whose proof is deferred to the full version:

Lemma 7.3. *Let $\lambda, \kappa \in (0,1)$ be such that $\lambda(1+\kappa) < 1$. Consider two sequences $\{a_i\}_{i\geq 0}, \{b_i\}_{i\geq 0}$ such that $a_i \in [0, \lambda^i]$ and $b_i \in [a_i(1+\kappa)^{-i}, a_i(1+\kappa)^i]$ for every $i \geq 0$. Let $s = \sum_{i=0}^\infty a_i < \infty$. Then, we have*

$$\frac{(1-\lambda)^{1-\eta}}{1-\lambda(1+\kappa)^{-1}}s^{1-\eta} \leq \sum_{i=0}^\infty b_i \leq \frac{(1-\lambda)^{1+\eta}}{1-\lambda(1+\kappa)}s^{1+\eta}. \tag{13}$$

for $\eta = \log_\lambda(1+\kappa)$.

Proof of Theorem 7.1. Let $\sigma_\ell(u,v)$ denote the sum of weights of walks from u to v of length ℓ, that is,

$$\sigma_\ell(u,v) = \sum_{W \in \mathrm{walk}_\ell(u,v)} w_\tau(W).$$

Then, clearly $\sigma(u,v) = \sum_{\ell=0}^\infty \sigma_\ell(u,v)$ holds. Similarly, we define $\sigma_\ell(u) = \sum_{v\in V}\sigma_\ell(u,v)$.

First, we analyze the relation between $w'(W) := w_{\tau'}(W)$ (which is obtained using $\boldsymbol{s}$) and $\hat{w}'(W) := w_{\hat{\tau}'}(W)$ for a walk $W = (v_0, v_1, \ldots, v_\ell)$. By the definition of $\hat{w}'(u,v)$ and $(\hat{\tau}', \hat{w}')$, we have

$$\begin{aligned}
\hat{w}'(W) &= \hat{\tau}'(v_\ell)\prod_{i=1}^\ell \hat{w}'(v_{i-1}v_i) = \frac{\tau(v_\ell)}{\hat{c}_R(v_\ell)}\prod_{i=1}^\ell\left(w(v_{i-1}v_i)\cdot\frac{\hat{c}(v_i)}{\hat{c}_R(v_{i-1})}\right) \\
&= \left(\frac{\tau(v_\ell)}{\hat{c}_R(v_0)}\prod_{i=1}^\ell w(v_{i-1}v_i)\right)\cdot\prod_{i=1}^\ell\frac{\hat{c}(v_i)}{\hat{c}_R(v_i)} = \frac{w_\tau(W)}{\hat{c}_R(v_0)}\cdot\prod_{i=1}^\ell\frac{\hat{c}(v_i)}{\hat{c}_R(v_i)}.
\end{aligned}$$

Taking the sum of $\hat{w}'(W)$ over all walks W from u to v of length ℓ, from the assumption on $\hat{c}_R(u)$, we have

$$\sigma_\ell(u,v)(1+\kappa)^{-\ell} \leq \hat{\sigma}'_\ell(u,v)\hat{c}_R(u) \leq \sigma_\ell(u,v)(1+\kappa)^\ell.$$

From random walkability, we have

$$0 \leq \hat{\sigma}'_\ell(u,v) \leq \hat{c}'_\ell(u) \leq \lambda^\ell \text{ and } \sum_{\ell=0}^\infty \hat{c}'_\ell(u) = \hat{c}'(u) = 1.$$

Therefore, using Lemma 7.3 and (11), we obtain

$$\underline{\alpha}\cdot\sigma(u,v)^{1+\beta} \leq \hat{\sigma}'(u,v)\hat{c}(u) \leq \overline{\alpha}\cdot\sigma(u,v)^{1-\beta}.$$ □

Next, we give a guarantee on the estimation quality of Algorithm 5.

Theorem 7.4. *Suppose that (11) holds for a sufficiently small κ. Then, Algorithm 5 returns an (ϵ,δ,p)-estimation of $\sigma(s,t)$ if we set $\gamma = \Omega(\epsilon^{-2}\log(1/p))$.*

We show this theorem using the following lemma:

Lemma 7.5. *Suppose that $\hat{c} = c$ holds. Then, Algorithm 5 returns an (ϵ,δ,p)-estimation of $\sigma(s,t)$ if we set $\gamma = \Omega(\epsilon^{-2}\log(1/p))$*

Proof. First, we show the claim holds if we modify Algorithm 5 so that we do not perform forward pushes, and instead we use $p_s(u) = 0$ $(u \in V)$ and $r_s(u) = \begin{cases} 1 & u = s \\ 0 & u \neq s \end{cases}$. In this case, the proof is almost identical to that of the original BiPPR given in [17]. Let $r_{\max} = \max_v r_t(v)$, v_i be the vertex chosen in the i-th iteration and $X_i = \frac{r_t(v_i)}{r_{\max}}$. Then,

$$\hat{\sigma} = q_t(s) + \frac{c(s)}{N_0}\sum_{i=1}^{N_0} r_t(v_i) = q_t(s) + \frac{c(s)r_{\max}}{N_0}\sum_{i=1}^{N_0} X_i.$$

We can analyze the concentration of $\frac{1}{N_0}\sum_{i=1}^{N_0} X_i$ using the Chernoff bound and thus obtain the desired statement.

For the complete proof for Algorithm 5, we return to the proof of the Chernoff bound (see, e.g., [11]). The Chernoff bound can be proven by bounding $\Pr[e^{\lambda X} > e^{\lambda a}]$ $(\lambda > 0)$ using Markov inequality

$$\Pr[e^{\lambda X} > e^{\lambda a}] < \frac{\mathrm{E}[e^{\lambda X}]}{e^{\lambda a}}$$

and optimizing λ. Therefore, if two random variables X, Y satisfy $\mathrm{E}[e^{\lambda X}] \leq \mathrm{E}[e^{\lambda Y}]$ for any $\lambda > 0$, Chernoff bounds satisfied by Y are all satisfied by X.

Let $v(s)$ be a random vertex that is chosen with probability equal to the similarity from s and

$$\Phi = \prod_{u\in V} e^{\lambda p_s(u)\frac{c(u)}{c(s)}\frac{r_t(u)}{r_{\max}}}\cdot\mathrm{E}\left[e^{\lambda\frac{c(u)}{c(s)}\frac{r_t(v(u))}{r_{\max}}}\right]^{N_0 r'_s(u)}$$

$$\Phi' = \prod_{u\in V} e^{\lambda p_s(u)\frac{c(u)}{c(s)}\frac{r_t(u)}{r_{\max}}}\cdot\mathrm{E}\left[e^{\lambda\frac{c(u)}{c(s)}\frac{r_t(v(u))}{r_{\max}}\frac{N_0 r'_s(u)}{\lceil N_0 r'_s(u)\rceil}}\right]^{\lceil N_0 r'_s(u)\rceil}.$$

It can be verified that $\Phi' = \mathrm{E}[e^{\lambda(\hat{\sigma}-q_t(s))}]$. Before performing forward pushes, $\Phi = \Phi_0 = \mathrm{E}\left[e^{\lambda\sum_{i=1}^{N_0}X_i}\right]$. From the independence of $X_1, X_2, \ldots$, we have $\Phi_0 = \left(\mathrm{E}\left[e^{\lambda X}\right]\right)^{N_0}$, where $X = \frac{r_t(v(s))}{r_{\max}}$. We can show that Φ is non-increasing in a forward push operation by the convexity of e^x. Furthermore, $\Phi' \leq \Phi$ can be proven using Hölder's inequality. Finally, we have $\Phi' \leq \Phi_0$ and thus we obtain the desired statement for Algorithm 5 with forward push when $\hat{c} = c$. □

Proof of Theorem 7.4. For simplicity, we modify the line 5 of Algorithm 5 to $N_0 \leftarrow \frac{\gamma\max_v r_t(v)}{\delta'}$ in the analysis.

Suppose the vertices pushed in the execution of forward push in Algorithm 5 are $s = u_1, u_2, \ldots, u_k$ in this order. Then, we construct a graph $G' = (V', E')$ from $G = (V, E)$ in the following way:

(1) We let $V' \leftarrow V, E' \leftarrow E$ and define a mapping $f : V \to V'$ by $f(u) = u$.

Table 1: Tested networks and precomputation time

Name	Type	n	m	precomputation time (s)
com-dblp	Undirected	317K	2.10M	1.289
web-Stanford	Directed	282K	2.31M	1.060
com-youtube	Undirected	1.13M	5.98M	4.193
soc-pokec	Directed	1.63M	30.6M	16.517
soc-LiveJournal	Directed	4.85M	69.0M	40.555
com-orkut	Undirected	3.07M	234M	107.122

(2) For each $i = k, k-1, \ldots, 1$, we create a fresh vertex x_i. Then, we let $V' \leftarrow V' \cup \{x_i\}$, $E' \leftarrow E' \cup \{(x_i, f(v)) \mid v \in N^+(u_i)\}$, $\hat{c}(x_i) \leftarrow \tau(u_i) + \sum_{v \in N^+(u)} w(u_i v)\hat{c}(f(v))$, $\hat{\tau}'(x_i) = \frac{\tau(u_i)}{\hat{c}(x_i)}$, $w(x_i v) = \hat{w}'(x_i v) = w(u_i v) \cdot \frac{\hat{c}(v)}{\hat{c}(x_i)}$ and finally, $f(u_i) \leftarrow x_i$.

Note that this construction of $\hat{c}, \hat{\tau}'$ and $\hat{w}'$ is well-defined since $\hat{c}(x_i)$ depends only on $x_{i+1}, \ldots, x_k$ and $u \in V$.

Suppose we run Algorithm 5 on G' instead of G, with the sequences of pushed vertices as follows:

- Suppose pushed vertices in the forward push of the run for G are $v_1, \ldots, v_l$ and let $f(v) = \{v\} \cap \{x_i \mid u_i = v\}$. Then, those for G' are $f(v_1), \ldots, f(v_l)$. Here, vertices in $f(v_i)$ for one i are pushed *at the same time.*
- Pushed vertices in the backward push are $x_1, \ldots, x_k$ in this order.

Then, the distribution of $\hat{\sigma}$ is identical for the runs for G and G'.

We can analyze the concentration of Algorithm 5 for G' (and the sequence of pushed vertices as described above) using the same way as in the proof of Lemma 7.5, because the invariant (1) is maintained in forward pushes for this setting. Thus we can argue that, if we set $\gamma = \Omega(\epsilon^{-2} \log(1/p))$, Algorithm 5 returns an (ϵ, δ, p)-estimation of $\mathrm{E}[\hat{\sigma}]$. Therefore, it suffices to show that $\mathrm{E}[\hat{\sigma}]$ can be made arbitrarily close to $\sigma(s,t)$ by choosing sufficiently small κ. Since we can obtain the same bounds for $\mathrm{E}[\hat{\sigma}]$ as those for $\hat{c}_R(u)$ in Theorem 7.1, the claim holds. □

8 EXPERIMENTS

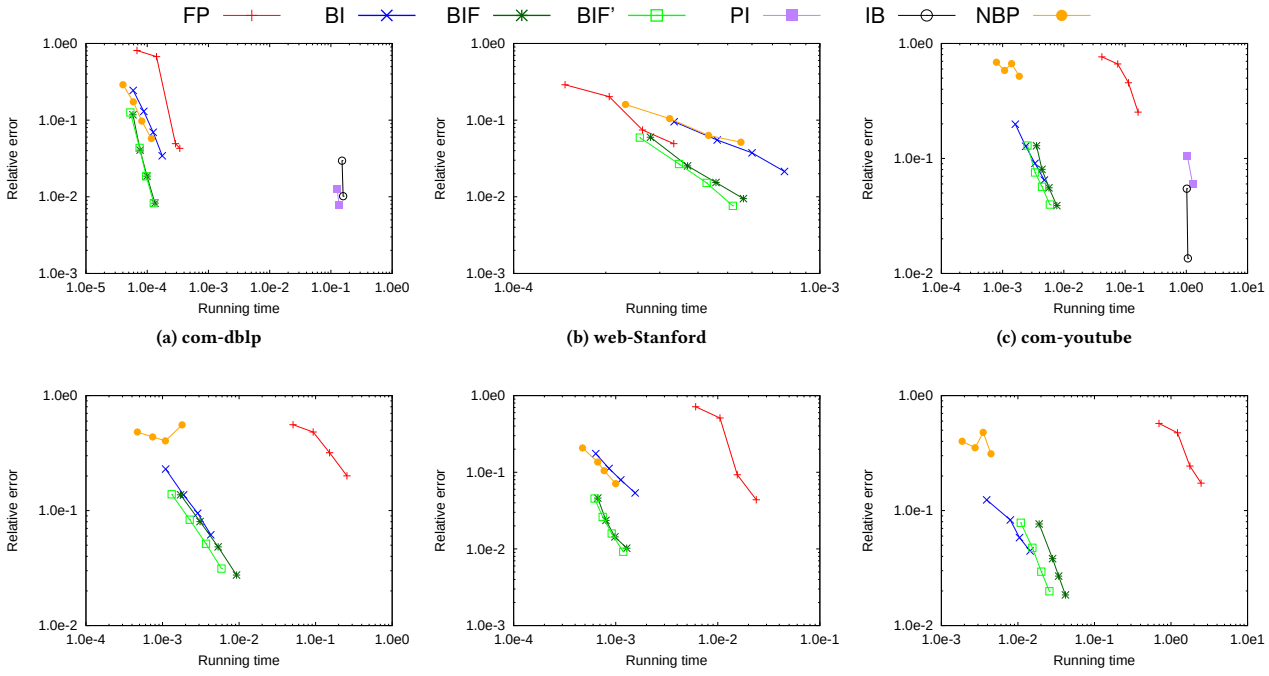
We experimentally evaluated our algorithms for one-to-one walk-based similarity estimation. The primary objective of this experiment is to show that our algorithms are efficient in the following extreme condition, which previous algorithms are difficult to handle: $\max_i \sum_j H(i,j)$ and $\max_j \sum_i H(i,j)$ are significantly larger than 1, where H is the transition weight matrix defined in Section 3.1.

Katz similarity with β close to $\frac{1}{\rho(A)}$ satisfies the above condition. Also, recall that Katz similarity can express any walk-based similarity by appropriately setting weights on edges. Hence, in this experiment, we used Katz similarity as a representative similarity notion and set $\beta = \frac{1}{1.1\rho(A)}$. Datasets used, all taken from SNAP [16], are shown in Table 1. Our codes are provided in the supplementary material.

Query generation. For each tested network, one-to-one similarity queries were generated as follows. First, we randomly chose the source vertex s uniformly or with probability proportional to Katz similarity values. Then, we computed similarity vector from s using power iteration. Finally, we chose the target vertex $t \neq s$ uniformly at random such that $\sigma_{\mathrm{Katz}}(s,t) \geq \delta_{\mathrm{index}} := \frac{1}{10n}$. If no such t was found, we returned to the first step and chose another s. We repeated these procedures until 1000 queries were obtained.

Tested algorithms. We implemented the following algorithms;

- Power iteration (PI).
- Iterative method with upper/lower bound guarantees (IB) [9].
- Forward push (FP).
- BiPPR with naive Monte Carlo for general path-based similarities (described in Section 4.2) (NBP).
- Bidirectional algorithm (BI, ours): Algorithm 5 with forward push disabled.
- BI with forward push (BIF, ours): Algorithm 5.
- BIF with a modified terminate condition (BIF', ours): Algorithm 5. We used $N_0 \max_u r_s(u) < \hat{c}(s)$ as the terminate condition in Line 7 of Algorithm 5.

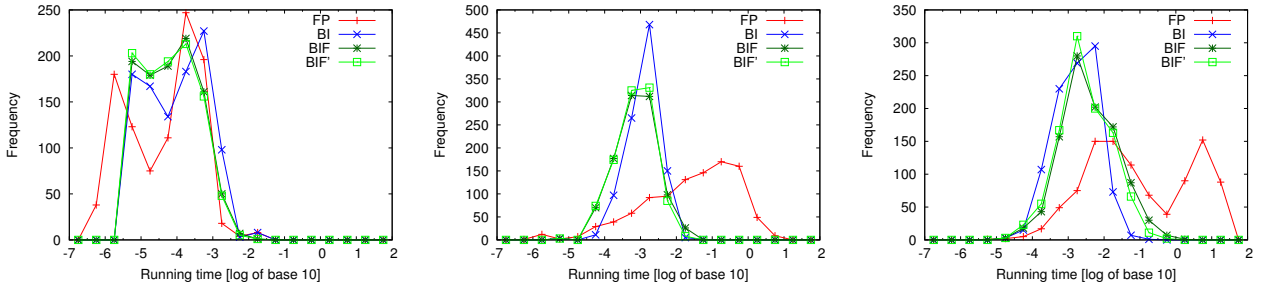


We implemented these algorithms in C++11 and ran them on a Linux (Ubuntu 16.04) desktop with Intel Core i7-6700 processor (3.4GHz) and 16 GiB of RAM.

Note that IB is applicable only to undirected networks. Furthermore, because PI and IB require iterations over all edges and thus take long execution time, we only ran them on com-dblp and com-youtube, which are relatively small.

To examine the relationships between execution time and estimation quality, we executed these algorithms with varying termination parameters δ. For BI, BIF, BIF' and NBP, we used $\gamma = 7$ as the original BiPPR [17]. Note that changing δ to $\frac{\delta}{c}$ is equivalent to changing γ to $c\gamma$. Therefore, using $\delta \neq \delta_{\mathrm{index}}$ is effectively equivalent to use $\delta = \delta_{\mathrm{index}}$ with different values of ϵ and p from the specified ones. For PI, the termination condition was set to $\|\boldsymbol{x}_i - \boldsymbol{x}_{i-1}\|_\infty < \delta$. For IB, we terminated iterations once the difference between upper and lower bounds on the similarity value became less than δ. For BI and BIF, we precomputed to provide the random neighbor oracle and used it in the query time.

Results. First, we report the precomputation time for generating the random neighbor oracle required for BI and BIF (see Table 1). The precomputation time is less than 2 min even for a graph with more than 200M edges (com-orkut), which is small, given that precomputation is required only once for each graph. Note that existing methods for similarity estimation such as BiPPR [17] and HubPPR [27] also use precomputation. In particular, it is reported that the latter method required more than 6,000 seconds for preprocessing com-orkut [27].



In Figure 2, we report the trade-off between the average relative error and the average running time for each instance. Except for web-Stanford, our proposed algorithms (BI, BIF, and BIF') outperform other baseline methods. The improvement is prominent in larger networks such as soc-pokec and com-orkut. In particular, for com-orkut, our algorithms achieved approximately 100 times faster running time and better relative errors than FP. BIF and BIF' also showed better error-time trade-offs than FP for web-Stanford. Additionally, BIF' consistently shows better performance than BIF. This suggests that controlling the amount of forward pushes is effective to improve performance. Finally, the performance of NBP significantly varies on different networks. Specifically, in com-youtube,

(a) com-dblp (b) web-Stanford (c) com-youtube

(d) soc-pokec (e) soc-LiveJournal (f) com-orkut

Figure 2: Average relative error vs. Average running time

(a) web-Stanford (b) soc-pokec (c) com-orkut

Figure 3: Distribution of running time

soc-pokec and com-orkut, increased running time (corresponding to smaller γ) does not necessarily improve the relative error. This implies that the performance of NBP can be unstable.

Figure 3 shows the distribution of query processing times. Parameters may be different among algorithms to equalize the relative error as much as possible. In this figure, a query with processing time t (in seconds) is assigned to the bin of width 0.5 containing the index $\log_{10} t$. We can observe that the processing time largely varies depending on the queries. As we have discussed before, vertices with larger centrality values tend to require more iterations. The query processing times of BI, BIF, and BIF' are more concentrated than that of FP except for BI in Figure 3a. This means that our algorithms are significantly faster than FP for difficult queries.

9 CONCLUSION

We proposed a *random-walk reduction* method that reduces the computation of any walk-based similarity to the computation of a stationary distribution of a random walk. With this reduction, we can exploit techniques for PPR to compute other walk-based similarities. As a concrete application, we designed an indexing method for walk-based similarities with which we can quickly estimate the similarity value of queried pairs of vertices, and theoretically analyze its approximation error. Our experimental results demonstrate that the instantiation of our method for Katz similarity is two orders of magnitude faster than existing methods on large real networks, without any deterioration in solution quality.

ABSTRACT

Revealing important vertices is a fundamental task in network analysis. As such, many indicators have been proposed for doing so, which are collectively called centralities. However, the abundance of studies on centralities blurs their differences.

In this work, we compare centralities based on their sensivitity to modifications in the graph. Specifically, we introduce a quantitative measure called (average-case) edge sensitivity, which measures how much the centrality value of a uniformly chosen vertex (or an edge) changes when we remove a uniformly chosen edge. Edge sensitivity is applicable to unweighted graphs, regarding which, to our knowledge, there has been no theoretical analysis of the centralities. We conducted a theoretical analysis of the edge sensitivities of six major centralities: the closeness centrality, harmonic centrality, betweenness centrality, endpoint betweenness centrality, PageRank, and spanning tree centrality. Our experimental results on synthetic and real graphs confirm the tendency predicted by the theoretical analysis. We also discuss an extension of edge sensitivity to the setting that we remove a uniformly chosen set of edges of size k for an integer $k \geq 1$.

1 INTRODUCTION

One of the most important problems in network analysis is revealing important vertices in a given network. To solve this problem, several measures of the importance of a vertex have been proposed, and these are collectively called *(network) centralities*. For example, the closeness centrality [4, 5, 27] and harmonic centrality [21] measure the importance of a vertex based on its distance to other vertices. The betweenness centrality [14] considers the number of shortest paths that pass through the vertex. PageRank [25] regards a vertex as important if a random walk on the network has a high staying probability at the vertex.

Table 1: Average-case edge (k-)sensitivity of centralities. Here, n is the number of vertices, m is the number of edges, D is the diameter of the graph, α is the decaying factor for PageRank, b is the number of bridges, and χ_k is the probability that the graph becomes disconnected by removing a uniformly chosen set of k edges.

Centrality	Upper bound ($k = 1$)	Lower bound ($k = 1$)	Upper Bound (general)
Closeness	$O\left(\frac{b+D}{m}\right)$	$\Omega\left(\frac{b+D}{m}\right)$	$O\left(\frac{k^2D}{m} + \chi_k\right)$

Spanning tree	$O\left(\frac{\sqrt{n}}{m}\right)$	$\Omega\left(\frac{1}{m}\right)$	$O\left(k\sqrt{\frac{kn}{m(m-k)}}\right)$

However, the abundance of studies on centralities raises another question: *Which centrality should we use?* One consideration in response to this question is that centralities have been used to analyze real-world networks and we may miss some edges when constructing network datasets. This motivates us to compare centralities based on their sensitivity to changes in the network.

Although some previous works have analyzed the sensitivity of centralities, it remains difficult to distinguish between centralities because only empirical results have been presented with respect to particular networks [7, 10, 13, 24, 34]. There are only a few theoretical works on the sensitivity of centralities, and most of them considered the sensitivity of a specific centrality and do not compare different centralities in terms of sensitivity [15, 26, 31]. To the best of our knowledge, the only theoretical work comparing the sensitivity of several centralities is by Segarra and Ribeiro [29], who analyzed the sensitivity of centralities to small changes in the weight of edges. However, many real-world networks are essentially unweighted. For such networks, their measure may not characterize the sensitivity well, because theirs necessarily considers *continuous* changes of the edge weights, which are not apparent for such networks.

Our contributions. In this work, we propose a novel quantitative measure for the sensitivity of centralities to edge removals, called

(average-case) edge sensitivity. Intuitively speaking, it measures how the centrality of a uniformly chosen vertex changes by removing a uniformly chosen edge. Not only is the proposed measure intuitive, as we will see soon, it also provides for a finer comparison of centralities than the sensitivity measure studied in [29].

We conducted a theoretical analysis of the edge sensitivities of six major centralities: the closeness centrality [4, 5, 27], harmonic centrality [21], betweenness centrality [14], endpoint betweenness centrality [9], PageRank [25], and spanning tree centrality [30]. An overview of our results is shown in Table 1, where the lower bounds indicate sensitivities of worst-case graphs. Our upper bounds show that, for a typical case of $D \approx 1/(1-\alpha) \ll b \approx n$, the harmonic centrality is the most stable (i.e., the least sensitive). Although the closeness centrality is very sensitive, it can be as stable as the harmonic centrality when the graph has only a small number of bridges. Our lower bounds show that our upper bounds are almost tight except for spanning tree centrality.

In practice, it is likely that we miss more than one edge when constructing network datasets and the edge sensitivity introduced above may not appropriately reflect such situations. To address this issue, for an integer $k \geq 1$, we introduce *(average-case) k-edge sensitivity*, which matches the previous edge sensitivity when $k = 1$. Intuitively speaking, it measures how the centrality of a uniformly chosen vertex changes by removing a uniformly chosen set of edges of size k. An overview of our results is shown in the last column of Table 1, which shows a similar tendency to the case of edge sensitivity. Note that $\chi_1 = b/m$. While Table 1 contains the lower bounds for sensitivity (in the worst case graph), we omitted the proof of these bounds from this paper due to the limitation of space.

Finally, we computed the (k-)edge sensitivities of synthetic and real-world graphs and obtained experimental results that confirm our theoretical bounds—expect for the spanning tree centrality, which was significantly less sensitive than predicted by our theoretical upper bound. Also, our experimental results suggest that edge sensitivity can be used as a good proxy for k-edge sensitivity when comparing centralities in terms of sensitivity against removals of multiple edges, which is desirable because computing the former is computationally less expensive than computing the latter.

Organization. The rest of this paper is organized as follows. In Section 2, we review previous works on the sensitivity of centralities. In Section 3, we introduce the notations used throughout this paper and definitions for the centralities we analyze. We define edge sensitivity in Section 4 and theoretically bound the edge sensitivities of those centralities in Section 5. In Section 6, we introduce and study k-edge sensitivity. Finally, Section 7 shows our experimental results, which confirm our theoretical analysis.

2 RELATED WORK

In this section, we review previous works pertaining to the sensitivity of centralities.

Most of the following works are empirical, however. In [7], the sensitivity of various centralities was experimentally analyzed using synthetic graphs, several robustness measures (such as the recall of vertices with the highest centralities), and several types of modifications to the graph (such as edge removal). Costenbader and Valente [10] studied the sensitivity of various centralities on graphs constructed from a larger graph by sampling vertices. Frantz *et al.* [13] conducted an empirical investigation of the relationship between the network topology and the sensitivity of centralities.

Sensitivity has been also studied from theoretical aspects. Ghosal and Ghosal and Barabási [15] theoretically analyzed the sensitivity of the ranking by PageRank on networks of several models. Platig et al. [26] and Tsugawa and Ohsaki [31] evaluated the sensitivity of the degree centrality. However, there are only a few theoretical works that compare sensitivities of centralities. Ng et al. [23] compares sensitivity of two eigenvector-based centralities (HITS [18] and PageRank [25]). Ufimtsev et al. [32] qualitatively disucussed how the centrality ranking is affected by the graph structure. Recently, Segarra and Ribeiro [29] introduced a sensitivity measure of a centrality for weighted networks. Their measure classifies centralities into three categories: *stable*, *continuous*, and *non-continuous*. As such, their measure is not useful for comparing centralities quantitatively.

3 PRELIMINARIES

In what follows, n and m denote the number of vertices and edges, respectively, of the graph we are concerned with.

Let $G = (V, E)$ be an undirected or directed graph. For an edge $e \in E$, we denote by $G \setminus e$ the subgraph $(V, E \setminus \{e\})$. Similarly, for a subset of edges $F \subseteq F$, $G \setminus F$ denotes the subgraph $(V, E \setminus F)$. For vertices $u, v \in V$, let $d_G(u, v)$ be the (geodesic) distance from u to v, that is, the length of a shortest path from u to v. If v is unreachable from u, we define $d_G(u, v) = \infty$. The diameter of G, denoted by D_G, is defined as $\max_{u,v \in V} d_G(u, v)$. Let $A_G \in \{0, 1\}^{n \times n}$ be the adjacency matrix of G. That is, $A_G(u, v) = 1$ if and only if $uv \in E$.

Let $G = (V, E)$ be a directed graph on n vertices. We denote the out-degree of a vertex v in G by $\delta_G(v)$. Let $\Delta_G \in \mathbb{R}^{n \times n}$ be a diagonal matrix whose diagonal element $\Delta_G(v, v)$ equals $\delta_G(v)$. Then, the row-normalized adjacency matrix $\bar{A}_G \in \mathbb{R}^{n \times n}$ is defined as $\bar{A}_G = {\Delta_G}^{-1} A_G$. If a vertex $u \in V$ has no outgoing edges, we let $\bar{A}_G(u, v) = 0$ for every $v \in V$.

If the graph G is clear from the context, we may omit G in the above-mentioned notations.

3.1 Centralities

In this paper, we discuss four vertex centralities, namely, the closeness, harmonic, and betweenness centralities, along with PageRank. Furthermore, we discuss an edge centrality, namely, the spanning tree centrality. Here, we present the definitions for these centralities.

Definition 3.1 (Closeness centrality [4, 5, 27]). *For a graph $G = (V, E)$, the* closeness centrality *of a vertex $u \in V$ is defined as*

$$\mathrm{CC}_G(u) = \frac{n-1}{\sum_{v \in V} d_G(u, v)}.$$

If G is disconnected, $\sum_{v \in V} d_G(u, v) = \infty$ and thus we let $\mathrm{CC}_G(u) = 0$.

Definition 3.2 (Harmonic centrality [21]). *For a graph $G = (V, E)$, the* harmonic centrality *of a vertex $u \in V$ is defined as*

$$\mathrm{HC}_G(u) = \sum_{v \in V, v \neq u} \frac{1}{d_G(u, v)}.$$

It should be noted that $\mathrm{HC}_G(u)$ *is well-defined even if* G *is not connected, because we have* $\frac{1}{d_G(u,v)} = 0$ *if* v *is unreachable from* u.

Definition 3.3 (Betweenness centrality [14]). *For a graph* $G = (V, E)$*, the* betweenness centrality *of a vertex* $u \in V$ *is defined as*

$$\mathrm{BT}_G(u) = \sum_{(s,t)\in V^2, s\neq u\neq t} \frac{\sigma_{G,st}(u)}{\sigma_{G,st}},$$

where $\sigma_{G,st}$ *is the number of shortest paths from* s *to* t *in* G *and* $\sigma_{G,st}(u)$ *is the number of such paths that pass through* u.

In this definition, $\sigma_{G,st}$ can be 0 if s and t are disconnected in G (then, $\sigma_{G,st}(u)$ is also 0 for every $u \in V$). We simply let $\frac{\sigma_{G,st}(u)}{\sigma_{G,st}} = 0$ if there is no path from s to t in G. This corresponds to taking the sum over pairs (s, t) such that s and t are connected.

There is a variant of betweenness centrality that counts the *shortest paths having* v *as an endpoint.*

Definition 3.4 (Endpoint betweenness [9]). *For a graph* $G = (V, E)$*, the* endpoint betweenness centrality *of a vertex* $u \in V$ *is defined as*

$$\mathrm{BT}'_G(u) = \sum_{(s,t)\in V^2} \frac{\sigma_{G,st}(u)}{\sigma_{G,st}}.$$

We can see that BT and BT′ are closely tied:

Proposition 3.5. *When* G *is connected,* $\mathrm{BT}'_G(v) = \mathrm{BT}_G(v) + 2n - 1$ *holds for every* $v \in V$.

Definition 3.6 (PageRank [25]). *Let* $G = (V, E)$ *be a directed graph. Let* $0 < \alpha < 1$ *be a decaying factor and* $\boldsymbol{\pi} \in \mathbb{R}^n_{\geq 0}$ *be an initial distribution such that* $\|\boldsymbol{\pi}\|_1 = 1$*. Then, the PageRank vector* $\mathrm{PR}_G \in \mathbb{R}^n_{\geq 0}$ *of* G *is defined as*

$$\mathrm{PR}_G = (1-\alpha)(I - \alpha \bar{A}_G^{\top})^{-1}\boldsymbol{\pi},$$

and the PageRank of a vertex u *is* $\mathrm{PR}_G(u)$.

As in [25], we use the uniform distribution as the initial distribution. That is, $\boldsymbol{\pi} = \frac{1}{n}\mathbf{1}$, where $\mathbf{1} \in \mathbb{R}^n$ is the all-one vector.

The four centralities above are all defined for vertices. We next present the definition for the spanning tree centrality, which is defined for edges.

Definition 3.7 (Spanning tree centrality [30]). *For a connected graph* $G = (V, E)$*, the* spanning tree centrality *of an edge* $e \in E$ *is defined as*

$$\mathrm{ST}_G(e) = \frac{\tau_G(e)}{\tau_G}$$

where τ_G *is the number of spanning trees in* G *and* $\tau_G(e)$ *is the number of spanning trees including* e.

Note that this definition can be extended to disconnected graphs by considering spanning forests instead of spanning trees.

4 AVERAGE-CASE EDGE SENSITIVITY

In this section, we introduce sensitivity notions regarding centralities.

4.1 Sensitivity of vertex centralities

We first consider the sensitivity of vertex centralities such as closeness and harmonic centralities.

Before providing the definition, we outline some requirements that the sensitivity notion must satisfy. First, it should be invariant under the scaling of centralities. Note that different centralities may have different scales: the closeness centrality of a vertex takes is value within $[0, 1]$, whereas the harmonic centrality of a vertex is at least 1 (unless the vertex is isolated). Moreover, there are some variations to the definition of a centrality. For example, the definition of the closeness centrality in [6] differs from ours by a factor of $n - 1$. Because we want to compare different centralities, their sensitivities should be invariant under scaling.

Second, we want to understand how the structure of the underlying network affects the sensitivity. Hence, the notion of sensitivity should be parameterized by the underlying network.

To describe our sensitivity measure, we first state some definitions. A vertex centrality can be regarded as a function that, given a graph $G = (V, E)$ and a vertex $v \in V$, computes the centrality value of v in G. With this observation, we say that a family of functions $C = \{C_G : V(G) \to \mathbb{R}_{\geq 0}\}_G$ indexed by a graph G is a *vertex centrality function.* For example, CC, HC, BT, and PR introduced in Section 3 are all centrality functions.

Definition 4.1 (Average-case sensitivity for vertex centralities). *For a graph* $G = (V, E)$ *and a vertex centrality function* $C = \{C_G\}_G$*, the* (average-case) edge sensitivity *of* C *on* G *is defined as*

$$S^v_C[G] = \frac{1}{|V||E|}\sum_{e\in E}\sum_{v\in V}\frac{\left|C_{G\setminus e}(v) - C_G(v)\right|}{C_G(v)}$$

In other words, the edge sensitivity is the expected value of the relative change of the centrality value of a uniformly chosen vertex when a uniformly chosen edge is removed. The smaller the edge sensitivity of a centrality is, the less sensitive its centrality is to changes in the network.

As explained above, the edge sensitivity is invariant under scaling:

Theorem 4.2. *Let* C *be a centrality function and* C' *be another centrality function, such that* $C'_G(u) = \lambda(G)C_G(u)$*, where* $\lambda(G) > 0$ *is a scaling factor that may depend on* G*. Then, we have* $S^v_C[G] = S^v_{C'}[G]$ *for any graph* G.

4.2 Sensitivity of edge centralities

Next, we extend the proposed edge sensitivity from vertex centralities to edge centralities, such as the spanning tree centrality.

As in the case of vertex centralities, we define the general notion of an edge centrality: We say that a family of functions $C = \{C_G : E(G) \to \mathbb{R}_{\geq 0}\}_G$ indexed by a graph G is an *edge centrality function.*

Definition 4.3 (Average-case sensitivity for edge centralities). *For a graph* $G = (V, E)$ *and an edge centrality function* $C = \{C_G\}_G$*, the edge sensitivity of* C *on* G *is defined as*

$$S^e_C[G] = \frac{1}{|E|(|E|-1)}\sum_{f\in E}\sum_{e\in E\setminus\{e\}}\frac{\left|C_{G\setminus f}(e) - C_G(e)\right|}{C_G(e)}$$

This sensitivity is also invariant under scaling per Theorem 4.2.

The distinction between $S_C^v[G]$ and $S_C^e[G]$ is not essential, because they are defined for different families of centrality functions. Thus, $S_C^v[G]$ and $S_C^e[G]$ are hereafter written as $S_C[G]$.

5 THEORETICAL ANALYSIS

In this section, we theoretically analyze the edge sensitivities of the centralities introduced in Section 3. The proofs of our lower bounds are deferred to the full version due to space limitation. Then, we compare those centralities in terms of edge sensitivity in Section 5.6.

5.1 Closeness centrality

As mentioned above, the closeness centrality of a vertex in a disconnected graph is 0, and hence its edge sensitivity is not well defined against disconnected graphs. For connected graphs, we have the following bound:

Theorem 5.1. *Let G be a connected undirected graph with at least 2 vertices and b bridges. Then, we have $\frac{b}{m} \le S_{\mathrm{CC}}[G] \le \frac{2D_G+b}{m}$.*

To prove this theorem, we use the following lemma:

Lemma 5.2 ([28]). *Let $G = (V, E)$ be an undirected graph and $F \subseteq E$. If $G \setminus F$ is connected, then $D_{G\setminus F} \le (|F|+1)D_G$ holds.*

Proof of Theorem 5.1. Let $B \subseteq E$ be the set of bridges in $G = (V, E)$. Since removing a bridge makes the graph disconnected, we have $\frac{|C_{G\setminus e}(v)-C_G(v)|}{C_G(v)} = 1$ if $e \in B$. Then, we have

$$S_{\mathrm{CC}}[G] \ge \frac{1}{|V||E|} \sum_{e\in B}\sum_{v\in V} \frac{\left|\mathrm{CC}_{G\setminus e}(v) - \mathrm{CC}_G(v)\right|}{\mathrm{CC}_G(v)} = \frac{b}{m}.$$

Let $W_G(u) = \sum_{v\in V} d(u,v)$. Then, $\mathrm{CC}_G(u) = \frac{n-1}{W_G(u)}$ holds. It is also easy to see that $W_G(u) \le W_{G\setminus e}(u)$ for any edge $e \in E$. Therefore, we have

$$\frac{\left|\mathrm{CC}_{G\setminus e}(v) - \mathrm{CC}_G(v)\right|}{\mathrm{CC}_G(v)} = \frac{W_{G\setminus e}(v) - W_G(v)}{W_{G\setminus e}(v)} \le \frac{W_{G\setminus e}(v) - W_G(v)}{W_G(v)}.$$

Using this, we obtain

$$\sum_{e\in E\setminus B} \frac{\left|\mathrm{CC}_{G\setminus e}(v) - \mathrm{CC}_G(v)\right|}{\mathrm{CC}_G(v)} \le \frac{1}{W_G(v)} \sum_{e\in E\setminus B} (W_{G\setminus e}(v) - W_G(v))$$
$$\le \frac{1}{W_G(v)} \sum_{w\in V}\sum_{e\in E\setminus B} (d_{G\setminus e}(v,w) - d_G(v,w)). \quad (1)$$

For $v, w \in V$, we consider a shortest path $p(v,w)$ connecting v and w in G. Note that $p(v,w)$ contains $d_G(v,w)$ edges. If an edge $e \in E\setminus B$ is not a member of $p(v,w)$, we have $d_{G\setminus e}(v,w) = d_G(v,w)$. Otherwise, we have $d_{G\setminus e}(v,w) \le 2D_G$ according to Lemma 5.2. Therefore,

$$\sum_{w\in V}\sum_{e\in E\setminus B} (d_{G\setminus e}(v,w) - d_G(v,w))$$
$$= \sum_{w\in V}\sum_{e\in (E\setminus B)\cap p(v,w)} (d_{G\setminus e}(v,w) - d_G(v,w))$$
$$\le \sum_{w\in V} 2D_G d_G(v,w) = 2W_G(v)D_G. \quad (2)$$

Using (1), (2), and the fact that $\frac{|C_{G\setminus e}(v)-C_G(v)|}{C_G(v)} = 1$ for $e \in B$, we obtain $S_{\mathrm{CC}}[G] \le \frac{2D_G+b}{m}$, as desired. □

5.2 Harmonic centrality

Theorem 5.3. *Let G be an undirected or directed graph. Then, we have $S_{\mathrm{HC}}[G] \le \frac{n-1}{nm} \sum_{v\in V} \frac{1}{\mathrm{HC}[G](v)}$.*

Proof. Analogous to the proof for the closeness centrality, we have for any vertex $v \in V(G)$,

$$\sum_{e\in E} \frac{\left|\mathrm{HC}_{G\setminus e}(v) - \mathrm{HC}_G(v)\right|}{\mathrm{HC}_G(v)} = \sum_{e\in E} \frac{\mathrm{HC}_G(v) - \mathrm{HC}_{G\setminus e}(v)}{\mathrm{HC}_G(v)}$$
$$= \frac{1}{\mathrm{HC}_G(v)} \sum_{e\in E}\sum_{w\in V, w\ne v} \left(\frac{1}{d_G(v,w)} - \frac{1}{d_{G\setminus e}(v,w)}\right)$$
$$= \frac{1}{\mathrm{HC}_G(v)} \sum_{w\in V, w\ne v}\sum_{e\in p(v,w)} \frac{1}{d_G(v,w)} \le \frac{n-1}{\mathrm{HC}_G(v)}.$$

Note that the inequality holds for both undirected and directed graphs. It follows that $S_{\mathrm{HC}}[G] \le \frac{n-1}{nm} \sum_{v\in V} \frac{1}{\mathrm{HC}[G](v)}$ holds. □

Corollary 5.4. *Let G be a (strongly) connected graph. Then, we have $S_{\mathrm{HC}}[G] \le \frac{\bar{d}_G}{m} \le \frac{D_G}{m}$, where $\bar{d}_G$ is the average distance between vertices: $\bar{d}_G = \frac{1}{n(n-1)} \sum_{u,v\in V, u\ne v} d(u,v)$.*

Proof. We have $\frac{n-1}{\mathrm{HC}[G](v)} \le \frac{1}{n-1} \sum_{w\ne v} d(v,w)$ by the HM-AM inequality. It follows that $\frac{n-1}{n} \sum_{v\in V} \frac{1}{\mathrm{HC}[G](v)} \le \bar{d}_G$. Combining this with Theorem 5.3, we obtain $S_{\mathrm{HC}}[G] \le \frac{\bar{d}_G}{m}$. □

5.3 Betweenness centrality

Our definition of edge sensitivity cannot be directly applied to the betweeness centrality because $\mathrm{BT}_G(v) = 0$ and $\mathrm{BT}_{G\setminus e}(v) > 0$ could hold at the same time, resulting in a zero-division problem. More specifically, consider a triangle graph consisting of three vertices $\{v, x, y\}$ and let $e = (x, y)$. Then, $\mathrm{BT}_G(v) = 0$ holds, whereas $\mathrm{BT}_{G\setminus e}(v) > 0$ because the only path between x and y in $G\setminus e$ passes through v.

Another issue with the betweenness centrality is its instability. Consider a complete graph K_n on n vertices. It is clear that $\mathrm{BT}_{K_n}(v) = 0$ for every v and $\mathrm{BT}_{K_n\setminus xy}(v) > 0$ for $v \ne x, y$. That is, removing an edge renders the centralities of $n-2$ vertices nonzero even though they were all zero before its removal.

However, we can give non-trivial bounds on the edge sensitivity of endpoint betweeness centrality:

Theorem 5.5. *Let G be a connected undirected graph. Then, we have $S_{\mathrm{BT}'}[G] \le \frac{{D_G}^2+3D_G}{m}$.*

Although we consider endpoint betweenness centrality rather than (normal) betweenness centrality, their values are relatively close for highly important vertices, since the average betweenness centrality is $\Omega(n)$. Therefore, in practice, we can suppose that analysis on endpoint betweenness centrality will provide useful results for betweenness centrality as well.

For a graph G, we denote the number of paths of length d between two vertices s and t in G by $\sigma_{G,st}^d$. Similarly, the number of such

paths passing through a vertex v is denoted by $\sigma^d_{G,st}(v)$. Before proving this theorem, we need the following technical lemma:

Lemma 5.6. *If s and t are connected in G, we have*

(1) $\sum_{v\in V}\sigma_{G,st}(v) = (d_G(s,t)+1)\sigma_{G,st}$,
(2) $\sum_{e\in E}(\sigma^{d_G(s,t)}_{G,st}(v) - \sigma^{d_G(s,t)}_{G\setminus e,st}(v)) = d_G(s,t)\sigma^{d_G(s,t)}_{G,st}(v)$.

Proof. (1) Both sides of the equation count the number of pairs (p,v), where p is a shortest path between s and t, and v is a vertex that p passes through.
(2) Note that $\sigma^{d_G(s,t)}_{G,st}(v) - \sigma^{d_G(s,t)}_{G\setminus e,st}(v)$ is the number of paths of length $d_G(s,t)$ between s and t passing through both v and e. Both sides of the equation count the number of pairs (p,e), where p is a path of length $d_G(s,t)$ between s and t, and e is an edge that p passes through. □

Here we define $d'_G(s,t)$ by $d'_G(s,t) = \begin{cases} d_G(s,t) & d_G(s,t) < \infty \\ -1 & \text{otherwise} \end{cases}$. Then, (1) of Lemma 5.6 can be generalized to graphs G in which s and t may not be connected: $\sum_{v\in V}\frac{\sigma_{G,st}(v)}{\sigma_{G,st}} = d'_G(s,t)+1$.

Proof of Theorem 5.5. For every pair of vertices $(s,t)\in V^2$, we let $P(s,t) = \left\{e\in E \mid d_G(s,t) = d_{G\setminus e}(s,t)\right\}$. To bound $S_{\mathrm{BT}'}[G]$, we first consider the *sum of absolute differences*:

$$A = \frac{1}{nm}\sum_{v\in V}\sum_{e\in E}\left|\mathrm{BT}'_{G\setminus e}(v) - \mathrm{BT}'_G(v)\right|.$$

Using the triangle inequality, we have

$$A \le \frac{1}{nm}\sum_{(s,t)\in V^2}\sum_{e\in E}\sum_{v\in V}\left|\frac{\sigma_{G\setminus e,st}(v)}{\sigma_{G\setminus e,st}} - \frac{\sigma_{G,st}(v)}{\sigma_{G,st}}\right|.$$

From Lemma 5.6, we have

$$\begin{aligned}
&\sum_{e\in E}\sum_{v\in V}\left|\frac{\sigma_{G\setminus e,st}(v)}{\sigma_{G\setminus e,st}} - \frac{\sigma_{G,st}(v)}{\sigma_{G,st}}\right| \\
&= \sum_{e\in E}\sum_{v\in V}\left|\frac{\sigma_{G\setminus e,st}(v)}{\sigma_{G\setminus e,st}} - \frac{\sigma^{d_G(s,t)}_{G\setminus e,st}(v)}{\sigma_{G,st}} + \frac{\sigma^{d_G(s,t)}_{G\setminus e,st}(v)}{\sigma_{G,st}} - \frac{\sigma_{G,st}(v)}{\sigma_{G,st}}\right| \\
&\le 2\cdot\sum_{e\in E}\sum_{v\in V}\left(\frac{\sigma_{G,st}(v)}{\sigma_{G,st}} - \frac{\sigma^{d_G(s,t)}_{G\setminus e,st}(v)}{\sigma_{G,st}}\right) \\
&\quad + \sum_{e\in P(s,t)}\sum_{v\in V}\left|\frac{\sigma_{G\setminus e,st}(v)}{\sigma_{G\setminus e,st}} - \frac{\sigma_{G,st}(v)}{\sigma_{G,st}}\right| \\
&\le 2D_G(D_G+1) + \sum_{e\in P(s,t)}(d'_{G\setminus e}(s,t) - d'_G(s,t)) \le 4{D_G}^2 + 2D_G.
\end{aligned}$$

Therefore, we obtain

$$\begin{aligned}
A &= \frac{1}{nm}\sum_{(s,t)\in V^2, s\neq t}\sum_{e\in E}\sum_{v\in V}\left|\frac{\sigma_{G\setminus e,st}(v)}{\sigma_{G\setminus e,st}} - \frac{\sigma_{G,st}(v)}{\sigma_{G,st}}\right| \\
&\le \frac{n-1}{m}\cdot(4{D_G}^2 + 2D_G).
\end{aligned}$$

Furthermore, $\mathrm{BT}'_G(u) \ge 2n-1$ follows from Proposition 3.5. Accordingly, we have $S_{\mathrm{BT}'}[G] \le \frac{A}{2n-1} \le \frac{2{D_G}^2+D_G}{m}$. □

5.4 PageRank

To analyze the edge sensitivity of PageRank, we use a random-walk-based representation of PageRank [3]. For a walk $w = w_0w_1\dots w_{\ell(w)}$ of length $\ell(w)$ in a graph G of n vertices and a matrix $M\in\mathbb{R}^{n\times n}$, we define the *weight of w with respect to M* by

$$W_M(w) = \prod_{i=0}^{\ell-1} M(w_i, w_{i+1}).$$

Lemma 5.7. *The Pagerank of a vertex $v\in V(G)$ satisfies*

$$\mathrm{PR}_G(v) = \sum_{w\in\mathrm{walks}_G(\star,v)}\frac{1-\alpha}{n}W_{\alpha\bar{A}_G}(w),$$

where $\mathrm{walks}_G(\star,v)$ *is the set of walks in G terminating at v.*

The following is almost immediate from the definition and we omit the proof:

Lemma 5.8. *Let* walks_G *be the (infinite) set of walks in G. Then, we have $\sum_{w\in\mathrm{walks}_G,\ell(w)=l}\frac{1-\alpha}{n}W_{\alpha\bar{A}_G}(w) \le (1-\alpha)\alpha^l$. Equality holds if every vertex in G has at least one out-going edge.*

We first bound $S_{\mathrm{PR}}[G]$ exclusively for special graphs.

Lemma 5.9. *Suppose that every vertex $v\in V$ satisfies $\delta_G(v)\ge 1$. Then, we have $S_{\mathrm{PR}}[G] \le \frac{2\alpha}{m(1-\alpha)^2}$.*

Proof. Let $e = st\in E$ be an edge to be removed, and let $M = \alpha\bar{A}_G$, $M'' = \alpha\bar{A}_{G\setminus e}$ and $M'\in\mathbb{R}^{n\times n}$ be the matrix obtained from M by replacing $M(s,t)$ with 0. Then, it is clear that $M\ge M'\le M''$ and thus $W_M(w)\ge W_{M'}(w)\le W_{M''}(w)$ holds for every walk w. Additionally, since every vertex in G has at least one out-going edge, we have $\sum_{v\in V}\mathrm{PR}_G(v) = 1 \ge \sum_{v\in V}\mathrm{PR}_{G\setminus e}(v)$ from Lemma 5.8. Therefore, we have

$$\begin{aligned}
&\sum_{v\in V}\left|\mathrm{PR}_G(v) - \mathrm{PR}_{G\setminus e}(v)\right| \le \frac{1-\alpha}{n}\sum_{w\in\mathrm{walks}_G(\star,v)}|W_M(w) - W_{M''}(w)| \\
&\le \frac{1-\alpha}{n}\sum_{w\in\mathrm{walks}_G(\star,v)}((W_M(w) - W_{M'}(w)) + (W_{M''}(w) - W_{M'}(w))) \\
&\le \frac{2(1-\alpha)}{n}\sum_{w\in\mathrm{walks}_G(\star,v)}(W_M(w) - W_{M'}(w)) \\
&\le \frac{2(1-\alpha)}{n}\sum_{w\in\mathrm{walks}_G(\star,v),e\in w}W_M(w).
\end{aligned}$$

From Lemma 5.8, we obtain

$$\begin{aligned}
\sum_{e\in E}\sum_{v\in V}\left|\mathrm{PR}_G(v) - \mathrm{PR}_{G\setminus e}(v)\right| &\le \frac{2(1-\alpha)}{n}\sum_{e\in E}\sum_{w\in\mathrm{walks}_G:\atop e\in w}W_M(w) \\
&\le \frac{2(1-\alpha)}{n}\sum_{w\in\mathrm{walks}_G}W_M(w)\ell(w) \le 2\sum_{\ell=0}^{\infty}\ell(1-\alpha)\alpha^\ell = \frac{2\alpha}{1-\alpha}.
\end{aligned}$$

Here note that $\mathrm{PR}(v)\ge\frac{1-\alpha}{m}$ holds because there is a walk of length 0 starting and ending at v for every $v\in V$. Finally we have

$$\begin{aligned}
S_{\mathrm{PR}}[G] &= \frac{1}{nm}\sum_{e\in E}\sum_{v\in V}\frac{\left|\mathrm{PR}_{G\setminus e}(v) - \mathrm{PR}_G(v)\right|}{\mathrm{PR}_G(v)} \\
&\le \frac{1}{nm}\cdot\frac{n}{1-\alpha}\sum_{e\in E}\sum_{v\in V}\left|\mathrm{PR}_{G\setminus e}(v) - \mathrm{PR}_G(v)\right| \le \frac{2\alpha}{m(1-\alpha)^2}.
\end{aligned}$$ □

From Lemma 5.9, we prove the same inequality for a general G:

Theorem 5.10. *We have* $S_{\mathrm{PR}}[G] \le \frac{2\alpha}{m(1-\alpha)^2}$.

Proof. Let $T = \{v \in V \mid \delta_G(v) = 0\}$, $F = \{(t,t) \mid t \in T\}$ and $G' = (V, E \cup F)$. We can see that $\mathrm{PR}_{G'}(v) = \mathrm{PR}_G(v)$ if $\delta_G(v) \ge 1$ and $\mathrm{PR}_{G'}(v) = \frac{\mathrm{PR}_G(v)}{1-\alpha}$ if $\delta_G(v) = 0$. Therefore, we have $\frac{\left|\mathrm{PR}_{G'\setminus e}(v) - \mathrm{PR}_{G'}(v)\right|}{\mathrm{PR}_{G'}(v)} = \frac{\left|\mathrm{PR}_{G\setminus e}(v) - \mathrm{PR}_G(v)\right|}{\mathrm{PR}_G(v)}$ for every $e \in E$ and $v \in V$. Accordingly from Lemma 5.9, we obtain

$$\begin{aligned} S_{\mathrm{PR}}[G] &= \frac{1}{nm} \sum_{e\in E} \sum_{v\in V} \frac{\left|\mathrm{PR}_{G\setminus e}(v) - \mathrm{PR}_G(v)\right|}{\mathrm{PR}_G(v)} \\ &= \frac{1}{nm} \sum_{e\in E} \sum_{v\in V} \frac{\left|\mathrm{PR}_{G'\setminus e}(v) - \mathrm{PR}_{G'}(v)\right|}{\mathrm{PR}_{G'}(v)} \\ &\le \frac{|E\cup F|}{|E|} S_{\mathrm{PR}}[G'] \le \frac{2\alpha}{m(1-\alpha)^2}. \end{aligned}$$

□

5.5 Spanning tree centrality

To analyze the edge sensitivity of the spanning tree centrality, we use the relationship between the spanning tree centrality and *effective resistance*, which is defined as follows:

Definition 5.11 (Effective resistance). *For an undirected graph $G = (V,E)$, we imagine an electric circuit obtained by replacing every edge in G with a resistor of a unit resistance. For every pair of vertices $(u,v) \in V^2$, the* effective resistance *between u and v is defined as the difference in their electric potential when we inject a unit electricity from u to v.*

Theorem 5.12 (see, e.g., [22]). *Let $G = (V,E)$ be an undirected graph. For every edge $e = uv \in E$, $\mathrm{ST}_G(e)$ is the effective resistance between u and v in G.*

The following pertains to effective resistance:

Theorem 5.13 (Rayleigh's monotonicity law [11]). *If the resistance of a resistor in a circuit increases, for every $(u,v) \in V^2$, the effective resistance between u and v does not decrease.*

Remark. *Theorem 5.13 applies to the removal of resistors, because the removal of a resistor corresponds to increasing its resistance to ∞.*

Theorem 5.14 (Dirichlet principle [11]). *For $v \in \mathbb{R}^V$, the energy consumption when the electrical potential of w is set to $v(w)$ for every $w \in V$ is $C(v) := \sum_{st\in E} (v(s) - v(t))^2$. Under the constraints of $v(x) = 1$ and $v(y) = 0$ $(x, y \in V)$, the energy $C(v)$ is minimized when the electrical flow determined by v satisfies Kirchoff's law. In other words, $C(v)$ is at least the reciprocal of the effective resistance between x and y.*

Based on these facts, we prove some technical lemmas that are useful for our analysis.

Lemma 5.15. *Let $G = (V,E)$ be an undirected graph. For every $e, f \in E$ $(e \ne f)$, we have $\mathrm{ST}_G(e) \le \mathrm{ST}_{G\setminus f}(e) \le \frac{\mathrm{ST}_G(e)}{1-\mathrm{ST}_G(e)}$.*

Proof. With Theorem 5.12, we can identify the spanning tree centrality of e with the effective resistance of $e \in E$. The first inequality immediately holds from Theorem 5.13.

We let $e = st$. Let $v \in \mathbb{R}^V$ be the electrical potential of every vertex when we apply a unit voltage between s and t in $G \setminus f$. From Theorem 5.14, the energy consumed when we apply a unit voltage between s and t in G is upper-bounded by the energy consumption when the electrical potential is given by v (note that this does not necessarily satisfy Kirchoff's law). Since this energy consumption is equivalent to the reciprocal of the effective resistance, we have $\frac{1}{\mathrm{ST}_G(e)} \le \frac{1}{\mathrm{ST}_{G\setminus f}(e)} + 1$. Then, it is clear that $\mathrm{ST}_{G\setminus f}(e) \le \frac{\mathrm{ST}_G(e)}{1-\mathrm{ST}_G(e)}$. □

Lemma 5.16. *Let $G = (V,E)$ be an undirected graph and $e, f \in E$ be distinct edges. Then,*

$$0 \le \frac{\mathrm{ST}_{G\setminus f}(e) - \mathrm{ST}_G(e)}{\mathrm{ST}_G(e)} \le \sqrt{2\left(\mathrm{ST}_{G\setminus f}(e) - \mathrm{ST}_G(e)\right)}.$$

Proof. The first inequality is immediate from Lemma 5.15.

Let $x = \mathrm{ST}_G(e)$ and $y = \mathrm{ST}_{G\setminus f}(e)$. To show the second inequality, it suffices to show $\frac{\sqrt{y-x}}{x} \le \sqrt{2}$. If $x \ge \frac{1}{2}$, we have $\frac{\sqrt{y-x}}{x} \le \sqrt{2}$ since $y \le 1$ (from the definition of a spanning tree centrality). If $x < \frac{1}{2}$, using Lemma 5.15, we have $\frac{\sqrt{y-x}}{x} \le \frac{1}{\sqrt{1-x}} \le \sqrt{2}$. In both cases, we obtain the desired inequality. □

Lemma 5.17. *Let $G = (V,E)$ be a connected undirected graph. Then, $\sum_{e\in E} \mathrm{ST}_G(e) = |V| - 1$.*

Proof. This follows immediately from $\sum_{e\in E} \tau_G(e) = (|V| - 1)\tau_G$, which holds because every spanning tree in G has $|V| - 1$ edges. □

Theorem 5.18. *Let G be a two-connected undirected graph. Then, we have $S_{\mathrm{ST}}[G] \le \sqrt{\frac{2(n-1)}{m(m-1)}}$.*

Proof. For $e, f \in E$ $(e \ne f)$, we let $\delta_G(e,f) = \mathrm{ST}_{G\setminus f}(e) - \mathrm{ST}_G(e)$. From Lemma 5.17, we have

$$\begin{aligned} \sum_{e,f\in E, e\ne f} \delta_G(e,f) &= \sum_{f\in E} \sum_{e\in E\setminus\{f\}} (\mathrm{ST}_{G\setminus f}(e) - \mathrm{ST}_G(e)) \\ &= \sum_{f\in E} \left(\sum_{e\in E\setminus\{f\}} \mathrm{ST}_{G\setminus f}(e) - \sum_{e\in E} \mathrm{ST}_G(e) + \mathrm{ST}_G(f) \right) \\ &= \sum_{f\in E} \mathrm{ST}_G(f) = n - 1. \end{aligned}$$

Additionally, from Lemma 5.16,

$$\sum_{e,f\in E, e\ne f} \frac{\mathrm{ST}_{G\setminus f}(e) - \mathrm{ST}_G(e)}{\mathrm{ST}_G(e)} \le \sum_{e,f\in E, e\ne f} \sqrt{2\delta_G(e,f)}.$$

Therefore, we have $\sum_{e,f\in E, e\ne f} \sqrt{2\delta_G(e,f)} \le \sqrt{2(n-1)m(m-1)}$ by the Cauchy-Schwarz inequality. Thus we have

$$S_{\mathrm{ST}}[G] = \frac{1}{m(m-1)} \sum_{e,f\in E, e\ne f} \frac{\mathrm{ST}_{G\setminus f}(e) - \mathrm{ST}_G(e)}{\mathrm{ST}_G(e)} \le \sqrt{\frac{2(n-1)}{m(m-1)}}$$

as desired. □

5.6 Comparison of centralities in terms of sensitivity

We turn now to a comparison of the centralities we have analyzed.

First, the edge sensitivities of the closeness and harmonic centralities are similar with regard to the diameter D_G and the number of edges m. However, the former degrades considerably when there are many bridges in the graph. Hence, the harmonic centrality is preferable to the closeness centrality unless the graph is highly connected.

In contrast, the edge sensitivity of endpoint betweenness centrality is $\Theta(D_G^2/m)$, which is conspiciously worse than that of the harmonic centrality.

The sensitivity of PageRank depends on the decaying factor α: the higher α is, the larger the sensitivity is. PageRank with larger value of α gives much weight on longer walks. Since longer walks are more likely to contain the randomly removed edge, PageRank can be more sensitive with larger α.

The edge sensitivities of the closeness, harmonic, and betweenness centralities depend on the diameter D_G, which is unavoidable according to our lower bounds (Table 1). By contrast, the edge sensitivity of PageRank depends on α (and m) rather than D_G. Although this implies that PageRank may be more stable than other centralities when the graph has a large diameter, the harmonic centrality is preferable for typical real small-world networks that have diameters of $O(\log n)$ [33].

Although our current bound on the edge sensitivity of spanning tree centrality is $O(\sqrt{n}/m)$, we cannot conclude that it is worse than other centralities, insofar as we do not have a matching lower bound.

6 AVERAGE-CASE k-EDGE SENSITIVITY

In this section, we discuss k-edge sensitivity, which is an extension of edge sensitivity for removing k edges.

6.1 Definition

Average-case edge sensitivity (Definition 4.1) considers the case that a (random) edge is missing in the observed graph. In practice, however, it is more likely that multiple edges are missing, and this motivates us to define the following *(average-case) k-edge sensitivity*:

Definition 6.1 (Average-case k-edge sensitivity for vertex centralities). *For a graph $G = (V, E)$ and a vertex centrality function $C = \{C_G\}_G$, the* k-edge sensitivity *of C on G is defined as*

$$S^v_{C,k}[G] = \frac{1}{|V|\binom{|E|}{k}} \sum_{F \subseteq E, |F|=k} \sum_{v \in V} \frac{\left|C_{G\setminus F}(v) - C_G(v)\right|}{C_G(v)}.$$

The k-edge sensitivity of an edge centrality $S^e_{C,k}[G]$ is defined analogously (note that the sum of the relative differences is taken over $v \in V \setminus F$). Again, we simply write $S^v_{C,k}[G]$ and $S^e_{C,k}[G]$ as $S_{C,k}[G]$. Note that $S_C[G] = S_{C,1}[G]$ holds and hence k-edge sensitivity is a natural extension of edge sensitivity. Also, it is notable that a k-edge sensitivity can be probabilistically defined:

$$S^v_{C,k}[G] = \mathrm{E}_F\left[\frac{1}{|V|}\sum_{v\in V}\frac{\left|C_{G\setminus F}(v) - C_G(v)\right|}{C_G(v)}\right],$$

where F is a uniformly chosen subset of E with cardinality k.

6.2 Theoretical analysis

In this section, we extend results in Section 5 to k-edge sensitivity.

Theorem 6.2. *Let G be a connected undirected graph. Then, $S_{\mathrm{CC},k}[G] \le \frac{k(k+1)D_G}{m} + \chi_k[G]$, where $\chi_k[G]$ is the probability that G becomes disconnected by removing a uniformly chosen set of k edges in G.*

Proof. We let $c(G,x) = x$ if G is connected and $c(G,x) = 0$ otherwise. For a fixed vertex $v \in V$,

$$\begin{aligned}
&E\left[c\left(G\setminus F, \sum_{w\in V}(d_{G\setminus F}(v,w) - d_G(v,w))\right)\right]\\
\le& E\left[c\left(G\setminus F, \sum_{w\in V, F\cap p(v,w)\neq\emptyset}(d_{G\setminus F}(v,w) - d_G(v,w))\right)\right]\\
\le& \sum_{w\in V} k(k+1)D_G d_G(v,w) = k(k+1)W_G(v)D_G
\end{aligned}$$

because F and $p(v,w)$ intersects with probability at most $\frac{kd_G(v,w)}{m}$, and if v and w are connected in $G \setminus F$, $d(v,w) \le (k+1)D_G$ follows from Lemma 5.2. The rest of the proof is similar to that of Theorem 5.1. □

Theorem 6.3. *Let G be a (strongly) connected graph. Then, we have $S_{\mathrm{HC},k}[G] \le \frac{kD_G}{m}$.*

Proof. Let π_{uv} be a shortest path from u to v in G. Suppose a subset of edges $F \subseteq E$ is removed from G. Then, the distance from u to v decreases only if F and π_{uv} shares at least one edge. If F is chosen uniformly at random from every subset of E with cardinality k, this occurs with probability at most $\frac{kd_G(u,v)}{m}$. Thus we have $S_{\mathrm{HC},k}[G] \le \frac{kD_G}{m}$ as in the proof of Theorem 5.3 and Corollary 5.4. □

Theorem 6.4. *We have $S_{\mathrm{PR},k}[G] \le \frac{2\alpha k}{m(1-\alpha)^2}$.*

Proof. The probability that a walk w of length $\ell(w)$ shares at least one edge with a uniformly random subset F of E with cardinality k is at most $\frac{k\ell(w)}{m}$. Therefore, as in the proof of Lemma 5.9, we have

$$\mathrm{E}\left[\sum_{v\in V}\left|\mathrm{PR}_G(v) - \mathrm{PR}_{G\setminus F}(v)\right|\right] \le \frac{2k\alpha}{1-\alpha}.$$

The rest of the proof is similar to that of Lemma 5.9 and Theorem 5.10. □

Theorem 6.5. *Let G be a undirected connected graph. Then, we have $S_{\mathrm{BT},k}[G] \le \frac{(k^2+3k){D_G}^2/2+kD_G}{m}$.*

To prove this, we introduce an extension of Lemma 5.6:

Lemma 6.6. *If s and t are connected in G, we have*

$$\mathrm{E}\left[\sigma^{d_G(s,t)}_{G,st}(v) - \sigma^{d_G(s,t)}_{G\setminus F,st}(v)\right] \le \frac{k}{m}\cdot d_G(s,t)\sigma^{d_G(s,t)}_{G,st}(v).$$

Table 2: Dataset for experiments on real graphs

Name	Directed?	n	m
ca-CondMat [20]	No	21363	91286
ca-GrQc [20]	No	4158	13422
email-EuAll [20]	Yes	34203	151132
facebook_combined [20]	No	4039	88234
petster-hamster [19]	No	2000	16098

Proof of Theorem 6.5. From Lemma 6.6, we have

$$\mathrm{E}\left[\sum_{v\in V}\left(\frac{\sigma_{G,st}(v)}{\sigma_{G,st}}-\frac{\sigma^{d_G(s,t)}_{G\setminus F,st}(v)}{\sigma_{G,st}}\right)\right]\leq\frac{kd_G(s,t)(D_G+1)}{m}.$$

Also, we have $E\left[d'_{G\setminus F}(s,t)-d'_G(s,t)\right]\leq k(k+1){D_G}^2$. Using them, the proof is analogous to that of Theorem 5.5. □

Theorem 6.7. *Let G be a undirected graph. Then, we have $S_{\mathrm{ST},k}[G]\leq\frac{k\sqrt{(k+1)n}}{m-k}$.*

Proof. Lemma 5.15 can be generalized as $\frac{1}{\mathrm{ST}_G(e)}\leq\frac{1}{\mathrm{ST}_{G\setminus F}(e)}+|F|$. Using this, we have

$$0\leq\frac{\mathrm{ST}_{G\setminus F}(e)-\mathrm{ST}_G(e)}{\mathrm{ST}_G(e)}\leq\sqrt{k(k+1)\left(\mathrm{ST}_{G\setminus F}(e)-\mathrm{ST}_G(e)\right)}.$$

which is an extension of Corollary 5.16. Additionally, we can see $\mathrm{E}\left[\sum_{e\in E\setminus F}\left(\mathrm{ST}_{G\setminus F}(e)-\mathrm{ST}_G(e)\right)\right]\leq\frac{k(n-1)}{m}$ as in the proof of Theorem 5.18. Therefore, by the Cauchy–Schwarz inequality, we obtain $S_{\mathrm{ST},k}\leq k\sqrt{\frac{(k+1)(n-1)}{m(m-k)}}$. □

6.3 Comparison of centralities in terms of k-edge sensitivity

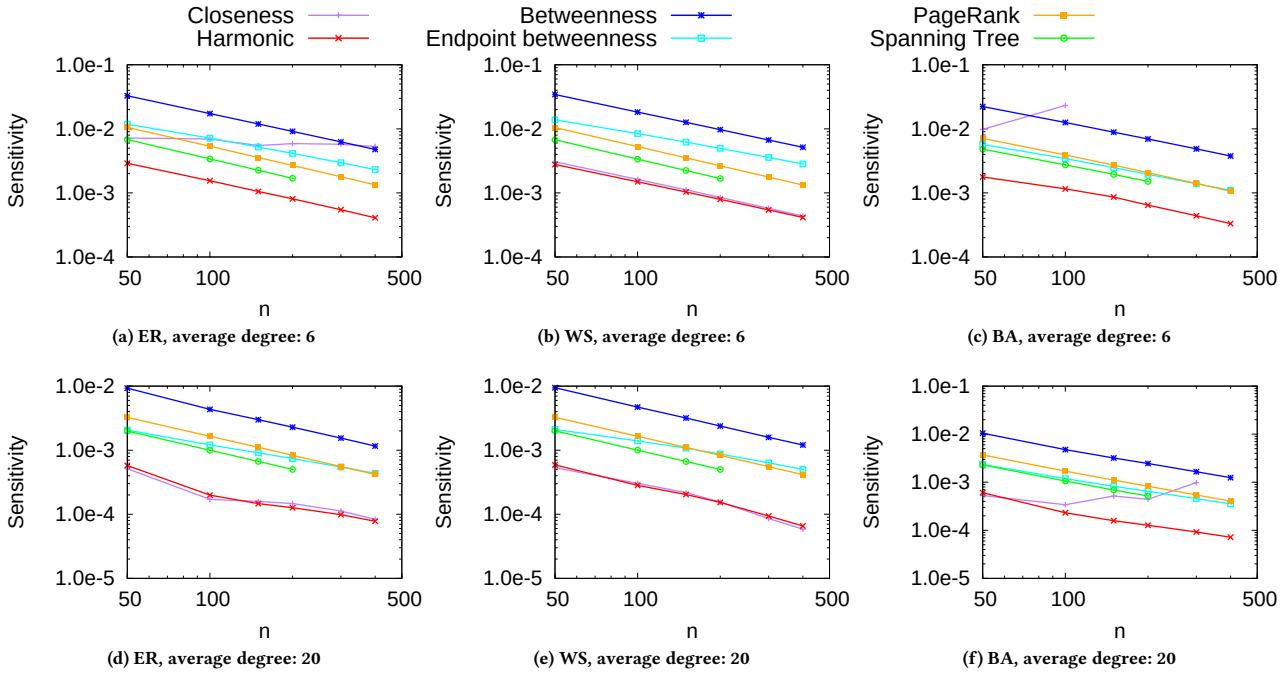
We first compare the upper bounds on k-edge sensitivity with the lower bounds on (1-)edge sensitivity, as a function of k. For the harmonic centrality and PageRank, the ratio is $O(k)$. This means that the harmonic centrality and PageRank are stable against removal of multiple edges as much as against removal of a single edge because, roughly speaking, removal of k edges will cause k times more changes in the centrality values than removal of one edge. However, this ratio is $O(k^2)$ for the closeness centrality and the endpoint betweenness centrality, and is $O(k^{1.5})$ for the spanning tree centrality. Recall that, in Section 5, we argued that the harmonic centrality is preferable for small-world networks. Our results for k-edge sensitivity reinforces this argument.

7 EXPERIMENTS

In Section 5, we analyzed the theoretical bounds with regard to the sensitivity of various centralities. In this section, we confirm that these bounds reflect actual tendencies by conducting experiments on synthetic and real graphs to answer this question. We also experimentally show that edge sensitivity is a good proxy for k-edge sensitivity for large k when comparing various centralities in terms of sensitivity against removals of multiple edges.

7.1 Method

We performed experiments on synthetic and real-world graphs. The former were intended to clarify the tendency of sensitivity on graphs of varying size. The latter were used to determine how our sensitivity metric applies to real-world networks.



In the experiments on synthetic graphs (Section 7.2), we first generated three kinds of undirected graphs with varying parameters and scales. We used the following three methods for generating graphs:

- Erdős-Rényi (ER) for uniformly random graphs [12]. Average degree: 6, 20.
- Watts-Strogatz (WS) for small-world graphs [33] w diameter of $O(\log n)$. Average degree: 6, 20. Rewiring probability: 0.2.
- Barabasi-Albert (BA) for scale-free graphs [1, 2] with a power-law degree distribution. Core size: 20. Edge probability in the core: 0.5. Average degree of non-core vertices: 6, 20.

We tested graphs of a different number of vertices: 50, 100, 150, 200, 300 and 400. For each setting, we generated 100 graphs. Then we exactly computed the sensitivity of each network for six centralities: the closeness centrality, harmonic centrality, betweeness centrality, endpoint betweenness centrality, PageRank, and spanning tree centrality. The (endpoint) betweenness centrality was computed using the Brandes' algorithm [8] and PageRank was computed using the power iteration method. The spanning tree centrality was computed with the formula provided in [17]. This formula requires computing the pseudo-inverse of matrices. We used the Eigen library [16] for this computation. Since the spanning tree centrality is computationally expensive, we computed it only for graphs of at most 200 vertices.

In the experiments on real-world graphs (Section 7.3), we used directed and undirected graphs provided in the Stanford Large Network Dataset Collection (SNAP) [20] and KONECT [19]. Details for these graphs are shown in Table 2. For each graph, we extracted the largest strongly connected component and removed multiple edges, leaving only single and self edges; n and m in Table 2 refer to the preprocessed graph. As it is too costly to compute sensitivity values for these networks, we estimated them with random sampling. Specifically, we randomly picked 1000 edges, and for each sampled edge e, we computed the *partial sensitivity* $\frac{1}{|V|}\sum_{v\in V}\frac{|C_{G\setminus e}(v)-C_G(v)|}{C_G(v)}$. The average partial sensitivity over all sampled edges was then used as an estimation of the sensitivity value. Furthermore, we derived the standard deviation of the partial sensitivities. We computed sensitivity of spanning tree using a sample of 112 edges (instead of 1000 edges) exclusively for small graphs. For the closeness centrality of undirected graphs, the partial sensitivity will be 1 when e is a bridge. Therefore, we first computed the set of bridges $B\subseteq E$ and then took a sample of 112 edges in $E\setminus B$. The sensitivity of the closeness centrality was estimated by first computing the partial sensitivity of the sampled edges and then augmenting the contribution of bridges to the sensitivity.

Using synthetic graphs, we also computed the k-edge sensitivity for $k>1$ (Section 7.4). The settings used to generate synthetic graphs are identical to the experiments for single-edge sensitivity on synthetic graphs, expect that we fixed the number of vertices to 400. After generating graphs, we estimated the k-edge sensitivity with different ratio of removed edges ρ: 0.01, 0.02, 0.03, 0.05, 0.07, 0.1, 0.15 and 0.2 (the graphs are different among experiments for different ρ). More specifically, for a graph with m edges and the ratio of removed edges ρ, the actual number k of the removed edges

(a) ER, average degree: 6 (b) WS, average degree: 6 (c) BA, average degree: 6

(d) ER, average degree: 20 (e) WS, average degree: 20 (f) BA, average degree: 20

Figure 1: Sensitivity on synthetic graphs of different number of vertices

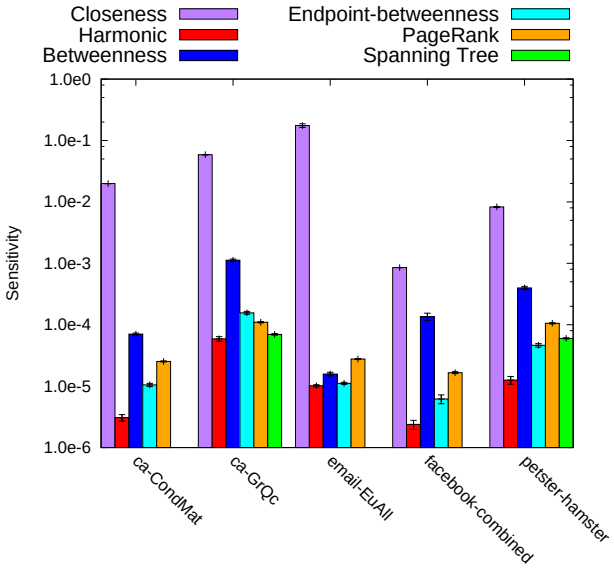


Figure 2: (Estimated) sensitivity of centralities on real-world graphs. The error bars show 1σ ranges.

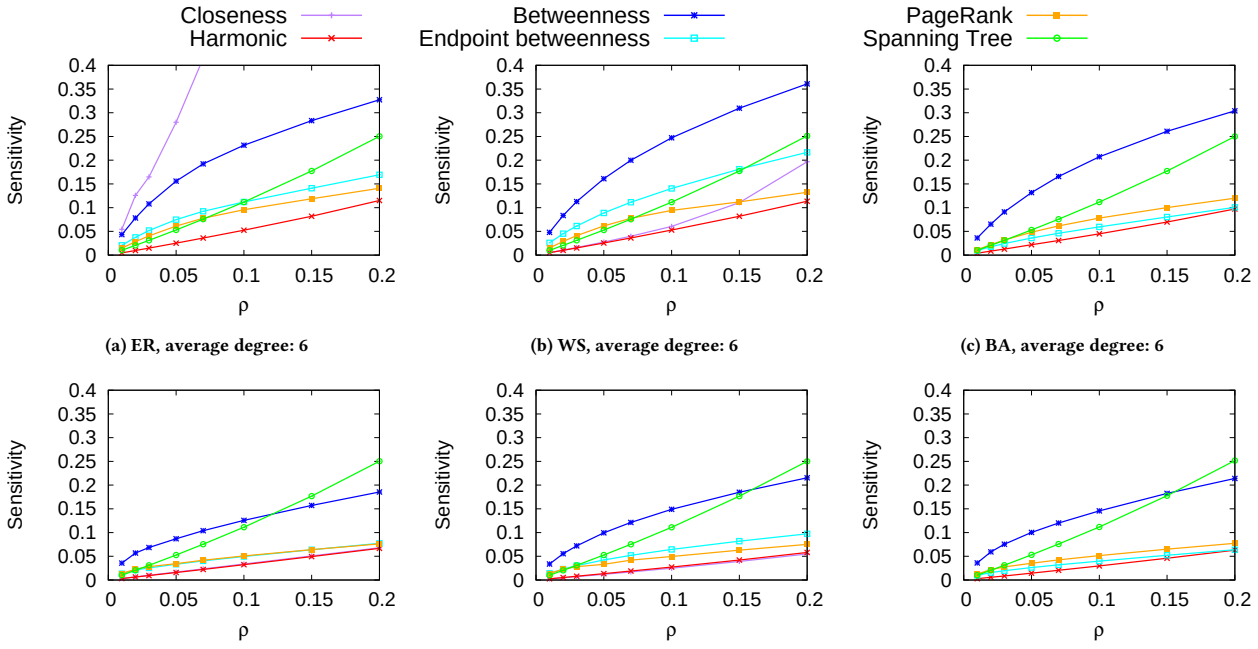
is ρm, rounded to the nearest integer. We estimated the k-edge sensitivity by random sampling with 500 trials (for the spanning tree centrality, 100 trials) of edge removal. The detailed procedure for random sampling is the same as that for estimating sensitivities of real-world graphs.

All the experiments were conducted on a Windows 10 desktop with an Intel Core i9-7960X (2.8GHz) processor and 32 GiB of RAM. Experiment codes were implemented in C++11 and compiled with gcc 5.4.0 on Ubuntu 16.04 on Windows Subsystem for Linux.

7.2 Synthetic graphs

Figure 1 shows the edge sensitivities of the six centralities on synthetic graphs. Some of the generated graphs were disconnected, and we report the average over connected graphs for the closeness centrality because it was not well defined on disconnected graphs. Additionally, as explained in Section 5, the original betweenness centrality suffers from the zero-division problem. Thus, we altered the definition of the sensitivity of the betweenness centrality to



$$\frac{1}{|V||E|}\sum_{e\in E}\sum_{v\in V}\frac{\left|C_{G\setminus e}(v)-C_G(v)\right|}{\max\{C_G(v),C_{G\setminus e}\}}.$$

We let $\frac{|C_{G\setminus e}(v)-C_G(v)|}{\max\{C_G(v),C_{G\setminus e}\}}=0$ when $C_G(v)=C_{G\setminus e}(v)=0$.

We observe that the sensitivity values decrease as the number of vertices increases, except in the case of the closeness centrality in Figure 1a, 1c, and 1f. As explained in Section 5, the sensitivity of the closeness centrality depends to a considerable extent on the number of bridges in the graph. Indeed, the graphs generated by ER with an average degree 6 may have some vertices of degree 1, making the edges adjacent to them bridges. Moreover, BA generates scale-free graphs, in which the degree distribution is highly biased. Thus, it is natural for graphs generated by BA to contain many vertices of degree 1.

On the other hand, in Figure 1b, 1d and 1e, the closeness and harmonic centralities have almost the same stability values. This suggests that the difference in sensitivity between the closeness and harmonic centralities is mainly due to the presence of bridges.

Apart from the inferiority of the closeness centrality on graphs with many bridges, the closeness and harmonic centralities were among the least sensitive, followed by the endpoint betweenness

(a) ER, average degree: 6 (b) WS, average degree: 6 (c) BA, average degree: 6

(d) ER, average degree: 20 (e) WS, average degree: 20 (f) BA, average degree: 20

Figure 3: Multi-edge sensitivity on synthetic graphs with different ratio of removed edges ($n = 400$)

centrality and PageRank. This result is consistent with our theoretical analysis, in which the closeness centrality (without the presence of bridges) and the harmonic centrality have smaller sensitivities than the endpoint betweenness and PageRank.

However, we observe that the sensitivity of spanning tree centrality is consistently less than the endpoint betweenness centrality and PageRank. Although our analysis in Theorem 5.18 states $S_{\mathrm{SP}}(G) = O(\sqrt{n}/m)$, our experimental results suggest that $S_{\mathrm{SP}}(G)$ is almost proportional to $\frac{1}{m}$ on synthetic graphs. Narrowing this gap will be pursued in future work.

7.3 Real-world graphs

In Figure 2, we show approximations to the edge sensitivities of the fix centralities on real-world graphs. We see tendencies that are similar to the results with synthetic graphs: the harmonic centrality was the least sensitive, followed by the spanning-tree centrality, endpoint-betweenness centrality and PageRank, and finally the betweenness centrality. Notably, the sensitivity of the closeness centrality varied significantly depending on the graph, which may caused by different ratios of bridges.

7.4 k-edge sensitivity

In Figure 3, we show the k-edge sensitivities of the six centralities on synthetic graphs. First, we can observe that the ranking among the six centralities with respect to k-edge centrality is almost the same as that with respect to edge sensitivity.

Next, we investigate how sensitivity values change as ρ increases. For all settings and all centralities, the k-edge sensitivity is almost proportional to ρ when ρ is small (specifically, $\rho < 0.05$). For the harmonic centrality and PageRank, this result is consistent with our analysis in Section 6, as our upper bounds for those centralities are linear in k. However, there are gaps between the empirical results and theoretical analysis for the closeness centrality and the betweenness centrality, for which our upper bounds are merely $O(k^2)$. Explaining these gaps is a future work. Also, we can observe that the sensitivity of the spanning tree centrality steadily grows as ρ increases, while others except for closeness tend to slow down. Investigating its reason is also a future work.

8 CONCLUSION

In this work, to compare centralities based on their sensivitity to modifications in the graph, we introduced a quantitative measure called (average-case) k-edge sensitivity, which measures how much the centrality value of a uniformly chosen vertex (or an edge) changes when we remove a uniformly chosen set of k edges. We theoretically gave upper bounds on the k-edge sensitivities of six major centralities. For $k = 1$, we also gave almost matching lower bounds except for the spanning tree centrality. Our experimental results on synthetic and real graphs confirmed the tendency predicted by the theoretical analysis and confirmed that single edge sensitivity can be used as a good proxy for k-edge sensitivity when comparing various centralities in terms of sensitivity against removals of multiple edges.

In this work, we considered edge removal on unweighted graphs as the error model. We suppose we can extend the analysis to other settings, such as edge addition, vertex removal, or graphs with different edge lengths. Analyzing the sensitivity of centralities on such settings will be a subject of future work.

ABSTRACT

Activity logs collected from wearable devices (e.g. *Apple Watch*, *Fitbit*, etc.) are a promising source of data to facilitate a wide range of applications such as personalized exercise scheduling, workout recommendation, and heart rate anomaly detection. However, such data are heterogeneous, noisy, diverse in scale and resolution, and have complex interdependencies, making them challenging to model. In this paper, we develop context-aware sequential models to capture the personalized and temporal patterns of fitness data. Specifically, we propose *FitRec* – an LSTM-based model that captures two levels of context information: context within a specific activity, and context across a user's activity history. We are specifically interested in (a) estimating a user's heart rate profile for a candidate activity; and (b) predicting and recommending suitable activities on this basis. We evaluate our model on a novel dataset containing over 250 thousand workout records coupled with hundreds of millions of parallel sensor measurements (e.g. heart rate, GPS) and metadata. We demonstrate that the model is able to learn contextual, personalized, and activity-specific dynamics of users' heart rate profiles during exercise. We evaluate the proposed model against baselines on several personalized recommendation tasks, showing the promise of using wearable data for activity modeling and recommendation.

1 INTRODUCTION

The development of wearable technologies has given people the opportunity to measure and track their activities via mobile devices (e.g. smart watches). Such devices collect various types of data, including health-related measurements (e.g. heart rate) and contextual measurements (e.g. location, altitude, activity type). An example of such data (from *endomondo.com*) is shown in fig. 1. Harnessing this data to model fitness is beneficial for developing safer and more reliable activity-related services [1]. However, this remains a challenging task for a number of reasons: (1) the collected sequential data are often heterogeneous and the interdependencies among different variables are hard to capture; (2) users' activity patterns and health conditions change over time; and (3) the data has high variance across users, and while large datasets can be easily collected, the amount of data associated with each user is limited.

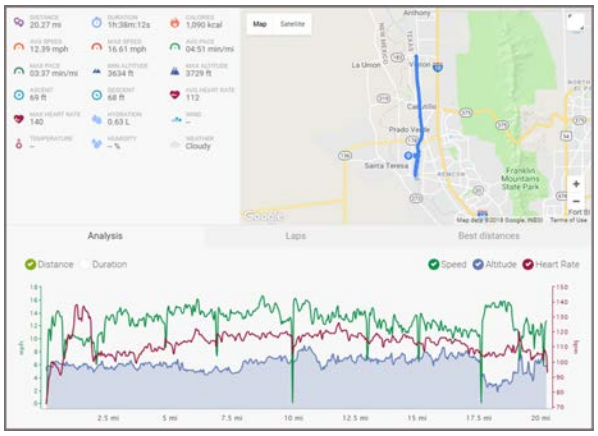

Figure 1: A representative example of our data collected from *endomondo.com*. The figure contains measurements during one workout, including route, speed, altitude and heart rate sequences as well as overall statistics.

Researchers have recently sought to incorporate deep learning techniques to capture the dynamics of sequential data. One of our goals is to adapt such models to capture personalized dynamics in GPS and heart rate data. Recurrent Neural Network (RNN) based models [6, 13] have been proposed to model multivariate sequential data and shown promising performance [5, 20]. Compared with traditional models, RNNs are able to learn complex non-linear relationships between input variables. Furthermore, RNNs are convenient for modeling sequential problems with different input and output structures (e.g. sequential inputs and sequential outputs, or sequential inputs and numerical outputs). This allows us to straightforwardly design model variants for different prediction tasks on our data. More recently, attention mechanisms [3] have further boosted the performance of RNN based models due to their ability to make the model aware of all previous hidden states.

In order to bring state-of-the-art models of sequential data to bear on large datasets of fitness activities, it is important to ask how we can *personalize* models of sequence data to individual users. Personalization is crucial when modeling people's fitness due to the wide variation among individuals. For example, users may differ

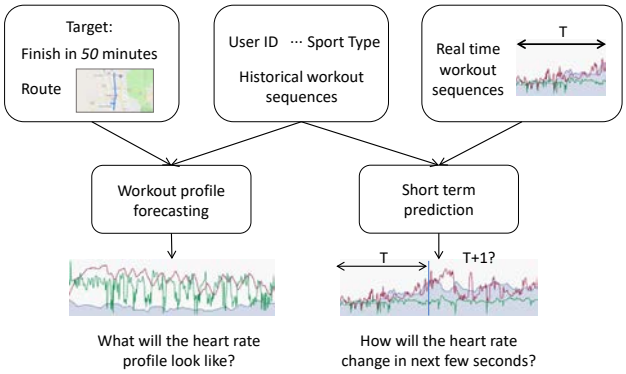

Figure 2: *FitRec* can be applied to two different tasks: workout profile forecasting and short term prediction.

significantly in comfort heart rate zones, adaptation ability for different exercises, etc. Accounting for such differences requires robust modeling techniques to capture the dynamics of both explicit and implicit user-dependent features. An effective model needs to efficiently learn both static and temporal features from historical data.

In this paper, we address these challenges by exploring a large-scale dataset of workout records and building a predictive model leveraging context within and across workouts. Specifically, we propose a Long Short-Term Memory (LSTM) based model *FitRec* that takes as input user attributes and multiple workout measurement sequences. *FitRec* infers static user embeddings based on the attributes and temporal user embeddings from historical workout measurements. By combining these inferred latent representations of our users, *FitRec* can then be applied to (1) Quantitative tasks, such as personalized sequential modeling to predict how workout measurements (e.g. heart rate) will change across a workout, either beforehand (i.e., based on a map of the intended route) or in real time as the user exercises; (2) Qualitative tasks, such as identifying important features that affect workout performance, or identifying clusters of users based on common embedding structures; and (3) Recommendation tasks, such as recommending alternate routes that will achieve a target heart rate profile.

In particular, we evaluate *FitRec* on two quantitative tasks: 'workout profile forecasting' and 'short term prediction' as shown in fig. 2. In the former, we are concerned with predictions such as *estimating a user's likely speed and heart rate profile given the activity they intend to perform* (e.g. cycling a particular GPS route); in the latter we are interested in short-term prediction, e.g. determining during an ongoing workout *how the user's heart rate will change in the next few seconds or minutes*. To apply to both tasks, *FitRec* uses shared embedding layers while adapting a common predictive component: a two-layer stacked LSTM module for workout profile forecasting and an attention-based encoder-decoder module for short term prediction. We also demonstrate the model's capability to provide personalized recommendations that could help users toward their fitness objectives. Workout profile forecasting can be used (for example) to recommend routes that match a user's desired exercise style, while short term prediction might be used to dynamically help a user match their target heart rate. Fitness and activity data have attracted interest in the data mining and recommendation fields because they contain rich contextual information (e.g. spatial and temporal information) about users that might complement existing recommender systems [2]. However, there have been few works studying how these data can be used in real-world recommendation applications.

The key contributions in this paper are threefold:

(1) We propose an LSTM-based model *FitRec* that considers context both within and across workouts. *FitRec* infers static user embeddings from user attributes and meanwhile learns temporal embeddings from users' recent workout sequences. *FitRec* can be applied to various tasks by using either a two-layer stacked LSTM module or an attention-based encoder-decoder module. We show the model's performance compared with prior sequential modeling baselines such as Multilayer Perceptrons (MLP) [15] and Dual-stage Attention-based RNNs (DA-RNN) [25].
(2) We demonstrate that *FitRec* can be used on two real-world recommendation tasks: workout route recommendation and short term heart rate prediction. We evaluate performance in terms of standard recommendation metrics (e.g. AUC, F1-score) and show that our model outperforms strong baselines.
(3) We contribute a workout dataset that contains over 250 thousand workout records with multiple types of heterogeneous sequential signals as well as metadata. To the best of our knowledge, we are the first to release a large-scale dataset of this type. Beyond the recommendation problems considered here, such a dataset has significant potential for re-use in research on heart rate data, sequence modeling, personalization, etc.

While there are several works focused on analyzing human activities, we are (to the best of our knowledge) the first to investigate personalized recommendation using sequential modeling methods on fitness-oriented objectives and to conduct extensive experiments on a real-world dataset.

2 RELATED WORK

Our work focuses on leveraging recent advances in RNN-based sequential modeling for fitness prediction and recommendation. We discuss the related work from each relevant area as follows.

Mining Sensor Data. One line of work falls into the category of *pervasive computing*, which studies how to collect and handle data from mobile and wearable devices. The data may include various types of human behavior such as sleep, exercise, surgery, health, etc. [16, 19, 23]. [1] discusses the challenges and recent advances in population-scale pervasive health research. Their work emphasizes the importance of sensor data for uncovering the causal relationships between human activity and health outcomes. [4] provides an overview of data mining research in the healthcare domain and concludes that the capability to build context-aware and personalized decision systems is important for the pervasive sensing market.

Recently, there is a growing trend toward modeling human wellness using sensor data. Farseev et al. collected users' exercise data and proposed a model to combine social network information to

predict user wellness trends [9]. Particularly, they focused on BMI (Body Mass Index) categorization during several periods for each specific user. [7] focused on detecting physical exercise types given limited training data. They extracted features from exercise data (e.g. heart rate, distance) and proposed an AdaBoost-based method to predict the exercise type (e.g walking, aerobics, running, etc.). Both of these works focus on handcrafting features from sensor data, which are then applied to classification problems. Although similar in data modality, our work differs in terms of the prediction tasks we consider, i.e., sequential modeling and sequence prediction.

Context-aware Modeling. Context-aware models have been successfully applied in many fields with abundant contextual information such as recommender systems, social networks, clinical predictions, etc. [8, 24]. Like these applications, fitness and exercise data naturally has heterogeneous input structure in the form of sequential measurements and contextual information. In [18] a recurrent model was proposed with a context-aware layer for predicting a patient's Blood Pressure (BP). The model considers contextual input (e.g. age, gender, BMI) which is encoded via one-hot vectors or numerical values. Experiments showed that adding this contextual information to the model improves BP prediction accuracy. Unlike their approach, we use attribute embedding and contextual embedding modules consisting of LSTM layers to learn from entire historical sequences. Furthermore, their blood pressure measurement data does not consist of measurements within each activity, which differs from the data we consider.

RNN based sequential modeling. In recent years, Recurrent Neural Networks (RNNs) have shown remarkable effectiveness in modeling sequential data, such as text, audio, and clinical data [20], among others. [17] introduced an LSTM-based model to address traditional multivariate time series prediction problems. They combined Convolutional Neural Networks (CNN) with a recurrent skip layer to capture both long- and short-term dependencies in time series data. The model achieves significant improvements over LinearSVMs and 'vanilla' RNNs. [25] proposed a dual-stage attention model to solve the problem of exogenous time series prediction. They designed an input level attention mechanism along with temporal attention to capture the relations between input variables. Similarly, we incorporate attention mechanisms in sequential data to explore the relations between contextual variables in exercise data.

Personalized Recommendation. Several works on personalized recommendation have tried to incorporate content (e.g. item attributes) and context (e.g. user clicks, purchases) to augment the model in straightforward and typically 'static' scenarios (e.g. e-commerce). Recently, researchers from both industry and academia have sought to develop systems for personalized fitness recommendation. [21] focused on personalized running route recommendation, by considering a variety of targets such as user preferences, goals, and environment. [9] combined workout and social network information from the same user in order to conduct wellness prediction. However, neither of these works focus on modeling sequential fitness data (e.g. heart rate sequences). Though [9] released a public dataset, unlike ours it does not provide complete sequential traces for each workout, but rather includes hand-crafted statistics extracted from each sequence.

Table 1: Notation

Notation	Description
$\mathcal{T}_{train}$, $\mathcal{T}_{test}$	training set and test set for two prediction tasks
$\mathbf{X}, \mathbf{Z} \in \mathbb{R}^{N \times T}$	contextual sequences of the current and the most recent workout
$\mathbf{y}, \mathbf{y}' \in \mathbb{R}^{T}$	target sequence of the current and the most recent workout
$\mathbf{a}$	attributes associated with the workout
T	length of input and target sequences
L	the number of sampled data points L
N	number of contextual sequences and each sequence is associated with a variable.
m	number of attributes
$\lvert a_i \rvert$	number of distinct values of the ith attribute
D_1	dimension of attribute embeddings
D_2	dimension of contextual embeddings
$\mathrm{E}_{a_i} \in \mathbb{R}^{\lvert a_i \rvert \times D_1}$	embedding matrix of the ith attribute
$\mathbf{e}_{a_i} \in \mathbb{R}^{D_1}$	attribute embedding learned from the ith attribute
$\mathbf{e}_t \in \mathbb{R}^{D_2}$	contextual embedding learned from historical workout sequences

While prior work has considered fitness and activity modeling from a variety of perspectives, we believe there is a research gap in terms of studying low-level sequential information (e.g. heart rate, pace) as a means of learning more fine-grained models of users and activities. This motivates us to model and publish a large-scale workout dataset with heterogeneous sequential and attribute data, and to conduct exploratory experiments on fitness recommendation tasks. We expect that our work will facilitate future study of both fitness and personalized heart rate profiling.

3 APPROACH

3.1 Notation and Tasks

Assume we are given N sequences $\mathbf{X} = (\mathbf{x}_1, \ldots, \mathbf{x}_T) \in \mathbb{R}^{N \times T}$ and one target sequence $\mathbf{y} = (y_1, \ldots, y_T) \in \mathbb{R}^T$, where $\mathbf{x}_t = (x_t^1, x_t^2, \ldots, x_t^N) \in \mathbb{R}^N, y_t \in \mathbb{R}$, and $t \in [1, T]$. Here $\mathbf{X}$ can be considered as a combination of various contextual sequences (e.g. distance, altitude) for the current workout and $\mathbf{y}$ is a target measurement sequence (e.g. heart rate, speed). Further we assume there are N historical contextual sequences $\mathbf{Z} = (\mathbf{z}_1, \ldots, \mathbf{z}_T) \in \mathbb{R}^{N \times T}$ and one historical target sequence $\mathbf{y}' = (y'_1, \ldots, y'_T) \in \mathbb{R}^T$, where $\mathbf{Z}$ and $\mathbf{y}'$ are from the most recent workout. For the dataset used in this work, the number of sampled data points L for each sequence of the workouts is equal. Therefore, we also assume the same length T for all sequences in our model. Note that this is not a requirement of our model, but merely a characteristic of the data we collect, in which all sequences are quantized to have the same number of samples regardless of the original workout duration. The model can be adapted to various sequence lengths by a simple padding strategy. Each workout is also associated with multiple attributes $\mathbf{a} = (a_1, \ldots, a_m)$ (e.g. userID, sport type, gender). Our notation is summarized in table 1.

We consider two types of sequential prediction problems: workout profile forecasting and short term prediction.

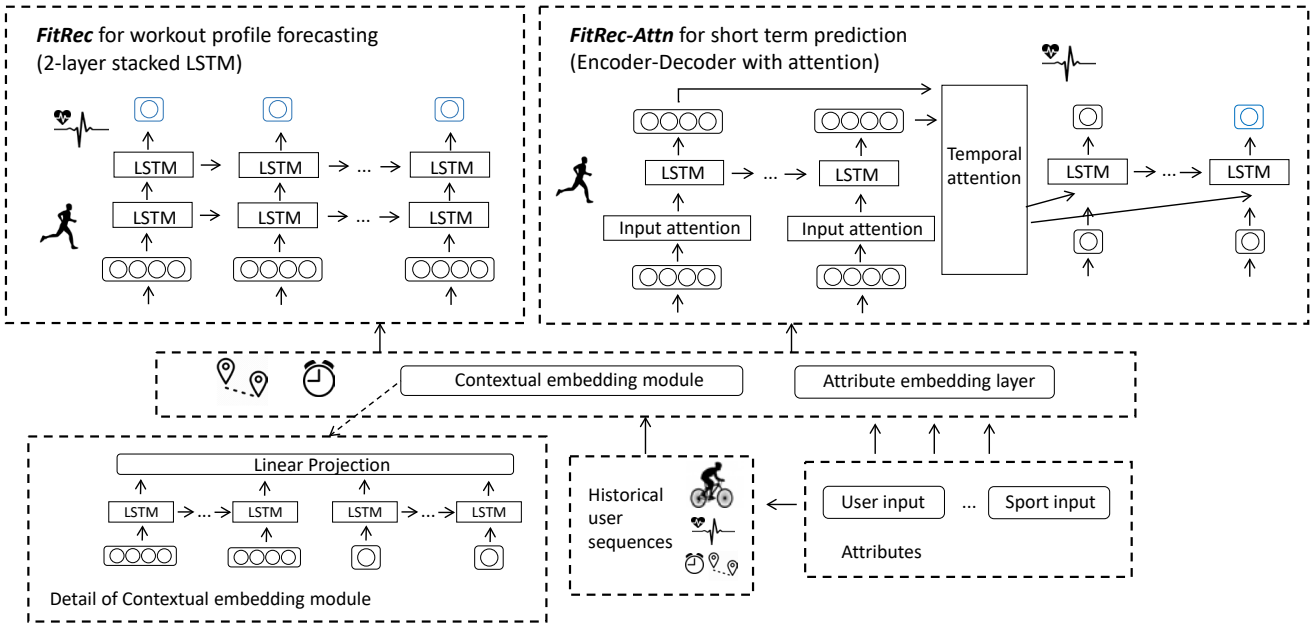

Figure 3: Model structure for workout profile forecasting (*FitRec*) and short term prediction (*FitRec-Attn*). *FitRec* contains a 2-layer stacked LSTM and *FitRec-Attn* has an encoder-decoder module with dual-stage attention. The final outputs are colored in blue.

3.1.1 Workout profile forecasting. Given the contextual sequences $\mathbf{X}$, attributes $\mathbf{a}$ for a candidate workout, historical sequences $\mathbf{Z}$ and $\mathbf{y}'$, as well as the total time of the workout, predict the entire target sequence $\mathbf{y} = (y_1, \ldots, y_T)$. Notably, the input and target sequences correspond to the whole workout and T equals the total length L of the workout. This prediction task might correspond to a scenario where a user specifies a route as well as their desired total time (i.e. how much time they plan to spend on the workout), and the system estimates their likely heart rate profile.[1]

3.1.2 Short term prediction. Given the contextual sequences $\mathbf{X}$, attributes $\mathbf{a}$ for a candidate workout, historical sequences $\mathbf{Z}$ and $\mathbf{y}'$, as well as the previous target sequence $(y_1, \ldots, y_{T-1})$, predict the target output y_T at time step T. Here the input and target sequences correspond to a fixed window of one workout (i.e. part of the whole workout) and T equals the window size (i.e. T is smaller than L). This task is essentially a form of auto-regressive modeling that allows us to predict short term heart rate dynamics during an activity.

3.2 Relation Between the Two Tasks

Our two tasks differ in terms of their given inputs, prediction outputs, and application scenarios as shown in fig. 2.

Workout profile forecasting aims to predict a user's workout performance (including speed and heart rate) given an expected workout time and route. The goal is to predict the overall trends and characteristics of each measurement (e.g. max/min/avg heart rate) before the user starts the workout. As a result, the model can help the user find workout plans that meet their expectations on performance, or could be used to find alternate workout routes that are similar to their previous routes in terms of how the user will respond to them. This model can be adapted to applications such as training schedule recommendation, alternative route recommendation, etc.

On the other hand, short term prediction focuses on forecasting sequential measurements during an ongoing workout. This is similar to traditional problems of time series prediction with exogenous variables [11, 25] but differs in that fitness data has measurements both within and across activities which need to be modelled separately. Short term prediction is useful in scenarios like anomaly detection and real-time decision making (e.g. advising a user that they should slow down in the next minute to avoid exceeding their desired maximum heart rate).

3.3 Model Structure

As shown in fig. 3, we propose two models: *FitRec* for workout profile forecasting and *FitRec-Attn* for short term prediction.

Both models share the same basic structure consisting of a contextual embedding module and an attribute embedding layer. These layers encode user attributes and historical information into an embedded representation that captures their latent individual attributes (e.g. their cardiovascular fitness, endurance, etc.) and can facilitate personalized prediction. Following the embedding layers, the two models have different predictive components. As shown on the top left of fig. 3, *FitRec* consists of a 2-layer stacked LSTM which simultaneously outputs the prediction of the target variable at all time steps. *FitRec-Attn* includes an encoder-decoder network with

[1] We also experimented with a variant where the total time was *not* provided as input, but found there to be excessive variance between (e.g.) running/sprinting/jogging styles such that heart rates could not be reliably estimated without first knowing a rough intended speed.

an attention mechanism that outputs the prediction at each time step one by one as shown on the top right of fig. 3. We describe the details for each component as follows.

3.3.1 LSTM to process sequences. In both models, we use Long Short-Term Memory (LSTM) [13] to process the input and target sequences. Given the input sequence $\mathbf{X} = (\mathbf{x}_1, \ldots, \mathbf{x}_t, \ldots, \mathbf{x}_T)$, an LSTM learns an update function

$$\mathbf{h}_t = f(\mathbf{h}_{t-1}, \mathbf{x}_t), \tag{1}$$

where $\mathbf{h}_t$, $\mathbf{h}_{t-1}$ are the hidden states of the LSTM at time step t and $t-1$, respectively, and $\mathbf{x}_t$ is the input at time step t. Different from traditional RNNs, the LSTM cell introduces several gates and memory cells. We follow the LSTM structure from [25, 28]:

$$\begin{aligned} \begin{pmatrix} \mathbf{i} \\ \mathbf{f} \\ \mathbf{o} \\ \mathbf{g} \end{pmatrix} &= \begin{pmatrix} \text{sigmoid} \\ \text{sigmoid} \\ \text{sigmoid} \\ \tanh \end{pmatrix} \mathbf{W} \begin{pmatrix} \mathbf{h}_{t-1} \\ \mathbf{x}_t \end{pmatrix} \\ \mathbf{s}_t &= \mathbf{s}_{t-1} \odot \mathbf{f}_t + \mathbf{i}_t \odot \mathbf{g}_t \\ \mathbf{h}_t &= \tanh(\mathbf{s}_t) \odot \mathbf{o}_t, \end{aligned} \tag{2}$$

where $\mathbf{s}$ is the cell state; $\mathbf{g}$ is the activation function applied on the input; $\mathbf{i}$, $\mathbf{o}$ and $\mathbf{f}$ are three sigmoid gates ('input,' 'output,' and 'forget,' respectively); and $\mathbf{h}$ is the hidden state of the cell. W is the learned weight matrix.

In the following sections, we use the notation 'LSTM' to represent the complete update function of an LSTM cell and ignore the cell state $\mathbf{s}$ for simplicity.

3.3.2 Context within and across activities. To address the difficulties in building personalized models, we consider learning attribute embeddings and contextual embeddings associated with the current workout. Specifically, for each attribute input (e.g. user, sport type, gender), we use attribute embedding layers to obtain latent representations of these attributes:

$$\mathbf{e}_{a_i} = \mathrm{E}_{a_i}(a_i), \forall i \in [1, m] \tag{3}$$

where $\mathbf{e}_{a_i}$ is the embedding for attribute a_i.

To extract contextual features from historical activity measurements, we use two LSTMs to process the historical sequences $\mathbf{Z}$ and $\mathbf{y}'$ respectively, then concatenate them and feed them into a linear projection layer to obtain a contextual embedding:

$$\begin{aligned} \mathbf{h}_{1,t} &= \mathrm{LSTM}_1(\mathbf{z}_t, \mathbf{h}_{1,t-1}), \\ \mathbf{h}_{2,t} &= \mathrm{LSTM}_2(y'_t, \mathbf{h}_{2,t-1}), \\ \mathbf{e}_t &= \mathbf{W}_e[\mathbf{h}_{1,t}; \mathbf{h}_{2,t}] + \mathbf{b}_e, \end{aligned} \tag{4}$$

where $\mathbf{h}_{1,t}$ and $\mathbf{h}_{2,t}$ are the hidden states of the two LSTMs, $\mathbf{e}_t$ is the projected contextual embedding, and $\mathbf{W}_e$ and $\mathbf{b}_e$ are trained parameters.

After obtaining these embeddings, they are repeated at each time step and concatenated with the contextual embedding and the input variables:

$$\mathbf{u}_t = [\mathbf{x}_t; \mathbf{e}_t; \mathbf{e}_{a_1}; \ldots; \mathbf{e}_{a_m}], \tag{5}$$

where $\mathbf{u}_t$ is the new concatenated contextual sequence input at time step t. The sequences $\mathbf{u} = (\mathbf{u}_1, \ldots, \mathbf{u}_T) \in \mathbb{R}^{K \times T}$ are then fed into the cascaded predictive module for different tasks. Here K is the dimension of each $\mathbf{u}_t$.

3.3.3 FitRec. We use a 2-layer LSTM model with a projection layer on the output for the workout profile forecasting problem, which we call *FitRec*:

$$\begin{aligned} \mathbf{h}_t &= \mathrm{LSTM}(\mathbf{u}_t, \mathbf{h}_{t-1}), \\ \hat{y_t} &= \mathrm{SELU}(\mathbf{W}_{NAT}\mathbf{h}_t + \mathbf{b}_{NAT}), \end{aligned} \tag{6}$$

where $\mathbf{h}_t$ is the hidden state of the LSTM's second layer, SELU is the scaled exponential linear unit activation function and $\mathbf{W}_{NAT}$ and $\mathbf{b}_{NAT}$ are learned parameters. The MLP output layer's dimension is set as the sequence length T. As shown in fig. 3, *FitRec* will output the prediction for the whole workout (all T time steps) simultaneously.

3.3.4 FitRec-Attn. Inspired by the success of the dual-stage attention RNN in modeling sequential data [25], we build *FitRec-Attn* – a dual-stage attention encoder-decoder model on top of the attribute and contextual embedding module for short term prediction.

Given the concatenated contextual sequences $\mathbf{u}$, we process them using an encoder LSTM with input attention. Input attention helps to find the importance of each input dimension among the concatenated contextual sequences. Consider $\mathbf{u}^k = (u_1^k, \ldots, u_T^k)$ for the kth input dimension of $\mathbf{u}$. An attention score s_t^k is calculated for $\mathbf{u}^k$ and the previous encoder hidden state $\mathbf{h}_{t-1}$, which represents the importance of that dimension at time step t. The weight is used to scale the original input and build a new input sequence $\tilde{\mathbf{u}_t} = (\alpha_t^1 u_t^1, \ldots, \alpha_t^K u_t^K)$:

$$\begin{aligned} s_t^k &= \mathbf{v}_s^\top(\mathbf{W}_s[\mathbf{h}_{t-1}; \mathbf{u}^k] + \mathbf{b}_s)\ 1 \le k \le K, \\ \alpha_t^k &= \frac{\exp(s_t^k)}{\sum_{j=1}^K \exp(s_t^j)}, \end{aligned} \tag{7}$$

where α_t^k is the normalized attention score, and $\mathbf{v}_s$, $\mathbf{W}_s$ and $\mathbf{b}_s$ are learned parameters. The newly computed $\tilde{\mathbf{u}}_t$ is used to update the encoder LSTM_e:

$$\mathbf{h}_t = \mathrm{LSTM}_e(\mathbf{h}_{t-1}, \tilde{\mathbf{u}}_t). \tag{8}$$

Following the encoder, a decoder LSTM with temporal attention is used to predict the target y_t. Specifically, the temporal attention score is calculated for each decoder hidden state $\mathbf{d}_t$ and all encoder hidden states, which represents how much the encoder hidden state is related to the decoder. Then the attention scores are used as weights to produce a context vector $\mathbf{c}_t$:

$$\begin{aligned} l_t^i &= \mathbf{v}_l^\top(\mathbf{W}_l[\mathbf{d}_{t-1}; \mathbf{h}_i] + \mathbf{b}_l)\ 1 \le i \le T, \\ \beta_t^i &= \frac{\exp(l_t^i)}{\sum_{j=1}^T \exp(l_t^j)}, \quad \mathbf{c}_t = \sum_{i=1}^T \beta_t^i \mathbf{h}^i \end{aligned} \tag{9}$$

where l_t^i and β_t^i are the attention score and normalized attention score for the t^{th} decoder hidden state and the i^{th} encoder hidden state. $\mathbf{v}_l$, $\mathbf{W}_l$ and $\mathbf{b}_l$ are learned parameters.

Once the context vector is obtained, it is concatenated with the previous target variable y_{t-1} and used to update the decoder LSTM:

$$\begin{aligned} \tilde{y}_{t-1} &= \tilde{\mathbf{w}}^\top[y_{t-1}; \mathbf{c}_{t-1}] + \tilde{b}, \\ \mathbf{d}_t &= \mathrm{LSTM}_d(\mathbf{d}_{t-1}, \tilde{y}_{t-1}), \end{aligned} \tag{10}$$

where $\tilde{y}_{t-1}$ is a linear transformation of the concatenated context variable and target variable at time step t (as in [25]).

Given the previous target sequence $(y_1, \ldots, y_{T-1})$, each y_{t-1} is processed sequentially and $\mathbf{c}_t$ and $\mathbf{d}_t$ are updated. Finally, we obtain the context vector and hidden state $\mathbf{c}_T$ and $\mathbf{d}_T$ at the last time step T. These two are fed into a linear output layer to predict the target variable $\hat{y_T}$ as shown in fig. 3:

$$\hat{y_T} = \mathbf{W}_{AT}[\mathbf{d}_T; \mathbf{c}_T] + \mathbf{b}_{AT}, \tag{11}$$

where $\mathbf{W}_{AT}$ and $\mathbf{b}_{AT}$ are learned parameters.

3.4 Objective Function

For both workout profile forecasting and short term prediction, we use the mean squared error as our loss function:

$$\mathcal{L} = \frac{1}{|N_{train}|} \sum_{\mathbf{y} \in \mathcal{T}_{train}} \sum_{t=1}^{L} (\hat{y_t} - y_t)^2, \tag{12}$$

where $|N_{train}|$ is the number of total time steps for all workouts in the training set, and L is the total length of each workout.

4 EXPERIMENTS

In this section, we first introduce the *Endomondo* dataset, a new real-world dataset for empirical study. Then we conduct experiments on this dataset and show the performance of our models for the two prediction tasks.

4.1 The Endomondo Dataset

We collect data from *endomondo.com*. The data includes both measurements (i.e., heart rate, timestamps, distance, speed) and contextual data (i.e., longitude, latitude, altitude, gender, sport, user identity). The original data has a high rate of missing measurements for distance and speed, presumably due to the fact that these fields are only available from certain devices. Hence we further introduce two derived sequences: (1) **derived distance**: Calculate the distance between two data points given their latitudes and longitudes via the Haversine formula [26]; (2) **derived speed**: Divide the derived distance and the time interval between two data points. In our experiments, we use the derived speed instead of the original speed (which we found to be unreliable due to missing data or erroneous magnitude values).

Table 2 lists the variables we use in this work ('Seq.' denotes whether the variable is sequential or not; 'Der.' denotes that a variable is derived). Our data includes several other variables such as weather, hydration, humidity, calories, cadence, etc., though these variables are much sparser than the variables listed (some are only available for certain sport types, or from certain wearables); we leave the exploration of these data for future work.

We discard abnormal data points based on simple rules (e.g. overly large magnitude, mismatching timestamps, abrupt changes in GPS coordinates).[2] We further keep users with at least 10 workout records to make sure there is enough data to evaluate our personalization strategies. Table 3 summarizes our dataset. The original dataset contains 253,020 workout records for 1,104 users.[3] After filtering, there are 167,373 workout records for 965 users. On average each user has over 175 workout records that cover an average span of around 2 years. This makes the dataset promising for the purpose of studying long-term temporal variation among users.

[2]Which may occur due to sensor error, or more simply due to a user forgetting to disable the device after returning to their car (for example).

[3]We collected a contiguous block of workouts, after which we collected the complete workout histories for all users represented in that block.

Table 2: Description of variables

	Variable	Seq.	Unit
Measure-ment	Heart Rate	✓	Beat per Minute (BPM)
	Timestamp	✓	Unix Timestamp
	Distance	✓	Mile
	Speed	✓	Mile per Hour (MPH)
Context-ual	UserID	✗	/
	Sport	✗	/
	Gender	✗	Male, Female
	Altitude	✓	Meter
	Longitude	✓	Degree
	Latitude	✓	Degree
Derived	Der. Distance	✓	Kilometer (KM)
	Der. Speed	✓	Kilometer per Hour (KMPH)

Table 3: Endomondo dataset statistics

Statistic	Original	Filtered	Re-sampled
# of workouts	253,020	167,373	102,343
# of users	1,104	956	887
Avg. length (hours)	5.998	1.486	1.059
Avg. span (days)	/	766	733

The original sequences as collected from *Endomondo* each contain $L = 500$ data points which are not necessarily sampled in fixed-width intervals. The sampling interval may vary from seconds to minutes. Rather than considering the problem of imputing missing values across long intervals, we simply discard workouts with sampling intervals greater than 1 minute. Furthermore, the workout data are truncated to 450 time points (out of an original 500) to account for the fact that many of the workouts tend to complete before the full 500 time-steps (e.g. during a user's cooldown).

For the problem of short term prediction, it is important to have a version of the dataset with a fixed sampling interval (i.e., so that our predictions always correspond to a fixed amount of seconds in the future). To this end, we produce a second version of the dataset that is re-sampled into fixed intervals using cubic spline interpolation followed by resampling in 10-second intervals. We discard workouts in cases where resampling generates out-of-bounds values. After resampling, we further discard those workouts with fewer than 300 samples (i.e., 300×10 seconds). Finally, we maintain a subset of 102,343 workout records as shown in table 3.

Our data are highly multi-modally distributed, as the relationship between variables for one user differs significantly from that of other users, and the structure of the data for one sport differs significantly from that of other sports (e.g. bicycling uphill vs. downhill results in quite different heart rate patterns than running uphill vs. downhill). Our experiments show that the proposed models are able to learn these complex relations among variables.

Table 4: Parameter settings in our experiments

Model	*FitRec*	*FitRec-Attn*
Hidden Size	64	64
Attribute embed. size	5	5
Contextual embed. size	64	64
Dropout	0.2	0.1
L2 Regularizer	0.01	0.002
Batch Size	512	5120
Learning Rate	0.001	0.005

4.2 Training Procedure

We sort each user's workouts in chronological order based on the first timestamp of each workout. Then we split and aggregate users' first 80% of workouts for training, the next 10% for validation and the final 10% for testing. This is to make sure the contextual information of a workout in the test set does not appear in the training set. During training, the target data are not scaled while the input data are scaled by representing the data points in terms of their z-scores.

We used Keras[4] and Pytorch[5] to implement our models. Our models are trained using Adam [14]. We set the size of the LSTM hidden state, attribute embedding and contextual embedding as 64, 5, and 64, respectively. Attribute embeddings are randomly initialized and learned from scratch. We add dropout before and after each LSTM layer and an ℓ_2 regularizer on attribute embeddings and contextual embeddings.

The best hyper-parameters are obtained via grid search on the validation set. The learning rate is chosen from {0.001,0.005,0.01}, the dropout rate from {0.1,0.2,0.3}, and our ℓ_2 regularizer from {0.002, 0.005,0.01, 0.02}. The detailed parameter settings are as shown in table 4. Training is terminated after 50 epochs. The model that achieved the best evaluation score on the validation set was run on the test data to obtain the final performance score. To train the models with contextual embeddings, we found it more stable to use a pre-training technique. Specifically, we first initialize the model parameters using the best model without contexutal embeddings, then continue training until convergence. All code and data are available publicly.[6]

4.3 Evaluation Metrics

We choose two popular metrics in sequential modeling: the Root Mean Squared Error (RMSE) and Mean Absolute Error (MAE) to evaluate performance on our two prediction tasks:

$$\text{RMSE} = \sqrt{\frac{1}{|N_{test}|} \sum_{\mathbf{y} \in \mathcal{T}_{test}} \sum_{t=1}^{L} (y_t - \hat{y_t})^2} \tag{13}$$

$$\text{MAE} = \frac{1}{|N_{test}|} \sum_{\mathbf{y} \in \mathcal{T}_{test}} \sum_{t=1}^{L} |y_t - \hat{y_t}|, \tag{14}$$

where $|N_{test}|$ is the number of total time steps of all workouts on the test set $\mathcal{T}_{test}$. Note that in our setting the two metrics have quite different semantics. For example, a model which correctly identified heart rate 'trends' but was shifted in time or scale might be considered an acceptable model; such predictions would incur a high MSE but a more moderate MAE.

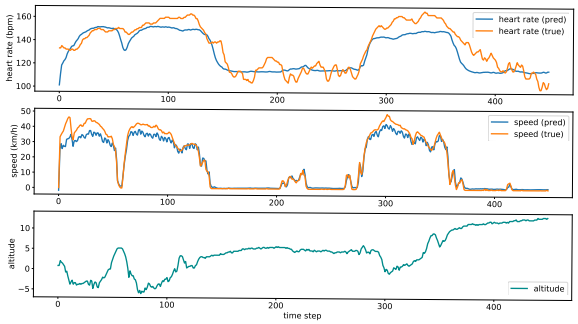
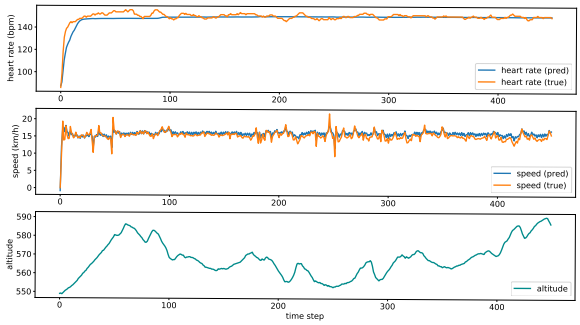
Table 5: Workout profile forecasting on speed and heart rate. *: significantly better than the second best score ($p < 0.05$).

	Speed (KMPH)		Heart rate (BPM)	
Model	RMSE	MAE	RMSE	MAE
Global mean (train)	11.997	8.532	24.302	18.185
User mean (train)	10.690	6.418	20.117	15.090
MLP	8.998	4.411	18.256	13.918
FitRec (U)	7.144	2.472	18.784	14.142
FitRec (U/S)	7.073	**2.381**	17.325	13.012
FitRec (U/S/G)	7.328	2.396	18.207	13.831
FitRec (U/S/C)	**7.025***	2.384	**17.051***	**12.847***



4.4 Results: Workout profile forecasting

We compare *FitRec* to two baselines and also conduct ablation tests. Our baselines are:



- **Global mean**. Predict the target variable at each time step as the global mean of the training set.
- **User mean**. For each workout from a user u, predict the target variable at each time step as the mean value of all u's sequences in the training set. This serves as a naïve personalized baseline.
- **MLP**. A variant of a traditional Multilayer Perceptron that concatenates the learned attribute embeddings, contextual embeddings and contextual inputs together as its input. The MLP predicts the target variable at each time step simultaneously. The dimension of the MLP's output layer is the total length of the sequence. This baseline is used to demonstrate that the LSTM component of *FitRec* is better at modeling these contextual inputs compared to an MLP.
- **FitRec** (U). *FitRec* model with user embedding only.
- **FitRec** (U/S). *FitRec* model with user embedding and sport embedding.
- **FitRec** (U/S/G). *FitRec* model with user embedding, sport embedding and gender embedding. This model is used to measure whether the gender embedding improves *FitRec*.
- **FitRec** (U/S/C). *FitRec* model with user embedding, sport embedding and contextual embedding.

We use *FitRec* to predict two types of workout profile: (1) speed and (2) heart rate, given the expected workout time and a specified route. In particular, the route is given as a distance sequence and an altitude sequence along the complete workout.

As shown in table 5, *FitRec* (U/S/C) with all embeddings outperforms each of the traditional baselines. Specifically, it decreases the RMSE of the best baseline (MLP) by 21.93% and 6.6% on speed prediction and heart rate prediction, respectively. The user mean baseline achieves lower RMSE and MAE than the global mean baseline, demonstrating the need for personalized models for this task. *FitRec* (U) with user embeddings achieves further improvements over the user mean baseline, which shows the efficacy of the learned embeddings in capturing individual patterns of users.

(a) Biking

(b) Running

Figure 4: Examples of predicted heart rate for different sports, altitude has much greater influence on heart rate and speed change when biking as compared to running (for example).

Furthermore, our ablation tests exhibit improvements due to the attribute embeddings and the contextual embedding. *FitRec* (U/S/C) outperforms *FitRec* (U) and *FitRec* (U/S), except for the MAE on speed prediction. This may be because speed is sensitive to sport type, and the previous workout that we use to learn the contextual embedding has a different sport type from the current workout; in such cases the contextual embedding may not be informative. Missing data issues aside, this model could, in the future, be straightforwardly extended to consider other attributes such as weather, humidity, etc.

It is also surprising to find out that an auxiliary gender embedding does not help improve the prediction accuracy of our model: *FitRec* (U/S/G) performs worse than *FitRec* (U/S). There are a few possible reasons. One is that our data includes 863 males, 80 females and 13 unknown users. Such an imbalance in data might make it difficult to learn patterns across different genders. Another possibility is that the user embedding might already encode the user's gender information. As such, an auxiliary gender embedding does not bring any further benefit to the model.

Figure 4 gives examples of the predicted heart rate and speed for biking and running instances. In both cases the predicted sequences closely match the trend of the ground-truth during the workout. Notably, *FitRec* is able to learn the semantics of different sport types. For example, entering a downhill portion of a bike ride causes a user's heart rate to drop substantially, whereas running downhill does not result in a heart rate reduction.

Table 6: Short term heart rate prediction. *: significantly better than the second best score ($p < 0.05$).

Model	Heart rate (BPM) RMSE	MAE
Windowed MLP	3.035	1.919
Seq2Seq+A	2.807	1.720
DA-RNN	2.816	1.733
FitRec-Attn (U)	2.795	1.705
FitRec-Attn (U/C)	**2.783***	**1.695***

4.5 Results: Short term prediction

For short term prediction, we consider three baselines for auto-regressive modeling and conduct ablation tests to compare against the performance of *FitRec-Attn*.

The baselines are:

- **Windowed MLP** [10]. A conventional time series model that considers a sliding window of the target variable's previous values, and predicts the target variable at the current time step.
- **Seq2Seq+A** [6]. A competitive encoder-decoder baseline that is widely used in sequential modeling. This model includes temporal attention between the encoder and decoder.
- **DA-RNN** [25]. A state-of-the-art attention based RNN model for auto-regressive time series modeling with exogenous variables. The model includes an input attention mechanism that assigns weights to each input variable as well as temporal attention.
- **FitRec-Attn** (U). *FitRec-Attn* model with user embedding only.
- **FitRec-Attn** (U/C). *FitRec-Attn* model with user embedding and contextual embedding.

Because our ablation tests showed that the gender embeddings did not improve results for short term prediction, we did not include them in this section.

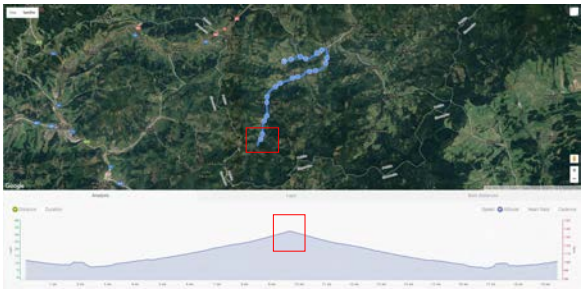
We use *FitRec-Attn* to predict the heart rate at each time step t given the speed and altitude sequences, the previous $T-1$ heart rate values, as well as the attribute embeddings and contextual embedding. We choose $T = 10$ in the experiments. We also experimented with $T = 5, 15, 20$ and found that values greater than 10 yield marginal improvement. When implementing Seq2Seq+A and DA-RNN, we only use speed and altitude sequences since they do not include the embedding modules for user and contextual embeddings. The baseline windowed MLP only considers the previous $T-1$ heart rate values as in traditional autoregressive models.

As shown in table 6, *FitRec-Attn* (U/C) achieves the best performance compared with the other baselines. When only considering speed and altitude as inputs, attention-based Seq2Seq outperforms the more sophisticated DA-RNN. This may be because that the number of input variables is relatively small (2 in this case), leaving the input attention of DA-RNN as but a source of extraneous complexity. On the other hand, by incorporating user embeddings and contextual embeddings, *FitRec-Attn* (U/C) improves results on both metrics compared to DA-RNN. This demonstrates the effectiveness of input attention when the input variable is high dimensional.

Table 7: Route recommendation performance

	AUC	Hit@10	NDCG
User mean (train)	0.500	0.100	/
MLP	0.506	0.106	0.212
FitRec (U)	0.639	0.214	0.262
FitRec (U/S)	0.643	0.234	0.266
FitRec (U/S/C)	**0.673**	**0.272**	**0.284**

5 PERSONALIZED RECOMMENDATION



So far we have shown the effectiveness of our model at generating 'black box' heart rate predictions given contextual inputs. In this section we illustrate the ability of *FitRec* to provide personalized recommendations in practice. We consider the following two recommendation tasks:

- Workout route recommendation: Given expected workout criteria (e.g. an expected workout time, an idiosyncratic heart rate or speed curve), we suggest routes (i.e. historical routes from all users) that will match the user's expectation. This might be applied if a user has particular heart rate targets in mind, or simply wishes to identify alternate routes that are 'similar to' (in terms of heart rate profile) a route a user has taken previously. Such a system could be used (for example) by a user who is traveling but wants to maintain their regular exercise routine by identifying qualitatively similar routes.
- Short term heart rate prediction: Predict whether a user's heart rate will exceed some threshold if they continue at the current pace during their workout. This might be used to build a personalized assistant that guides a user's behavior (e.g. speed up or slow down) during a workout.

5.1 Route Recommendation

5.1.1 Evaluation Methodology. We evaluate our route recommendation task in terms of ranking performance. To do so, we first use *FitRec* to generate a ranked list of candidate routes, given a user's expected workout criteria. Then, for each workout in the test set (positive sample), we consider its route (i.e. distance and altitude sequences) as the positive route, and randomly sample another 100 workouts as negative routes. That is, given target workout criteria (heart rate etc.) as input, we are evaluating the model's ability to correctly identify the real workout that generated these criteria by assigning it a higher score than randomly chosen alternatives. Given these positive and negative routes, *FitRec* generates a predicted heart rate sequence for each of them. The similarity between the predicted sequences and the ground-truth heart rate sequence is calculated using fast dynamic time warping (fastDTW) [27]. We use DTW to measure similarity rather than the ℓ_2 loss because it is less sensitive to temporal shifting.

After sorting these similarity scores in descending order, we obtain the ranked list of all routes, and are interested in the ranked position of the positive route amongst the negative routes. Here we consider three recommendation metrics that are commonly used in ranking-based recommendation [12]: AUC, Hit Rate@K (Hit@K) and Normalized Discounted Cumulative Gain (NDCG). AUC accounts for the overall ranking of the positive route, Hit@K measures whether the positive route appears in the top K of the list, and the NDCG uses a graded relevance criterion to evaluate the overall quality of the ranking.

(a) Map of the ground-truth route.

(b) Map of the recommended alternate route.

Figure 5: Examples of a recommended route. The model recommends an alternate route that is similar to the ground-truth (i.e., both routes are comparable hill-climbs).

5.1.2 Performance Analysis. Table 7 shows the performance of route recommendation on the test set. We find that baseline models exhibit poor performance on personalized route modeling: (1) The user mean baseline does not take into account the route (i.e., distance, altitude) information; and (2) the MLP model considers routes as input during learning, but fails to rank the positive routes higher than other routes (its AUC of 0.506 is close to that of the User Mean baseline). On the other hand, *FitRec* with user embeddings is able to recognize the difference between routes and outperforms baseline models in all metrics. After adding the attribute embeddings and contextual embedding, the model's performance is further improved.

Figure 5 presents an example of a recommended route given by our model (i.e., the route ranked first on the ranked list, other than the ground truth) along with the ground-truth route. As the route map shows (marked in blue),[7] both the ground truth route and the recommended route are 'hill climbs' of approximately the same length and difficulty (the red bounding box in each route map is the region with the greatest altitude during the workout). This shows the effectiveness of the model to recommend alternate but semantically similar routes.

[7] Snapshot from *endomondo.com*

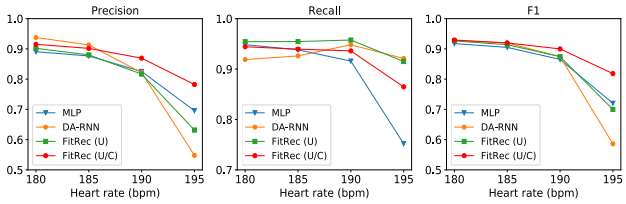


Figure 6: Performance of short-term excessive heart rate prediction

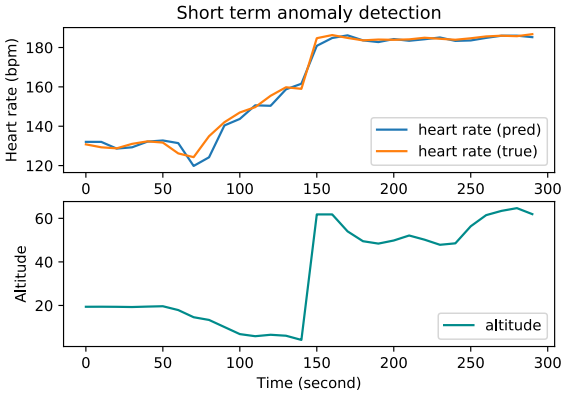

Figure 7: Example of short term excessive heart rate prediction.

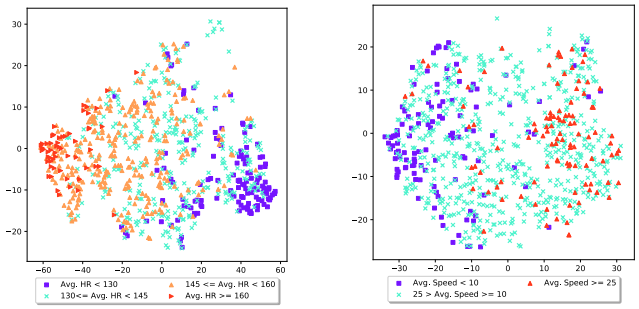

5.2 Short term heart rate prediction

The goal of this task is to predict whether a user's heart rate will exceed some level if the user continues their workout at the current speed. We assume there is a threshold value predefined by each user that she/he considers to be a desirable maximum heart rate. We consider four different threshold values: 180, 185, 190, 195 and compute three metrics to demonstrate the effectiveness of our model to anticipate rapid heart rates in test sequences.

5.2.1 Evaluation Methodology. For each workout we construct two binary sequences $(b_1, \ldots, b_L)$ and $(b_1^*, \ldots, b_L^*)$ (of predictions), where b_t / b_t^* equals 1 if the groundtruth / predicted (respectively) heart rate at timestep t exceeds a pre-defined threshold (zero otherwise). We then calculate Precision, Recall, and Macro-F1 scores based on these two binary arrays to evaluate the performance of predicting whether the speed will exceed the threshold.

5.2.2 Performance Analysis. Figure 6 demonstrates the performance of *FitRec-Attn* when given different threshold values. As we can see, *FitRec-Attn* (U/C) achieves a better F1-score compared to other baseline models for all threshold values. Specifically, the improvement of *FitRec-Attn* increases as the threshold value increases.

Figure 7 shows an example of short term heart rate prediction. Note that for this task, the model takes as input the observed heart rate values for the previous $T-1$ time steps; therefore the prediction is more accurate than in our previous experiment. In the figure we see an abrupt change in altitude, following which the model successfully predicts the heart rate will reach a high value (i.e. over 185 BPM).

(a) User embedding learned for heart rate prediction.

(b) User embedding learned for speed prediction.

Figure 8: 2d t-SNE of the learned user embedding, and its relationship to user segments in terms of heart rate and speed.

5.3 What have the user embeddings learned?

To qualitatively explain what has been captured by the learned user embeddings, we use t-SNE [22] to project them into low-dimensional vectors. Figures 8a and 8b show the 2d t-SNE of the user embeddings learned for the tasks of predicting heart rate and speed, respectively.

For heart rate, we calculate the average heart rate of each user based on all of their workouts. We classify them into four categories by threshold values: < 130, < 145, < 160, and ≥ 160 (BPM). Similarly for speed, we calculate the average speed of each user for all of their workouts. We classify them into three categories by thresholds: < 10, < 25, and ≥ 25 (KM per Hour). As shown in figs. 8a and 8b, users that fall into the same class (i.e., with similar average heart rate and average speed) seem to have closer user embeddings.

6 CONCLUSIONS

We present *FitRec* – a system that addresses sequential prediction problems in fitness and exercise data and can serve as a building block for developing personalized fitness recommendation applications. We achieve this by learning embedded representations from auxiliary information such as user identity, sport type and historical workout sequences, each of which is incorporated into an LSTM based sequential modeling framework. We verify that the model is capable of providing high quality prediction on tasks centered around estimating users' heart rate sequences, such as workout profile forecasting and short term prediction. We conduct extensive experiments on a new real-world dataset and demonstrate that the model outperforms other baselines without auxiliary embedded representations consistently on both tasks. Furthermore, the model shows promising performance on recommendation tasks such as recommending alternate workout routes and short-term excessive heart rate prediction. Visualizations also show that the learned embedded representations are useful for identifying distinct user segments. In the future, we are interested in applying *FitRec* to recommendation tasks with more complex scenarios (i.e. safety-aware route recommendation) and incorporating other auxiliary data (i.e. interactive recommendation).

ABSTRACT

Product descriptions play an important role in the e-commerce ecosystem, conveying to buyers information about a merchandise they may purchase. Yet, on leading e-commerce websites, with high volumes of new items offered for sale every day, product descriptions are often lacking or missing altogether. Moreover, many descriptions include information that holds little value and sometimes even disrupts buyers, in an attempt to draw attention and purchases. In this work, we suggest to mitigate these issues by generating short crowd-based product descriptions from user reviews. We apply an extractive approach, where review sentences are used in their original form to compose the product description. At the core of our method is a supervised approach to identify candidate review sentences suitable to be used as part of a description. Our analysis, based on data from both the Fashion and Motors domains, reveals the top reasons for review sentences being unsuitable for the product's description and these are used, in turn, as part of a deep multi-task learning architecture. We then diversify the set of candidates by removing redundancies and, at the final step, select the top candidates to be included in the description. We compare different methods for each step and also conduct an end-to-end evaluation, based on rating from professional annotators, showing the generated descriptions are of high quality.

1 INTRODUCTION

The importance of content on e-commerce websites has been widely recognized. High-quality and trusted product content has been empirically shown to have a substantial influence on user behavior, which is manifested in conversion rates and the volume of sales [28, 35, 39]. Product descriptions are an important element of the content displayed on product pages, alongside the product's title, image, and key attributes, such as model name, color, or size. Yet, such descriptions are often lacking or missing; for example, the majority of the Fashion products on eBay have no description at all. Even when available, product descriptions are often long and tedious to read, containing a lot of information that is insignificant for potential buyers. Our own analysis indicates that substantial portions of the product description sentences include details specific to a single listing or seller, information about the brand as a whole, and pure marketing statements.

We refer to a *product description* as a written (textual) presentation of what the product is, how it can be used, and why it is worth purchasing. The purpose of a product description is to provide customers with details about the features and benefits of the product so they are compelled to buy.[1] In line with previous research on e-commerce content, we expect a good description to be informative, readable, objective, and relevant to the product (e.g., as opposed to a specific listing or a whole brand) [58]. We focus on concise descriptions of several sentences, which can be quickly consumed in their entirety and are especially suitable for small-screen devices, as e-commerce mobile applications have seen a remarkable growth and account for a major portion of the overall e-commerce traffic [29, 31]. Like other types of product content, credible descriptions have been shown to increase sales, while lacking descriptions withhold users from reaching a purchase decision or effectively searching for products [36].

In light of the aforementioned challenges, we propose to use the "crowd" to generate trustworthy product descriptions, by leveraging the products' user reviews [15, 27, 38]. Such reviews are often abundant on e-commerce websites and reflect the perspective of those who have already purchased the product. Therefore, potential buyers tend to trust reviews much more than they trust seller-provided content [30, 59].

User reviews primarily aim at reflecting a buyer's subjective perspective and include personal opinions, stories, experiences, and complaints, which are not suitable to include in a product description (e.g., "*My old shoes wore down and I needed a new pair*" or "*I can plug it to each of my three cars*"). The large volumes of user reviews accumulated for popular products, with each review typically containing multiple sentences, makes them practically

[1] This definition is largely based on that by the Shopify e-commerce platform: https://www.shopify.com

impossible to consume. As a result, users often read only a few reviews and may miss helpful information that appears in others. We observe that some portion of the review sentences are descriptive of the product [15], and suggest an extractive approach to generate *crowd-based* descriptions by combining original review sentences.

The transformation from reviews to descriptions is a challenging task, which to the best of our knowledge, is novel. While reviews aim to reflect the buyer's perspective, descriptions typically reflect the viewpoint of the seller. Moreover, while reviews are meant to reflect a variety of subjective opinions, descriptions are expected to provide objective fact-based information. Several prior studies have examined review summarization (e.g., [26, 45, 71]), however such summaries do not necessarily contain descriptions of the product.

Our extraction of candidate sentences from user reviews, to be included in the product depiction, is primarily supervised. We examine both classic machine learning models and deep learning approaches for the classification task, trained over thousands of sentences in two key e-commerce domains: Fashion and Motors. We also analyze the key reasons making review sentences unsuitable for a description. A deep multi-task learning classifier, which is based on mapping the top reasons to auxiliary tasks, is found to yield the best performance for the candidate identification task.

Following, we select the top sentences out of the candidate set for the final product description. To this end, we use a sentence similarity measure that helps diversify and avoid redundancies. Semantic similarity based on word embedding is found to be more effective than a bag-of-words approach. We experiment with several basic methods to produce the final description, which rely on the classification score from the candidate extraction process and the similarity measure. We perform a large-scale evaluation of the descriptions based on thousands of ratings from professional annotators, comparing the different methods and inspecting three description lengths: 3, 5, and 7 sentences.

The main contributions of this work can be summarized as follows:

- To the best of our knowledge, this is the first work to suggest the extraction of product descriptions from reviews.
- We provide analysis and examples of how review sentences can be used for descriptions (what portion, which kind of sentences) across two principal yet very different e-commerce domains.
- We develop a classifier for identifying review sentences suitable for product descriptions, reaching an AUC of over 0.92.
- We present an end-to-end system for description generation from reviews, comparing different approaches for sentence selection, reaching an average rating of 4.3 (out of 5) per description.

2 RELATED WORK

Textual product descriptions have been explored in the e-commerce literature along with other seller-provided product content types, such as titles [19, 52], images [6, 20], and attributes [52, 55]. Some of the studies refer to the product description in a broad sense, which encompasses the other content types, e.g., the list of structured attributes [2], title [66], or product image [48]. Other studies refer to a product description similarly to us, as the textual writeup that extends the title and attributes. Probst et al. [57] studied the extraction of attribute-value pairs from such product descriptions, in order to enrich the product's structured representation, used for tasks such as recommendation and matching. Shinzato and Sekine [62] proposed an unsupervised approach for the same task. Dumitru et al. [11] applied text mining and clustering techniques over product descriptions in order to recommend product features for a given domain. In a recent study, Pryzant et al. [58] showed that product descriptions of the type we study can help predict the product's business outcome. Experimentation was based on product descriptions and sales records from the Rakuten Japanese e-commerce website. None of these studies, however, provided a definition of a product description as presented in this work.

As mentioned in the Introduction, a related task to the one we explore is review summarization. Different from standard text summarization [18], where the goal is to generate a concise summary for a single [64] or multi-document [40], review summarization aims at extracting and summarizing opinions about a product from multiple reviews [45, 70]. Most studies focus on identifying the key attributes of an entity, such as a product, a movie, or a hotel, and then extracting key phrases that describe these attributes or the sentiment towards them (e.g., [26, 37, 56, 73]). Techniques used for this type of summarization include rule-based mining [42], topic modeling [51, 67], and neural networks [46, 68]. An overview of review summarization techniques can be found in several surveys [32, 41, 43, 54].

While summarization seeks a good coverage of the main topics within the set of reviews, sometimes revolving around key product attributes, we aim to identify a unique subset of the reviews' content that is descriptive of the product . A sentence that may be pivotal to the set of reviews, and thereby for its summary, might not be appropriate for a description. For example, the sentence "*I like this hat very much*" may be included in a review summary, but poses low value for a product description, as it is subjective and provides little information about the product. In our experiments, described later in this paper, we found that fewer than 10% of the review sentences were suitable "as is" to take part in the product description.

Another related body of research has focused on extracting experiences [50, 53] and tips [21, 72] from user reviews. Somewhat similarly to the motivation presented in this work, these studies aim at helping users sift through the large volumes of reviews by identifying a more specific type of information within the reviews. Nonetheless, extracting experiences and tips is each inherently different than extracting descriptive sentences: experiences are subjective in nature, reflecting the unique viewpoint of an individual user (or group) and are thus not suitable, almost by definition, to be part of a product description. Tips, on the other hand, are defined as concrete and typically actionable pieces of advice. Therefore, their extraction actually aims at excluding purely descriptive sentences, of the type pursued in this work.

3 DATASETS AND CHARACTERISTICS

In this section, we describe the datasets used for our analysis and experimentation and their characteristics.

Datasets. Our research is based on two product datasets from two principal yet very different e-commerce domains: Fashion (clothing, shoes, and jewelry) and Motors (automotive parts and

Table 1: Fashion and Motors dataset characteristics.

	Fashion				Motors			
	Avg	Std	Median	Max	Avg	Std	Median	Max
Reviews per product	1118	1371	596	8271	883	985	378	7352
Sentences per review	3.71	3.09	3	103	4.05	3.73	3	98
Words per sentence	8.04	6.43	6	58	9.24	7.26	7	63
Number of products	892				807			
Number of reviews	997,274				712,904			

accessories). Both datasets were obtained from a large e-commerce website in the United States, representing best-selling products in each of the two domains.[2] The datasets contain, per product, both its description and user reviews. Table 1 presents the characteristics of the two datasets. The number of products is rather similar in both datasets, while for Fashion there are more reviews per product and for Motors the number of sentences per review and their length in words is slightly higher. In addition, we used two larger datasets with over 10 million reviews of over 10,000 best-selling products in each domain (Fashion and Motors), for pre-training word embeddings, as will be described later in this paper.

Data Annotation. Labeling for training and evaluation in this work was performed by in-house professional editors (annotators), with domain expertise in both Fashion and Motors. The pool included a total of 20 editors, of whom different subsets were selected for different tasks, proportionally to the task's size. Unless otherwise stated, each evaluation was performed by a single editor.

Description Characteristics. The descriptions in our dataset are substantially longer than those we aim to generate. The average number of sentences per description in the Fashion dataset is 28.2 (std: 12.9, median: 27, min: 11, max: 65) and for motors it is 26.8 (std: 12.1, median: 29, min: 9, max: 68). To get a preliminary sense of the content of these descriptions, 50 descriptions from each dataset were annotated by two professional annotators. Only 45% of the sentences were labeled as suitable for a product description, with the key reasons for the sentences not being adequate including purely subjective marketing statements, accounting for slightly over 20% of the sentences (e.g., "*Give your clothes the luxury they deserve with these wonderful hangers!*"); information specific to a seller or a listing (18%; "*1 year limited warranty*"), and description of the brand as a whole (15%; "For over 35 years, we have been one of the largest sunglasses brands.")

Reviews vs. Descriptions. In essence, reviews and descriptions hold fundamentally contrasting characteristics: reviews reflect a subjective opinion based on an individual experience, while descriptions are expected to be "dryer", explaining what the product is and why it is worth purchasing. As a first step, we set out to examine the most prominent language differences between reviews and descriptions. To this end, we used Kullback-Leibler (KL) divergence, which is a non-symmetric distance measure between two given distributions [4]. Specifically, we calculated the terms, per each of the two domains, which contribute the most to the KL divergence between the language model of the reviews versus the language model of the descriptions and vice versa [22].

[2]As of July 2018.

Table 2: Most distinctive unigrams for reviews vs. descriptions ('Reviews') and vice versa ('Descriptions') in Fashion and Motors.

Fashion		Motors	
Reviews	Descriptions	Reviews	Descriptions
i	your	i	power
my	designed	my	generator
it	you	it	protection
they	features	was	your
was	comfort	great	fuel
but	jewelry	but	torqx
very	cotton	have	portable
great	imported	so	provides
good	inches	works	uego
these	fashion	this	economy
them	polyester	good	watts
bought	technology	they	designed
me	provides	very	advanced

Table 2 presents the most distinctive unigrams. It can be seen that the unigram list most characterizing reviews (relative to descriptions) is rather similar between Fashion and Motors. The first-person pronouns 'i' and 'my' are at the top of the two lists, both common on reviews yet hardly occurring on descriptions. For example, 'i' occurs on 3.43% of the Fashion review sentences and 3.11% of the Motors review sentences, whereas for descriptions it occurs on 0.03% and none of the sentences for both datasets, respectively. Other prominent unigrams on the review lists include 'was', which typically reflects a past-tense experience ('bought' can also be observed on the Fashion list); the third-person pronouns 'it' and 'they'; the adjectives 'good' and 'great', which often reflect a subjective opinion; and the emphasizing adverb 'very'. Further down the list, beyond Table 2, we also encountered unigrams that refer to aspects of a specific listing of the product, which may vary from one seller to another, such as 'price', 'cheap', and 'shipping'; other third-person references such as 'she' or 'son'; and verbs that reflect subjectivity ('recommend', 'like', 'love') or past tense ('arrived', 'purchased', 'got', 'ordered').

The most characterizing unigrams for descriptions relative to reviews are more dissimilar between Fashion and Motors. As can be seen in Table 2, each list includes its own domain-specific descriptive words, such as 'jewelry', and 'cotton' for Fashion, or 'power' and 'fuel' for Motors. The second-person pronoun 'your' ranks high on both lists, indicating that while first- and third-person language is used almost exclusively on reviews, second-person language is more characteristic of descriptions (e.g., 'your' occurs on 1.34% of the Fashion description sentences versus only 0.18% of the review sentences). The only other common words between the two lists are 'provides' and 'designed'.

Overall, the above analysis gives an indication of the key differences in the language of reviews versus descriptions. Following, review sentences to be used as part of a description need to be carefully selected. We elaborate on this process in the next section.

4 CANDIDATE SENTENCE EXTRACTION

In this section, we describe a key component of our description generation method: the extraction of candidate review sentences that can be used for the product's description. Given the set of all user reviews for the product, our goal is to identify a set of sentences

that can be used in their original form for a description of the same product. We first apply rule-based filtering based on the analysis presented in the previous section. We then apply a supervised approach that learns to identify review sentences suitable for a description. We examine different types of classifiers for this task and compare their performance based on a large labeled set of review sentences.

4.1 Rule-Based Filtering

Considering our analysis of linguistic differences between descriptions and reviews, we established several simple rules to identify review sentences that cannot be used as part of a description: (1) **Short**: sentences of 3 words or fewer generally introduce little information and do not flow well as part of a product description. For example, "*Recommended*", "*Very good quality*", or "*no complaints*", as well as "*good fit*" or "*very soft*" for Fashion and "*easy to install*" or "*works as expected*" for Motors, were among the most common short review sentences in our datasets. Overall, short sentences accounted for 17.1% of all review sentences in the Fashion domain and 17.9% in Motors. (2) **Personal**: sentences with a first-person pronoun, such as 'i', 'my', 'our', or 'us', or a 3rd-person *personal* pronoun, such 'she', 'his', 'hers', but not 'it' or 'them'. As demonstrated in the previous section, such pronouns hardly ever occur on a product description. Examples include "*I like the color of these jeans*"; "*Perfect fit for our car*"; "*My husband makes good use of them"; and "best gift for his birthday*". Overall, 35.9% of the review sentences matched this filtering criterion in the Fashion domain and 37.8% in Motors. (3) **Listing-specific**: Some review sentences refer to listing-specific aspects, as observed in the previous section. Examples include "*Great value for a fair price*" or "*Delivery was smooth and fast*". Since our goal is to produce a description at the product level rather than the listing (item) level, such aspects are not suitable for referencing as part of the description, since they may vary according to the seller. Our blacklist for this rule included the unigrams 'price', 'cheap', 'expensive', 'delivery', 'shipping', 'seller', and 'warranty'. Overall, 5.7% of the review sentences matched this rule in the Fashion domain and 6.1% in Motors.

Our rules aim to filter out sentences that are not suitable for a description with a very high likelihood, almost by definition. We therefore did not filter out other potential candidates, such as sentences in past tense, since these can sometimes be appropriate (e.g., "Tested on several cars"). We also did not automatically filter out sentences from reviews with low ratings, because the vast majority of the reviews in our dataset had a positive rating, in line with past work that indicated online user reviews tend to the positive [8]. Overall, 53.7% and 55.2% of the review sentences were filtered out using the three rules above, for Fashion and Motors, respectively.[3]

4.2 Automatic Classification

After the initial rule-based filtering, we set out to explore a supervised approach, where we trained a classifier to predict whether a product review sentence is suitable as a description sentence for the same product. To this end, we sampled uniformly at random, out of all review sentences that were not filtered out by the rules, 25K sentences for each of the two datasets, Fashion and Motors. Each of the 25K sentences were then labeled by a group of 10 annotators, who were asked to mark them as either '*good*' or '*bad*', i.e., suitable to be part of a product description or not. In case the sentence was labeled *bad*, the annotators also selected a reason. The set of reasons was identified in an earlier round of labeling, and included 'other' in case none of the 10 reasons was appropriate. The annotators received detailed guidelines, explaining what makes a sentence suitable versus unsuitable for a description, with examples of *good* and *bad* sentences, as well as examples for each of the possible reasons for *bad*. They also performed qualification tests, i.e., an iterative process of labeling, followed by feedback from other annotators, until the quality was aligned among all. At the end of the process, the inter-annotator agreement for the task of *good* versus *bad* labeling, measured by Cohen's kappa [9], was 0.89 for Fashion and 0.9 for Motors, calculated over a set of 300 sentences labeled by two different annotators. Overall, 8.55% of the Fashion and 7.97% of the Motors sentences were labeled *good*.

Table 3: Reasons for review sentences labeled '*bad*' and their distribution (portion of all sentences marked *bad*) for Fashion and Motors.

Reason	% Fashion	% Motors	Example
Subjective	52.50%	52.43%	It was the easiest jumpstart ever.
Missing context	16.86%	16.82%	Otherwise it remains idle.
Refers to a listing's aspect	8.40%	6.73%	10 bucks for 3 pairs is a great deal.
Non-informative	7.95%	6.42%	This shirt is great.
Poor language and spelling	4.91%	5.17%	Extremly easy setup let's you pull you vehecle's code fast.
Negative sentence	3.90%	4.25%	Only issue is the pretty thin material.
Expresses explicit doubt	2.40%	2.30%	Probably good also for bicycle tires.
Refers to the description	1.83%	1.74%	The hat is exactly as described.
Other	1.49%	1.24%	Like others here have said, this gas can has a long rotating nozzle.
Too specific/detailed	0.64%	2.52%	Great for Honda 2003 2.0L.
Offensive language	0.12%	0.19%	Fantastic product, bright as sh*t.

Table 3 lists the different reasons for *bad* sentences. It can be seen that the distribution is similar for Fashion and Motors, with subjective sentences accounting for a little over half of the *bad* sentences in both, followed by sentences with a missing context. The only noticeable difference between the domains is for the too specific/narrow reason, which is generally uncommon, but occurred substantially more frequently in Motors.

4.2.1 Good vs. Bad Review Sentences. Before building our classifier, we performed a statistical analysis comparing the review sentences labeled *good* by our annotators with review sentences labeled *bad*.

Table 4 presents the most distinctive unigrams and bigrams for *good* review sentences versus *bad* review sentences and vice versa, for Fashion and Motors. Distinctive terms were calculated using KL divergence as described in Section 3. It can be seen that *good* sentences in both domains include positive adjectives and adverbs, such as 'easy' and 'very', which are at the top of both unigram lists, as well as 'great', 'sturdy', 'nice', and 'well', which are used to describe products as easy to use/install/assemble; being of good/high quality or well made; or being perfect/excellent/great for a specific use. While many of the terms are common for both domains, in Fashion traits such as comfortable, durable, or fitting

[3]The portions of all three rules do not sum up to the total number of filtered sentences, since some sentences matched more than one rule.

Table 4: Most distinctive unigrams and bigrams for *good* sentences vs. *bad* sentences ('*Good*') and vice versa ('*Bad*') in Fashion and Motors.

Fashion				Motors			
Good	*Bad*	*Good*	*Bad*	*Good*	*Bad*	*Good*	*Bad*
easy	was	easy to	a little	easy	was	easy to	it was
very	but	good quality	it was	very	but	to use	so far
sturdy	not	well made	so far	great	it	very easy	than the
quality	it	very sturdy	a bit	use	would	to install	better than
comfortable	love	perfect for	but the	install	not	works great	a little
nice	than	are very	as expected	quality	than	good quality	a bit
well	as	they fit	they were	works	had	well made	seems to
great	buy	great for	but it	well	as	to apply	as advertised
durable	had	high quality	happy with	nice	buy	very well	as described
is	would	to assemble	but they	your	this	comes with	happy with

well are salient, while in Motors aspects of installation, application, and work are more dominant. For *bad* sentences, there is also a substantial overlap between the domains, implying the language differences between *good* and *bad* sentences can be generalized. The list of terms reflects some of the key reasons for sentences not fitting into a description, such as subjective viewpoints (e.g., 'better than', 'happy with', 'love'), personal experiences in past tense ('it was'), expression of doubt ('seems to'), negative sense ('but', 'not') and a reference to the description itself ('as described', 'as advertised').

Table 5 shows the portion of sentences labeled as *good* according to various characteristics of the sentence and the review it originated from, for Fashion and Motors. Inspecting the sentence length, starting 4 words, it can generally be seen that shorter sentences are somewhat more likely to be labeled *good*. For Fashion, the "optimal" sentence length is 6-8 words, while for Motors the percentage of *good* sentences consistently decreases with the length. Long sentences are more likely to include expressions that would make them unsuitable for a description based on some of the reasons detailed in Table 3, particularly subjectivity, which is the most common. Looking at the length of the review, it can be observed that sentences originating from long reviews are less likely to be *good*. For both Fashion and Motors, the review length that yields the highest portion of *good* is 3 sentences. Finally, inspecting the position of the sentence within the review (while controlling for the review length), there is a consistent trend indicating that sentences that occur towards the beginning of the review (not necessarily the first sentence) have higher likelihood to be *good*. The last sentence of the review has a particularly low likelihood to fit a description. This trend is consistent for Fashion and Motors and persists for higher review lengths not shown in Table 5. Overall, it suggests that users are more likely to include descriptive details earlier in the review.

4.2.2 Supervised Approaches. For the *good* versus *bad* classification task, we experimented with both traditional machine learning models and deep learning approaches. For the latter, we examined the effect of an attention mechanism and the use of a multi-task learning approach that tries to predict a reason for a sentence being inadequate for a description. We used 5-fold cross-validation to tune the hyper-parameters and evaluate the classifiers. As evaluation metric, we used the area under the ROC curve (AUC).

Table 5: Percentage of *good* sentences in Fashion ('F') and Motors ('M') distributed by sentence length, review length, and sentence position within the review.

Sentence length (words)		4	5	6	7 – 8	9 – 10	11 – 12	13 – 15	16+
	F	9.22%	9.96%	10.21%	10.38%	8.32%	7.81%	6.69%	6.05%
	M	11.07%	9.91%	9.43%	8.86%	7.42%	6.86%	6.60%	6.63%
Review length (sentences)		1	2	3	4	5 – 6	7 – 9	10+	
	F	7.49%	9.19%	10.27%	9.46%	8.33%	8.11%	6.81%	
	M	9.15%	10.04%	10.30%	9.88%	8.24%	6.69%	5.66%	
Sentence position in review				1st	2nd	3rd	4th	5th	
	F	Review length 3		11.48%	9.24%	8.90%			
		Review length 4		10.67%	11.16%	7.02%	5.27%		
		Review length 5		8.92%	10.99%	8.72%	6.64%	4.35%	
	M	Review length 3		12.25%	8.78%	7.56%			
		Review length 4		11.31%	10.76%	7.97%	6.82%		
		Review length 5		9.89%	11.50%	8.88%	5.59%	3.86%	

Table 6: AUC performance results for classifying review sentences as *good* or *bad* for the product's description.

Classifier	Fashion	Motors
Naïve Bayes	0.779	0.798
XGBoost	0.831	0.839
LSTM	0.914	0.916
LSTM-Attention	0.915	0.916
LSTM-MTL	**0.924**	**0.924**

Naïve Bayes and XGBoost. We examined two common models for text classification: Naïve Bayes [60] and XGBoost [7]. Our features included textual features, specifically the unigrams, bigrams, and trigrams of the review sentence, and statistical features of the sentence and originating review, based on Table 5. For Naïve Bayes, we tuned the type of n-grams (unigrams, bigrams, or trigrams) and for XGBoost, in addition, the maximum depth of a tree, minimum child weight, as well as the learning rate and number of rounds (trees). Results for both classifiers are presented at the top rows of Table 6, indicating XGBoost achieved a higher AUC.

To better understand the contribution of non-textual features, which are based on the characteristics presented in Table 5, we trained the XGBoost classifier with different feature subsets (while always using textual features). Feature types included sentence length (in words and characters), review length (in words and sentences), and position (absolute position and normalized by the total number of review sentences). Results, presented in Table 7, indicate that position features yielded a slightly higher performance gain than sentence and review length. Overall, however, as can be observed in the 'All' row, the contribution of these features on top of the textual features was minor (+0.97% for Fashion and +0.96% for Motors). We therefore did not use these features in the remainder of our experiments and worked with the review text only.

While the XGBoost classifier demonstrated reasonable performance, we set out to explore how it can be further enhanced. In recent years, various applications in text classification have shown significant improvement by the use of deep learning models [17, 34].

Table 7: AUC performance of the XGBoost classifier with textual features when using ('Only') or disregarding ('Exclude') additional types of features. The 'All' row refers to all additional types jointly.

Additional Features	Fashion		Motors	
	Only	Exclude	Only	Exclude
Sentence Length	0.824	0.828	0.833	0.835
Review Length	0.828	0.826	0.835	0.834
Sentence Position	0.829	0.828	0.837	0.836
All	0.831	0.823	0.839	0.831

We therefore explored several deep learning approaches for our task:

LSTM. A recurrent neural network based on long short-term memory (LSTM) [25] architecture, with pre-trained word2vec embeddings using continuous bag of words (CBOW) with negative sampling [49]. We experimented with pre-training over Wikipedia and over our own datasets of more than 10 million product reviews for Fashion and Motors, respectively, as described in Section 3. Pre-training using our own data, with separate models for Fashion and Motors, consistently achieved a slightly better performance. We henceforth only report the results when using word2vec pre-trained based on our own data.

LSTM with Attention. Attention mechanisms enable the network to focus on relevant parts of the input [69]. The overall architecture of the "attention network" consists of two components: an LSTM-based word sequence encoder and a word-level attention layer. Given a review with the words $w_i, i \in [1, N]$, we first embed the words using pre-trained word2vec, as previously described. We then use the LSTM network to produce the hidden states $h_i, i \in [1, N]$. The attention mechanism is subsequently used to put more focus on certain words in the review sentence. For example, in the sentence "*this is a high quality product*" the words "*high quality*" should receive higher weight. We feed the word annotation h_i through a single-layer perceptron network to receive u_i, a latent representation of h_i. Then, we calculate the similarity of u_i with a word-level context vector, normalized by a softmax function, to produce the word's importance weight. We then construct the review vector as a weighted sum of the word annotations based on each word's weight.

Deep Multi-Task Learning. Multi-task learning (MTL) is based on the idea that features trained for one task can be useful for related tasks. Models for all tasks of interest are jointly trained with an additional linkage between their trainable parameters, aiming at improving the generalization error [5]. Multi-task learning can be viewed as a form of inductive transfer learning, which can help improve the model by introducing an inductive bias. In the case of MTL, the inductive bias is provided by the *auxiliary tasks*, which lead the model to prefer hypotheses that explain more than one task. MTL has been widely used for deep learning tasks, e.g., in computer vision [16] and natural language processing [23, 63].

Our network is based on an MTL hard parameter sharing architecture [61], which includes an LSTM layer shared among all tasks and separate feed-forward networks per task. We learned the task of predicting if a review sentence could be included as part of a description (*good*/*bad*) with the additional auxiliary tasks that specialize on a specific reason, particularly each of the top four reasons listed in Table 3, which cover over 80% of the *bad* sentences in both Fashion and Motors. Each specialized classifier is trained to predict if the sentence falls under the specific reason for not fitting in a description. For example, the 'subjectivity' classifier learns to predict subjective sentences. Overall, the specialized classifiers may help the main task of predicting *good* or *bad* sentences. Similarly to the LSTM with attention, given a review sentence, we first embed the words using our pre-trained word2vec, and then use the shared LSTM encoder to produce the latent representation of the review sentence. This representation is then fed in parallel into 2-5 fully-connected feed-forward networks (one per task), each with two hidden layers, trying to predict the output for that task independently. The ultimate loss function to be optimized assigns a weight to each of the task-specific loss functions. Notice the weighted loss function serves for optimization at training time, while testing remains for the *good* versus *bad* task only. In Figure 1, we demonstrate our MTL hard parameter sharing network, with a shared LSTM layer and 5 separate feed-forward layers, one for each task.

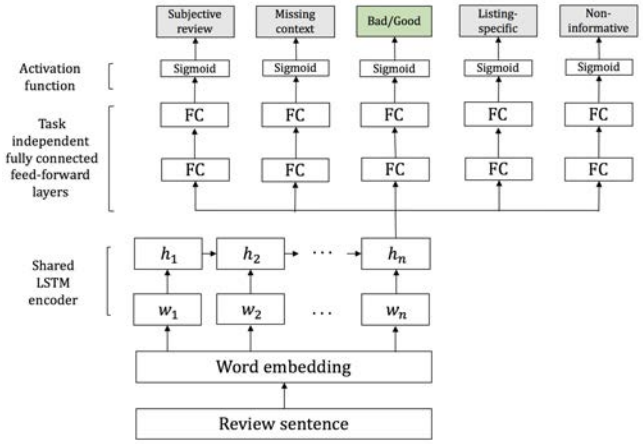

Figure 1: Hard parameter sharing for deep multi-task learning architecture.

For each of the three deep learning methods, hyper-parameter tuning included the batch size, the dropout rates, and the number of hidden units in the LSTM layers. In addition, we experimented with both Adam [33] and RMSProp [65] optimizers. For the MTL architecture, we also tuned the subset of tasks to be included and their weight in the loss function, as well as the dropout rates and number of hidden units of the feed-forward layers.

4.2.3 Performance Results. Table 6 presents the AUC results for the *good* versus *bad* task. Evidently, the deep learning classifiers achieved substantially better results than the Naïve Bayes and XGBoost classifiers. The attention mechanism did not lead to any performance gain, possibly due to the sentences' length: as shown in Table 1, the median number of words per review sentence is 6 and 7, for Fashion and Motors, respectively. The effectiveness of the attention mechanism, however, typically lies in longer sentences [44]. The LSTM-based MTL model achieved the best AUC

Table 8: AUC performance of the deep MTL classifier with different subsets of the four auxiliary tasks: subjective ('subj'), missing context ('MC'), listing-specific ('LS'), and non-informative ('NI').

Fashion		Motors	
Subj, MC, LS, NI	0.921	Subj	0.920
LS, NI	0.922	MC, LI	0.922
Subj	0.922	MC, LS, NI	0.923
Subj, LS, NI	0.923	SUBJ, MC	0.923
Subj, MC	**0.924**	**Subj, MC, LS, NI**	**0.924**

results for both datasets, Motors and Fashion. Table 8 presents the auxiliary task subsets that yielded the best performance. For Motors, the combination of all four auxiliary tasks led to the best performance, while for Fashion it was the combination of the subjective and missing context tasks. Indeed, these are the two most common reasons for sentenced being labeled *bad*, as shown in Table 3. Other combinations listed in Table 8 yielded close performance to the top ones. Noticeably, using only one auxiliary task – for identifying subjective sentences – produced a substantial part of the performance gain compared to the vanilla LSTM, especially for Fashion. As previously shown (Table 3), 'subjective' is the most common reason, covering over half of the *bad* sentences for each of the two domains.

As mentioned before, we compared Adam and RMSProp optimizers. The latter was found to perform better, slightly but consistently across different number of tasks, for both Fashion and Motors.

5 DIVERSIFICATION

In order to create coherent and concise descriptions, we wished to avoid the inclusion of very similar sentences in the same description. After identifying candidate sentences for the description, our next step was therefore the identification of redundant sentences in order to increase the diversity in the content of the final description. The diversification phase was based on the computation of similarity between candidate sentences. To this end, we used the common cosine similarity measure, while experimenting with three sentence representation methods:

Weighted Bag-of-Words (BOW). Each sentence is represented as the TD-IDF weighted vector of its words [1].

Average Embedding. The weighted BOW approach measures similarity based on actual word overlap. In order to capture deeper semantic similarity, an embedded representation of the sentence can be used. Specifically, we apply word embedding using word2vec and average over all the sentence's words to produce the final sentence representation. The word2vec model is trained separately for Fashion and Motors, based on the dataset of over 10 million reviews per domain, as described in Section 3.

Weighted Embedding. This method applies the same word2vec embedding as described above, but instead of averaging the embeddings to generate the sentence representation, a common word weighting approach is applied [3]. This weighting is performed using TF-IDF scores, as it has been empirically shown to achieve similar results to learning the language model of the sentences.

Table 9: Accuracy for classifying sentence pairs as similar or not using different representations.

Sentence Representation	Fashion	Motors
Weighted bag of words	76.6	78.3
Average embedding	88.3	88.6
Weighted embedding	**92.2**	**91.7**

To decide whether two sentences are different enough to be included in the description, a similarity threshold θ for each method had to be determined. To avoid using a hard-coded threshold, we learned θ in an unsupervised manner from the data, for each of the two domains (Fashion and Motors). To this end, we considered the product descriptions in both of our datasets, which were manually curated by domain experts. We measured the similarity between each pair of sentences within each description and considered the 90-th percentile as the threshold θ. Intuitively, we set our threshold to allow a similarity level that is aligned with the typical degree of similarity that exists in professionally-written descriptions.

In order to compare the three representations, we conducted a small-scale experiment. For each domain (Fashion and Motors), we sampled 1000 pairs of sentences in the following way: we sampled 200 products from the respective dataset uniformly at random. For each product, we sampled 10 pairs of review sentences, uniformly at random out of all (unordered) pairs of sentences labeled *good*. We evaluated only *good* sentences, since the *bad* sentences were not considered for the final description. The sampled pairs were labeled by 3 professional annotators as either similar or not. The annotators were instructed to label a pair of sentences as similar in case one of them did not add any substantial piece of information to the reader on top of the other. The agreement between annotators, measured by Cohen's Kappa, was 0.84 for Fashion and 0.86 for Motors, calculated over 100 pairs for each domain, which were evaluated by two different annotators.

Overall, 35.2% of the sentences were labeled as similar, indicating there was indeed a high level of redundancy among *good* sentences. We tested each of the three methods against this labeled set by calculating its accuracy, i.e., the portion of pairs it correctly classified out of the 1000 pairs. Results are depicted in Table 9. It can be seen that both embedding-based methods reached a substantially higher accuracy than the weighted BOW method, for both domains. Weighted embedding slightly outperformed average embedding at over 90% for both domains, and was therefore our choice as sentence similarity method for the rest of our experiments.

6 FINAL DESCRIPTION GENERATION

In this section, we describe our methods for producing the final product description. Following, we present a detailed evaluation of the generated descriptions. Our evaluation compares the different methods for producing the descriptions and different description lengths by their overall quality ratings, as well as by ratings of more specific description aspects. In addition, we present results over publicly available data and experiment with cross-domain description generation.

6.1 Sentence Selection

The final step of our product description generation process is the selection of the final sentence set. From the previous steps, we have a list of candidate sentences, with their classification score reflecting their likelihood to be suitable to a product description, a similarity metric that can be applied to a pair of candidate sentences to measure their closeness, and a similarity threshold θ reflecting the desired similarity between sentences in a description. With these in hand, we examine four methods to generate the final description, given an integer K that determines the desired number of sentences in the description.

Greedy approach. This method traverses the list of candidates according to their *good*/*bad* classification score, from highest to lowest, and adds a candidate to the description if (and only if) it is not similar (i.e., has a similarity score of θ or higher) to any of the candidates already selected for the description. The process stops when K sentences have been added.

LexRank. This method uses LexRank, a common extractive summarization method that yielded high performance results for several text summarization tasks [12]. Specifically, LexRank assigns an importance score per sentence, using random walks and eigenvector centrality. We apply LexRank on top of the list of candidate sentences and use its score to rank the candidate sentences. Intuitively, the LexRank score indicates how well the candidate covers the information included in the other candidates. The method then operates similarly to the greedy approach: after ranking the candidate sentences by their LexRank score, the list is traversed by descending score and a sentence is added in case it is not similar to any of those previously selected for the description.

K-means classification score. This method partitions the candidate sentences into K clusters using the k-means algorithm [47] with k=K. The distance between sentences is calculated as $(1-s)$, where s is our sentence similarity measure described in Section 5. For the final product description, the clusters are traversed from the largest (representing the highest number of review sentences) to the smallest and from each cluster, the sentence with the highest classification score is added to the description.

K-means centroid. The method works as the previous one, but instead of selecting the candidate with the highest classification score from each of the K clusters, the candidate closest to the centroid is selected, assuming it best represents the cluster.

Note that smart ordering of the sentences within the final description is beyond the scope of this work. Currently, the sentences are ordered by classification score (greedy), summarization score (LexRank), or cluster size (both k-means methods).

6.2 End-to-End Description Evaluation

For an end-to-end evaluation of our approach, we set out to examine full descriptions generated using one of the four methods described above. For candidate sentence extraction, we used the LSTM-MTL classifier and for similarity measure we used weighted sentence embedding, since both were found to yield the best performance for their respective tasks, as previously reported. We experimented with descriptions of three lengths: 3, 5, and 7 sentences. These represent relatively concise content, which can be swiftly consumed in its entirety, and is especially suitable for small-screen devices, such as mobile phones. We generated descriptions for all products in both the Fashion and Motors datasets. Using our candidate extraction method (Section 4), we identified review sentences that were suitable for a description for each product in the sample. On average, for each Fashion product we identified 46.1 *good* sentences (std: 9.3, median: 43, min: 24, max: 97) and for Motors 47.3 (std: 11.7, median: 45, min: 19, max: 103). For each such product, we then generated descriptions of length 3, 5, and 7, using each of the four methods described above (a total of 12 description versions). These descriptions were evaluated by 15 professional annotators. We ensured each annotator evaluated no more than one description per product.

Figure 2: Product description evaluation interface.

Annotators were presented with the product's title, image, and generated description and were asked to rate the quality of the description's text for serving as the product's description, on a 5-point Likert scale, from 'very bad' to 'very good'. In addition, to examine finer-grained aspects of the description's quality, along the lines presented in the Introduction, annotators were asked to assess, on the same scale, to what extent the description's text was readable, informative, objective, and relevant to the product. They were provided with good and bad examples for each of the questions. Figure 2 demonstrates the user interface developed to collect annotators' input.

The inter-annotator agreement for the main quality evaluation question, measured using weighted Kappa [10], was 0.83 for Fashion and 0.84 for Motors, calculated over a set of 200 generated descriptions evaluated by two different annotators. Table 10 presents a few examples of our generated descriptions, which were rated 5.

6.2.1 Rating Results. Table 11 shows the ratings of the main question (overall description quality) in our end-to-end evaluation. Generally, the generated descriptions received high ratings, with an average of above 4 for all methods except for the greedy approach. Ratings for Fashion and Motors were similar, giving some indication that our method may be generalized to other e-commerce domains. Among the four methods, LexRank achieved the highest ratings, consistently for all three description lengths for both Fashion and Motors. At the other extreme, the greedy approach yielded substantially lower ratings than the other methods. K-means with the closest-to-centroid selection was consistently the second best, higher than k-means with highest-score selection. This suggests that selecting the sentence based on representation of the whole cluster rather than the individual prediction score for description suitability is preferable. The superiority of the LexRank approach implies that good representation of the whole set of candidates for final sentence selection works well. All differences between the

Table 10: Example descriptions rated 5.

Domain	Product	Description
Fashion	Socks	Perfect thickness for shoes or boots. Extra padding at toes. The quality is excellent. Easy to handle and very comfortable. No shrinkage in washer or dryer.
Fashion	Jacket	The cuffs on the sleeves are adjustable, which is perfect for keeping wind out when biking or for just a tighter fit around your wrists. It's very soft on the skin. The zipper works easily. The material is well made and the hood tucks away easily and hides well when not needed. Folds up to fit in bag.
Motors	Scratch removal system	Great for minor to moderate damage. Use it for removing scratches from your car. There is enough for several repairs. Coat twice for extra protection. Very recommended after wax.
Motors	Motor oil	It works well and lasts for a reasonable period of time. The oil is still very clean when changed. Engine runs smoother and pulls better. Good oil for any motorcycle. This oil is made for high temp engines.
Toys	Magnetic cubes	Works for all ages – toddlers to teens. The letters are a great addition and a fun way for young kids to learn their alphabet. Very colorful and high quality magnetic toy! Very easy to build. Perfect for family time.
Electr.	Mobile phone	This phone has a very good battery. The screen is big enough for watching movies. Includes power charger and headphones. The quality of photos is excellent. The phone is very smart and connects well with other devices.

Table 11: Average rating of description quality of 3, 5, and 7 sentences for products in Fashion and Motors.

	K=3		K=5		K=7	
	Fashion	Motors	Fashion	Motors	Fashion	Motors
Greedy	3.95	3.92	3.81	3.81	3.80	3.77
K-means score	4.10	4.09	4.08	4.06	4.04	4.01
K-means centroid	4.29	4.28	4.17	4.22	4.26	4.23
LexRank	**4.36**	**4.30**	**4.38**	**4.35**	**4.36**	**4.33**

methods were statistically significant, except between LexRank and k-means-centroid with K=3.[4] As for the length of the description, there was no consistent trend, but the highest ratings for LexRank were achieved for K=5 sentences by an insignificant difference from both K=3 and K=7 sentences.

Figure 3 presents the rating results for the additional questions in our evaluation, relating to the different quality aspects. Across all questions, LexRank consistently achieved the best ratings, with the rest of the methods ranked similarly to the general quality question. Among the four questions, ratings were highest for product relevance, with LexRank achieving an average of over 4.5 for all three description lengths. This indicates that as could be expected,

[4]Statistical significance was measured using one-way ANOVA with Tukey post-hoc comparisons for $p<0.01$.

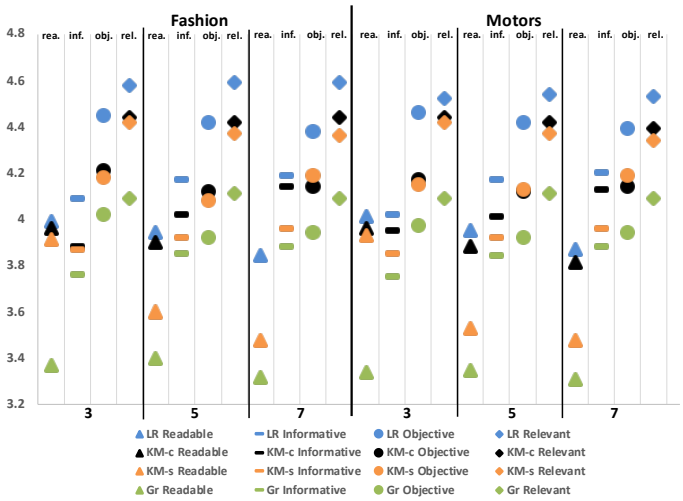

Figure 3: Average rating of four aspects (readable, informative, objective, relevant) for descriptions of length 3, 5, and 7 sentences, generated by four methods: LexRank (LR), K-Means centroid (KM-c), K-Means score (KM-s), and Greedy (Gr).

the reviews serve as a relevant source of information about the product. Objectivity was also rated high in general, indicating our method for filtering the objective parts out of the subjective reviews (step 1) works well. Readability received the lowest rating, with the greedy approach (and for K=5 and K=7 also k-means with highest-score selection) performing especially poorly. Inspecting the ratings by description length, objectivity and readability tend to decrease with description length, while informativeness increases. Product-relevance remains stable regardless of the description length. Overall, it is expected that as the description is longer, it is more likely to contain non-objective parts and become less readable due to connectivity or repetition issues, while it is also likely to contain more details and therefore become more informative. Inspecting the different ratings in Figure 3, descriptions of 5 sentences seem to yield the best trade-off between these two trends. For instance, consider the first example in Table 10. When the generated description with K=3 included the first 3 sentences, its 'informative' rating reduced. On the other hand, when the K=7 version included the extra sentence "*Best socks for sports, especially running*," the 'objective' rating reduced.

6.2.2 Evaluation over public data. The datasets used in this work are proprietary and cannot be shared due to business sensitivity. We therefore set out to get a sense how well our method performs on publicly available data. As a first step, we observe that 13.5% (120 in total) of the Fashion products and 16.7% (135) of the Motors products sent for our end-to-end evaluation are included in a large publicly-released e-commerce dataset [24]. Inspecting the ratings for these product subsets only, the results were almost completely identical to those reported for all products (Table 11 and Figure 3) and are thus not separately reported.

As a second (and final) step, we conducted another evaluation, in which all products in the public dataset [24] with at least 10

Table 12: Average rating of 5-sentence descriptions generated using the LexRank method over public data for Fashion and Motors (upper section) and for Toys and Electronics using cross-domain learning (lower section).

	Overall	Readable	Informative	Objective	Relevant
Fashion	4.34	3.88	4.20	4.40	4.53
Motors	4.32	3.95	4.22	4.43	4.50
Electronics	4.11	3.60	4.05	4.18	4.21
Toys	4.05	3.62	4.09	4.21	4.27

reviews between January and July 2014 (the most recent months in the dataset) were evaluated end-to-end using the LexRank method with k=5 sentences, by 3 professional annotators. This set included 140 Fashion products and 120 Motors products. Results, depicted in the upper section of Table 12, are very similar (±1.5%) to those reported for our own datasets in Table 11 and Figure 3.

6.2.3 Cross-Domain Generation. Finally, we set out to explore if our approach can be used across domains. To this end, we trained a model based on both the Fashion and Motors data and generated descriptions for two additional e-commerce domains: Toys and Electronics. As in the previous experiment, we generated descriptions of 5 sentences using the LexRank method for all products in these domains with at least 10 reviews between January and July 2014, resulting in a total of 55 products for Toys and 75 for Electronics [24]. These descriptions were evaluated by the same 3 annotators and the lower section of Table 12 presents their ratings. It can be seen that while the overall quality ratings are somewhat lower than for Fashion and Motors, they are still just above 4 on average. There is a rather similar rating decrease across all four quality aspects relative to Fashion and Motors, with the sharpest decline being for readability. The last two examples in Table 10 demonstrate generated descriptions for Toys and Electronics.

7 CONCLUSION AND FUTURE WORK

In this paper, we presented a method for automatic generation of product descriptions based on online user reviews. Product descriptions provided by sellers are often missing or lacking. Hence, customers turn to product reviews and often spend a significant amount of time sifting through them before making a purchase. However, users might still find it hard to extract the relevant information from thousands of reviews available online. Moreover, many reviews include personal and subjective opinions, while the users are sometimes only interested in the key product details before purchasing [15].

We first studied the main differences between the reviews and descriptions and adopted a supervised deep multi-task learning approach to identify appropriate review sentences. Afterwards, we introduced a similarity measure between review sentences that helped us eliminate redundancies when creating the descriptions. Finally, we used extractive text summarization to create a coherent and concise product description. We provided an extensive set of experiments that demonstrated our approach is productive.

Our experiments inspected two principally different e-commerce domains: Fashion and Motors. The similar results throughout our evaluation for both domains, as well as the analysis revealing common review language characterizing sentences that can be used for a description, suggest that our approach can be generalized to additional domains. Indeed, cross-domain description generation, trained over a combination of Fashion and Motors reviews, showed promising results when applied to two other primary e-commerce domains: Toys and Electronics. Our evaluation and examples also illustrate that our descriptions are somewhat different than seller-provided descriptions. A presentation of such descriptions on product pages may include an indication they are crowd-based or stem from user reviews. In addition, the descriptions can be presented as a bulleted list, as currently done on some e-commerce websites, to provide an alternative user experience and mitigate readability issues.

For future work, we plan to focus on four main directions. Currently, we select K sentences for the description without any special ordering. We believe that proper ordering may increase the readability of the descriptions. Second, automatically deriving the value of K based on the product and review content can further improve description quality. Third, abstractive approaches [13, 14], which adapt the original review text and combine content from different sentences, are also worth exploring, and can help generate descriptions of even higher quality based on fewer reviews. Finally, personalizing the generated descriptions for the individual consumer can help make them even more compelling.

ABSTRACT

There are thousands of data repositories on the Web, providing access to millions of datasets. National and regional governments, scientific publishers and consortia, commercial data providers, and others publish data for fields ranging from social science to life science to high-energy physics to climate science and more. Access to this data is critical to facilitating reproducibility of research results, enabling scientists to build on others' work, and providing data journalists easier access to information and its provenance. In this paper, we discuss Google Dataset Search, a dataset-discovery tool that provides search capabilities over potentially all datasets published on the Web. The approach relies on an open ecosystem, where dataset owners and providers publish semantically enhanced metadata on their own sites. We then aggregate, normalize, and reconcile this metadata, providing a search engine that lets users find datasets in the "long tail" of the Web. In this paper, we discuss both social and technical challenges in building this type of tool, and the lessons that we learned from this experience.

KEYWORDS

data discovery, search, metadata, structured data

1 WHY IT CAN BE DIFFICULT TO FIND DATASETS ON THE WEB

Data is the main substrate of research for scientists in many disciplines, for the work of journalists, for the analysis by policy makers, and for those of us who are curious to understand our world better. Data is published on the Web by national and regional governments, scientific publishers, commercial data providers, research consortia, specialized data repositories, data aggregators, and so on. There are thousands of data repositories on the Web [16] and many individual data publishers, from high school teams publishing the results of their science-fair projects to national research labs. The more data we publish on the Web, the more complex the problem of data discovery becomes: how do we find the data that we need for the task at hand and how do we assess its credibility, veracity, and suitability for our task? The following are some of the key factors that contribute to the difficulty of data discovery today.

Proliferation of data publishers: In the early days of the Web, many users discovered what was available on the Web by browsing through directories such as the Yahoo! Web directory. Eventually though, the Web became too large for any directory to be sufficiently comprehensive and *search* became the primary way of finding where the information was on the Web. Today, the world of publishing datasets on the Web is in a similar transition: there are a number of well respected directories of dataset publishers (e.g., DataCite [29], re3data [16], Scientific Data in Nature [19]), but now they inevitably miss new datasets or repositories [7]. In addition, they miss datasets published by individual data providers, such as a scientist publishing the dataset resulting from her experiment on her own site. Finally, many curated resources collecting dataset repositories focus largely on government and research data and miss repositories that come from the private sector. Yet, there are valuable datasets that originate from companies who may charge or have more restrictive licensing terms for their data (e.g., ceicdata.com). Thus, the time is ripe to add Web-wide search capabilities for datasets and not to rely exclusively on curated directories.

The "long tail" and the "deep Web": Web search engines often fail at finding data for a variety of reasons: many pages describing datasets are in the "long tail" of the Web [8]. In many cases, data repositories do not make the individual pages for datasets easily crawlable because they are accessible only through queries, a phenomena referred to as the "deep Web" [18]. Consider, for example, Open Data Network [23], which hosts many datasets from local governments in the United States. It is a resource that many data journalists use (but many social-science researchers may not know about). The only way to get to a page for any specific dataset that Open Data Network hosts is by typing in a search term where that dataset will be listed among the results. For many such pages, search engines end up indexing some datasets as they appear in search results and not others.

Specialization in data-publishing communities: Research has become more interdisciplinary and scientists must be able to find data in the disciplines that they are less familiar with. A professional will most likely know her go-to data repositories in her specialized field by reading relevant papers, by asking colleagues, and through word of mouth. Then as she looks for data, she most likely uses the search tools within a specific data repository, which are usually perfectly suited for that type of data (e.g., social-sciences data, environmental, economic). However, these methods no longer work when you start looking for data in a discipline that you are

https://doi.org/10.1145/3308558.3313685

not intimately familiar with. For example, an epidemiologist trying to understand how a new virus spreads may want to understand environmental factors that coincided with the spread of the virus, yet she might not have any colleagues who know the landscape of the environmental data well. If you are a new researcher, or someone who is not very "plugged into" a research community, you might not even have anybody to ask. Just as Google Scholar has revolutionized vertical search for academic publishing, a specialized vertical search engine can fundamentally improve data discovery across all scientific disciplines.

In this paper, we discuss Google Dataset Search (https://g.co/datasetsearch), a search engine over dataset metadata that we built with an open ecosystem at its core: data publishers, large and small, use Schema.org or W3C DCAT markup to describe the metadata semantics on the individual pages of each dataset, a Web crawler collects this metadata, and Dataset Search augments and indexes this metadata to provide a vertical search over all the dataset metadata on the Web. As new publishers add metadata markup to their sites, Dataset Search includes them after the crawler visits and processes the pages. Dataset Search was launched as public beta at the beginning of September 2018.

Specifically, this paper makes the following contributions:

- We **present a search engine over dataset metadata** that can scale to all metadata published on the Web through an open ecosystem.
- We identify a set of **challenges** in building a search engine over structured data in such an open ecosystem.
- We describe our **technical approach** to normalize metadata, to reconcile it to a knowledge graph, to identify duplicates, and to index the data to provide a data-discovery system in the context of the whole Web.
- We discuss practical **lessons learned** from building a vertical search engine in an open ecosystem.

2 RELATED WORK

There are several key lines of work that both informed and enabled our work on Dataset Search.

Many scientific disciplines have come to a consensus (or have been compelled by funding agencies and academic publishers) that it is important to publish data and to cite it. There are, for example, peer-reviewed journals dedicated to publishing valuable datasets, such as Nature Scientific Data [19]. There are efforts such as DataCite [29], which provide digital object identifiers (DOIs) for datasets and both encourage and enable scientists to publish their datasets. Providing mechanisms for citing data enables scientists to get credit for publishing the data. Many scientific communities have signed on to the principles of management and stewardship of the data in a FAIR way (findable, accessible, interoperable, and reusable) [34]. Recently there have been efforts to create standards around citation of datasets. Fenner and colleagues describe a roadmap for implementing the Joint Declaration of Data Citation Principles [7]. Among the principles outlined in the article is the requirement that datasets have a landing page and a recommendation that the landing pages use Schema.org to describe its contents.

Naturally, as scientists pay more attention to publishing data, many scientific communities create data portals for scientists in that community to publish their datasets. These portals are usually designed for the specific type of data in that domain, and focus on the interface and interaction that suits scientists in that domain. There are hundreds of such repositories, with re3data.org, a registry of research data repositories, listing more than 2,000 repositories.

It is no wonder that such proliferation of repositories leads to the problem of data discovery. A qualitative study by Koesten and colleagues [17] found that more than 50% of users who searched for data using a mix of Web search engines, domain-specific repositories, and recommendations from colleagues reported difficulty in finding the datasets that they need. Kacprzak and colleagues [13] analyze the differences between search behavior for datasets and Web searches. Their analysis of query logs from four major open data portals, showed that queries for datasets are short, portal search engines are used in an exploratory manner and that the topics of queries for data differ from topics in Web search queries. Their findings indicate that the tools for querying datasets are not as well developed as Web search engines, and require more human work (e.g., scrolling through more search results returned from short queries) than Web search.

One approach for providing access to multiple data repositories is to harvest the metadata from these repositories through their APIs. For example Open Data Portal Watch [20] collects metadata from more than 260 repositories, focusing on government data. The Open Data Portal Watch developers evaluate and compare the quality of the metadata for these repositories. DataMed [22] is an example of a similar approach in the domain of life sciences, collecting metadata from 75 repositories. These approaches inherently rely on having the portal owners know the list of dataset repositories in advance.

A complementary approach to collecting metadata from a specific set of dataset publishers is to allow dataset publishers to submit their datasets to the repositories. Data-management systems such as CKAN [3], Quandl [26], Kaggle [14], and Microsoft Azure Marketplace [1] are repositories of data from multiple sources, organized for distribution and sharing. In all these systems, dataset owners actively choose to contribute their datasets to the system or to annotate the datasets with metadata. However, in all these systems, if dataset owners want their dataset metadata to appear in more than one repository, they need to submit the description of their dataset in each of those repositories separately.

The distinguishing characteristic of Dataset Search is the open ecosystem: the owners of datasets or data repositories need to markup the metadata only once, in a place where they publish and maintain it on their own site. Once they do, any Web crawler can pick it up and the datasets from this new source will show up in Dataset Search, or in other tools that rely on this metadata. In other words, repository owners do not need to submit their datasets anywhere proactively or to have a data portal know about the existence of their repository. As long as their Web pages are accessible to a general Web crawler and have the structured metadata on the pages, their datasets will be included. Researchers have explored this "post-hoc" approach in the context of enterprise data management [12]. To the best of our knowledge, Dataset Search is the first such approach for datasets in the context of the entire Web.

We chose to rely primarily on Schema.org for describing dataset metadata because both search engines and open-source tools have used it successfully to build an open ecosystem for various types

of content [11]. Erickson and colleagues [5] first proposed to use Schema.org to describe open government data and provided the first definitions for `http://schema.org/Dataset` based on W3C DCAT [4]. And in recent years, scientific community has also embraced it for publishing data: There are mappings from other metadata standards to Schema.org. For example, Sansone and colleagues define a mapping from the DATS standard in the biomedical community to Schema.org [30]. Wang and colleagues use Schema.org to describe research-graph data, which captures researchers, datasets and scholarly articles [33]. Efforts such as bioschemas.org [10] extend Schema.org to include domain-specific terminology and relationships. All these efforts enabled Dataset Search to start with an ecosystem that already had some metadata in Schema.org. Our team could then work with these communities to build on the existing efforts to encourage adoption.

3 DEFINING THE PROBLEM

In order to define the problem of dataset search on the Web and to highlight the key requirements for a product that would support it, we conducted interviews with scientists, journalists, and other data consumers. Many of them emphasized that outside of any niche community, nobody can enumerate all the dataset repositories that exist, even in a single discipline. Therefore, our goal was to enable an open ecosystem that anybody can join at any time: from a large institutional repository to a group of students who want to publish the results of an experiment.

When defining the problem of building a search engine over datasets, the first definition we must consider is the definition of a dataset, and, more specifically, a **dataset as published on the Web**. For the purposes of the work described in this paper, we have adopted an operational rather than a declarative definition: anything that a data provider considers to be a dataset is a dataset. This definition means that we can include individual tables, files, images, binary files, maps, or collections of any of the above. On the one hand, this definition removes the need to "police" what a dataset is and allows providers in different domains to share data in a format that makes sense to them (e.g., binary NetCDF for climate data). On the other hand, this approach puts a bigger burden on tools such as Dataset Search to ensure that its users get high quality and meaningful results.

Furthermore, we focus on the problem of search over dataset **metadata**, which includes data *about* a dataset. Metadata describes salient properties of a dataset, such as its title and description, provider, spatial and temporal coverage, and so on (see http://schema.org/Dataset for a sample of metadata properties).

We define the task of **searching for datasets on the Web** in the following way: Given a set of Web pages that publish dataset metadata, unknown in advance, build a search engine over this metadata to enable users to find datasets on those pages. Specifically, this problem setting highlights the following requirements:

- The system needs to be open, allowing any new provider to join by publishing their metadata.
- The search is over metadata, and does not have to include the data itself. Indeed, a data provider may require the users to pay for data or to create a free account to obtain access (the licensing terms themselves are part of the metadata).
- The metadata must be published by the dataset publishers themselves, using a standard that our and other solutions can interpret.

4 TECHNICAL CHALLENGES

We now describe the technical challenges that we had to address in building Dataset Search. Most of these challenges would apply to building any large-scale vertical search engine in an open ecosystem, and are not specific to datasets.

4.1 Metadata quality

At its core, Dataset Search is a search engine over metadata provided by data publishers on the Web. As a result, the quality of the metadata varies greatly. We have observed that *"everything that can go wrong, will go wrong"* when you are operating at this scale in an open ecosystem. For a simple example, consider representation of dates, which appear in several properties of dataset metadata, including publication date of a dataset, its modification date, and its temporal coverage. The Schema.org standard requires that dates follow the ISO 8601 format (e.g., `"2018-11-01"`). However, we have found dates in every possible format, including sentences such as `"Published in December, 2015"`—in different languages. Similarly, spatial-coverage definitions in metadata may include latitude and longitude for points defining a geographic shape. We have observed cases were providers mixed up the order of latitude and longitude. In some cases, dataset title and its identifier were swapped, and so on. Because metadata is usually generated programmatically, such problems usually affect all metadata from a given repository, which may include hundreds or thousands of datasets.

The Schema.org specification also leaves some details about how the providers should specify the metadata open to interpretation. For instance, one can specify `encodingFormat` either at the level of a dataset, or at the level of `distribution`, which is a property of a `http://schema.org/Dataset`. In the context of dataset publishing, the distinctions between publisher and provider are often blurred and imprecise. Other such examples abound. Thus, to make the search useful, we must clean up and normalize the metadata as much as we can (Section 5.2).

4.2 Metadata duplication in search results

In addition to the quality of individual metadata, the pages where metadata appears can also cause problems. Many dataset repositories are themselves search engines over the metadata for the datasets that they host. Therefore, a description of each dataset appears in two contexts in the repository pages: (1) in pages listing search results, and (2) on dataset profile pages for each individual dataset. We refer of these descriptions within the same site as **duplicates**. The potential number of pages in the first category is exponential, whereas the second category has one page for each dataset. Both types of pages are usually generated programmatically from a database or an index. We found that frequently developers attach metadata to each dataset in search-result listing, and may or may not attach it to the profile page. As a result, a crawler may potentially pick up an exponentially large number of copies of metadata for the same dataset, one from each search-result page where that dataset appears. However, from the point of view of a

dataset-search tool, the page that we really want to take the user to is the profile page for a dataset, and not a listing of search results. Thus, we must distinguish between these different types of pages and identify which metadata copy refers to the profile page (Section 5.4).

4.3 Dataset replication and provenance

While having multiple copies of metadata descriptions for the same dataset within a single repository is undesirable (Section 4.2), replication of the description of the same dataset in *different* repositories not only happens frequently but also provides a signal about the quality of the dataset itself. The presence of a dataset in multiple repositories often signals that the dataset is widely used and provides some indication about its credibility. We refer to the copies of metadata descriptions of the same dataset in different repositories as **replicas**. If we can cluster the replicas present in different repositories, we can give users a choice of which repository to go to. Hence, we face the challenge of identifying the replicas across repositories. The Schema.org standard provides a way to specify the original dataset explicitly through a `http://schema.org/sameAs` link: a dataset description can point to the original dataset description on another site through this link. Relying on `sameAs` links offers only a small part of the solution: First, the links are not always reliable. Second, when we examine the metadata that we collected, we find that less than 1% of dataset descriptions have explicit `sameAs` links to other domains, whereas we identified that about 25% of them are likely replicas of another dataset. Thus, we must rely on heuristics and other properties that could serve as proxies for `sameAs` as we cluster the replicas (Section 5.4).

4.4 Churn and stale sites

Search engines optimize their crawl schedules to crawl sites that their users visit often at a higher rate than the sites in the long tail [8]. While this optimization is entirely reasonable at Web scale, we need to tune it to improve the discoverability of content from the long tail by taking into account the utility of the metadata. Many of the pages that describe individual datasets are in that heavy long tail of the Web and therefore the problem of churn and stale links is exacerbated in this vertical. Even though we do not run our own crawl and rely on a general Google crawl, we still should not be sending users to stale pages. For the pages that we ultimately identify as dataset pages, we work with the crawl-scheduling team to ensure that we minimize the number of stale links.

While we cannot measure the churn among the datasets that the crawler does not see, we measure the churn in the dataset metadata for the descriptions in our index. For Dataset Search, over the past two months, on any given day, on average, 3% of the datasets are deleted from our index, and 7-10% of new datasets are added. We discuss our approach to addressing this churn efficiently in Section 5.5.

4.5 Ranking and relevance

One of the key research questions in building any vertical search engine is understanding what ranking signals make sense for that vertical. Initial studies indicate that there is a difference in how users expect datasets to be ranked [12, 15]. Because explicit links between dataset metadata are still relatively rare, traditional Web-based ranking methods are not effective. While we hope that eventually citing and referencing dataset will become as common a practice as citing and referencing scientific papers, it is not the case today. Thus, traditional scholarly metrics are not readily applicable either.

In addition, because metadata is often limited and minimalistic, it may not provide enough signal to decide whether a dataset is relevant to the user's query. We can fall back on the information on the rest of the page, if it is more expansive than the metadata, or recover additional metadata from the data itself (Section 5.6).

4.6 Multiple dataset-metadata standards

While Schema.org is widely used by search engines and other applications to improve many Web-based tools that need to rely on semantics of the data on a Web page, it is not the only open standard for describing dataset metadata. Several other standards exist, most notably, the W3C Data Catalog Vocabulary (DCAT) [4]. Mappings between Schema.org and the various extensions to DCAT are currently under discussion at W3C and Schema.org. We found that at the moment, only 2% of dataset descriptions (in JSON-LD, RDFa or Microdata) use the DCAT standard while the rest use Schema.org. However, the datasets that use the DCAT standard include hundreds of thousands of datasets from government portals around the world, and in particular portals with geo-spatial data. Therefore, to get better coverage and to be inclusive of other standards, we process both Schema.org and DCAT metadata, as long as the latter is also represented syntactically in a supported syntax, to allow the regular crawl processing to extract the triples (Section 5.7).

5 IMPLEMENTING DATASET SEARCH

To enable the open ecosystem, we rely primarily on Schema.org, a non-proprietary format to describe metadata on the Web in a structured form, providing basic semantics (Figure 1). As we mentioned in Section 4.6, we also support DCAT. Any dataset provider can add simple markup to Web pages that describe datasets. Our Web crawler then crawls this page and parses the HTML and the embedded markup (either as RDFa, microdata, or JSON-LD). Dataset Search does not require its own crawl; it builds upon the crawl and extraction infrastructure of the general Google Web crawl. Specifically, we rely on the Google Web crawl, which already processes structured-data markup and generates triples for each page, regardless of the specific vocabulary that the providers use (Schema.org, DCAT, etc.). The crawl and extraction of the triples from the pages are not contributions of this paper.

Dataset Search collects the metadata, links it with other resources, and builds an index of this enriched corpus of metadata. Once we built the index, we can start answering user queries—and figuring out which results best correspond to the query.

We will now describe the details of the key components of the pipeline in Figure 1.

5.1 From Schema.org to protocol buffers

Google Web crawl and its associated processing, relying on the underlying standards, parses RDFa, Microdata and JSON-LD to a common graph data model, broadly corresponding to W3C's RDF

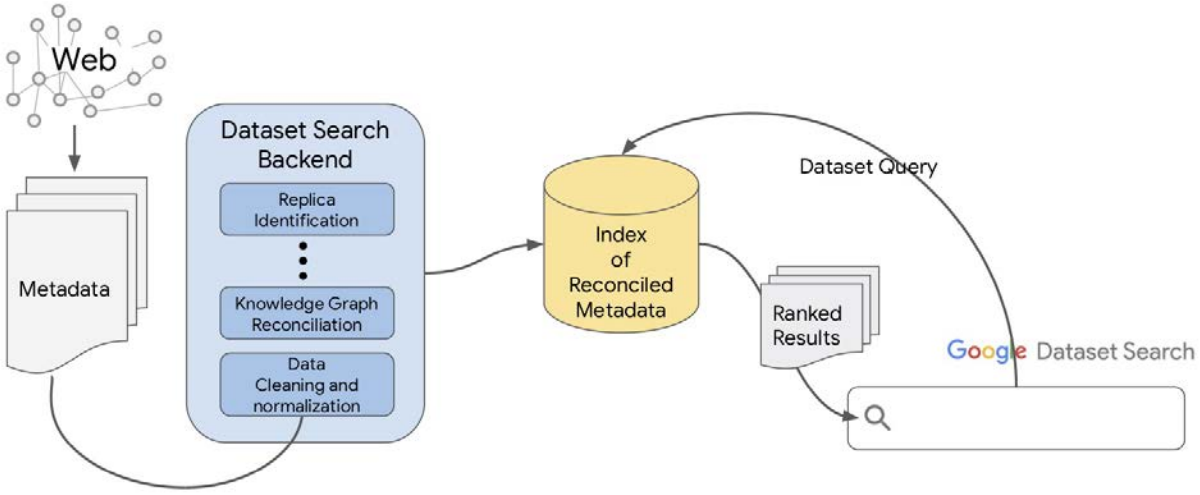

Figure 1: An overview of the Dataset Search components. Google crawler collects the metadata from the Web; Dataset Search backend normalizes and reconciles the metadata; we then index the reconciled metadata and rank results for user queries.

triples [28]. We then look for the triples that use our vocabularies of interest, Schema.org and DCAT. Specifically, we collect all the triples for all the pages that have elements of specific types: `http://schema.org/Dataset`, `http://schema.org/DataCatalog`, and `http://www.w3.org/ns/dcat#Dataset`.

For a set of triples from each page, we traverse the graph to collect all the properties and related objects for each dataset in a protocol buffer [32], a nested-relational record corresponding to each metadata entry. A dataset record can point to other records such as organizations that provided a dataset or a record describing the distribution of a dataset. A single Web page can have multiple dataset records on it.

The specification of the graph traversal captures the mapping from Schema.org and DCAT vocabularies to the corresponding elements in the protocol-buffer definition (e.g., example fields in Figure 2). The schema of the protocol buffer for the metadata largely corresponds to `http://schema.org/Dataset` and therefore the transformation of metadata at this stage is rather small.

To improve scalability, we use the graph query independently on the triples from each individual page rather than try to extract information from a graph that includes all metadata triples on the Web. Because the links across different pages must specify objects on another page directly through a URL (e.g., a provider of this dataset on page *A* is described on page *B*), we can do this reconciliation post-hoc. So, essentially, each page corresponds to its own, possibly disconnected graph. At the same time, doing graph traversal only for a single page is dramatically more scalable.

The information that we extract through graph traversal constitutes the **raw metadata**, metadata that closely mimics the structure of Schema.org properties on the original page.

In the next few steps, we describe how we create **reconciled metadata** for each dataset, accounting for the different levels of quality and variety of the modeling patterns used.

5.2 Normalizing and cleaning the metadata

As we mentioned in Section 4.1, we must assume that we will encounter every possible misuse and mis-interpretation of Schema.org properties when we operate at the scale of the whole Web. Thus, we perform a number of operations to normalize and clean up the metadata.

First, for the properties where we observe different patterns on the Web, we analyze the common patterns used and try to account for all of them. For instance Figure 2 shows the different patterns that we observed for defining downloads and distribution. In the figure, the first example of raw metadata defines the format of the dataset (CSV) at the level of the dataset itself and stores the download URL as the value of the `http://schema.org/distribution` property. Other examples in the figure deal with these two pieces of information differently. All these patterns are commonly used in our corpus. We mine these patterns by traversing either the initial graph or the resulting protocol buffer. Once we identify the patterns, we write adapters to convert all of them into the same modeling pattern in the reconciled metadata record. The right-hand side of Figure 2 shows this reconciled result.

Similarly, we have developed adapters for other metadata fields: We understand a lot more representations of dates than the ISO standard required by the Schema.org specification (Section 4.1. We will pick up digital object identifiers (DOIs) for a dataset from a variety of fields, and not just `http://schema.org/identifier`. We will use a uniform field, `provider`, for the many different fields that dataset providers used to identify this property. As we collect more metadata, our set of such adapters grows. Our decisions in these steps are guided by two factors: (1) the frequent usage patterns that we observed in the data; and (2) our understanding of what we expect the users to see in Dataset Search results.

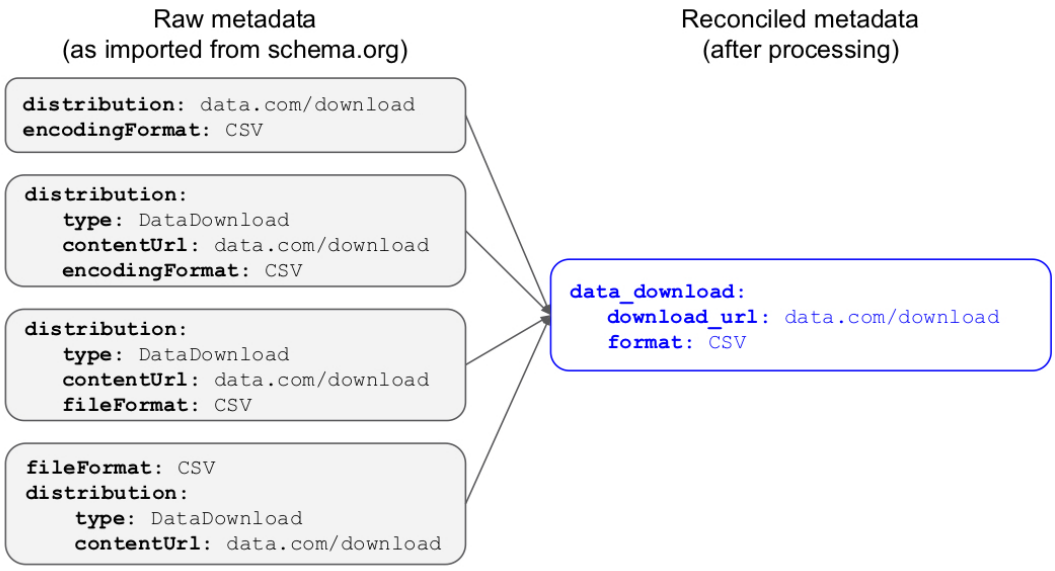

Figure 2: Normalizing raw patterns. The diagram gives an example of the variety that we have observed in metadata definitions. The examples on the left are a protocol-buffer version of the representation, as imported directly from Schema.org metadata. All these examples reconcile to the same pattern, shown on the right.

5.3 Reconciling metadata to a knowledge graph

Most companies today have a knowledge graph that describes types of entities and relationships between them that are critical to the company's products. In our case, such a knowledge graph describes and links information about many entities, including the ones that appear in dataset metadata: organizations providing datasets, locations for spatial coverage of the data, funding agencies, and so on. Therefore, we try to reconcile information mentioned in the metadata fields with the items in the knowledge graph. We can do this reconciliation with good precision for two main reasons. First, we know the types of items in the knowledge graph and the types of entities that we expect in the metadata fields. Therefore, we can limit the types of entities from the knowledge graph that we match with values for a particular metadata field. For example, a provider of a dataset should match with an organization entity in the knowledge graph and not with, say, a location. Second, the context of the Web page itself helps reduce the number of choices, which is particularly useful for distinguishing between organizations that share the same acronym. For example, the acronym CAMRA can stand for "Chilbolton Advanced Meteorological Radar" or "Campaign for Real Ale." If we use terms from the Web page, we can then more easily determine that CAMRA is in fact the Chilbolton Radar when we see terms such as *clouds*, *vapor*, and *water* on the page.

This type of reconciliation opens up lots of possibilities to improve the search experience for users. For instance, Dataset Search localizes results by showing reconciled values of metadata in the same language as the rest of the page. Additionally, it can rely on synonyms, correct misspellings, expand acronyms, or use other relations in the knowledge graph for query expansion.

5.4 Finding duplicates and aggregating replicas

As we discussed in Sections 4.2 and 4.3, the same dataset description may appear in multiple places. We refer to such dataset descriptions as *duplicates* is they occur within the same site. Duplicates usually appear because site developers chose to mark up dataset descriptions both when listing search results and in profile pages for individual datasets. For Dataset Search users we should be indexing only one of the many duplicates within a single site, preferably the one that appears on the profile pages.

When a dataset (e.g., a popular one), appears in different repositories, we refer to these descriptions as *replicas*. Because we have somewhat of a "bird's eye" view of the Web, we can often find where all these different replicas are, and group them together, giving the user a choice of which repository they want to get this dataset from.

While presenting multiple duplicates is not useful for users, replicas from different repositories can be useful for a user, giving her a choice to go to the repository that she trusts or knows.

Our approach to identifying duplicates and replicas are very similar—with the main difference being whether or not we include the site domain into consideration.

First, Schema.org has a way to specify the connection explicitly, through `http://schema.org/sameAs`. In our experience, when this property was present, it was a strong indicator that datasets are the same, whether they are duplicates within the same site or replicas across different sites. Indeed, if developers must include Schema.org for metadata in search results in addition to the profile pages on their site, our guidelines[1] suggest using `sameAs` to point to the profile page.

[1] https://developers.google.com/search/docs/data-types/dataset

Second, we found that sometimes two datasets can be identified as duplicates or replicas not because they point to each other through `sameAs`, but rather because they both point to the same canonical page for that dataset. The latter page itself might not even have Schema.org metadata and hence will not be in our corpus.

Finally, we use a number of other heuristics that, in combination, provide a signal on possible duplicates or replicas: for example, two datasets sharing a large part of their metadata; or pointing to the same URL as their download URL, are likely related. In practice, each one of these signals can fail or be subject to mis-representation or misinterpretation by data providers. So, we use a combination of signals to determine whether or not dataset descriptions appear to be the same.

To identify these duplicates and replicas at scale, we compute a hash value (fingerprint) for each combination of values for a dataset that may be an indication that it is a replica or a duplicate of another dataset. For instance, these combinations of values may include dataset title and description, or dataset title and a download URL. We heavily pre-process the fields that we use to compute the fingerprint: we normalize the text, remove delimiters and any special symbols, and remove spaces. This normalization is usually sufficient because data providers normally copy the metadata directly from one site to another. Once we have the fingerprints for these field combinations, we construct a graph where nodes represent datasets and edges connect nodes that share at least one fingerprint (Figure 3). Our goal is to identify connected components within this graph: each connected component is a cluster of duplicates, if the nodes are from the same site, or replicas, if they are from different sites. In the example in Figure 3, datasets *A*, *B*, and *C* are all duplicates (or replicas). Even though datasets *A* and *B* do not share any fingerprints; they are both the same as dataset *C*. Hence, we can infer that they are part of the same cluster.

We first use this algorithm to compute duplicates, grouping only datasets within a single domain by adding the domain to each fingerprint, thus ensuring that descriptions from different domains will never end up in the same cluster. We then choose one representative from a cluster (Figure 4). We use heuristics to maximize the probability that this representative refers to a profile page for a dataset and not a listing of search results. We then run the same algorithm to compute replicas on this de-duped set. We use a MapReduce version of a connected-component algorithm [27] to compute these clusters efficiently.

Table 1 shows the distribution for different sizes of *replica clusters*. Recall that replicas are cases where the same dataset appears on different sites. The vast majority of clusters have only two replicas, whereas there are a few with as many as 40 or 50 replicas in different domains, with the largest cluster having 58 datasets.

5.5 Scalability of the backend

As with any system that operates at Web scale, we must address scalability of our implementation. We discuss the scalability of the Dataset Search backend from Figure 1, because we could rely on other, already scalable, systems for crawl, indexing, and querying.

Figure 4 highlights the backend architecture. After we traverse the graph of triples on each individual page, we generate a protocol buffer (a record) for each dataset. We then do most of the processing

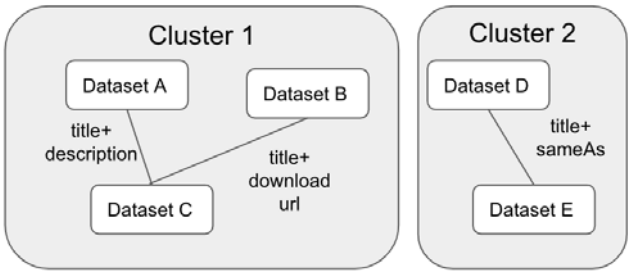

Figure 3: Clusters of replicas or duplicates as connected components. Each pair of datasets may share some fingerprints (e.g., based on title+description). We identify connected components in the graph to cluster all replicas of the same dataset. Table 1 profiles the sizes of clusters that we found.

Table 1: Distribution of replica clusters. Each cluster groups together dataset descriptions from different Web domains that we determine to be replicas.

Number of datasets in a replica cluster	Fraction of clusters
2	82.57%
3	15.17%
4	1.88%
5	0.28%
6 and larger	0.11%

that we described in earlier sections (cleaning, normalization, reconciliation to the knowledge graph) on each dataset independently and in parallel, using MapReduce. Note that for each enrichment that we discuss, we do not need to know how the other records look like. Furthermore, because only a small percentage of datasets changes from day to day (Section 4.4), we do not need to re-process the majority of the datasets, and only re-process the new or modified ones. This architecture is inspired by enterprise dataset search, such as Goods [12].

The identification of duplicates and replicas, however, must be done for the entire corpus each time, because newly added datasets may appear in any of the clusters. Thus, we run the clustering algorithms for identifying both replicas and duplicates daily.

5.6 Indexing and ranking the results

The collection of structured metadata and the replica-aggregation results go into our index. For each dataset, we index the links to its replicas along with its metadata to enable us to retrieve all the information about the whole cluster at the same time. When we collect the results returned from the index, we cluster the replicas together, to show them as a single entry in the list of results.

When the user issues a query, we search through our corpus of datasets using the same methodology as a Web search engine. Just like with any search, we need to determine whether a document is relevant for the query and then rank the documents in terms of how relevant and how important they are. Because there are no large scale studies on how users search for datasets, as a first

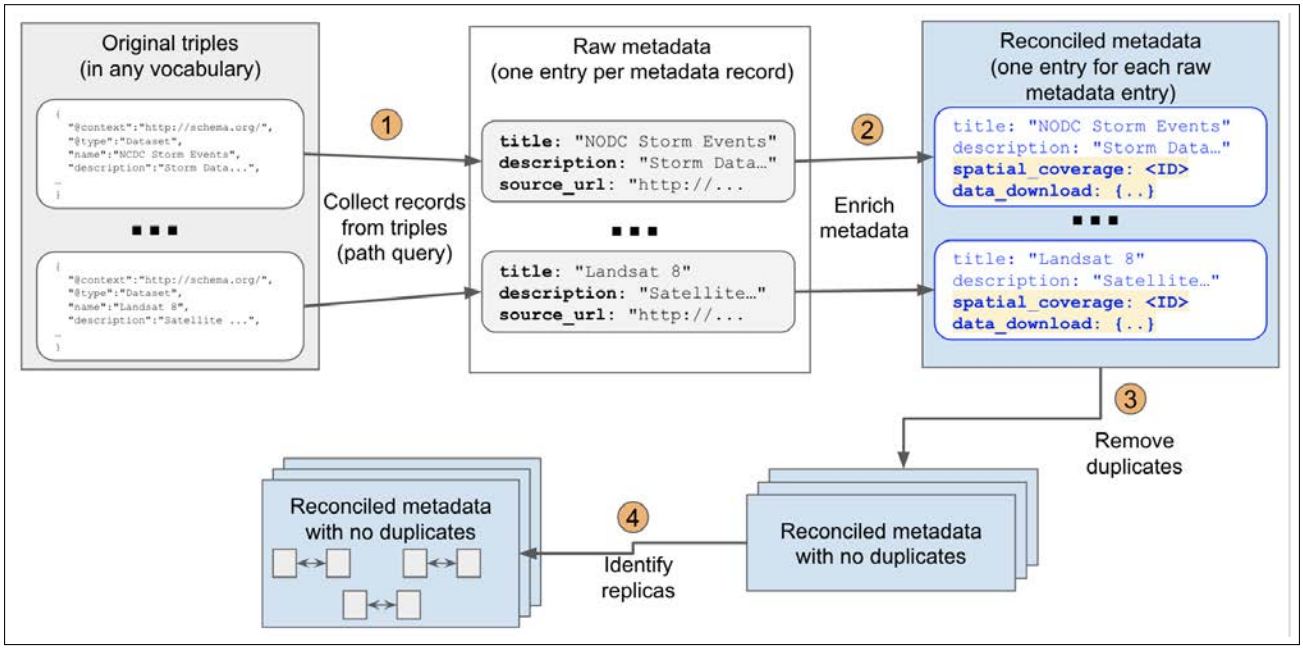

Figure 4: Dataset Search backend: Processing triples on each page results in individual records for each dataset. We then process each record independently to enrich the metadata (e.g., the highlighted portion for reconciled metadata on the right). Steps 1 and 2 happen in parallel, using MapReduce. The algorithms on finding duplicates (step 3) and replicas (step 4) then run on the whole corpus.

approximation, we rely on Web ranking: after all, metadata records come from Web pages. And while this approach provides a good starting point, it is not enough: because many of the pages are in the long tail, the differences in ranking are often not very meaningful. Thus, we add signals that take into account metadata quality. We hope that as we gain more insight on how users query and use Dataset Search, we will be able to develop ranking models that are more specialized for searching datasets.

Finally, Figure 5 shows a screenshot of the user interface: As the user enters a search strings, she gets a list of datasets, with some salient metadata, along with one or more domains where we found that dataset. The page with details for the selected result shows the reconciled metadata.

5.7 Improving coverage and recall

In Section 4, we highlighted challenges to having as broad coverage as possible. First, relying exclusively on the Schema.org vocabulary misses many government sites and we would like to be able to process triples that use other vocabularies or ontologies (Section 4.6). Recall that in the first step of our pipeline, we use a graph traversal to go from a set of triples corresponding to a page to a protocol buffer that represents the record for a dataset metadata. We have extended the graph traversal to understand the DCAT vocabulary as well, using the mapping between the two vocabularies [24]. The DCAT essentially becomes just another vocabulary that we must be able to understand. We referred to Schema.org throughout this paper, mostly to make it easier to read, note that we include the DCAT standard as well. Supporting multiple vocabularies requires some maintenance overhead to ensure that mappings are still valid, we do not expect the number of vocabularies to grow or for the mapping to change frequently. Because most of the tooling is still optimized for Schema.org, we usually still recommend to our partners to use Schema.org if it is feasible for them.

As we mentioned in Section 4.2, in some repositories, search is the only way to get to individual datasets. Thus, it may be hard for a crawler to get a full list of datasets in a repository. Sitemaps have been a common solution to this problem and we have strongly encouraged dataset-repository owners to maintain sitemaps that list all their datasets in our guidelines.[2]

6 THE STATUS OF DATASET METADATA ON THE WEB

Several researchers and practitioners have encouraged the use of Schema.org for dataset discovery on the Web in the last 1-2 years (e.g., [7]). Our team also participated in such efforts [21]. This community building was necessary prior to launching any vertical search based on this metadata: We needed to avoid the cold-start problem of not having any metadata to search over when a product is launched. Our approach involved public blog posts [21] and presentations to raise awareness of problems in data discovery today and the need for standardized Web-based metadata. We have also identified 2-3 disciplines for which we attempted to have more comprehensive coverage. We consulted experts in those disciplines to get a list of prominent repositories in those fields, the repositories

[2]https://developers.google.com/search/docs/data-types/dataset

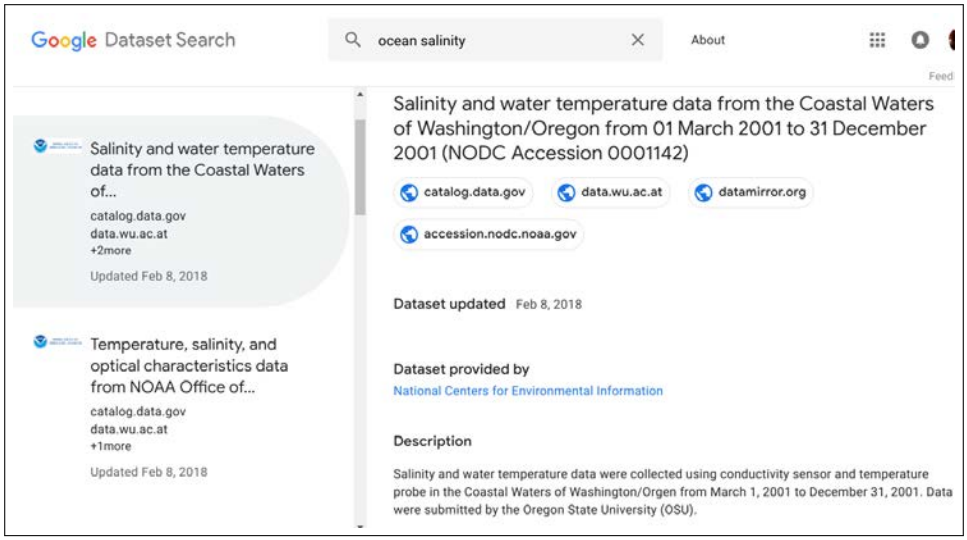

Figure 5: Dataset Search: Query results show the list of matches and the details for each match. The example in the figure shows multiple repositories where the metadata for the selected dataset is available.

without whom any dataset search is not viable. We then worked with the developers of these repositories directly to bootstrap the ecosystem. As the leaders in the domains added the metadata to their pages, developers of other repositories often followed suit.

We found that while having key partners gave us confidence that we will have datasets that many scientists consider important, the majority of domains by the time we launched were not from the partners that we explicitly contacted. At the time of the launch, there were thousands of domains that had `http://schema.org/Dataset` and millions of datasets. As the products that use this metadata begin to appear, the number of domains and datasets is growing: about 30% increase in the number of domains and 90% increase in the number of datasets in the first three months.

7 DISCUSSION

We now discuss the lessons that we learned when building Dataset Search (Section 7.1), the feedback that we received from users after the initial public beta launch (Section 7.2), and future work (Section 7.3).

7.1 Lessons learned

In our efforts to build Dataset Search based on an open ecosystem, we have learned several lessons that we think might be valuable to others building similar vertical search engines or those who work on tools and applications that rely specifically on dataset metadata.

Build an ecosystem first: Often, the immediate impulse of technologists is to build technical solutions for a given problem. In the case of Dataset Search, a key technical problem is to identify and extract metadata for datasets spread across the entire Web. Open information extraction from long tail sources is a known hard problem (e.g., [6, 25, 31]). Therefore, posing the problem of collecting metadata as a solely technical problem makes the solution significantly less feasible. Relying on an open source standard that enables dataset providers to describe their datasets and creating an ecosystem for publishing metadata led to several benefits. First, we have an immediate solution to the problem of collecting metadata at Web scale. This problem would have been a much more daunting and time consuming feat if we used a purely technical solution. Second, the majority of dataset repositories already store this metadata in a structured form in their own database, generating dataset profile pages programmatically from these databases. Rather than trying to reverse-engineer this metadata from a variety of fonts, layouts, frames, and so on, we get much better fidelity by simply having this structured data populate the corresponding metadata fields. Finally, we can think of the ecosystem as a means of bootstrapping a technical solution: The ecosystem provides an abundant supply of data needed to train systems that may be able to assist in identifying more landing pages with metadata or enriching the metadata we have already collected (Section 7.3).

Open non-proprietary standard is key: When deciding which standard to adopt for the metadata markup we chose non-proprietary open standards, Schema.org and DCAT. It takes about the same amount of development or manual effort on behalf of dataset owners or repository developers to create metadata that conforms to any standard, proprietary or otherwise. However, the value of markup that uses a non-proprietary standard potentially can be many times that of a proprietary standard because many different search engines and other applications can use the markup easily. We found that it was much easier to encourage developers to provide markup in non-proprietary standard than it would have been in a proprietary one: many commented that the perceived increased value because markup can be leveraged by multiple applications was important. Just as significant was the understanding that they were not adding the metadata to benefit a single corporation or a single search engine but rather enhancing the discoverability of their data across all tools.

Bootstrapping requires influencers and incentives: One of the hardest aspects of creating a thriving data ecosystem is the process of bootstrapping. It is a chicken-and-egg problem: We need data providers to use the markup and data providers need some meaningful application that uses that markup to justify implementing it. A couple of factors made this task easier for the case of building Dataset Search. First, the open-data community, which builds many of the dataset repositories, generally understands the value of metadata and explicit semantics in its description. For the most part, this audience is as receptive as one could find to these ideas. Second, the encouragement was coming from teams that were planning to deploy the solution at a major search-engine company, Specifically, Google has used Schema.org in many of its products [11]. This history gave the developers a sense of how this metadata may end up manifesting itself in such products. It is important to note, however, that influence does not have to be purely based on traffic or the number of users. The influence may come from funding agencies, for example. We believe that using a non-proprietary standard is necessary but not sufficient for a healthy ecosystem: until the ecosystem is sufficiently large, many data providers will still need some incentive to implement the markup.

Semantics and knowledge graph are critical ingredients: We use lightweight semantics in many parts of Dataset Search. The Schema.org standard itself allows data providers to specify semantics of the content of a Web page using agreed upon vocabulary. In Section 5.3, we discussed the use of semantics to improve the accuracy of reconciliation to the knowledge graph and the use of the knowledge graph itself to add semantics to search, similar to other semantic-search approaches [2]. Furthermore, the key ingredient of our work is the core idea underlying the Semantic Web: resources on the Web should be linked and have their semantics described using shared vocabularies.

7.2 What users want

After collecting user feedback in the first month after the launch, we have learned what features our users seem to desire the most. By far the most requested feature for Dataset Search was to include some sort of faceted browsing. While free text queries are easy to use, users also want to be able to filter the results by date, location, size of a dataset, licensing terms, and other attributes. One of the reasons why we did not include this feature initially was the sparsity of metadata. the majority of dataset descriptions simply lack any values for the fields that one would naturally include in filtering. Thus, filtering results by the values of these sparsely populated fields, will severely impact recall in a faceted search. We hope that as the ecosystem grows and tools like Dataset Search highlight the specific attributes that we use, metadata providers will find it useful to specify values for these attributes, thus making filtered search more feasible.

One of the major components in Dataset Search is the identification of replica datasets across different repositories (Section 5.4). This feature was well received and users have asked that we infer more than simple replica relationships: Not surprisingly, data provenance is key for many researchers who rely on the data [9]. If we can identify the primary or canonical source for the data, we can highlight it better, giving users the choice to go to that source, or to another repository that they are more familiar with.

Finally, users have also requested that we index the data itself in addition to metadata. There are many challenges associated with obtaining, parsing, and indexing the raw data but we hope to include this feature in future iterations of Dataset Search.

7.3 Future work

There are many technical challenges that we need to address to make Dataset Search a more comprehensive and useful tool for dataset discovery.

First, we need to improve the **quality of the metadata** that we have by learning from the existing metadata, by linking to other resources such as academic publications, by understanding data provenance and the evolution of the metadata on the Web. We also need to make sure that the metadata faithfully describes the content of the page: technically nothing stops a data provider from adding `http://schema.org/Dataset` to a page describing a job posting, for instance. And indeed, we have observed many such instances in the data that we crawled. We hope that now that there is a huge variety of dataset pages that are marked up with Schema.org, researchers can use these pages to learn how a page describing a dataset might look like and to build classifiers for such pages.

To improve the **ranking of datasets**, we need to learn from the user interactions. As with any ranking problem, the result users click on for a given query, can help us build new models to improve the ranking.

We hope to improve the **coverage** both by encouraging the growth of the explicit metadata on the Web and using existing metadata for training methods that can extract new metadata.

Finally, we hope that the presence of tools that treat datasets as prominent first-class objects and encourage/reward citing of the data, will lead to an ecosystem where data owners find it valuable and rewarding not only to publish their data but also to describe it better and more fully.

8 CONCLUSIONS AND FUTURE WORK

We have described Dataset Search, a vertical search engine for data discovery that is based on an open ecosystem where data providers describe their metadata in Schema.org, an open non-proprietary standard. Using this community standard has allowed us to grow the coverage quickly, before any applications or products that rely on this metadata even appeared. The response from users to the launch of Dataset search has been extremely positive, not only from scientists and data geeks, but also from journalists and government agencies. We hope that the number of dataset repositories that publish their metadata continues to grow and that other tools start using more actively the metadata that these repositories publish, building other applications that make datasets first-class citizens in scientific and public discourse.

ACKNOWLEDGEMENTS

We would like to thank Xiaomeng Ban, Lee Butler, Thomas Chen, Corinna Cortes, Kevin Espinoza, Archana Jain, Mike Jones, Kishore Papineni, Chris Sater, Gokhan Turhan, Shubin Zhao and Andi Vajda for their work on the project and all our partners, collaborators, and early adopters for their help.

ABSTRACT

In 2017, Internet ad spending reached 209 billion USD worldwide, while, e.g., TV ads brought in 178 billion USD. An Internet advertising campaign includes up to thousands of sub-campaigns on multiple channels, e.g., search, social, display, whose parameters (bid and daily budget) need to be optimized every day, subject to a (cumulative) budget constraint. Such a process is often unaffordable for humans and its automation is crucial. As also shown by marketing funnel models, the sub-campaigns are usually interdependent, e.g., display ads induce awareness, increasing the number of impressions—and, thus, also the number of conversions—of search ads. This interdependence is widely exploited by humans in the optimization process, whereas, to the best of our knowledge, no algorithm takes it into account. In this paper, we provide the first model capturing the sub-campaigns interdependence. We also provide the IDIL algorithm, which, employing Granger Causality and Gaussian Processes, learns from past data, and returns an optimal stationary bid/daily budget allocation. We prove theoretical guarantees on the loss of IDIL w.r.t. the clairvoyant solution, and we show empirical evidence of its superiority in both realistic and real-world settings when compared with existing approaches.

1 INTRODUCTION

Since the early stages of the Internet, one of the most remunerative ways to economically exploit this novel media channel is *online advertising*. For instance, two of the largest companies of the Internet era, namely Google and Facebook, get most of their incomes from the placement of advertisements. In 2017 alone, advertising revenues have totalled about 88 billion USD in the US [16] and about 209 billion USD worldwide. Search is the most important advertising channel, with around 40% of the total spent. The choice of the ads to be displayed and their placement on a webpage are made through auctioning mechanisms [18]. An advertising *campaign* consists of a number (up to thousands) of *sub-campaigns* and a cumulative (per day or month) budget constraint. Each sub-campaign is characterized by an *ad*, a *targeting*, a *bid*, and a *daily budget*, and these last two parameters, crucial for the outcomes of the auctions, can be optimized every day using past performance. Such an optimization process is often unaffordable for humans and its complete, or partial, automation can lead to a significant improvement in revenues.

In addition to search advertising, other advertising channels can be used nowadays, e.g., display and social. The diversification of ad channels is a crucial degree of freedom that one can exploit when setting up an advertising campaign. Indeed, different channels deeply affect each other's performance as Internet users regularly surf from one to another. For instance, Lewis and Nguyen [21] provide empirical evidence that display advertising increases the search activity on a product for some days after the display ads visualization. Kireyev et al. [19] show a similar result between display and search advertising by using the Granger Causality test. The authors also show that this interdependence usually induces delayed dynamics, e.g., an increase in the display advertising impressions can lead to an increase in the conversions of search ads with a delay of some days. Hoban and Bucklin [13] study how display advertising affects user behavior at every level of the marketing funnel [15], while Dinner et al. [4] show that online advertising can even affect the performance of (traditional) non-online advertising. The sub-campaigns interdependence is customarily exploited by experts in the field, e.g., setting up sub-campaigns (called *assist*) not providing direct conversions but increasing the number of conversions on the search engine channel. Besides, capturing the interdependence can provide a direct method for comparing and optimizing

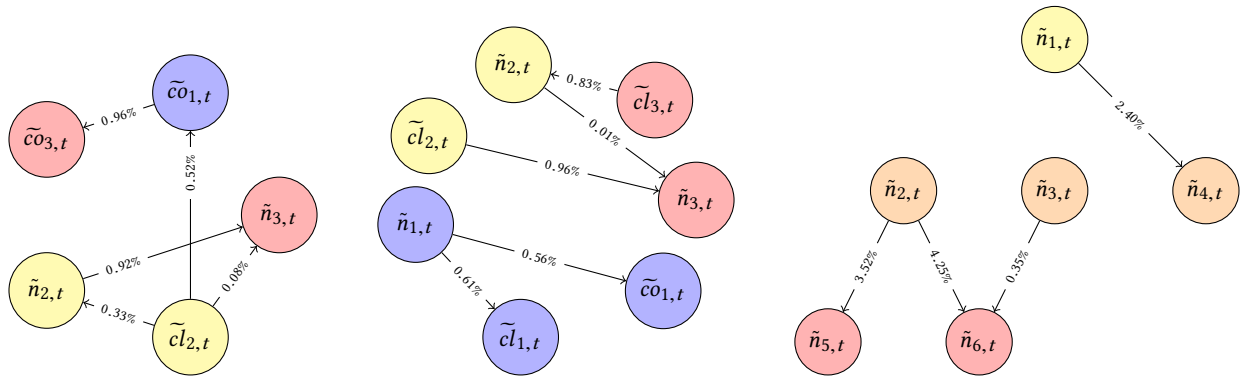
the performance of sub-campaigns on different channels. Indeed, sub-campaigns on different channels need to be evaluated using different performance metrics, and how to combine them is still an open issue. For instance, display and social ads provide very few conversions compared to search ads but allow search ads to generate a larger number of conversions, and therefore an optimization method based only on the number of conversions might not provide optimal allocations. The same holds in the search channel for branding and no-branding sub-campaigns. Although this problem is central in advertising, to the best of our knowledge, no model in the economic literature captures such interdependence.

Related work. Zhang et al. [39] propose an offline joint bid/daily budget optimization algorithm. In addition to neglecting interdependences between sub-campaigns, this work suffers from some weaknesses. In particular, the authors assume a specific family of functions describing the relationship between the parameters and do not provide any theoretical bound on the estimation error. Furthermore, some parameters (e.g., the ad position for each impression and click) cannot be observed by an advertiser, not allowing their estimation and, therefore, the use of the model in practice. Some of these weaknesses have recently been addressed by Nuara et al. [25], who provide an online joint bid/daily budget optimization algorithm called AdComB-TS and exploiting Gaussian Processes [29]. However, this work overlooks the sub-campaigns interdependence. Other related works follow. Thomaidou et al. [32] separate the optimization of the bid from that of the budget, using a genetic algorithm to optimize the budget and then applying some bidding strategies. Markakis and Telelis [22] study the convergence of some bidding strategies. Another related research field is the study of user behaviors from logging data [27, 31], both on social networks [28], and on search engines [37]. However, these approaches assume to keep track of all the actions of each user perfectly, and this is usually unfeasible for most of the advertising tools used by companies. Less related works concern the optimization of the daily budget [17, 36], bidding strategies in display advertising [20, 34, 35, 38], video advertising [10], and targeting [6]. Finally, some works deal with the attribution problem in display advertising [11, 19].

Original contributions. We extend the work by Nuara et al. [25], designing an algorithm based on both learning and optimization techniques that can be adopted for the optimization of real-world Internet advertising campaigns and that, exploiting sub-campaigns interdependence, outperforms the algorithms known so far. To do that, we provide a novel model that, on one side, is expressive enough to capture the interdependences and, on the other side, is simple enough to require few data for its estimation.[1] From of the proposed model, we design a data-driven algorithm, called IDIL, which consists of two phases: the *Interdependence Graph Learning Phase* and the *Estimation and Optimization Phase*. In the former phase, the IDIL algorithm learns the sub-campaigns interdependence structure (represented as a graph), identifying the pairs of sub-campaigns with the most significant interdependences by applying the Granger Causality test. This is crucial since the number of pairs of interdependent sub-campaigns dramatically increases the amount of data required to have accurate estimates of the model parameters. In the latter phase, the IDIL algorithm computes the optimal joint bid/daily budget allocation exploiting Gaussian Process modeling [29] and an *ad hoc* dynamic programming procedure. In particular, Gaussian Processes exploit some form of functional regularity to describe the relationships among the problem parameters, without forcing them belong to a specific family of curves.

Finally, we show that neglecting the sub-campaigns interdependence can lead to massive losses even in simple and common scenarios and we theoretically bound the loss of our algorithm. Furthermore, we experimentally evaluate its performance in both realistic and real-world settings, showing the superiority of its performance compared to the previous approaches that neglect the sub-campaigns interdependence.

2 INTERNET ADVERTISING CAMPAIGN



Assume to have an Internet advertising campaign $C = \{C_1, \dots, C_N\}$, with $N \in \mathbb{N}$, where C_j is the j-th sub-campaign. At day t, we are asked to set for each sub-campaign C_j a bid $x_{j,t} \in [\underline{x}_j, \overline{x}_j]$, and a daily budget $y_{j,t} \in [\underline{y}_j, \overline{y}_j]$, subject to that the daily cumulative budget of all the sub-campaigns cannot exceed $Y \in \mathbb{R}^+$. At day $t+1$, we get a report on the performance of the campaign C at the previous day t, which specifies, for every C_j, the tuple $(\widetilde{n}_{j,t}, \widetilde{cl}_{j,t}, \widetilde{co}_{j,t}, \widetilde{c}_{j,t})$, where $\widetilde{n}_{j,t}$ denotes the number of impressions, $\widetilde{cl}_{j,t}$ denotes the number of received clicks, $\widetilde{co}_{j,t}$ denotes the cumulate value of the conversions, and $\widetilde{c}_{j,t}$ denotes the amount of money spent for it.[2]

As aforementioned, both experts in the field of Internet advertising and studies in the Internet economic field, e.g., Kireyev et al. [19] and Hoban and Bucklin [13], demonstrate that impressions, clicks, and conversions of a sub-campaign might be influenced by the same kind of quantities of the other sub-campaigns. We extend the previous studies on the sub-campaigns interdependence, applying the Granger Causality test [12, 33] to two real-world Internet advertising campaigns optimized by an Italian web media agency using the AdComb-TS algorithm [25]. The algorithm, being online, produces policies explorative enough to make the test significant.

At first, we test for Granger causality the data collected for 8 months (from 1/1/2018 to 1/8/2018) from an Internet advertising campaign for a financial service of an insurance company: data correspond to $N = 12$ sub-campaigns, on Google AdWords (search), Facebook (social), and Google display with a cumulative budget of $Y = 600$ Euros. The results obtained from the Granger Causality test are shown in Figure 1, where the most significant elements of $(\widetilde{n}_{j,t}, \widetilde{cl}_{j,t}, \widetilde{co}_{j,t}, \widetilde{c}_{j,t})$ are represented as nodes of different colors according to their specific channel (as detailed in the caption of the figure) and the detected interdependences (with a p-value less than 5%) are represented as directed edges. In particular, Figure 1a shows the results when all the sub-campaigns data are aggregated, while Figure 1b focuses on a specific subset of sub-campaigns who share the same targeting (retired people). These results confirm the presence of the interdependence between display and search advertising as previously observed in the literature. They also show

[1] Due to learning, a sophisticated model may provide poor performance. This is because an excessively complex model could need a large amount of data for the training and collecting such data could require a long time, even longer than the time horizon considered in the optimization process.

[2] We recall that the money spent in one day for a sub-campaign may be different from the daily budget previously allocated.

(a) First dataset, overall people (b) First dataset, only retired people (c) Second dataset

Figure 1: Graphs representing the interdependences of real-world Internet advertising sub-campaigns inferred by Granger Causality test from real data. The numbers on the edges are the p-values (in terms of %) of the Granger Causality test; display ads are depicted in blue, social ads in yellow, and search ads in orange (for branding sub-campaigns) and red (for other search sub-campaigns). The second dataset graph refers to interdependence among impressions $\tilde{n}_{j,t}$ of different sub-campaigns C_j.

that social and search advertising are interdependent and that the interdependences may be targeting specific. Moreover, the interdependence between clicks and impressions of the social channels and the impressions of the search one in this specific scenario seems to be more relevant than others, since they appear in both graphs. Furthermore, the Granger Causality test detects that interdependence dynamics between sub-campaigns are delayed up to 2 days.

At second, we test for Granger causality the data collected for 3 months (from 20/7/2018 to 20/10/2018) from an Internet advertising campaign of a different financial product of the same company with about $Y = 1100$ Euros. There are $N = 14$ sub-campaigns belonging to social and search advertising channels. The resulting graph is depicted in Figure 1c (with a p-value less than 5%). As in the previous dataset, many sub-campaigns are subject to interdependence. In particular, in this case, the interdependence phenomenon is only among impressions, suggesting that these can be the most significant in practice. Moreover, differently from the previous case, we distinguish search sub-campaigns into two subclasses which are at different depths in the marketing funnel: branding (orange nodes) or no-branding (red nodes). Finally, the delay of the interdependence dynamics is up to 3.

3 OPTIMIZATION PROBLEM

We provide our optimization problem capturing the sub-campaigns interdependence. For the sake of presentation, we focus on the interdependence between the impressions of different sub-campaigns.[3] Our goal is the maximization of the revenue earned each day from an Internet advertising campaign subject to a cumulative budget constraint. Formally, given a campaign C and a cumulative daily budget of Y, we aim to find, at day t, the value of bid $x_{j,t}$ and the value of daily budget $y_{j,t}$ for every sub-campaign C_j that maximise the revenue by solving the following optimization problem:

$$\max_{x_{j,t}, y_{j,t}} \sum_{j=1}^{N} v_j \; w_j \; n_j(x_{j,t}, y_{j,t}, u_{j,t}) \tag{1a}$$

$$\text{s.t.} \sum_{j=1}^{N} y_{j,t} \leq Y \tag{1b}$$

$$\underline{x}_j \leq x_{j,t} \leq \overline{x}_j \qquad \forall j \tag{1c}$$

$$\underline{y}_j \leq y_{j,t} \leq \overline{y}_j \qquad \forall j \tag{1d}$$

where $n_j(x_{j,t}, y_{j,t}, u_{j,t})$ is the expected number of impressions given bid $x_{j,t}$, daily budget $y_{j,t}$, and *influence index* $u_{j,t}$, representing the influence of other sub-campaigns towards C_j and computed by using the number of impressions of those sub-campaigns that are interdependent with sub-campaign C_j (see below); w_j and v_j are the click-trough rate and the value per click for the sub-campaign C_j, respectively, and, therefore, $v_j \; w_j \; n_j(x_{j,t}, y_{j,t}, u_{j,t})$ is the revenue provided by sub-campaign C_j.[4] We denote with $(\boldsymbol{x}^*, \boldsymbol{y}^*, \boldsymbol{u}^*)$ the optimal solution to the optimization problem.

To model the sub-campaigns interdependence, we define:

Definition 1. *Given an advertising campaign C, an* interdependence graph $\mathcal{G} := (C, D)$ *is a graph in which the adjacency matrix $D = \{d_{ij}\}, D \in \{0,1\}^{N \times N}$ has elements $d_{ij} = 1$ iff the sub-campaign C_i influences the performance of the sub-campaign C_j.*

We assume that the graph $\mathcal{G}$ is a Directed Acyclic Graph (DAG), i.e., there are no dependency cycles among the sub-campaigns. This assumption is supported by the model of the marketing funnel, in which the majority of the users flows from the top to the bottom, and different advertising channels are positioned at different levels of the funnel. Without loss of generality, we assume that the order over the indices of the sub-campaigns is one of the topological

[3] The use of such quantities is also supported by the experimental results of Section 2, where the interdependence among impressions is the most significant. However, different models, e.g., including the interdependence between the clicks and the conversions, are straightforward extensions of what is proposed in this section.

[4] The optimization problem in Equations (1a)–(1d) reduces to the one by Nuara et al. [25] when there is no interdependence, i.e., if $n_j(x_{j,t}, y_{j,t}, u_{j,t}) = n_j(x_{j,t}, y_{j,t})$, for every C_j.

orders induced by $\mathcal{G}$. Given the interdependence graph $\mathcal{G}$, a formal definition of the influence index $u_{j,t}$ is:

$$u_{j,t} := \frac{1}{K} \sum_{i=1}^{j-1} \sum_{h=t-1}^{t-K} d_{ij}\, n_i(x_{i,h}, y_{i,h}, u_{i,h}), \tag{2}$$

where K is a maximum lag order, meaning that users are influenced by ads at most for K consecutive days. Notice that the first sub-campaign C_1, being influenced by no other sub-campaign, has $u_{1,t} = 0$ since the first summation in Equation (2) is over an empty set. The above definition of $u_{j,t}$ is based on the assumption that the increase in the number of impressions provided by a user coming from any sub-campaign influences the number of impressions of C_j in the same way. While this assumption might seem simplistic, it is necessary to keep at a pace the complexity of training the model. Indeed, a more complex model, e.g., where there is a different influence index for every pair of sub-campaigns, might be an option, but this would require an excessively large amount of data for the training of the model, which is not a viable option within the time horizon of the optimization process.

The optimization problem in Equations (1a)-(1d) can be solved using dynamic programming techniques, once all its parameters are known. However, the advertiser does not know the function $n_j(\cdot,\cdot,\cdot)$ that returns the number of impressions for sub-campaign C_j, as well as its click-trough rate w_j and its value per click v_j. Therefore, we resort to learning techniques to produce estimates of these parameters relying on historical data. We assume to have a dataset $Z := \{\boldsymbol{z}_{j,t}\}$ of τ samples that provides, for each day $t \in \{1,\dots,\tau\}$ and each sub-campaign C_j with $j \in \{1,\dots,N\}$, the following values: $\boldsymbol{z}_{j,t} := (\tilde{x}_{j,t}, \tilde{y}_{j,t}, \tilde{n}_{j,t}, \tilde{cl}_{j,t}, \tilde{co}_{j,t}, \tilde{c}_{j,t})$. This is a tuple with the used bid $\tilde{x}_{j,t}$ and daily budget $\tilde{y}_{j,t}$, the received impressions $\tilde{n}_{j,t}$, clicks $\tilde{cl}_{j,t}$, values of the conversions $\tilde{co}_{j,t}$, and costs $\tilde{c}_{j,t}$. We require that the data collected up to day τ to be exploratory enough to properly model the sub-campaigns interdependences.

4 THE IDIL ALGORITHM

The pseudo-code of the IDIL algorithm is provided in Algorithm 1. It requires a dataset Z and two confidence levels $\alpha_{ADF} \in (0,1)$ and $\alpha_{GC} \in (0,1)$ in input. The first phase of the algorithm (Lines 1–8) is called *Interdependence Graph Learning Phase* and is devoted to learning the interdependence graph of the sub-campaigns. The output of this phase is an estimate $\hat{D}$ of the actual adjacency matrix D. The second phase of the algorithm (Lines 9–13) is called *Estimation and Optimization Phase* and is devoted to the estimation of the parameters for each sub-campaign C_j (i.e., $\hat{n}_j(\cdot,\cdot,\cdot), \hat{v}_j, \hat{w}_j$), using Gaussian Process [29] modeling, and solving the optimization problem in Equations (1a)-(1d), once the parameters have been replaced with their estimates. The outputs of this phase are $(\hat{\boldsymbol{x}}^*, \hat{\boldsymbol{y}}^*, \hat{\boldsymbol{u}}^*)$, i.e., the optimal bid, daily budget, and influence index for each sub-campaign.

4.1 Interdependence Graph Learning Phase (Lines 1–8)

The task of learning $\hat{D}$ is obtained by resorting to the Granger Causality test [12]. This test has been used in many different fields to infer the structure among datastreams, e.g., sensor networks

Algorithm 1 IDIL

by Alippi et al. [1] and Roveri and Trovò [30], and economics by Calderón and Liu [2]. While in its original formulation the test assumes that the analysed time series are stationary, we rely on a generalization of this test, proposed by Toda and Yamamoto [33], which is suitable for integrated and cointegrated time series.

The basic idea of this approach is to estimate a Vector AutoRegressive model of order $K_{GR} + d_{\max}$ for the vector $(\widetilde{n}_{1,t},\dots,\widetilde{n}_{N,t})$, where $d_{\max} \in \mathbb{N}$ is the maximum integration order of the time series that we analyse and $K_{GR} \in \mathbb{N}$ is a lag order which is estimated from the data.[5] The use of $K_{GR} + d_{\max}$ lags ensures that the test statistic used in the Granger Causality test for stationary time series has the same asymptotic distribution of the stationary case and, therefore, statistically valid conclusions can be drawn. More specifically, to test if the impressions of the campaign C_i influence the impressions of the campaign C_j, we estimate the parameters a_{jlm}, for each $m \in \{1,\dots,K_{GR}+d_{\max}\}$, of the model:

$$\widetilde{n}_{j,t} = \sum_{l=1}^{N} \sum_{m=1}^{K_{GR}+d_{\max}} a_{jlm}\, \widetilde{n}_{l,t-m} \quad \forall h \in \{1,\dots,N\}$$

and we test for the hypothesis:

$$H_0 : \forall m \in \{1,\dots,K_{Gr}\}\ a_{jim} = 0,$$
$$H_1 : \exists m \in \{1,\dots,K_{Gr}\} \mid a_{jim} \neq 0.$$

The complete description of this procedure is provided by Toda and Yamamoto [33]. The test states that if we reject H_0 there is

[5] d_{max} can be estimated using the Augmented Dickey Fuller test [3], which requires a confidence level $\alpha_{ADF} \in (0,1)$, while K_{GR} can be estimated from the dataset Z by standard techniques, see Ozcicek and Mcmillin [26] for details.

evidence, with confidence α_{GC}, that the impressions from C_i are influencing those of C_j.

The IDIL algorithm works as follows. For each sub-campaign, we estimate $d_{\max}$ performing the Augmented Dickey Fuller test $\mathsf{ADF}(\tilde{\boldsymbol{n}}_{\boldsymbol{j}}, \alpha_{ADF})$ on the time series $\tilde{\boldsymbol{n}}_{\boldsymbol{j}} := (\tilde{n}_{j,t}, \ldots, \tilde{n}_{j,\tau})$ with confidence α_{ADF} (Lines 1–3), and inferring the time series order adf_j, and, finally, we perform the Granger Causality test on each pair of sub-campaigns (Lines 5–7). The result of this procedure is a matrix $\hat{P}$ containing the p-values of the pairwise tests, which is used to generate a valid estimate of the adjacency matrix $\hat{D} \in \{0,1\}^{N \times N}$. This operation is performed by $\mathsf{DAG}(\hat{P}, \alpha_{GC})$ (Line 8) by selecting the largest subset S of the p-values $\hat{p}_{ij} < \frac{2\alpha_{GC}}{N(N-1)}$ s.t. the matrix $\hat{D} := \{d_{ij} = 1 \text{ iff } p_{ij} \in S\}$ to correspond to a DAG.[6] This procedure ensures an overall confidence α_{GC} on the Granger Causality test, thanks to the Bonferroni correction for multiple tests, and it avoids that the presence of false positives in the detection of interdependences. Indeed, the edges generated by false positive detections might provide adjacency matrices $\hat{D}$ whose corresponding graph presents cycles, which would compromise the execution of the following optimization procedure.

4.2 Estimation and Optimization Phase (Lines 9–13)

The second phase of the IDIL algorithm exploits predictive models to estimate unknown functions and quantities in the optimization problem defined in Equations (1a)-(1d), and solves it in a dynamic programming fashion with an *ad hoc* procedure.[7]

We use Gaussian Processes (GPs) to compute, for each sub-campaign C_j, the function $\hat{n}_j(x, y, u)$ estimating the expected number of impressions $n_j(x, y, u)$, given the chosen bid x, the allocated budget y, and the influence index u generated by the sub-campaigns influencing the sub-campaign C_j (Line 10). The estimate $\hat{w}_j$ of the click-through rate w_j and the estimate $\hat{v}_j$ of the value per click v_j are the average ratios between the number of clicks and the number of impressions and between the number of conversions and the number of clicks, respectively (Lines 9-12). Finally, the estimated influence index is computed as follows:

$$\hat{u}_{j,t} := \frac{1}{K_{GR}} \sum_{i=1}^{j-1} \sum_{h=t-1}^{t-K_{GR}} \hat{d}_{ij}\, \hat{n}_i(x_{i,h}, y_{i,h}, \hat{u}_{i,h}), \tag{3}$$

where we use K_{GR}, obtained from the Granger Causality test, as an estimate of the actual lag K.

The optimization procedure is an extension of the optimization algorithm by Nuara et al. [25], to handle also campaigns in which the revenue given by a budget allocated to a sub-campaign depends on the budget allocated to other sub-campaigns. The OPT algorithm, presented in Algorithm 2, takes as input the estimates of the adjacency matrix $\hat{D}$, the number of impressions function $\hat{n}_j(\cdot,\cdot,\cdot)$, the click-trough rate $\hat{w}_j$, the value per click $\hat{v}_j$, and a set of available daily budget values $\{b_1, \ldots, b_B\}$, which are, for simplicity, evenly spaced in the range $[0, Y]$.

[6] An adjacency matrix $\hat{D}$ identifies a DAG if and only if a depth-first search of the corresponding graph yields no back edges.

[7] For the sake of presentation in what follows we assume that the number of impressions is monotonically increasing in the influence index. A version of the optimization procedure able to handle general cases is discussed in the final part of this section.

Algorithm 2 $\mathsf{OPT}(\hat{\boldsymbol{n}}, \hat{\boldsymbol{v}}, \hat{\boldsymbol{w}}, \hat{D})$

Input: estimated adjacency matrix $\hat{D}$, estimated models $\hat{n}_j(\cdot,\cdot,\cdot)$, $\hat{w}_j$, $\hat{v}_j$, discretization of the total budget $\{b_1, \ldots, b_B\}$
Output: optimal bid/budget allocation $(\hat{\boldsymbol{x}}^*, \hat{\boldsymbol{y}}^*, \hat{\boldsymbol{u}}^*)$

1: **for** $i \in \{1, \ldots, B\}$ **do**
2: $\quad \Pi_{1,i,1} \leftarrow (b_i\ \mathbf{0}_{N-1})$
3: $\quad L_{1,i,1} \leftarrow \hat{v}_1\ \hat{w}_1\ \hat{n}_1(\chi_1, b_i, 0)$
4: $\quad M_{1,i,1} \leftarrow \hat{n}_1(\chi_1, b_i, 0)\ \hat{\boldsymbol{d}}_1$
5: **for** $j \in \{2, \ldots, N\}$ **do**
6: $\quad$ **for** $i \in \{1, \ldots, B\}$ **do**
7: $\quad\quad c \leftarrow 1$
8: $\quad\quad$ **for** $k \in \{1, \ldots, i\}$ **do**
9: $\quad\quad\quad m = |\{\Pi_{j-1,k,h}\}_h|$
10: $\quad\quad\quad$ **for** $h \in \{1, \ldots, m\}$ **do**
11: $\quad\quad\quad\quad l \leftarrow \hat{n}_j(\chi_j, b_i - b_k, M_{j-1,k,h}(j))$
12: $\quad\quad\quad\quad \bar{\Pi}_c \leftarrow (\mathbf{0}_{j-1}\ (b_i - b_k)\ \mathbf{0}_{N-j}) + \Pi_{j-1,k,h}$
13: $\quad\quad\quad\quad \bar{L}_c \leftarrow \hat{v}_j\ \hat{w}_j\ l + L_{j-1,k,h}$
14: $\quad\quad\quad\quad \bar{M}_c \leftarrow\ l\ \hat{\boldsymbol{d}}_j + M_{j-1,k,h}$
15: $\quad\quad\quad\quad c \leftarrow c + 1$
16: $\quad\quad c \leftarrow 1$
17: $\quad\quad$ **for** $h \in \{1, \ldots, |\{Lt_c\}_c|\}$ **do**
18: $\quad\quad\quad$ **if** $\nexists k \mid \bar{L}_h < \bar{L}_k \wedge \forall p \in \{j+1, \ldots, N\} | \bar{M}_h(p) < \bar{M}_k(p)$ **then**
19: $\quad\quad\quad\quad \Pi_{j,i,c} \leftarrow \bar{\Pi}_h$
20: $\quad\quad\quad\quad L_{j,i,c} \leftarrow \bar{L}_h$
21: $\quad\quad\quad\quad M_{j,i,c} \leftarrow \bar{M}_h$
22: $\quad\quad\quad\quad c \leftarrow c + 1$
23: **for** $j \in \{1, \ldots, N\}$ **do**
24: $\quad \hat{y}^*_j \leftarrow \max_i \Pi_{N,i,1}(j)$
25: $\quad \hat{u}^*_j$ computed as in Equation (3)
26: $\quad \hat{x}^*_j = x^*_j(\hat{y}^*_j, \hat{u}^*_j)$
27: **return** $(\hat{\boldsymbol{x}}^*, \hat{\boldsymbol{y}}^*, \hat{\boldsymbol{u}}^*)$

The OPT algorithm uses three structures Π, L, and M defined as follows: $\Pi_{j,i,h}$ is a vector that specifies a partial budget allocation with cumulative budget of b_i among the sub-campaigns $C_1, \ldots, C_j$; $L_{j,i,h}$ is the revenue provided by the partial budget allocation $\Pi_{j,i,h}$; $M_{j,i,h}$ is a vector that specifies the value of the influence index of the sub-campaigns $C_{j+1}, \ldots, C_N$ provided by the sub-campaigns $C_1, \ldots, C_j$ when the partial allocation $\Pi_{j,i,h}$ is used. The third index h in the structures mentioned above is necessary since the algorithm may need to store multiple partial budget allocations for each j and i. More precisely, the set $\{\Pi_{j,i,h}\}_h$ contains Pareto-efficient partial budget allocations, where the optimality criteria are the revenue and the influence indices of campaigns $C_{j+1}, \ldots, C_N$. For instance, given two partial budget allocations Π_{j,i,h_1} and Π_{j,i,h_2}, where the former has high revenue and a small number of impressions and the latter *vice versa*, it is not possible to decide which one is the optimal before evaluating their influence on the sub-campaigns $C_{j+1}, \ldots, C_N$ and therefore we need to store both.

At first, the algorithm initializes the values of the structures for $j = 1$ (Lines 1–4), corresponding to the allocations of the partial budget to the sub-campaign C_1. For each budget b_i, we allocate

it to C_1, formally, $\Pi_{1,i,1} = (b_i, \mathbf{0}_{N-1})$, where $\mathbf{0}_{N-1}$ denotes a null vector of size $N-1$. The sub-campaign C_1, being the first in the topological ordering induced by $\hat{D}$, is not subject to any interdependence from other sub-campaigns. Therefore, the computation of the revenue $\{L_{1,i,1}\}_i$ and the influence index vector $\{M_{1,i,1}\}_i$ is performed using the previously estimated models.[8] The vector $M_{1,i,1}$ is computed as $M_{1,i,1} = n_1(\chi_1, b_i, 0)\ \hat{\boldsymbol{d}}_1$, where $\hat{\boldsymbol{d}}_i$ is the i-th row of the adjacency matrix $\hat{D}$. This means that $M_{1,i,1}(j)$, i.e., the j-th element of $M_{1,i,1}$, is equal to $n_1(\chi_1, b_i, 0)$ if the sub-campaign C_1 influences the campaign C_j and zero otherwise.

For all the $j \in \{2, \ldots, N\}$, the algorithm computes the elements of the three structures Π, L, and M using the values previously computed at the $j-1$-th step, in a dynamic programming fashion (Lines 5–22). For each daily budget b_i and for each daily budget $b_k \leq b_i$, we compute the revenue and the influence index provided by the allocation of a daily budget of $b_i - b_k$ to the sub-campaign C_j and the remaining daily budget of b_k to the sub-campaigns $C_1, \ldots, C_{j-1}$. We do this by enumerating all the Pareto-efficient partial allocations $\Pi_{j-1,k,1}, \Pi_{j-1,k,2}, \ldots$ of the first $j-1$ sub-campaigns, then allocating daily budget $b_i - b_k$ to the sub-campaign C_j and, finally, we evaluate the total revenue $\bar{M}_c$ and the influence indices vector $\bar{L}_c$ provided by the partial allocations obtained, denoted with $\bar{\Pi}_c$ (Lines 9–15).[9] After that, the algorithm discards all the candidate partial allocations which are Pareto dominated (Lines 16-22); see Matthias [24] for details on Pareto efficiency and dominance.[10] Finally, the algorithm returns the optimal allocation (Lines 23–27): the optimal budgets $\hat{y}_j^*$ are the elements of $\max_i \Pi_{N,i,1}(j)$; the optimal influence indices $\hat{u}_j^*$ are computed using Equation (3); the optimal bids $\hat{y}_j^*$ are computed using the impressions models $\hat{n}_j(\cdot,\cdot,\cdot)$.

The complexity of the OPT algorithm is $O\left(\sum_j B^{\sum_i \hat{d}_{ij}+2}\right) \leq O\left(N\ B^2\ B^{\max_j \sum_i \hat{d}_{ij}}\right)$ and strictly depends on the maximum indegree of the interdependence graph corresponding to $\hat{D}$. The complexity reduces to that one of the algorithm proposed by Nuara et al. [25] when the sub-campaigns are not interdependent. Notice that capturing only the pairs of sub-campaigns with the most significant interdependence is a crucial issue from a computational point of view since, taking into account all the possible pairs of sub-campaigns, the complexity is bounded by $NB^2 \frac{B^{N+1}-1}{B-1}$, which is intractable when N is large as it happens in real-world applications.

5 THEORETICAL PROPERTIES OF THE IDIL ALGORITHM

We analyse the properties of our problem and those of the IDIL algorithm. Initially, we analyse the suboptimality of any algorithm ignoring the sub-campaigns interdependencies w.r.t. our algorithm, i.e., when the learner uses an adjacency matrix $\hat{D} = 0$, and the real one D is non-null. The following theorem shows that ignoring the sub-campaigns interdependences might be arbitrarily suboptimal.

Theorem 5.1. *Given the problem of optimizing an advertising campaign C, employing a model $\hat{n}_j(x, y)$ for the number of impressions that ignores the sub-campaigns interdependence may result in an arbitrary large loss in terms of* revenue, *defined as:*

$$R_t = \sum_{j=1}^{N} v_j\ w_j\ n_j(x_{j,t}, y_{j,t}, u_{j,t}). \tag{4}$$

Proof. Consider a campaign C with $N = 2$ sub-campaigns, adjacency matrix $D = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, click-through rates $w_1 = w_2 = 1$, values per click $v_1 = 0$ and $v_2 = 1$, lag $K = 1$, and impression functions identified by two GPs having the following mean value:

$$n_1(x_{1,t}, y_{1,t}, u_{1,t}) = H\, y_{1,t},$$
$$n_2(x_{2,t}, y_{2,t}, u_{2,t}) = \Upsilon\, u_{2,t}\, y_{2,t} = \Upsilon\, n_1(x_{1,t-1}, y_{1,t-1}, u_{1,t-1})\, y_{2,t},$$

where $\Upsilon \in [0, 1]$, $H \in \mathbb{R}^+$. Moreover, assume to have a total budget of Y and to sample the solution space uniformly during training. Asymptotically (when we have an infinite number of samples or $\tau \to \infty$), a model that provides a stationary allocation and knows the sub-campaign interdependencies would compute the revenue:

$$\begin{aligned} R_t &= \sum_{j=1}^{N} v_j\ w_j\ n_j(x_{j,t}, y_{j,t}, u_{j,t}) = \Upsilon\, n_1(x_1, y_1, u_1)\, y_2 \\ &= \Upsilon\, H\, y_1\, y_2 = \Upsilon\, H\, (Y - y_2)\, y_2, \end{aligned}$$

where we drop the temporal indices since the proposed solution is stationary and $y_1 + y_2 = Y$. The budget allocation maximizing the revenue is $y_2 = \frac{Y}{2}$, with a revenue $R_t = \Upsilon\, H\, \frac{Y^2}{4}$.

On the other hand, a model ignoring the sub-campaigns interdependence estimates the impressions of the sub-campaign C_2 as:

$$\tilde{n}_2(x_{2,t}, y_{2,t}) = \int_0^{HY} n_2(x_{2,t}, y_{2,t}, u)du = \int_0^{HY} \Upsilon u\ y_{2,t} du = \frac{\Upsilon H^2 Y^2}{2} y_{2,t},$$

and the revenue one maximises becomes:

$$\tilde{R}_t = \sum_{j=1}^{N} v_j\ w_j\ n_j(x_{j,t}, y_{j,t}, u_{j,t}) = \tilde{n}_2(x_{2,t}, y_{2,t}) = \frac{\Upsilon H^2 Y^2}{2} y_2.$$

The budget allocation maximising $\tilde{R}_t$ is $y_2 = Y$, with a real revenue $R_t = 0$. Hence, the difference of revenue of the two algorithms is $\Upsilon H \frac{Y^2}{4} - 0$, which is arbitrarily large as H goes to ∞. □

When the model is flexible enough to model the actual process properly, we can bound its error, formally, defined as follows:

Definition 2. *Given a dataset Z, the* total (estimation) error *is:*

$$E_\tau := \sum_{j=1}^{N} \left[v_j w_j n_j(x_j^*, y_j^*, u_j^*) - \hat{v}_j \hat{w}_j \hat{n}_j(\hat{x}_j^*, \hat{y}_j^*, \hat{u}_j^*) \right],$$

where the tuples $(\hat{x}_j^*, \hat{y}_j^*, \hat{u}_j^*)$ are elements of the (stationary) output $(\hat{\boldsymbol{x}}^*, \hat{\boldsymbol{y}}^*, \hat{\boldsymbol{u}}^*)$ of the IDIL algorithm using the estimates of the parameters, and (x_j^*, y_j^*, u_j^*) are elements of the (stationary) output of the IDIL algorithm using the real parameters.

We can show the following:

[8] We define χ_j as the bid that maximise the number of impressions given a budget y and a influence index u, or, formally, $\chi_j := \chi_j(y, u) = \arg\max_x \hat{n}_j(x, y, u)$.

[9] In the pseudo-code, we denoted the number of Pareto optimal allocations at the $j-1$-th row with a budget of b_i with $|\{\Pi_{j-1,i,h}\}_h|$.

[10] Notice that the inequality in Line 18 is designed for settings in which the number of impressions is monotonically increasing in the influence index. However, removing the condition in Line 18, the proposed method also applies to problems without such a monotonicity assumption. This comes at at the cost of storing a larger number of partial allocations in $\{\Pi_{j,i,h}\}_h$.

Theorem 5.2. *When the expected number of impressions $n_j(\cdot,\cdot,\cdot)$ of every sub-campaign C_j is distributed as a Gaussian Process, the total error between the real revenue and the estimated one using the output of the IDIL algorithm is upper bounded, with a probability of at least $1-\delta$, as follows:*

$$E_\tau \leq 2N v^{(\max)} \sqrt{\frac{1}{2\tau}\log\frac{6N}{\delta}}\left(\hat{n}^{(\max)} + \hat{\sigma}_\tau^{(\max)}\sqrt{2\log\frac{3N}{\delta}}\right) + N v^{(\max)}\ \hat{\sigma}_\tau^{(\max)}\sqrt{2\log\frac{3N}{2\delta}},$$

where $\hat{n}^{(\max)} := \max_j \max_{(x,y,u)} \hat{n}_j(x,y,u)$ is the maximum number of estimated expected impressions over all the sub-campaigns, $\hat{\sigma}_\tau^{(\max)} := \max_j \max_{(x,y,u)} \hat{\sigma}_{j,\tau}(x,y,u)$ is the maximum estimated standard deviation, and $v^{(\max)}$ is the maximum value per click.

We remark that Rasmussen and Williams [29] show that, in a generic GP, $\hat{\sigma}_\tau^{(\max)} \to 0$ as $\tau \to \infty$. Therefore, the total error E_τ decreases as the number of samples τ in the training set Z increases.

Proof. Since estimates for click-through rate $\hat{w}_j$ and value per click $\hat{v}_j$ are sum of i.i.d. random variables with finite support $[0,1]$ and $[0, v^{(\max)}]$, respectively, we can apply the Hoeffding's bound [14] and state that, with a probability of at least $1-\delta$:

$$w_j - \hat{w}_j \leq \sqrt{\frac{1}{2\tau}\log\frac{1}{\delta}}, \tag{5}$$

$$v_j - \hat{v}_j \leq v^{(\max)}\sqrt{\frac{1}{2\tau}\log\frac{1}{\delta}}, \tag{6}$$

where τ is the number of samples we use to compute the estimates. By assumption, the number of impressions are generated by a GP and we have that for each input (x,y,u) in the GP domain $\frac{n_j(x,y,u)-\hat{n}_j(x,y,u)}{\hat{\sigma}_{j,\tau}(x,y,u)} \sim \mathcal{N}(0,1)$, where $\hat{\sigma}_{j,\tau}(x,y,u)$ is the standard deviation computed by the GP at the point (x,y,u) by relying on τ samples in the training set Z. This implies that, with a probability of at least $1-\delta$, it holds:

$$n_j(x,y,u) \leq \hat{n}_j(x,y,u) + \hat{\sigma}_{j,\tau}(x,y,u)\sqrt{2\log\frac{1}{2\delta}}, \tag{7}$$

where the last inequality is due to the fact that, for a Gaussian random variable $X \sim \mathcal{N}(0,1)$, it holds $\forall\, x>0,\ \mathbb{P}(X>x) \leq \frac{1}{2}e^{-\frac{x^2}{2}}$.

Focus on E_τ. Sum and subtract from it the following quantities: $\hat{w}_j v_j n_j(x_j^*,y_j^*,u_j^*)$, $\hat{w}_j\hat{v}_j n_j(x_j^*,y_j^*,u_j^*)$, and $\hat{w}_j\hat{v}_j\hat{n}_j(x_j^*,y_j^*,u_j^*)$ for each $j \in \{1,\dots,N\}$. The total error can be decomposed as:

$$E_\tau = \sum_{j=1}^{N}\Bigg(\underbrace{(w_j-\hat{w}_j)v_j n_j(x_j^*,y_j^*,u_j^*)}_{E_{1j}} + \underbrace{\hat{w}_j(v_j-\hat{v}_j)n_j(x_j^*,y_j^*,u_j^*)}_{E_{2j}} + \underbrace{\hat{w}_j\hat{v}_j[n_j(x_j^*,y_j^*,u_j^*)-\hat{n}_j(x_j^*,y_j^*,u_j^*)]}_{E_{3j}}\Bigg) + \underbrace{\sum_{j=1}^{N}\hat{w}_j\hat{v}_j\hat{n}_j(x_j^*,y_j^*,u_j^*) - \sum_{j=1}^{N}\hat{w}_j\hat{v}_j\hat{n}_j(\hat{x}_j^*,\hat{y}_j^*,\hat{u}_j^*)}_{E_4}.$$

If we focus on E_{1j}, with probability at least $1-\delta$, it holds:

$$\begin{aligned}E_{1j} &= (w_j-\hat{w}_j)\,v_j\,n_j(x_j^*,y_j^*,u_j^*)\\ &\leq v^{(\max)}\sqrt{\frac{1}{2\tau}\log\frac{2}{\delta}}\left(\hat{n}_j(x_j^*,y_j^*,u_j^*) + \hat{\sigma}_{j,\tau}(x_j^*,y_j^*,u_j^*)\sqrt{2\log\frac{1}{\delta}}\right)\\ &\leq v^{(\max)}\sqrt{\frac{2}{\tau}\log\frac{2}{\delta}}\left(\hat{n}_j^{(\max)} + \hat{\sigma}_{j,\tau}^{(\max)}\sqrt{2\log\frac{1}{\delta}}\right),\end{aligned}$$

by relying on the inequalities in Equations (5) and (7), subsequently using a union bound over these two events, then defining $\hat{n}_j^{(\max)} := \max_{(x,y,u)}\hat{n}_j(x,y,u)$ and $\hat{\sigma}_{j,\tau}^{(\max)} := \max_{(x,y,u)}\hat{\sigma}_{j,\tau}(x,y,u)$, and finally since $v_j \leq v^{(\max)}$.

Similarly, we derive the following bound holding with probability at least $1-\delta$ for E_{2j}:

$$E_{2j} \leq v^{(\max)}\sqrt{\frac{1}{2\tau}\log\frac{2}{\delta}}\left(\hat{n}_j^{(\max)} + \hat{\sigma}_{j,\tau}^{(\max)}\sqrt{2\log\frac{1}{\delta}}\right),$$

by relying on the inequality in Equation (6), and the fact that $w_j \leq 1$.

Let us focus on E_{3j}. Using the inequality in Equation (7), we have that with probability at least $1-\delta$:

$$\begin{aligned}E_{3j} &= \hat{w}_j\,\hat{v}_j\,[n_j(x_j^*,y_j^*,u_j^*) - \hat{n}_j(x_j^*,y_j^*,u_j^*)]\\ &\leq v^{(\max)}\,\hat{\sigma}_{j,\tau}(x_j^*,y_j^*,u_j^*)\sqrt{2\log\frac{1}{2\delta}} \leq v^{(\max)}\,\hat{\sigma}_{j,\tau}^{(\max)}\sqrt{2\log\frac{1}{2\delta}},\end{aligned}$$

where we used $\hat{w}_j \leq 1$, and $\hat{v}_j \leq v^{(\max)}$.

Finally, let us focus on E_4. The vector $(\hat{\boldsymbol{x}}^*,\hat{\boldsymbol{y}}^*,\hat{\boldsymbol{u}}^*)$ is the optimal solution of the optimization problem stated in Equations (1a)-(1d). Therefore, by definition, we have that for each $(\boldsymbol{x},\boldsymbol{y},\boldsymbol{u})$ satisfying the constraints in Equations (1a)-(1d) the following holds:

$$\sum_{j=1}^{N}\hat{w}_j\hat{v}_j\hat{n}_j(x_j,y_j,u_j) - \sum_{j=1}^{N}\hat{w}_j\hat{v}_j\hat{n}_j(\hat{x}_j^*,\hat{y}_j^*,\hat{u}_j^*) \leq 0,$$

which holds also for $(\boldsymbol{x}^*,\boldsymbol{y}^*,\boldsymbol{u}^*)$ and, therefore, E_4 is negative.

Recalling that $\hat{n}^{(\max)} := \max_j \hat{n}_j^{(\max)}$ and $\hat{\sigma}_\tau^{(\max)} := \max_j \hat{\sigma}_{j,\tau}^{(\max)}$, it holds, with probability at least $1-\delta$:

$$\begin{aligned}E_\tau &= \sum_{j=1}^{N}(E_{1j}+E_{2j}+E_{3j}) + E_4\\ &\leq 2Nv^{(\max)}\sqrt{\frac{1}{2\tau}\log\frac{6N}{\delta}}\left(\hat{n}^{(\max)} + \hat{\sigma}_\tau^{(\max)}\sqrt{2\log\frac{3N}{\delta}}\right) +\\ &\quad N v^{(\max)}\,\hat{\sigma}_\tau^{(\max)}\sqrt{2\log\frac{3N}{2\delta}},\end{aligned}$$

which concludes the proof. □

Our analysis has, so far, focused on the static properties of our problem. However, the scenario we are studying is a dynamical system due to the potentially delayed effects induced by the sub-campaigns interdependence. Therefore, when using a stationary allocation, it is crucial to show that the dynamics always reach a steady state in finite time and their length is upper bounded. In this context, a steady state is reached when a stationary allocation provides a constant number of impressions for each sub-campaign for at least K consecutive days. We can show the following:

Theorem 5.3. *Using the stationary allocation* $(\hat{\boldsymbol{x}}^*, \hat{\boldsymbol{y}}^*, \hat{\boldsymbol{u}}^*)$ *we reach a steady state after at most* $K\ \Gamma + 1$ *days, where* K *is the maximum lag of the influence index* $u_{j,t}$ *and* Γ *is the length of the longest path of the graph* $\mathcal{G}$.

The above theorem states that the more complex the process (e.g., presenting a cascade of interdependences), the more we have to wait to completely remove the effects of a suboptimal allocation.

Proof. Consider an adjacency matrix $\hat{D}$ and assume that the lag K is the same for all the performance indices $u_{j,t}$. Moreover, consider the sub-campaigns $C_{i_1}, \ldots, C_{i_\Gamma}$ that make up the longest path on the graph $\mathcal{G}$. To achieve the steady state revenue provided by the allocation $(\hat{x}^*_{i_\Gamma}, \hat{y}^*_{i_\Gamma}, \hat{u}^*_{i_\Gamma})$, an algorithm needs that all the incoming-neighbour sub-campaigns have reached the optimal allocation for K consecutive days, so as to provide exactly $\hat{u}^*_{i_\Gamma}$ as influence index. In particular, this also happens for the sub-campaign C_{i_Γ}.

By induction, this reasoning can be applied for all nodes C_{i_h} in the longest path up to C_{i_2}. Therefore, every time we traverse a node, we require K days to conclude the transient for that node, for a total of $K\ \Gamma$ days. Instead, the node C_{i_1}, being at the beginning of the longest path, has no incoming neighbours and, therefore, the allocation prescribed by the optimal solution is $(\hat{x}^*_{i_\Gamma}, \hat{y}^*_{i_\Gamma}, 0)$. This implies that the allocation is achieved on the same day that the stationary allocation is used, leading to a total number of $K\ \Gamma + 1$ days to reach the desired allocation on the longest path $C_{i_1}, \ldots, C_{i_\Gamma}$.

The same reasoning can be replicated on any other path, but since their length is shorter or equal to the longest one, the maximum number of days required to reach the allocation $(\hat{\boldsymbol{x}}^*, \hat{\boldsymbol{y}}^*, \hat{\boldsymbol{u}}^*)$ takes no longer than $K\ \Gamma + 1$ days. □

6 EXPERIMENTAL EVALUATION

We experimentally evaluate the IDIL algorithm in a real-world setting and in a synthetic setting, generated by using a realistic simulator. We compare the revenue R_t produced by IDIL and AdComB-Mean (an off-line version of the algorithm proposed by Nuara et al. [25] neglecting any sub-campaign interdependence).

6.1 Real-world Setting

In this experiment, we rely on the data of the second campaign described in Section 2 to train our model. We recall that the length of the dataset is $\tau = 93$ days (from 20/7/2018 to 20/10/2018), the advertising campaign is composed of $N = 14$ sub-campaigns belonging to both social and search advertising channels. The corresponding estimated interdependence graph is provided in Figure 1c. From 21/10/2018 to 4/11/2018 (15 days), the campaign optimization has been performed by the IDIL algorithm.

When comparing the policies produced by IDIL with those produced by AdComB-Mean (the off-line version of AdComB-TS), the former policies appear more suitable then the latter ones, as a more significant portion of the budget is allocated to social sub-campaigns and branding search sub-campaigns. The interdependence suggested by the Granger Causality Test are confirmed by estimations provided by the GPs. Indeed, in Figure 2, we show the expected value of the prediction provided by GPs of the number of impressions for the sub-campaign C_6 with a bid value of $x = 1$ (i.e., one of the most frequent choice during the training set) and

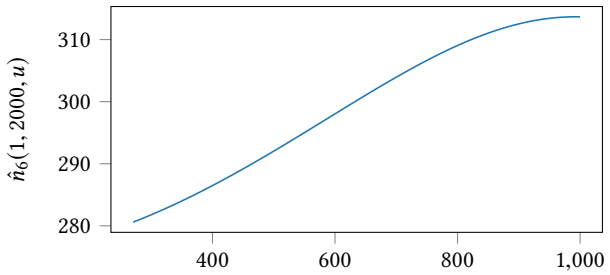

Figure 2: GPs estimation of the number of impressions $\hat{n}_6(1, 2000, u)$ depending on the influence index u.

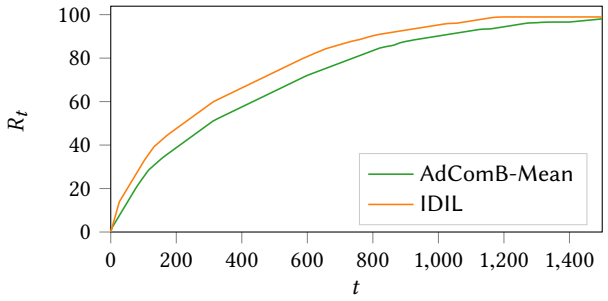

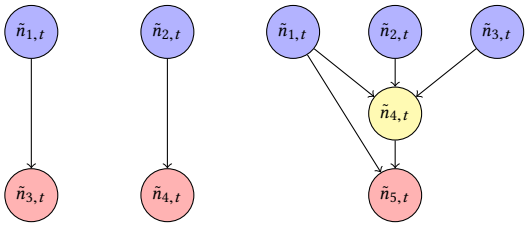

Figure 3: Comparison of the expected revenue R_t given by the AdComB-Mean and IDIL algorithms.

$y = 2000$ (i.e., a budget large enough to capture all the available user for this sub-campaign). The number of impressions increases as the value of the influence index increases, suggesting that a positive correlation between C_2 and C_3 impressions, and C_6 ones exist. However, since in a real setting we cannot exclude the presence of negative interdependence, to compute the optimal allocation with the IDIL algorithm, we remove the condition in Line 18 of Algorithm 2, to be able to provide the optimal allocation even if generic interdependence among sub-campaigns are present. In Figure 3, we show the expected revenue given by optimal policies computed by AdComB-Mean and IDIL for different values of the total budget Y. In this scenario, the exploitation of the sub-campaigns interdependence can lead to a potential revenue increase up to 13%.

In the 15 days of campaign optimization performed by the IDIL algorithm, the number of daily conversions increased by 11% w.r.t. the average of the previous 30 days (the result is compatible with our prediction, given that AdComB-TS/Mean provide very close performance). Although this is a promising result, there is no statistical significance that the IDIL algorithm outperforms in practice AdComB-TS/Mean. Due to the impossibility to directly compare the performance of the two algorithms online (e.g., by using an A/B testing system), we resort to a realistic synthetic environment.

6.2 Synthetic Settings

We evaluate the performance of the IDIL algorithm in two synthetic settings, generated by a realistic simulator, comparing the revenue R_t produced by the following algorithms: IDIL, DA-IDIL (Dependency Aware-IDIL), a variation of the IDIL algorithm *a priori* knowing the dependency matrix D, and AdComB-Mean.

(a) Setting 1 **(b) Setting** 2

Figure 4: Interdependence graph $\mathcal{G}$ for the two synthetic experimental settings.

Synthetic Data Generation. The synthetic settings are generated as follows. At day t, each sub-campaign C_j is characterized by the set of the users $S_{j,t} = s_{j,t} \cup \left(\bigcup_{i \neq j} s_{ij,t}\right)$ that could potentially visualize the ad of the sub-campaign C_j. More precisely, we distinguish the set of the users $s_{j,t}$, that would visualize the ad of C_j without having previously visualized the ads of the other interdependent sub-campaigns, from the set of the users $s_{ij,t}$, that would visualize the ad of C_j only after having visualized the ad of C_i. Notice that $s_{ij,t}$ is non-empty only if the sub-campaigns C_i and C_j are interdependent and, more precisely, if $d_{ij} \neq 0$.

The number of users $|s_{j,t}|$ is sampled from $\mathcal{N}(\mu_j, \sigma_j^2)$, i.e., a Gaussian distribution with mean μ_j and variance σ_j^2. Each user in $s_{j,t}$ is characterized by a click probability $p_j^{(cl)}$ and a conversion probability $p_j^{(co)}$ specific for the sub-campaign C_j. Conversely, the number of users $|s_{ij,t}|$ is modeled through a linear combination of the number of daily impressions $n_{i,t-1}, \ldots, n_{i,t-K}$ (whose generation is described in what follows), where K represents the maximum delay in the interdependence dynamics. Formally, we have that $s_{ij,t} := p_{ij}^{(res)} \sum_{k=1}^{K} \beta_k \, n_{i,t-k}$, where $\beta_k \in [0,1]$ are randomly sampled coefficients and $p_{ij}^{(res)}$ is the probability that a user having visualized ad of C_i is a potential user that may visualize C_j. Each user in $s_{ij,t}$ is characterized by a click probability $p_{ij}^{(cl)}$ and a conversion probability $p_{ij}^{(co)}$.

At each day t, setting the bid/budget pairs on each sub-campaign allows the advertiser to take part to $A_j \leq |S_{j,t}|$ multislot auctions based on the Vickrey-Clarke-Groves mechanism [5, 7–9, 23], in which γ_j available ad slots are allocated to a subset of δ_j advertisers ($\gamma_j \leq \delta_j$). More specifically, each advertiser submits her bid b_h and those with the first γ_j highest values $b_h \; \rho_h$ are allocated in the γ_j slots, where ρ_h is the probability that h-th ad is clicked given it has been observed. The bids b_h of the other ads participating in the auctions are drawn from a truncated Normal distribution $\mathcal{N}(\mu^{(b)}, \sigma^{(b)})$, and the click probabilities ρ_h are uniformly sampled in $[0,1]$. In the case the advertiser wins the m-th auction, the ad gets an impression ($n_{m,j,t} = 1$, otherwise $n_{m,j,t} = 0$). The ad is allocated in a the l-th slot, the ad can be visualized by an user $S_{j,t}$ according to the probability of being observed $p^{(obs)}(l)$. After the impression, the user can click on the ad and generate a conversion according to the click $p_j^{(cl)}$ and conversion $p_j^{(co)}$ probabilities if the user belongs to $s_{j,t}$, and according to the click $p_{ij}^{(cl)}$ and conversion $p_{ij}^{(co)}$ probabilities if the user belongs to $s_{ij,t}$. A click on the ad of C_j provided by the user corresponding to the m-th auction is denoted by $cl_{m,j,t} = 1$ ($cl_{m,j,t} = 0$ otherwise), and imposes a payment of $CPC_{m,j,t}$, as specified by the VCG auction (see [23] for details). The auctions are generated until the daily budget $y_{j,t}$ allocated on the sub-campaign C_j is totally spent, i.e., the total number of auctions A_j is s.t. $\sum_{m=1}^{A_j} CPC_{m,j,t} = y_{j,t}$ or until $A_j = |S_{j,t}|$. Finally, in the case a click happens, the m-th user may convert ($co_{m,j,t} = 1$) or not ($co_{m,j,t} = 0$). The daily impressions, the daily clicks, the daily conversions (assuming unitary value per conversion), and the daily costs are computed as $n_{j,t} = \sum_{m=1}^{A_j} n_{m,j,t}$, $cl_{j,t} = \sum_{m=1}^{A_j} cl_{m,j,t}$, $co_{j,t} = \sum_{m=1}^{A_j} co_{m,j,t}$, respectively.

Table 1: Parameters of the synthetic settings.

	Setting 1				Setting 2

We report in Table 1 the values of the main parameters used in the two synthetic settings in which we test our algorithm.

Synthetic Setting 1. There are $N = 4$ sub-campaigns, with delayed dynamics of $K = 5$ days, whose interdependence graph is shown in Figure 4a. The longest path of the interdependence graph $\mathcal{G}$ is $\Gamma = 1$. C_1 and C_2 are on the display advertising channel and are targeted to a wide range of daily users, thus generating a large number of daily auctions, but their conversion probability is low. C_3 and C_4 are on the search advertising channel, generating a small number of daily auctions, but their conversion probability is high.

We use $Y = 500$ and $B = 10$ daily budget values evenly spaced in the range $[0, 500]$. The GPs used to estimate the impressions model of the sub-campaigns adopt a squared exponential kernel in which the kernel parameters are chosen as recommended by Rasmussen and Williams [29]. We evaluate the performance of the algorithms with different numbers of samples $\tau \in \{60, 80, 100\}$ in the training set Z. In the first τ days, a uniformly random allocation is used to collect data and, after that, the algorithms compute the optimal solution based on their estimates and then set it.

Results. In Figure 5a, we report the average (over 100 repetitions) revenue R_t produced by the algorithms with a training of $\tau = 100$ samples. From $t = 100$ on, the optimal stationary solution is used. The average revenue of each algorithm peaks at $t = 101$ and, for $t > 101$, decreases by converging to a steady state within $K\,\Gamma + 1 = 6$

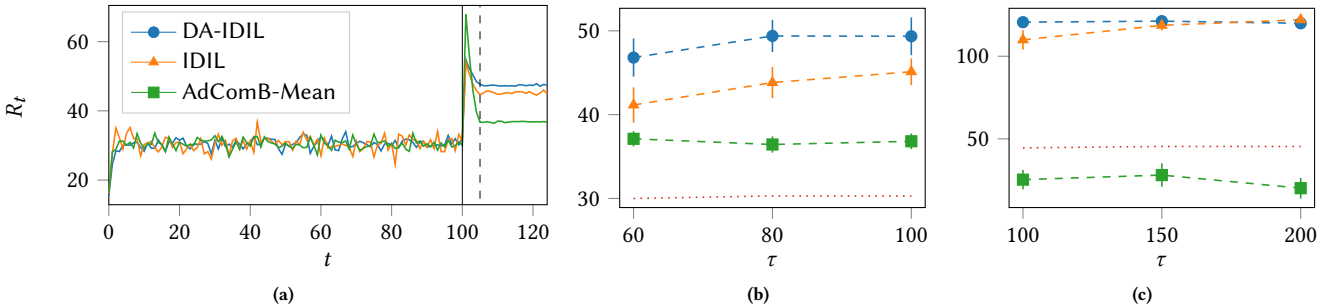

Figure 5: Results for the Settings 1 and 2. (a) Revenue R_t over time for the Setting 1. (b) Revenue R_t in steady state conditions for different training sizes τ in Setting 1. (c) Revenue R_t in steady state conditions for different training sizes τ in Setting 2. In (b) and (c), the revenue of the random allocation is reported with a dotted magenta line and the vertical lines represent the 95% confidence intervals for the algorithms revenue.

days. The peak is generated by the presence of a large number of residual users who have observed display ads during training and who, after $t = 100$, observe search ads. These residual users decrease for $t > 101$ until they reach a steady state. Thus, (temporary) peaks may be achieved with non-stationary policies.

The DA-IDIL algorithm exhibits the best performance, exploiting the *a priori* knowledge of the adjacency graph D. The gap between the revenue produced by the IDIL and DA-IDIL algorithms, due to the estimation error introduced on $\hat{D}$, is sufficiently small, showing that the Granger Causality test used by the IDIL algorithm works well in practice. Instead, the revenue produced by the AdComB-Mean algorithm, neglecting the interdependence among sub-campaigns, is much smaller than that produced by the other two algorithms. This is due to the very different budget allocations chosen by the three algorithms: the IDIL and DA-IDIL algorithms optimally balance the budget on all the sub-campaigns, while the AdComB-Mean algorithm greedily invests the budget only in the search sub-campaigns C_3 and C_4. Interestingly, the performance of the AdComB-Mean algorithm is quite similar to that of the uniformly random allocation used during training.

In Figure 5b, we report the average revenue R_t at the steady-state (averaged over the 100 independent repetitions and over $t \in \{106, \dots, 120\}$) and the 95% confidence intervals as the number of samples τ used for training increases. All algorithms always perform better than the uniformly random allocation. The performance of both the IDIL and DA-IDIL algorithms is significantly better than the one provided by AdComB-Mean (confidence intervals do not overlap). The use of more training samples provides an improvement in terms of steady-state revenue for the IDIL and DA-IDIL algorithms. On the other hand, the performance of the AdComB-Mean algorithm does not benefit from having more samples, which is probably due to the presence of a model bias induced by the fact that it neglects the sub-campaign interdependence.

Synthetic Setting 2. There are $N = 5$ sub-campaigns, whose interdependence graph is shown in Figure 4b. The longest path of the interdependence graph $\mathcal{G}$ is $\Gamma = 2$. C_1, C_2, and C_3 are display sub-campaigns directed to a wide audience and have a low cost per impression, but a low conversion rate. C_4 is a social sub-campaign, whose number of impressions is influenced by the influence index of the display sub-campaigns. Finally, C_5 is a search sub-campaign, whose impressions depend on the influence index of C_1 and C_4. The interdependence among the sub-campaigns occurs within $K = 3$ days and is modeled as in Setting 1. We set a cumulative budget of $Y = 500$ and the budget discretization from the interval $[0, 500]$ with $B = 100$. The number of samples for training is $\tau \in \{100, 150, 200\}$.

Results. In Figure 5c, we report the average (over 100 repetitions and over $t \in \{107, \dots, 120\}$) revenue of the algorithms. The performance of AdComB-Mean is worse than the one of the uniformly random allocation and gets worse as τ increases. This is an empirical confirmation of the statement of Theorem 5.1, showing that a solution that is optimal without interdependence might perform arbitrarily bad. Conversely, the performance of IDIL and DA-IDIL are significantly larger than that of the uniformly random allocation and increase as the number of samples increases.

Final Remarks. Results obtained in synthetic settings show that this model, relying on a training time which is reasonable for the application, provides a significant improvement in terms of revenue of an Internet advertising campaign. Experts in the marketing field confirmed the feasibility of what proposed in terms of learning time. Conversely, adopting more complex models would most likely result unaffordable in most of the cases, since accurate estimations would require a larger training set and, therefore, excessively long learning periods in real-world scenarios.

7 CONCLUSIONS AND FUTURE WORKS

In this paper, we formalize, for the first time, the problem of optimizing an Internet advertising campaign with sub-campaigns interdependence. We design the IDIL algorithm that, given a set of past observations, models these interdependences and returns an optimal allocation of the bid/daily budget on the sub-campaigns maximizing the revenue. We analyse the properties of the IDIL algorithm both theoretically, providing a bound on the total error, and empirically, showing that it provides revenues on synthetic datasets significantly better than the state of the art in the field.

In the future, we will extend our algorithm to an online framework and test it in a real-world application.

ABSTRACT

We propose a new variant of the k-median problem, where the objective function models not only the cost of assigning data points to cluster representatives, but also a penalty term for disagreement among the representatives. We motivate this novel problem by applications where we are interested in clustering data while avoiding selecting representatives that are too far from each other. For example, we may want to summarize a set of news sources, but avoid selecting ideologically-extreme articles in order to reduce polarization.

To solve the proposed k-median formulation we adopt the local-search algorithm of Arya et al. [2], We show that the algorithm provides a provable approximation guarantee, which becomes constant under a mild assumption on the minimum number of points for each cluster. We experimentally evaluate our problem formulation and proposed algorithm on datasets inspired by the motivating applications. In particular, we experiment with data extracted from Twitter, the US Congress voting records, and popular news sources. The results show that our objective can lead to choosing less polarized groups of representatives without significant loss in representation fidelity.

1 INTRODUCTION

Consider the problem of summarizing a set of news articles on a given topic. A standard approach to this problem is clustering: design a distance function that captures similarity between the news articles and apply a clustering algorithm on the resulting metric space. Common clustering formulations, such as k-median or k-means, can be used [17]. The original set of input news articles can then be summarized by the (small) set of cluster representatives. In some cases, however, we may be interested in selecting cluster representatives that are not too far from each other. For example, we may want to find a set of representative news articles that are not too extreme so that they can provide a basis for constructive deliberation. This motivation is similar to recent proposals in the literature that aim to reduce polarization in social media [13] and balance the users' content consumption [14]. In this work we are interested in developing computational methods for clustering data in a way that the disagreement of the cluster representatives is minimized.

Another motivating example appears in the context of electing a *k-member committee* to represent a set of individuals, such as the employees of an organization or the members of a political party. Assuming that all individuals have public opinions on a set of issues, clustering these individuals on an opinion-representation space will give a committee that faithfully represents the set of individuals with respect to the issues under consideration. Despite providing a good representation, however, a committee elected with a standard clustering approach may fail to reach consensus due to potential heterogeneity within the committee members. Heterogeneity within elected members of an assembly is a widely acknowledged problem in politics — for instance, division of representatives often results in paralysis in various left-wing political formations.[1] As in the previous example, we are interested in electing a committee in a way that the disagreement of the elected members is minimized while ensuring a faithful representation of the constituents.

Motivated by the previous examples we introduce a new formulation of the k-median problem, where in addition to the k-median objective we also seek to minimize disagreement between the cluster representatives. As it is customary, we consider a metric space (X, d), where d is a distance function for objects in X. We distinguish two subsets of X, the set of facilities F and the set of clients C. The goal is to select a set of k facilities $S \subseteq F$ — the cluster representatives — so as to minimize the overall cost

$$cost(S) = \sum_{c \in C} \min_{s \in S}\{d(c, s)\} + \frac{\lambda}{2} \sum_{s_i \in S} \sum_{s_j \in S} d(s_i, s_j). \qquad (1)$$

The first term is the same as in the standard k-median, and expresses the cost of serving each client by its closest selected facility. The second term is the one introduced in this paper and expresses

disagreement between cluster representatives. The parameter λ determines the relative importance of the two terms. Despite clustering being one of the most well-studied problems in statistical data analysis, and the numerous formulations and problem variants that have been studied in the literature, to our knowledge, the problem defined above has not been considered before.

As expected, the problem defined by optimizing Equation (1) is **NP**-hard; in fact optimizing each of the two terms separately is an **NP**-hard problem. Given the hardness of the problem, it is compelling to consider algorithms with provable approximation guarantees. For the k-median algorithm several approximation algorithms exist [11, 22]. A local-search algorithm, which is simple to implement and scalable to large datasets, has been proposed by Arya et al. [2]. The algorithm starts with an arbitrary solution and considers a swap of p selected facilities with p non-selected facilities; the swap is materialized if the cost improves, and the process continues until the cost cannot be improved. Arya et al. show that this algorithm achieves an approximation guarantee equal to $3 + 2/p$, and the running time is $O(n^p)$. In particular, for $p = 1$, the algorithm gives an approximation guarantee equal to 5, while the running time is linear.

In this paper we show how to adapt the local-search algorithm of Arya et al. [2] for the problem we consider and obtain an approximation guarantee $O(k)$ in the general case. The proposed algorithm considers 1-facility swaps, i.e., $p = 1$. Furthermore, when the clusters of the obtained solution have size $\Omega(\lambda k)$, the approximation factor becomes 11, i.e., constant. We complete the analysis of the proposed problem by deriving bounds on the objective function.

Our contributions in this paper are summarized as follows.

- We introduce the *reconciliation k-median* problem, a novel clustering problem formulation where we aim to optimize the data representation cost plus a term for agreement between the cluster representatives.
- We adapt the local-search algorithm of Arya et al. [2] and obtain provable approximation guarantees for the proposed clustering problem.
- We run experiments on datasets extracted from the Twitter social network, US Congress voting records, and popular news sources. The results show that the proposed objective can lead to the choice of less polarized groups of representatives, as measured by a well-known method for ideology estimation [4] and an objective estimate of the political leaning of news sources.

The rest of the paper is structured as follows. In Section 2 we present a brief overview to the literature that is most related to our work. In Section 3 we formally define the reconciliation k-median problem. In Section 4 we present the local-search algorithm and state its approximability properties. In Section 5 we present our experimental evaluation, while Section 6 is a short conclusion. To improve readability, the hardness proof of the reconciliation k-median problem and the proof of the approximation guarantee of the local-search algorithm are presented in the Appendix.

2 RELATED WORK

Data clustering is one of the most well-studied problems in data analysis, with applications in a wide range of areas [17]. Among the numerous formulations that have been proposed, in this paper we focus on the k-median problem setting, which has been studied extensively in the theoretical computer-science literature. Charikar et al. [11] gave the first constant-factor approximation algorithm for the k-median problem, followed by improvements that relied on both combinatorial and LP-based algorithms [10, 18, 19]. In this paper we build upon the local-search algorithm of Arya et al. [2]. This is a simple-to-implement and scalable algorithm that had been offering the best performance guarantee for over a decade. The current best approximation guarantee is $2.67 + \epsilon$, provided by the algorithm of Byrka et al. [8], which optimizes a part of the algorithm of Li and Svensson [22]. However, the algorithm is not practical.

Variants of the k-median problem have also been considered, including the Euclidean k-median [1], capacitated k-median [7], ordered k-median [9], and more. To our knowledge, however, this is the first work to study the problem of k-median clustering with a penalty on the disagreement of the cluster representatives. Instead, researchers have studied the problem of selecting k points to *maximize* the sum of pairwise distances, i.e., the *dispersion* of the selected point set. Several constant-factor approximation algorithms have been proposed for the maximum-dispersion problem [12, 16]. However, the maximization makes the problem different and it is not clear how to adapt those algorithms in our setting.

One of our motivating applications is summarization of social-media content with the aim of reducing polarization and balancing the information content delivered to users. This is a relatively new research area that is receiving increasing interest [4, 13, 14, 23, 24]. However, to the best of our knowledge, none of the proposed approaches uses a clustering formulation.

The second motivating application is election of committees and representatives. In some cases, election questions can also be formulated as voting problems. Voting in general has been studied extensively in social sciences and economics literature. From the algorithmic perspective, researchers have studied questions about voting in social networks and concepts such as liquid and viscous democracy [6, 26]. In addition to being not directly related to our paper, this line of work does not directly model agreement between elected representatives.

3 PROBLEM FORMULATION

3.1 Preliminaries

We formulate our problem in the general setting of *metric facility location* [19]. We consider a metric space (X, d) and two subsets $F, C \subseteq X$, not necessarily disjoint. The set F represents *facilities*, and the set C represents *clients*. A special case of interest is when clients and facilities are defined over the same set, i.e., $F = C$. In our discussion we consider the more general case that the sets of clients and facilities are disjoint. The function $d : X \times X \to \mathbb{R}$ is a distance measure between pairs of points in X. When $c \in C$ and $s \in F$, the distance $d(c, s)$ represents the cost of serving client c with facility s. The number of facilities is denoted by $m = |F|$ and the number of clients by $n = |C|$.

The goal is to open k facilities — i.e., choose k points in F — such that the cost of serving each client in C with the nearest *selected* facility is minimized. Given a set of facilities $S \subseteq F$, with $|S| = k$, and $s \in S$, we use $N_S(s)$ to denote the set of clients served by facility s in

the solution S, that is, $N_S(s) = \{c \in C \mid s = \text{argmin}_{x \in S}\, d(c, x)\}$. In the *facility location* formulation each facility has an associated cost, which is incurred if the facility is opened (selected). The objective is to minimize the total cost of serving all clients plus the cost of opened facilities, while there is no restriction on the number of opened facilities. When the cost of opening each facility is zero and it is required to open at most k facilities, the problem is known as *k-median*.

3.2 Reconciling cluster representatives

The problems described above, facility location and k-median, are commonly used to find cluster representatives without regard to the relative position of the representatives themselves. As discussed in the introduction, our goal is to modify the problem definition so as to find solutions in which the cluster representatives are close to each other. To achieve our goal we propose the following clustering variant, which we name reconciliation k-median.

Problem 1 (recon-k-median). *Given a metric space (X, d), two sets $F, C \subseteq X$, $k \in \mathbb{N}$, and a real number $\lambda > 0$, find a set $S \subseteq F$ with $|S| = k$, so as to* minimize *the cost function*

$$cost(S) = \sum_{s \in S} \sum_{c \in N_S(s)} d(c, s) + \frac{\lambda}{2} \sum_{s_i \in S} \sum_{s_j \in S} d(s_i, s_j). \qquad (2)$$

In order to characterize the hardness of this problem, we analyze the two terms of the objective in isolation. The first term, which results from setting $\lambda = 0$, is equivalent to the classical metric k-median problem, shown to be **NP**-hard by Papadimitriou [25]. To analyze the second term, we define the following equivalent problem, which asks to find a subset of k points that minimize the sum of pairwise distances in a metric space, i.e., minimum pairwise distances (mpd).

Problem 2 (mpd). *Given a metric space (X, d), a subset of objects in the metric space $F = \{x_1, \ldots, x_n\} \subseteq X$, and a number $k \in \mathbb{N}$, with $k < n$, define a matrix $\mathbf{A} \in \mathbb{R}^{n \times n}$ as $\mathbf{A}_{ij} = d(x_i, x_j)$ for all $x_i, x_j \in F$. The goal is to find a binary vector $\mathbf{x}$ of dimension n that has exactly k coordinates equal to 1 and minimizes the form $\mathbf{x}^T \mathbf{A}\, \mathbf{x}$. In other words, we want to find*

$$\begin{aligned} \min \quad & \mathbf{x}^T \mathbf{A}\, \mathbf{x}, \\ \textit{subject to} \quad & \mathbf{x} \in \{0, 1\}^n \textit{ and } \mathbf{x}^T \mathbf{1} = k. \end{aligned}$$

The following lemma establishes that there exists no polynomial-time algorithm to find the exact solution to the mpd problem, unless **P** = **NP**. The proof is given in the Appendix.

Lemma 1. *Problem* mpd *is* **NP**-*hard.*

Lemma 1 establishes that optimizing separately the second term of the objective function (2) is an **NP**-hard problem. Note, however, that the hardness of the two terms in Problem 1 does not immediately imply the hardness of the overall problem. Consider, for instance, an objective of the form $\min_{\mathbf{x}} \{f(\mathbf{x}) + (c - f(\mathbf{x}))\}$. Even though optimizing f can be an arbitrary **NP**-hard problem, the overall problem has a constant value, and thus, it is trivial to optimize — there is nothing to be done. We now show that Problem 1 is indeed **NP**-hard.

Lemma 2. *Problem* recon-k-median *is* **NP**-*hard.*

Proof. Consider an instance of the mpd problem, for a given set F and a number k, and form an instance (F, C, k, λ) of the recon-k-median problem, where C is any arbitrary set of clients with $F \cap C = \emptyset$. Set $d(s, c) = \frac{1}{2} \max_{s_i, s_j \in F}\{d(s_i, s_j)\}$, for all $c \in C$ and $s \in F$. Note that the distance function d is still a valid metric. We have that $\sum_{c \in C} \min_{s \in S} d(c, s)$ is constant for any potential solution set $S \subseteq F$, which implies that optimizing recon-k-median is equivalent to optimizing mpd. Thus, from Lemma 1 we obtain that recon-k-median is **NP**-hard. □

3.3 Bounds on the objective

To complete the analysis of the recon-k-median problem we offer bounds on the objective, which can be used to evaluate the quality of the solution obtained by any algorithm for the problem at a given instance. For this to be useful, the bounds need to be non-trivial and as close as possible to the optimal solution. We will first show how to obtain a lower bound on the second term of the objective, that is, $\sum_{s_i, s_j \in S} d(s_i, s_j)$. We first introduce the following definition.

Definition 1. *Given two sequences of real numbers $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n$ and $\mu_1 \geq \mu_2 \geq \cdots \geq \mu_m$, with $m < n$, we say that the second sequence interlaces the first if*

$$\lambda_i \geq \mu_i \geq \lambda_{n-m+i} \textit{ for } i = 1, \ldots, m$$

We will employ the following result from Haemers [15].

Lemma 3. *Let $\mathbf{A}$ be a symmetric $n \times n$ matrix, and let $\mathbf{B}$ be a principal submatrix of $\mathbf{A}$. Then the eigenvalues of matrix $\mathbf{B}$ interlace those of matrix $\mathbf{A}$.*

We now state the following result.

Theorem 1. *Let $\mathbf{D}$ be the pairwise distance matrix of facilities of an instance of* recon-k-median *problem. Define matrix $\widetilde{\mathbf{D}}$ so that $\widetilde{\mathbf{D}}_{ij} = \sqrt{\mathbf{D}_{ij}}$, that is, a matrix whose entries are the square roots of the entries of $\mathbf{D}$. Let $\lambda_i(\widetilde{\mathbf{D}})$ denote the i-th absolutely largest eigenvalue of $\widetilde{\mathbf{D}}$. Then*

$$k\lambda_1(\mathbf{D}) \geq \sum_{s_i \in S} \sum_{s_j \in S} d(s_i, s_j) \geq \sum_{i=n-k+1}^{n} \lambda_i^2(\widetilde{\mathbf{D}}).$$

Proof. Observe that for any real symmetric matrix $\mathbf{D}$, $\|\mathbf{D}\|_F^2 = \sum_i \sigma_i^2(\mathbf{D}) = \sum_i \lambda_i^2(\mathbf{D})$. It is easily seen that if $\mathbf{x}$ is a binary vector with exactly k entries equal to 1, $\mathbf{x}^T \mathbf{D}\, \mathbf{x}$ is equal to the sum of the entries of a $k \times k$ principal submatrix of $\mathbf{D}$, which is in turn equal to the squared Frobenius norm of the corresponding submatrix of $\widetilde{\mathbf{D}}$. Combined with Theorem 3, this proves the lower bound.

The upper bound follows immediately from the variational characterization of the eigenvalues [see 20, chap. 9.2]. □

A lower and upper bound on the first term of the objective can simply be given by $\sum_{c \in C} \min_{s \in F} d(c, s)$ and $\sum_{c \in C} \max_{s \in F} d(c, s)$, respectively. This is useful only for problem instances where the number of facilities is relatively small compared to the number of clients.

Algorithm 1 Local search

```
1: procedure LocalSearch(F, C, k, λ)
2:     S ← random subset of F of cardinality k
3:     converged ← false
4:     while not converged do
5:         if there exist s ∈ S and t ∈ F \ S such that cost(S \ {s} ∪ {t}) < cost(S) then
6:             S ← S \ {s} ∪ {t}
7:         else converged ← true
8:         end if
9:     end while
10:    return S
11: end procedure
```

4 THE LOCAL-SEARCH ALGORITHM

In this section we present the proposed algorithm for the RECON-k-MEDIAN problem and state its properties. The algorithm uses the local-search strategy, proposed by Arya et al. [2], but adapted for the objective function of RECON-k-MEDIAN. The algorithm starts with an arbitrary solution consisting of k selected facilities. It then proceeds in iterations. In each iteration it considers whether it is possible to swap a selected facility with a non-selected facility and obtain an improvement in the objective score. If such an improvement is possible, the corresponding swap is performed. The algorithm terminates when no such swap is possible. At each point during its execution, the algorithm maintains a set of k clusters over the set of clients, and a selected facility for each cluster, defined by assigning each client to its closest selected facility. Pseudocode of this local-search procedure is given in Algorithm 1.

For the analysis we denote by $S = \{s_1, \ldots, s_k\} \subseteq F$ the solution returned by `LocalSearch`, and $O = \{o_1, \ldots, o_k\} \subseteq F$ the optimal solution. As mentioned before we use the notation $N_S(s)$ to denote the set of clients that are assigned to facility s in the solution S, and $N_O(o)$ to denote the set of clients that are assigned to facility o in the optimal solution O.

To analyze the performance of `LocalSearch` we follow the ideas of Arya et al. [2]. The proofs are included in the Appendix.

As a result, in the most general case, the `LocalSearch` algorithm yields a $O(\lambda k)$-factor approximation guarantee on the quality of the solution achieved.

THEOREM 2. *Let (F, C, k, λ) be an instance of the* RECON-k-MEDIAN *problem. Let S be a solution returned by the* `LocalSearch` *algorithm, and let O be an optimal solution. Then*

$$cost(S) \leq (\lambda k + 5) cost(O). \tag{3}$$

Furthermore, we are able to improve the analysis and obtain an approximation guarantee that does not depend on the number of facilities k. For the improved result we need to make the mild assumption that the number of clients in any cluster of the optimal solution and the solution returned by the algorithm is $\Omega(\lambda k)$. In particular, we have.

THEOREM 3. *Let (F, C, k, λ) be an instance of the* RECON-k-MEDIAN *problem. Let S be a solution returned by the* `LocalSearch` *algorithm, and let O be an optimal solution. Assume that $|N_S(s)| \geq \lceil 2\lambda \rceil k$ for all $s \in S$ and $|N_O(o)| \geq \lceil 2\lambda \rceil k$ for all $o \in O$. Then*

$$cost(S) \leq \max\{11, 4\lambda\}\, cost(O).$$

The running time of the `LocalSearch` algorithm is $O(nmk)$ per iteration. For most applications k is considered to be a constant. When the number of facilities m is of the same order of magnitude with the number of clients n, e.g., in the important special case $F = C$, the algorithm has quadratic complexity per iteration. However, in many applications the number of facilities is significantly smaller than the number of clients. Thus, we expect that the algorithm is very efficient in practice for those cases.

We also note that Arya et al. [2] show how to perform swaps of p facilities simultaneously and obtain an improved performance guarantee at the expense of increased running time. In our case, the penalty term in our objective, which captures the disagreement among the cluster representatives, makes the analysis significantly more complex and it is not clear how to use simultaneous swaps in order to achieve a similar quality-performance trade-off. Thus, this direction is left for future work.

5 EXPERIMENTAL EVALUATION

We perform experiments to assess the proposed concept of clustering with reconciliation of representatives, as well as the performance of the proposed `LocalSearch` algorithm.[2] Our objective is to evaluate by some objective measure whether the proposed problem formulation, as well as natural variations, can lead to a choice of representatives or sources that are more moderate, less polarizing and more likely to reach consensus.

To enrich the experimental setting and produce a more interesting set of empirical observations, we relax some of the requisites of our theoretical results. Namely, observe that in order to prove the approximation guarantees of the `LocalSearch` algorithm, we require that the distance function satisfy the properties of a metric, and that it be the same for facilities and clients. However, we believe that in practical scenarios, one might benefit from considering a wider set of options, especially if we consider the exploratory nature of clustering algorithms. Therefore, we measure dissimilarity between objects using functions that do not necessarily qualify as metrics, and we consider different ones for facilities and clients.

At a high level, our experimental methodology is as follows: We start with a dataset for which clients and facilities model a natural clustering problem and for which a distance function d is available. For the facilities of the dataset we seek to obtain a polarity score π, which is independent of the distance function d: facilities with similar polarity scores π are more likely to agree. In addition, facilities with scores closer to the middle of the spectrum are less likely to disseminate extremist ideologies. We then apply our clustering algorithm with varying values of the parameters k and λ. We are interested in answering the following questions:

Q1. How does the agreement between selected representatives or the polarization of information sources (measured by the independent polarity score π) change as a function of λ? In other words, can we get more reconciled representatives or less extreme sources by increasing the weight of

[2] Our implementation of the algorithm is available at https://github.com/brunez/recon-kmedian-ls

the disagreement penalty term (second term of the objective function (2))?

Q2. How does the k-median score change as a function of λ? In other words, can we find solutions with more reconciled representatives but without significant loss in representation fidelity (i.e., first term of the objective function (2))?

Q3. What is the impact of the parameter k on both polarity score and k-median score?

For our experimental evaluation we use the following datasets.[3]

`Twitter`: The dataset, obtained by Lahoti et al. [21], consists of a set of politically active Twitter accounts. We remove stubs — i.e., accounts that follow only one account and have no followers — resulting in 3 302 362 accounts. Out of those we consider 500 popular ones — with at least 50 000 followers — as candidate facilities, that is, representatives. As remarked in the beginning of section 5, we can extend the proposed framework by considering different metrics for the two terms of the objective function. This corresponds to a practical setting where the agreeability of the selected representatives is measured differently than their affinity to their respective consituents. Specifically, for this dataset we consider the following distance functions.

(1) **Facility-Client:** We compute distances between facilities and clients as the length of the shortest path between two Twitter accounts in the undirected follower Twitter graph.[4]

(2) **Facility-Facility:** To compute distances between facilities we use shortest-path distances, as before. We also use Euclidean distances on the spectral embedding with γ components, as described by Belkin et al. [5]. We scale the resulting distance matrix so that the average of all entries is equal to that of the shortest-path distance matrix. This way we ensure that the magnitude of λ has an equivalent effect using the different metrics.

`Congress`: We collect roll call voting records from the present US Congress using the public domain `congress` API.[5] We build a dataset where each row corresponds to a Congress representative and each column is a binary variable representing the issue being voted. Missing values are imputed using class-conditional means, where the classes we consider are the two parties: democrats and republicans. "*Present*" and "*Not voting*" votes are considered to be missing. We omit votes where all representatives are missing. We also omit representatives for whom we could not obtain an ideology estimate using the approach described below, or who missed too many votes. For this dataset, we use the Euclidean distance between the vectors corresponding to each of the representatives. To make this experiment closer to a plausible practical scenario, we restrict half of the facilities to be democrats and the other half to be republicans. In addition, clients are served by the closest facility of the same party.

`Domains`: We combined the domain-related data described in the work of Bakshy et al. [3] with the `Twitter` dataset. The set of facilities consisted of 469 domains hosting the news sources most often shared on the Facebook social network. The client set is comprised of 6 104 of the most politically active Twitter users. We consider two alternatives for computing the distances.

(1) *Mentions*: Given a facility f and a client c, let n_{cf} be the number of times a tweet by c contains a link to f. Then $d(f,c) = (n_{cf}+1)^{-1}$. To compute the pairwise distances between facilities we do the following. Consider two facilities, f and g. Let S_f (respectively S_g) be the set of clients that have tweeted a link to f (respectively g) at least once. We define $W = \sum_{c \in S_f \cup S_g} \left(\log n_{cf} \mathbb{I}\{c \in S_f\} + \log n_{cg} \mathbb{I}\{c \notin S_f\}\right)$, where $\mathbb{I}$ is the indicator function. Then

$$d(f,g) = 1 - \frac{\sum_{c \in S_f \cap S_g} \log n_{cf}}{W}. \tag{4}$$

We define $\log 0 = 0$. Since the objective function of RECON-k-MEDIAN (Equation (1)) sums over all ordered pairs of facilities, this distance function is in effect symmetric when applied to our problem. Note that this is akin to the Jaccard index for set similarity, but each element is weighted with a measure of its relevance.

(2) *Latent*: We construct a matrix A such that A_{ij} is the number of times a tweet by user j contains a link to domain i. We compute the singular value decomposition $A = U\Sigma V^T$ and extract the latent representation for both domains and users in the first 9 components (which account for 50% of the total Frobenius norm of A). If $k = 9$, domain i is represented as $U_{i,:k}$ and user j as $V_{i,:k}$. To compute both facility-facility and facility-client distances we take the Euclidean distances between the corresponding latent representations.

The characteristics of the datasets are summarized in Table 1.

For all datasets, in order to compute the objective of RECON-k-MEDIAN we take averages instead of the sums of distances. Note that this amounts to scaling both sums, so it is equivalent to setting λ to a particular value. The advantage of taking averages is that λ has an impact at small values, i.e., at "small" factors of 1.

Ground truth polarity scores (π). To measure the polarity scores of the facilities we employ different methods depending on the dataset.

In the case of `Twitter` and `Congress` we use the approach described by Barberá [4], which estimates the ideological leaning of a Twitter account as a real value. For `Twitter`, we use polarity scores collected at the same time as the follower graph (July 2017). For `Congress`, we collected the ideological estimates in May 2018. Using this method and the proposed datasets, all the elicited polarity scores are between -3 and 3. We measure the polarity of the chosen representatives as follows. Given a solution $S = \{s_1, \ldots, s_k\}$, let $\pi(s_i)$ denote the estimated polarity of facility s_i. We define the polarity of solution S as the sample standard deviation of the set $\{\pi(s_1), \ldots, \pi(s_k)\}$.

For `Domains`, we use the ideological leaning score associated to each domain as described in the work of Lahoti et al. [21]. These scores were computed roughly as the fraction of interactions (visits or shares) by conservative users, out of total interactions. We translated the scores so that they fall between -0.5 (left) and 0.5 (right). In this scenario, we are interested in choosing less polarized sources. We therefore measure the polarity of the chosen set as the ℓ-2 norm of the vector $(\pi(s_1), \ldots, \pi(s_k))$.

[3] The datasets are available at https://doi.org/10.5281/zenodo.2573954

[4] The follower graph corresponds to a snapshot taken in July 2017.

Table 1: Summary of the datasets.

Name	Number of clients	Number of facilities	Distance functions
`Twitter`	3 302 362	500	Shortest path, Spectral embedding + Euclidean
`Congress`	420	420	Euclidean
`Domains`	6 104	469	Weighted Jaccard + Mentions, Latent space + Euclidean

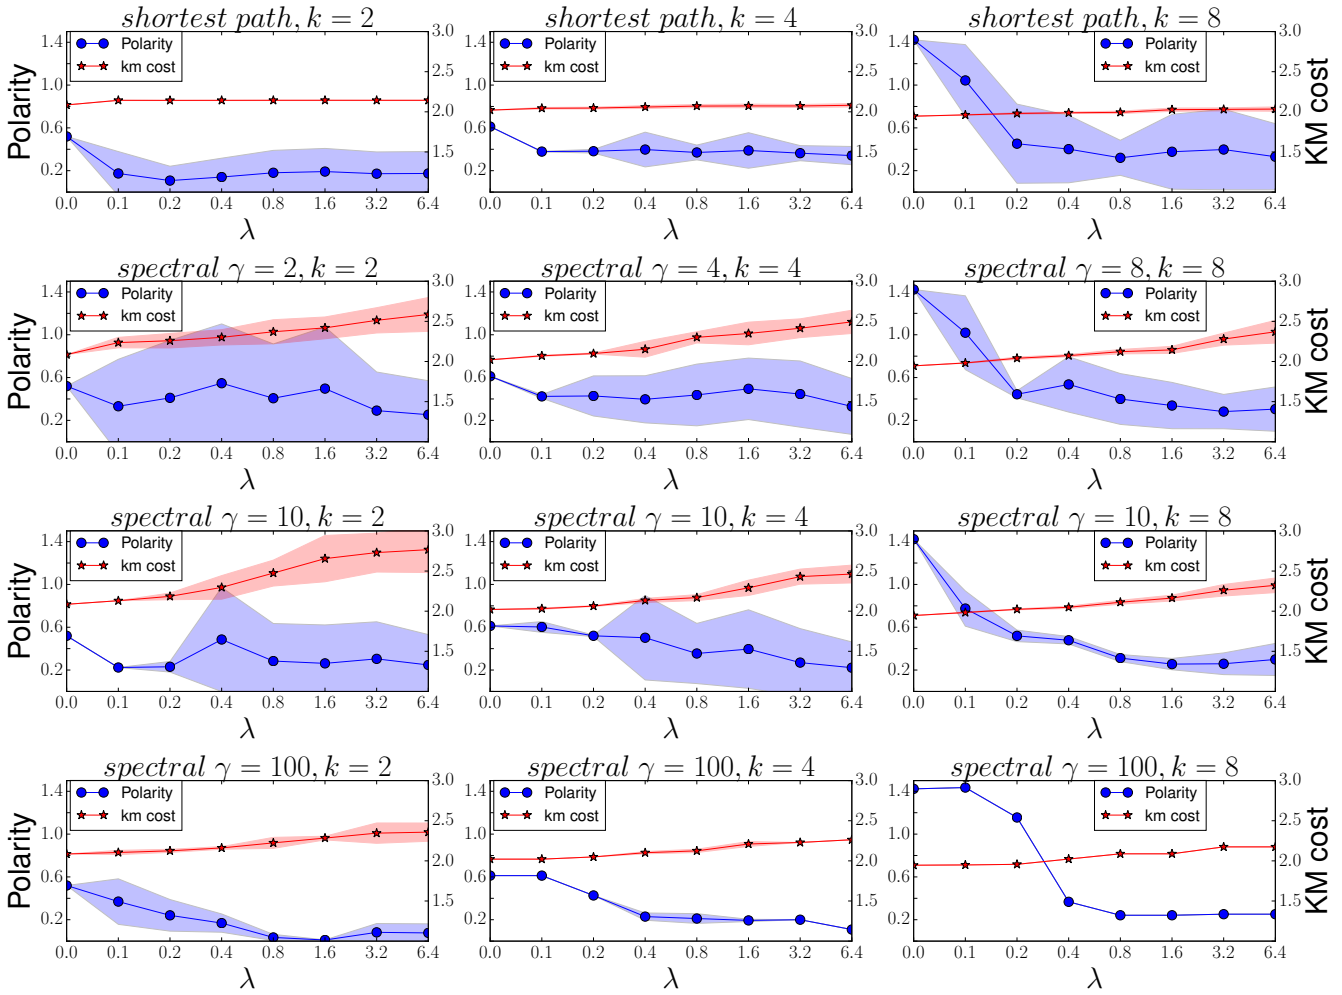

Figure 1: Results on the `Twitter` dataset with different metrics and values of k.

Results on `Twitter` dataset. We run the algorithm on the `Twitter` dataset setting the number of selected facilities to $k = 2, 4, 8$ and $\lambda = 0, 2^i/10$ for $i = 1, \ldots, 6$. For computing the pairwise distances between facilities we use either the shortest path metric or the spectral embedding with $\gamma = k, 10, 100$. Figure 1 illustrates the results. We depict, as a function of λ, the polarity of the chosen representatives, measured as described above, along with the k-median cost of the solution — i.e., the first term of the objective function (2). We run the algorithm 40 times for each setting and report the average and standard deviation bands. We can see that increasing the value of λ leads to significantly less polarized representatives in various cases. The effect is most noticeable for larger values of k, and particularly consistent using the spectral embedding with 100 components. An interesting result on this dataset is that we can achieve significant decreases in polarity without incurring much additional k-median cost. That is, it is possible to elect a much more agreeable committee — with respect to the chosen polarity measure — without notable loss in representation fidelity.

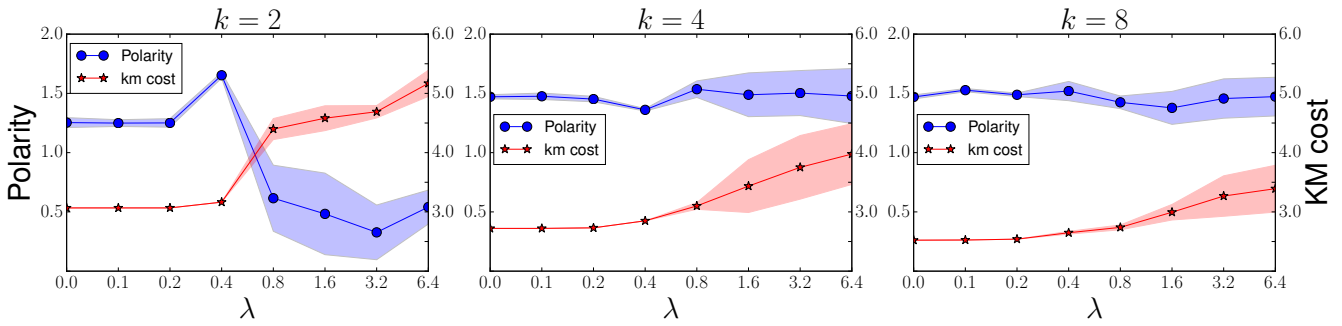

Figure 2: Results on the `Congress` dataset for different values of k.

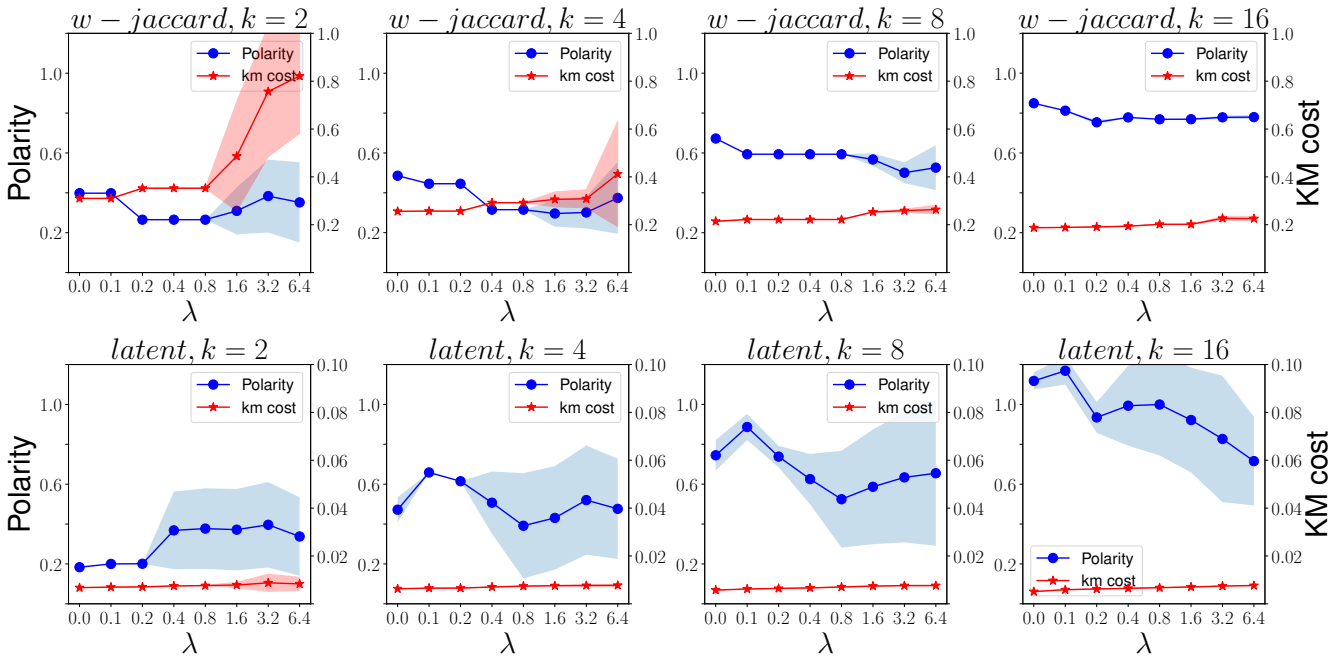

Figure 3: Results on the `Domains` dataset with different metrics and values of k.

Results on `Congress` dataset. We run the algorithm on the `Congress` dataset, using the same configurations as for `Twitter`. Figure 2 illustrates the results. Here, the decrease in polarity is only clear in the case $k = 2$, for values of λ at least 0.8. It should be noted, however, that the voting data and the polarity scores come from completely different sources. It would therefore be interesting to carry out further experiments with these data.

Results on `Domains` dataset. We run the algorithm on the `Domains` dataset, using the same configurations as for `Twitter` but considering $k = 16$ as well, as in the case of news sources it is practical to consider larger sets. Figure 3 shows the results, using the distance function defined in Equation (4) (*w-jaccard*) and the latent representation (*latent*). We run each configuration 80 times and report average results and standard deviation bands. The reduction in polarity is noticeable, in particular using the latent representation with larger values of k. For very small sets of news sources (e.g., $k = 2$) the method does not exhibit a reduction in polarity. In order to gain further insight on the impact of the penalty term, we report an example of the news sources that appear more frequently as λ increases. Specifically, we take a case where decrease in polarity is noticeable (*latent*, $k = 8$, $\lambda = 0.8$). We then collect the 16 sources that appear the most, and do the same for $\lambda = 0$. The results are shown in Table 2. For each domain, we report the frequency (i.e., the fraction of times it was part of the solution out of the 80 runs), the ideological score and the number of times it was mentioned in the collected tweets.

Number of iterations. Even though the time complexity of the local-search algorithm per iteration is not too high, a legitimate concern to be raised is the possibility that it might require a large

number of iterations to converge. Our observations, however, suggest that in practice a small number of iterations — where by iteration we understand the inspection of all candidate changes — are necessary. Table 3 shows the average and maximum number of iterations for the `Twitter` dataset.

6 CONCLUSIONS

We have considered the problem clustering data so as to optimize the total representation cost plus an additive term to penalize disagreement among the chosen representatives. The proposed problem, which we name reconciliation k-median, has applications in summarizing data with non-polarized representatives, as well as in electing k-member committees that are more likely to reach consensus. We have shown the proposed problem to be **NP**-hard and derived bounds on the objective. Inspired by the literature on related problems, we have analyzed a local-search algorithm in this context and derived approximation guarantees, of factor $O(\lambda k)$ in the general setting, and constant under mild assumptions. Through experiments on real data coming from a social network and voting records, we have shown empirically how the proposed formulation can lead to the choice of less polarized groups of representatives, as measured by a well-known method for ideology estimation, as well as less ideologically-extreme sets of news sources. This work opens various enticing directions for future inquiry. First it would be interesting to determine whether the approximation guarantees can be improved, as well as to attempt to find tight examples to know the possible extent of said improvement. Second, it would be interesting to perform further experiments on similar and other datasets. It is particularly compelling to improve our understanding of how different metrics can interact with known methods for estimating polarization.

APPENDIX

6.1 Hardness results

Here we prove Lemma 1, which is a key ingredient of the proof of hardness for RECON-k-MEDIAN. Before we proceed, we provide a definition of Densest k-subgraph, a well-known **NP**-hard optimization problem which we employ in our reduction.

PROBLEM 3. *(densest k-subgraph — DkS) Given a simple graph $G = (V, E)$ with $|V| = n$ and adjacency matrix A, and a number $k \in \mathbb{N}$ with $k < n$, find*

$$\min_{\mathbf{x}} \quad \mathbf{x}^T \mathbf{A}\, \mathbf{x}, \qquad \textit{subject to} \quad \mathbf{x} \in \{0,1\}^n \textit{ and } \mathbf{x}^T \mathbf{1} = k.$$

We can now prove the aforementioned lemma.

PROOF OF LEMMA 1. We proceed by reduction from Densest k-subgraph (DkS).

Consider an instance of DkS, $G = (V, E)$, $|V| = n$ with adjacency matrix A. We define a matrix $\tilde{A}$ as follows:

$$\tilde{A}_{ij} = \begin{cases} A_{ij} & (i,j) \in E \\ 0 & i = j \\ 2 & \text{otherwise.} \end{cases}$$

Notice that this matrix is symmetric, the diagonal (and nothing else) is zero, and since $\min_{i \neq j} \tilde{A}_{ij} = 1$ and $\max_{i \neq j} \tilde{A}_{ij} = 2$, for all i, j, and ℓ

$$\tilde{A}_{ij} \leq \tilde{A}_{i,\ell} + \tilde{A}_{\ell,j}.$$

We want to show that if

$$\mathbf{x} = \operatorname*{argmin}_{\substack{\mathbf{x} \in \{0,1\}^n \\ \mathbf{x}^T \mathbf{1} = k}} \mathbf{x}^T \tilde{A} \mathbf{x},$$

then

$$\mathbf{x} = \operatorname*{argmax}_{\substack{\mathbf{x} \in \{0,1\}^n \\ \mathbf{x}^T \mathbf{1} = k}} \mathbf{x}^T A \mathbf{x}.$$

We can write $\mathbf{x}^T \tilde{A} \mathbf{x} = \sum_i \sum_j \tilde{A}_{ij} \mathbb{I}\{x_i = x_j = 1\} = M + 2N$, where we have defined

$$M = |\{(i,j) | x_i = x_j = 1\} \cap E|$$
$$N = |\{(i,j) | x_i = x_j = 1\} \cap \bar{E}|$$

That is, M is the number of pairs in $\mathbf{x}$ with a corresponding edge in G, and N is the number of pairs in $\mathbf{x}$ *without* a corresponding edge in G. Note that $M + N = 2\binom{k}{2} = k^2 - k$.

Similarly, $\mathbf{x}^T A \mathbf{x} = \sum_i \sum_j A_{ij} \mathbb{I}\{x_i = x_j = 1\} = M$, where $M = k^2 - k - N$.

Suppose $\mathbf{x}$ minimizes MPD but it does not maximize DkS. Then for some $\mathbf{x}'$,

$$\mathbf{x}'^T A \mathbf{x}' > \mathbf{x}^T A \mathbf{x},$$

which implies

$$M' > M,$$

or

$$\mathbf{x}'^T \tilde{A} \mathbf{x}' = M' + 2N' < M + 2N = \mathbf{x}^T \tilde{A} \mathbf{x}.$$

This contradicts the initial assumptions, hence if $\mathbf{x}$ minimizes MPD, $\mathbf{x}$ maximizes DkS. □

6.2 Approximation guarantees

We employ the following notation:
– $f(S) = \sum_{x \in C} d(x, s(x))$, where $s(x)$ is the facility assigned to client x;
– $g(S) = \frac{1}{2} \sum_{x \in S} \sum_{y \in S} d(x,y)$;
– $N_S(s)$ is the set of clients served by facility s in solution S.

Proof of theorem 3. From Arya et al. [2], we know there exists a set of k pairs $\Sigma = \{(o_i, s_j) \mid i,j \in [k]\} \subset O \times S$ satisfying the following properties:

(1) Every $o \in O$ is considered in exactly one pair.
(2) Every $s \in S$ is considered in two pairs at most.

From the local optimality of S we have

$$f(S - s_j + o_i) - f(S) + g(S - s_j + o_i) - g(S) \geq 0,$$

for any $i,j \in [k]$. Again from Arya et al. [2], we know we can choose the set of pairs Σ such that the following inequality holds:

$$5f(O) - f(S) \geq \sum_{(o_i,s_j) \in \Sigma} \Big(f(S - s_j + o_i) - f(S) \Big). \tag{5}$$

Furthermore, since S and $S - s_j + o_i$ differ in one centroid only, we have

$$\begin{aligned} g(S - s_i + o_j) - g(S) &= \sum_{x \in S - s_j + o_i} \sum_{y \in S - s_j + o_i} d(x,y) - \sum_{x \in S} \sum_{y \in S} d(x,y) \\ &= \sum_{\substack{s \in S \\ s \neq s_j}} d(o_i, s) - \sum_{s \in S} d(s, s_j). \end{aligned}$$

Summing this difference over all k pairs we get

$$\begin{aligned} &\sum_{(o_i,s_j) \in \Sigma} (g(S - o_i + s_i) - g(S)) \\ &\qquad = \sum_{(o_i,s_j) \in \Sigma} \left(\sum_{s_p \in S, s_p \neq s_j} d(o_i, s_p) - \sum_{s_p \in S} d(s_p, s_j) \right). \end{aligned}$$

Therefore, we have

$$5f(O) + \sum_{(o_i,s_j) \in \Sigma} \sum_{s \in S, s \neq s_j} d(o_i, s) \geq f(S) + \sum_{(o_i,s_j) \in \Sigma} \sum_{s \in S} d(s_j, s).$$

We consider this inequality, and modify it so that it becomes dependent only on factors of $f(O)$, $g(O)$, $f(S)$, $g(S)$. To accomplish this, we will consider the set of pairs Σ.

First, let us examine the following quantity:

$$\sum_{(o_i,s_j) \in \Sigma} \sum_{s \in S, s \neq s_j} d(o_i, s).$$

By the triangle inequality, we have that the sum corresponding to each pair $(o_i, s_j) \in \Sigma$ is bounded as follows:

$$\sum_{\substack{s \in S \\ s \neq s_j}} d(o_i, s) \leq \sum_{\substack{s \in S \\ s \neq s_j}} d(o_i, o_{h_s}) + d(o_{h_s}, x) + d(x, s), \tag{6}$$

where o_{h_s} is such that $N_O(o_{h_s}) \cap N_S(s) \neq \emptyset$ and $x \in N_O(o_{h_s}) \cap N_S(s)$. If $N_S(s) \subseteq N_O(o_i)$, we consider $d(o_i, s) \leq d(o_i, o_{h_s}) + d(o_i, x) + d(x, s)$, choosing o_{h_s} as described below.

For notational convenience, we define

$$\sigma(o_i) = \sum_{\substack{s \in S \\ s \neq s_j}} d(o_i, o_{h_s}) + d(o_{h_s}, x) + d(x, s),$$

for each $(o_i, s_j) \in \Sigma$ — note that each o_i appears exactly once in the pairs in the set Σ, so the pair (o_i, s_j) is uniquely determined by o_i.

We want to choose the entries of inequality (6) such that

– every entry of the form $d(o_i, o_{h_s})$ appears twice;
– every entry of the form $d(o_{h_s}, x)$ appears once;
– every entry of the form $d(x, s)$ appears once.

Algorithm 2 Reverse procedure to choose the replacements

```
for i = 1, ..., k do
    B_i ← ∅
end for
for i = 1, ..., k do
    r ← random ordering of 1, ..., k
    for every j = 1, ..., k
    B_i ← B_i ∪ {r(j)}
end for
```

To achieve this, we need a set of replacements such that for each $\sigma(o_i)$, the $k-1$ corresponding replacements contain $k-1$ distinct entries of the forms $d(o_i, o_{h_s})$, $d(o_{h_s}, x)$, $d(x, s)$.

We define a function μ that maps each $x \in C$ to a pair (o_i, s_j) such that $x \in N_S(s_j) \cap N_O(o_i)$. Since $|N_S(s_i)| \geq k$ and $|N_O(o_i)| \geq k$ by assumption, we can choose a subset $\tilde{C} \subseteq C$ of k^2 points such that each $s \in S$, as well as each $o \in O$, appears in k of the k^2 pairs associated to the chosen points. We now define k multisets $B_j = \{i : \forall x \in \tilde{C}$ such that $\mu(x) = (o_i, s_j)\}$. That is, each $s_j \in S$ corresponds to a multiset B_j, which contains the index of each $o_i \in O$ with which s_j shares a client in $\tilde{C}$, including repetitions.

For $i = 1, \ldots, k$ we define the multisets $K_i = \{i, i, \ldots, i\}$, $|K_i| = k$ and $M = \bigcup_i K_i$. Consider the procedure outlined by Algorithm 2. It is clear that such a procedure can produce any partition of the multiset M into k sets containing k elements each. Consider the orderings such that said procedure results in the partition $B_1, \ldots, B_k$. If we reverse the procedure using those orderings, we obtain the desired sequence of replacements. Note that for any entry $d(o_i, s)$ in $\sigma(o_i)$ such that $N_S(s) \subseteq N_O(o_i)$, we can make the rest of the replacements first and then choose o_{h_s} from the remaining elements of O. Additionally, note that each sum $\sigma(o_i)$ requires us to make only $k-1$ replacements. Since the above method provides k satisfactory replacements for each sum, we can simply pick $k-1$ of those. We can now conclude that

- every element of the form $d(o_i, o_j)$ can only appear either in $\sigma(o_i)$ or in $\sigma(o_j)$. Since for all $\sigma(o_i)$, the entry $d(o_i, o_j)$ is unique, each $d(o_i, o_j)$ appears at most twice;
- for any element of the form $d(o, x)$, $o \in O$, x is unique;
- for any element of the form $d(s, x)$, $s \in S$, x is unique.

We have established the following inequality

$$\sum_{(o_i, s_j) \in \Sigma} \sum_{\substack{s \in S \\ s \neq s_j}} d(o_i, s) \leq 2g(O) + f(O) + f(S). \tag{7}$$

We now examine the quantity

$$\sum_{(o_i, s_j) \in \Sigma} \sum_{s \in S} d(s_j, s). \tag{8}$$

For every two facilities $s_i, s_j \in S$, either

- $d(s_i, s_j)$ appears in the sum;
- $d(s_i, s_j)$ does not appear in the sum. This implies 1) s_i, s_j are not part of any pair in Σ and 2) some other s_h appears in two pairs (remember that there are exactly k pairs and each $s \in S$ takes part in at most two). Since the summation $\sum_{s_j \in S} d(s_h, s_j)$ is computed over all elements of S, we have two appearances of $d(s_h, s_i)$ and other two of $d(s_h, s_j)$ (one for each summation corresponding to the two pairs involving s_h). Since $d(s_h, s_j) + d(s_h, s_i) \geq d(s_i, s_j)$, we can replace $d(s_h, s_j) + d(s_h, s_i)$ with $d(s_i, s_j)$ in the sum (8) and the inequality still holds.

This implies the following:

$$\sum_{(o_i, s_j) \in \Sigma} \sum_{s \in S} d(s_j, s) \geq g(S).$$

Combining this with inequality (5) we can state

$$10f(O) + 2 \sum_{(o_i, s_j) \in \Sigma} g(S - s_j + o_i) - 2f(S) - 2g(S) \geq 0. \tag{9}$$

Considering each cluster in both S and O to have at least $\lceil 2\lambda \rceil k$ points, we can extend the result to account for λ. To do this, we apply the replacements leading to inequality (7) $\lceil 2\lambda \rceil$ times to the sum $2\lambda \sum_{(o_i, s_j) \in \Sigma} \sum_{\substack{s \in S \\ s \neq s_j}} d(o_i, s)$ and obtain

$$2\lambda \sum_{(o_i, s_j) \in \Sigma} \sum_{\substack{s \in S \\ s \neq s_j}} d(o_i, s) \leq 4\lambda g(O) + f(O) + f(S)$$

To see this, note that for every entry of the form $d(o_i, x)$ or $d(s_j, x)$, x is still unique. Combining this with inequality (9), we have

$$10f(O) + 4\lambda g(O) + f(O) + f(S) \geq 2f(S) + 2g(S),$$

which implies

$$11f(O) + 4\lambda g(O) \geq f(S) + g(S).$$

Therefore,

$$\max\{11, 4\lambda\}\, cost(O) \geq cost(S).$$

□

Theorem 4. *Let (F, C, k, λ) be an instance of problem 1. Let $S = \{s_1, \ldots s_k\}$ be a solution output by algorithm 1 and let $O = \{o_1, \ldots o_k\}$ be an optimal solution.. Then*

$$cost(S) \leq (\lambda k + 5)\, cost(O) \tag{10}$$

The proof, which we omit due to space constraints, is similar to that of theorem 3.

ABSTRACT

Neural networks have recently been shown to be highly effective at predicting links for constructing knowledge graphs. Existing research has mainly focused on designing 1) deep neural network models that are expressive in capturing fine-grained semantics, e.g., NTN and ConvE, but that are however less scalable; or 2) shallow models that are scalable, e.g., TransE and DistMult, yet limited in capturing expressive semantic features. In this work, we demonstrate that we can get the best of both worlds while drastically reducing the amount of data needed to train a deep network by leveraging active learning.

We present a novel deep active learning framework, ActiveLink, which can be applied to actively train any neural link predictor. Inspired by recent advances in Bayesian deep learning, ActiveLink takes a Bayesian view on neural link predictors, thereby enabling uncertainty sampling for deep active learning. ActiveLink extends uncertainty sampling by exploiting the underlying structure of the knowledge graph, i.e., links between entities, to improve sampling effectiveness. To accelerate model training, ActiveLink further adopts an incremental training method that allows deep neural networks to be incrementally trained while optimizing their generalizability at each iteration. Extensive validation on real-world datasets shows that ActiveLink is able to match state-of-the-art approaches while requiring only 20% of the original training data.

1 INTRODUCTION

Knowledge graph construction is a key application for transforming Web content into machine-processable data [9]. A fundamental task in knowledge graph construction is link prediction, where the goal is to create or recover missing links in knowledge graphs, e.g., identifying the birthplace of a person or the CEO of a company. This task is generally formulated as a statistical relational learning problem, for which a variety of techniques such as latent factor models [25], random walks [19] and neural networks [22] have been explored. Among them, neural network-based methods, which learn semantic representations of entities and relations, have significantly advanced the state of the art in the past few years [5, 8, 30, 33, 38].

A focal point of research efforts on neural network-based methods has been designing models that are scalable enough to be applied to large knowledge graphs (e.g., millions of facts), while being able to precisely capture the semantics of entities and relations. Shallow models, such as translational distance models (e.g., TransE [5] and TransH [36]) and semantic matching models (e.g., DistMult [38], ComplEx [33]), were proposed to leverage simple algebraic operations – e.g., inner product and matrix-vector product – for modeling interactions among entities and relations in learning their representations [35]. While being scalable, these models are intrinsically lacking expressive power and thus are limited in capturing fine-grained semantics [8]. In contrast, deep models [9, 30] are better at learning expressive features. However, these models are more complex in terms of parameters. Consequently, model training requires very large amounts of data, which are rarely available in real-world scenarios [35].

Few studies have tackled this problem from the perspective of *data selection*. Better selecting training data is not only useful for reducing the size of the training data, thereby improving the efficiency of model training, but also beneficial for reducing the cost in acquiring additional data to improve link prediction performance. In this work, we propose to adopt active learning [7, 13, 27], which allows the model to choose the data from which it learns best. In the active learning setting, models initially trained on a small amount of data actively select the most informative data samples (often based on model uncertainty), which are then used in combination with existing training data to *retrain* the model. With such a selecting-retraining process iterating multiple times, the model can reach *state-of-the-art performance* with *significantly less training data* compared to conventional supervised learning settings.

The idea of combining deep learning models and active learning, i.e. *deep active learning*, has recently drawn attention for image [13, 16, 34] and text classification [29, 40]. Few approaches have however considered deep active learning for link prediction in knowledge graphs. Unlike image and textual data, the underlying data for link

prediction is relational: entities are connected by relations. This inherently provides an additional source of signals for data sampling in deep active learning: entities that are close to each other in the knowledge graph are more likely to share some similarity, thus to be more redundant for data sampling in the active learning process. By taking advantage of the underlying data structure, it is therefore possible to improve the effectiveness of data sampling.

While active learning is sample-efficient, it can still be computationally expensive since it requires to retrain models from scratch at every iteration of the active learning process. This problem becomes significant for deep active learning as it typically takes much more time to train a deep learning model than traditional machine learning models. Reducing the computational complexity is thus particularly important in our context, where the size of the training samples can easily blow up to tens of thousands of samples (an order of magnitude larger than what is used for image classification [13]). A straightforward workaround would be to incrementally train the model using the newly selected data or combining it with existing training data [29]. However, these methods will potentially bias the model towards the small amount of newly selected data, or towards the data selected in early iterations of the process. How to incrementally train deep link prediction models with optimal generalizability hence remains a key open research question.

In this paper, we introduce ActiveLink, a novel deep active learning framework for knowledge graphs that takes advantage of the underlying graph structure to improve the sampling effectiveness and to allow deep models to be incrementally trained in an unbiased manner. Our framework inherits from recent advances in Bayesian deep neural networks [12, 37] and takes a Bayesian view on existing neural link predictors. By doing so, it allows any neural link predictor to take into account uncertainty, thus enabling uncertain sampling in a deep active learning setting. In order to fully exploit the graph structure, ActiveLink incorporates uncertainty sampling into a clustering algorithm, which allows to identify redundant pieces of data in the knowledge graph for more effective data sampling. To accelerate model training, ActiveLink further adopts a principled method for unbiased incremental training based on meta-learning [2, 10]. Specifically, at each active learning iteration, we update the model parameters using the newly selected data samples with the meta-goal of generalizing the model for future predictions, which is approximated by generalizing the model based on the samples selected in preceding iterations. To do so, we strike a balance between the importance of newly and previously selected data in order to reach an unbiased estimate of the model parameters.

In summary, we make the following key contributions:

- We present a unified Bayesian view on neural link prediction, which allows any neural link predictor to be used in an uncertainty-based deep active learning setting;
- We propose a new data sampling algorithm that takes advantage of both model uncertainty and the underlying graph data structure to improve data sampling effectiveness;
- We introduce a new meta-learning method to incrementally train deep neural networks for link prediction through deep active learning with optimized generalizability;
- We demonstrate the effectiveness of our approach through an extensive evaluation on real-world datasets. Overall, ActiveLink is able to match the state-of-the-art approach while requiring *significantly less* (20% only) training data.

To the best of our knowledge, this is the first work considering deep active learning for link prediction in knowledge graphs. Our work is an initial yet important step towards improving link prediction performance through the efficient creation of training data. By strategically picking which data samples are used to train neural link predictors, ActiveLink provides an approach to effectively refine large training data and offers a route to efficiently create high-quality data (e.g., through crowdsourcing [39]). The later is highly important for scenarios where data creation is expensive, e.g., knowledge graph construction for specific domains.

2 RELATED WORK

In this section, we first discuss related work on neural network-based methods for link prediction, then review recent advances in deep active learning.

2.1 Neural Link Prediction

Existing neural link prediction methods fall into two broad categories, i.e., deep and shallow models, depending on whether or not the network contains at least one hidden layer. In the following, we review representative techniques for each category and discuss the limitations these techniques suffer from.

Shallow Models. Translational distance models are typical shallow models. A representative model is TransE [5], which learns low-dimensional representations (i.e., embeddings) for both entities and relations in a knowledge graph by minimizing the distance between linked entities. Extensions such as TransH [36] and TransR [21] project embeddings onto relation hyperplanes/spaces to learn relation-specific representations of entities. Another line of work learns representations for entities and relations by considering the match of their semantic representations as the learning target. A representative model of that line is RESCAL [24], which learns embeddings of entities while representing relations as a matrix to model the pairwise interactions between latent factors of two entities. DistMult [38] extends such a method by restricting relation matrices to diagonal ones; while being efficient, it can only be applied for symmetric relations. ComplEx [33] overcomes this issue by adopting complex-valued embeddings to model asymmetric relations. HolE [23] uses cross-correlation to decrease the number of parameters in relation representation and allows for modeling asymmetric relations. All these methods model the interactions between entities and relations through simple operations, e.g., matrix-vector products between relation matrices and entity embeddings.

Deep Models. Instead of using simple algebraic operations, a different line of work considers the use of neural networks with hidden layers to model the complex interaction patterns between entities and relations. An early piece of work [30] proposes Neural Tensor Network (NTN), which matches the embeddings of paired entities and relations by considering both linear and non-linear mappings, including those represented by relation-specific matrices and tensors and a hidden layer with non-linear transformation. Similar

models include semantic matching energy (SME) [4] and multilayer perceptrons (MLP) [9], which simplify NTN by discarding tensor parameters to improve model scalability. ConvE [8] is a recent work demonstrating that employing a 2-dimensional convolution and hidden-layers makes it possible to improve the model expressiveness while keeping a *relatively* smaller number of parameters.

Shallow models intrinsically lack expressive power, making them incapable of capturing fine-grained semantics of entities and relations [8]. Deep models have more expressive power but often involve much more parameters; consequently, model training is not scalable for large knowledge graphs in real-world scenarios. For instance, NTN has a time complexity two order of magnitude greater than TransE [35]. Our work takes an orthogonal perspective to improve the training efficiency of deep models by reducing the amount of training data while maintaining excellent performance through deep active learning.

2.2 Deep Active Learning

While extensive research has been carried out on both deep learning and active learning, researchers only recently started to investigate active learning approaches for deep neural networks. In the following, we briefly review related work that converges to the current notion of deep active learning.

Active Learning. In the traditional active learning setting, the model selects unlabeled data samples which supposedly can provide the strongest supervision; these samples are labeled and then used to retrain the model. The potential benefit of a data sample is generally measured by the model's uncertainty in making predictions for that sample, i.e., the so-called *uncertainty sampling* [7, 20]. It can be instantiated through different acquisition functions, such as maximum entropy [28], BALD [15], and variation ratios [11]. Besides uncertainty sampling, additional criteria can also be taken into account, e.g., how well a data sample will reduce the estimate of the expected error [26], which attempts to select data samples that directly optimize prediction performance. Such a criterion, however, is less practical as it is generally difficult to have an analytical expression for the expected prediction error.

Deep Active Learning. A key obstacle in applying active learning to deep neural networks is the fact that neural networks only make deterministic predictions, making it challenging to represent model uncertainty. A popular workaround has been to employ an active learning model (e.g., a Gaussian process) which is kept separate from the neural network classifier [17]. A more consistent solution is to leverage recent developments in Bayesian deep learning, which can generally be categorized into two classes. The first one is based on stochastic gradient descent (SGD). Welling et al. [1, 37] show that by adding the right amount of noise to standard SGD, the parameter converges to samples from the true posterior distribution. The second class of methods is based on dropout, which is a technique originally proposed to prevent over-fitting in training deep learning models [14, 31]. Gal et al. [12] showed that when considering dropout during prediction in a similar way as for model training, the predictions are equivalent to sampling from the approximate true posterior distribution of the parameters, thus turning a deterministic predictive function into a stochastic (uncertain) one.

Recent Applications. Deep active learning was first applied to image classification [13, 16]. These works showed that the Bayesian approach significantly outperforms deterministic predictions in deep active learning across multiple uncertainty-based acquisition functions. Recently, a few studies have investigated deep active learning approaches to textual data, including sentence classification [40] and named entity recognition [29]. These applications demonstrate that deep active learning can considerably reduce the amount of data used to train the model.

To the best of our knowledge, we are the first ones to leverage deep active learning for link prediction. Unlike image and textual data, data samples in link prediction are connected by a set of links, which provides an additional source of signals that we take advantage of thanks to a new data sampling algorithm. Moreover, we introduce a new principled method for incremental training, which is particularly useful to improve the computational efficiency of deep active learning on link prediction.

3 THE ACTIVELINK FRAMEWORK

This section introduces our proposed framework for deep active learning, which we refer to as ActiveLink. We first introduce a unified Bayesian view on neural link prediction, which allows any neural link predictor to represent prediction uncertainty, thereby enabling uncertainty sampling in ActiveLink. Next, we introduce two key features of ActiveLink: 1) structured uncertainty sampling, a data sampling method that leverages both model uncertainty and the underlying structure of the knowledge graph to better approximate sample informativeness ; 2) meta-incremental training, a meta-learning approach that allows the link prediction model to be incrementally trained in new iterations of the active learning process by optimizing the generalizability of the model for future predictions.

Problem Statement. Throughout this paper we use boldface lowercase letters to denote vectors and boldface uppercase letters to denote matrices. We use capital letters (e.g., $\mathcal{P}$) in calligraphic math font to denote sets. Following this, we denote a knowledge graph by $\mathcal{G} = \{(s, r, o)\} \subset \mathcal{E} \times \mathcal{R} \times \mathcal{E}$, where $\mathcal{E}$ is the entity set, $\mathcal{R}$ is the relation set, and where a triple (s, r, o) represents a relationship $r \in \mathcal{R}$ between a subject $s \in \mathcal{E}$ and an object $o \in \mathcal{E}$.

Given a budget B, our goal is to select B triples from $\mathcal{G}$ to train a deep neural link predictor with optimal performance. We consider an active learning approach to this problem, which decomposes the problem into multiple iterations. At every iteration, we select k ($k < B$) triples from $\mathcal{G}$, and update the parameters of the link predictor using these triples in combination with previously selected triples. We consider data sampling performed in a greedy fashion, that is, at each iteration we select only k triples with the highest informativeness as determined by ActiveLink. The key problem for ActiveLink is therefore two-fold. 1) Effectiveness: selecting the most informative triples at each iteration, which is important for training a link predictor with high accuracy. 2) Efficiency: training the link predictor in an incremental fashion. Effectiveness and efficiency are addressed by structured uncertainty sampling and meta-incremental training, respectively, as we introduce next.

3.1 Uncertainty Sampling

We start by introducing a unified Bayesian view on neural link predictors. Based on this abstraction, we then introduce an uncertainty sampling method for deep active learning of neural link predictors.

Neural Link Predictors as Scoring Functions. Neural link predictors are often viewed as scoring functions $f_r(s, o)$, which in our context take as input a potential triple (s, r, o), and output a score representing the plausibility of the triple being true. Taking this view, the classic MLP model [9] is defined as follows:

$$f_r(s, o) = \mathbf{w}^\intercal g([\mathbf{s}; \mathbf{r}; \mathbf{o}]\mathbf{W}) \tag{1}$$

where $\mathbf{s}$ and $\mathbf{o}$ are entity embeddings, and $\mathbf{r}$ is a relation embedding; these embeddings are concatenated (denoted by $[;]$) to be used as the input for a fully connected layer parameterized by the linear transformation matrix $\mathbf{W}$ and a non-linear function g (e.g., tanh); $\mathbf{w}$ is a linear transformation vector that takes as input the output of the fully connected layer to obtain the final score.

The state-of-the-art model Convolutional 2D Knowledge Graph Embeddings (ConvE) [8] is similarly defined as follows:

$$f_r(s, o) = g(vec(g([\bar{\mathbf{s}}; \bar{\mathbf{r}}] * w))\mathbf{W})\mathbf{o} \tag{2}$$

where $\bar{\mathbf{s}}$ and $\bar{\mathbf{r}}$ are 2D reshaping of the entity and relation embeddings, which are concatenated and used as an input for a 2D convolutional layer with filters w; vec is a vectorization operation that transforms the feature map given by the convolutional layer to a vector; $\mathbf{W}$ is the weight matrix and g is a non-linear function (rectified linear units (ReLU) [18] are used in the original work).

Neural Link Predictors as Bayesian Models. To allow for uncertainty sampling in deep active learning, we adopt the Bayesian approach to deep neural networks recently developed by Gal and Ghahramani [12]. To this end, we first reformulate neural link predictors as parameterized likelihood functions, such that the output represents the probability of a triple being true. We then pose a prior distribution on the parameters, to transform a deterministic neural link predictor into a Bayesian model.

Denoting all parameters, including entity and relation embeddings and all weight parameters (i.e., linear transformation matrices and vectors), as Θ, we can rewrite any neural link predictor as $f_r^\Theta(s, o)$, which can then be reformulated as a likelihood function by introducing an additional softmax layer:

$$p(y|(s, r, o), \Theta) = \text{softmax}\,(f_r^\Theta(s, o)) \tag{3}$$

where y is the output of the link predictor representing whether a triple is true or not. To make neural link predictors Bayesian, we define a prior over the parameters Θ:

$$\Theta \sim p(\Theta|K) \tag{4}$$

e.g., a standard Gaussian prior parameterized by K (the co-variance matrix). With this definition, model training will result in a posterior distribution over the parameters, i.e. $p(\Theta|\mathcal{D}_{train})$ (where $\mathcal{D}_{train}$ is the training data), instead of point estimates (i.e., fixed values for the parameters). The prediction for an arbitrary input (s, r, o) can be described as a likelihood function:

$$p(y|(s, r, o), \mathcal{D}_{train}) = \int p(y|(s, r, o), \Theta)p(\Theta|\mathcal{D}_{train})d\Theta \tag{5}$$

which provides a more robust prediction than non-Bayesian methods as it takes into account the uncertainty of the parameters.

The problem of inferring the exact posterior distribution for the parameters, $p(\Theta|\mathcal{D}_{train})$, is intractable. Gal and Ghahramani [12] recently proposed in that context Monte Carlo (MC) dropout, which is a simple yet effective method for performing approximate variational inference. MC dropout is based on dropout [14, 31], which is typically used during model training to randomly drop hidden units of the network at each parameter update iteration; this reduces complex co-adaptations of neurons that can easily lead to overfitting. Gal and Ghahramani [12] prove that by performing dropout during the forward pass when making predictions, the output is equivalent to the prediction when the parameters are sampled from a variational distribution of the true posterior.

Formally, MC dropout is equivalent to sampling from a variational distribution $q(\Theta)$ that minimizes the Kullback-Leibler (KL) divergence to the true posterior $p(\Theta|\mathcal{D}_{train})$. Given this, we can perform a Monte Carlo integration to approximate Equation 5:

$$\begin{aligned} p(y|(s, r, o), \mathcal{D}_{train}) &\approx \int p(y|(s, r, o), \Theta)q(\Theta)d\Theta \\ &\approx \frac{1}{T}\sum_{t=1}^{T} p(y|(s, r, o), \widehat{\Theta}) \end{aligned} \tag{6}$$

where $\widehat{\Theta}$ is the parameters sampled T times from $q(\Theta)$, i.e., $\widehat{\Theta} \sim q(\Theta)$. To summarize, MC dropout provides a practical way to approximately sample from the true posterior without explicitly calculating the intractable true posterior.

Deep Uncertainty Sampling. Active learning aims at selecting the most informative data samples (triples, in our case) to train the model. This is often formulated as an acquisition function, defined as follows:

$$(s, r, o)^* = \underset{(s,r,o)\in\mathcal{G}}{\arg\max}\ \phi((s, r, o)) \tag{7}$$

The key to developing a good sampling strategy is designing an effective informativeness measure. With the Bayesian formulation of neural link predictors, the informativeness of a triple can be quantified by model uncertainty. A typical uncertainty measure is Shannon entropy:

$$\begin{aligned} &\phi((s, r, o)) = H[y|(s, r, o), \mathcal{D}_{train}] \\ &= -\sum_{C\in\{0,1\}} p(y = C|(s, r, o), \mathcal{D}_{train}) \log p(y = C|(s, r, o), \mathcal{D}_{train}) \\ &= -\sum_{C\in\{0,1\}} (\frac{1}{T}\sum_t \hat{p}_C^t) \log(\frac{1}{T}\sum_t \hat{p}_C^t) \end{aligned} \tag{8}$$

where $\frac{1}{T}\sum_t \hat{p}_C^t$ is the averaged predicted probability of class C for (s, r, o) ($C \in \{0, 1\}$ i.e., the triple being true or not), sampled T times by Monte Carlo dropout. Note that Θ is marginalized in the above equation as in Equation 6.

3.2 Structured Uncertainty Sampling

Besides model uncertainty, knowledge graphs provide an additional source of signals to represent data informativeness given their data structure: entities are linked by relations. Considering an existing pool of data sampled in preceding iterations, we make the following assumptions:

(1) Entities linked with those in the training pool are less informative than entities not linked;

(2) More generally, entities that are intensively linked with each other are less informative with respect to each other than those sparsely linked.

Relations therefore provide a source for measuring the informativeness of data samples from the perspective of the redundancy between data samples. This comes in contrast to representing informativeness from the perspective of the models. We are, therefore, interested in designing a data sampling method that exploits relations in knowledge graphs and that potentially combines it with model uncertainty.

To this end, we leverage clustering algorithms to identify groups of entities based on relations among entities. Our basic assumption is that entities belonging to the same cluster are more redundant with each other. Therefore, we construct our initial training set by picking from each of the c clusters a single data sample (i.e., a triple). After the model is trained on the initial set, at each of the following active learning iterations we select clusters based on their potential redundancy with respect to existing training data. Following the idea that data samples belonging to the same cluster are less informative, we select a sample from each of the selected clusters to form a new dataset for model training.

The above process is described by the high-level pseudo code in Algorithm 1. The key steps are the selection of clusters (row 10-12) and the selection of data samples from the clusters (row 13-15). For cluster selection, the redundancy score (row 11) is calculated as the averaged similarity between all data samples — specifically, cosine similarity between entity embeddings — in the cluster and those in the existing training pool. The selection of data samples within the cluster is based on model uncertainty (row 14). By doing so, we incorporate uncertainty sampling into the sampling algorithm.

We consider K-means for clustering entities, which are represented by low-dimensional embedding learned through TransE [5]. K-means allows picking the number of resulting clusters c. If c is less than the sample size k required for the active learning iteration, the sampling algorithm will be collapsed such that cluster selection is not considered and data samples will be selected from all clusters. In this case, we take the n_j most uncertain triples from cluster C_j, where n_j is proportional to the size of C_j.

We note that our algorithm is not restricted to any specific clustering algorithm. More advanced clustering methods can be applied, e.g., those based on relations among entities as well as entity attributes [3, 6]. Since our goal is to show that clustering can be an effective means to leverage the underlying structure of knowledge graphs for data sampling, we experiment on K-means as it is one the most widely used clustering methods. Comparison of different clustering methods is left for future work.

Algorithm 1: Structured Uncertainty Sampling

Input: Knowledge graph $\mathcal{G} = \{(s, r, o)\}$, budget B, #clusters c, #samples per iteration k ($k < B$), link predictor M
Output: Triples sampled at i-th iteration $\mathcal{T}_i$ ($i \in \{0, 1, \ldots\}$)

1 $C \leftarrow$ Cluster entities in $\mathcal{G}$;
2 $C^k \leftarrow$ Pick k clusters from C;
3 $\mathcal{T}_0 \leftarrow \emptyset$;
4 **foreach** $C_j \in C^k$ **do**
5 $(s, r, o) \leftarrow$ Pick a triple from C_j;
6 Add (s, r, o) to $\mathcal{T}_0$;
7 **while** $\sum_{l=1}^{i} |\mathcal{T}_l| \leq B$ **do**
8 Incrementally train M on $\mathcal{T}_i$;
9 $i++; \mathcal{T}_i \leftarrow \emptyset$;
10 **foreach** $C_j \in C$ **do**
11 Compute $redundancy_score(C_j)$;
12 $C^k \leftarrow$ Pick k clusters based on the scores;
13 **foreach** $C_j \in C^k$ **do**
14 $(s, r, o) \leftarrow \arg\max\ \phi((s, r, o)), \forall s \in C_j$;
15 Add (s, r, o) to $\mathcal{T}_i$;

3.3 Meta-Incremental Training

In the traditional active learning setting, newly selected data samples are combined with existing training data to retrain the model from scratch. This is highly time-consuming when training deep models (our experiments show that model retraining from scratch takes 3 times longer than updating the model parameters from the previous iteration; see Section 4.3 for more details). We are, therefore, interested in incremental training of deep models using the newly selected data samples in every iteration of active learning.

A straightforward workaround is to fine-tune the model trained on the previous iterations using the new data samples only, which is a widely used approach in transfer learning. Such an approach, however, is likely to bias the model to the small amount of newly selected data. To prevent the model to get biased, recent work has proposed to combine the newly selected data with the existing training data and incrementally train the model with a small number of epochs [29]. This however, may not allow to fully exploit the newly selected data, compared with the data selected early that has already been used to update parameters in previous iterations. A central problem here is how to strike a good balance between the importance of new and previously selected data to reach an unbiased estimate of model parameters.

To solve this problem, we propose to adopt a meta-learning approach, where we update model parameters with the meta-goal that the updated model is most generalizable to future predictions. This is achieved in a two-step parameter updating scheme: we temporarily update model parameters with a standard gradient descent step using the newly selected data, followed by a meta-learning step where the learning algorithm performs a gradient descent step with the objective that model parameters will be more generalizable. The generalizability of the updated model parameters is approximated by the prediction loss on data samples selected in the current and the previous iterations.

Formally, in the i-th active learning iteration, model parameters learned in the previous iteration, denoted by Θ_{i-1}, are first updated to Θ'_i by a gradient descent step on the newly selected data $\mathcal{T}_i$:

$$\Theta'_i = \Theta_{i-1} - \alpha \Delta_\Theta \mathcal{L}(f_{\Theta_{i-1}}, \mathcal{T}_i) \tag{9}$$

where f denotes the model, α is the learning rate, $\mathcal{L}(f_{\Theta_{i-1}}, \mathcal{T}_k)$ is the loss function applied to the data samples of $\mathcal{T}_i$ given existing model Θ_{i-1}, and Δ_Θ is the gradient of Θ with respect to the loss.

Algorithm 2: Meta-Incremental Training

Input: The current iteration i, data selected in the current iteration $\mathcal{T}_i$, model parameter from the previous iteration Θ_{i-1}, window size w, data selected in iterations within the window $\{\mathcal{T}_{i-w}, \mathcal{T}_{i-w+1}, \ldots, \mathcal{T}_{i-1}\}$, learning rate α and β

1 **Output:** Updated model parameters Θ_i
2 **while** *True* **do**
3 **for** $l = i - w; l \leq i; l++$ **do**
4 Evaluate $\Delta_\Theta \mathcal{L}(f_{\Theta_l}, \mathcal{T}_l)$;
5 $\Theta'_l \leftarrow \Theta_{i-1} - \alpha \Delta_\Theta \mathcal{L}(f_{\Theta_{i-1}}, \mathcal{T}_l)$;
6 $\Theta_i \leftarrow \Theta_{i-1} - \beta \Delta_\Theta \sum_{l=i-w}^{i} \mathcal{L}(f_{\Theta'_l}, \mathcal{T}_l)$;
7 $\Theta_{i-1} \leftarrow \Theta_i$;
8 **if** *converged* **then**
9 break;

To avoid overfitting, we use a meta-learner that makes use of the triples selected in previous iterations within a certain time window w, i.e. $\{\mathcal{T}_{i-w}, \mathcal{T}_{i-w+1}, \ldots, \mathcal{T}_{i-1}\}$, and update the parameters such that the updated model generalizes well to data in these iterations:

$$\min_{\Theta} \sum_{l=i-w}^{i} \mathcal{L}(f_{\Theta'_l}, \mathcal{T}_l) = \sum_{l=i-w}^{i} \mathcal{L}(f_{\Theta_{i-1} - \alpha \Delta_\Theta \mathcal{L}(f_{\Theta_{i-1}}, \mathcal{T}_l)}, \mathcal{T}_l) \quad (10)$$

wherein Θ'_l represents the parameters updated with Equation 9 using data selected in the l-th iteration ($i - w \leq l \leq i$). With such an objective, the meta-learning step is then performed by stochastic gradient descent as follows:

$$\Theta_i = \Theta_{i-1} - \beta \Delta_\Theta \sum_{l=i-w}^{i} \mathcal{L}(f_{\Theta'_l}, \mathcal{T}_l) \quad (11)$$

where β is the meta-learning rate. Such a meta-learning step involves a second-order derivative (i.e., Hessian) with respect to the parameters, which is readily supported by some standard deep learning libraries.

The overall incremental training algorithm is described in Algorithm 2. We use mini-batch gradient descent for Meta-Incremental training, where mini-batches of data samples selected in the current and previous iterations are used in the inner loop of the meta-learning process (row 3-5) and different mini-batches of these iterations are used for meta-learning loops. Parameters are updated by the meta-learning step (row 6) several times until the current iteration converges.

4 EXPERIMENTS AND RESULTS

In this section, we report on a set of experiments we have conducted to evaluate the performance of ActiveLink.[1] We first evaluate our new data sampling method and the incremental training method of ActiveLink separately, by answering the following question:

- **Q1:** How effective are our uncertainty sampling and structured uncertainty sampling methods in determining the informativeness of data samples?
- **Q2:** How effective is our meta-incremental training method in speeding up the deep active learning process?

Subsequently, we evaluate ActiveLink as a whole by considering the following issues:

- **Q3:** How effective is ActiveLink compared with a traditional supervised learning method (i.e., non-active learning) for training neural link predictors?
- **Q4:** How do parameter settings of ActiveLink, including #samples per iteration and #clusters for data sampling and window size for incremental learning, affect the performance?

In addition, we investigate the generalizability of Activelink across neural link predictors and its scalability on a big dataset. In the following, we start by introducing our experimental setup, before answering each of the above questions in a separate subsection.

4.1 Experimental Settings

Dataset. We experiment on two publicly accessible datasets: FB15K-237 and WikiMovie:

- **FB15K-237** [32] is a subset of Freebase widely used for link prediction evaluation [5, 8, 36]. The knowledge graph mainly describes facts about sports, movies and actors. The original dataset FB15K was contributed by Bordes et al. [5]. Toutanova and Chen [32] noted that FB15K suffers from the test leakage problem: simple rule-based models can reach high prediction performance on the test triples by inverting triples in the training set. We use FB15k-237, a corrected version where inverse relations are removed.
- **WikiMovie** is a subset of Wikidata[2] that contains facts about movies such as directors, actors and genre. The original data is large but sparse. For example, 53% of the entities appear in only one triple, making it difficult to evaluate the link prediction models; by contrast, 95% of the entities in FB15K-237 have at least three training examples. As such, we filtered the dataset to keep a subset with only entities that appear in at least two triples. We prepare two versions of the WikiMovie dataset, namely WikiMovie-300K and WikiMovie-1M, which contain 300K and 1M triples, respectively.

We report key statistics of our datasets in Table 1. We note that WikiMovie-300K contains a comparable number of triples as FB15K-237 yet much more entities. Consequently, link prediction is more difficult on WikiMovie-300K. The comparison of ActiveLink performance on these two datasets, therefore, helps to investigate the impact of data sparsity on ActiveLink performance. WikiMovie-1M is used below to study the scalability of the ActiveLink framework in terms of reducing the amount of data needed to train neural link predictors on large knowledge graphs.

Comparison Methods. To demonstrate the effectiveness of both model uncertainty and data redundancy (considering the underlying data structure), we compare the following data sampling methods:

- **Random**, which randomly selects data samples at every active learning iteration;
- **Structured**, a variant of our method that randomly selects triples from each cluster (similar to stratified sampling);

[1] Our code and data are available at https://github.com/eXascaleInfolab/ActiveLink.

[2] https://www.wikidata.org/

Table 1: Descriptive statistics of the datasets.

	#Entities	#Relationships	#Triples
FB15K-237	14,541	474	310,116
WikiMovie-300K	36,001	588	286,683
WikiMovie-1M	104,500	788	987,896

- **Uncertainty**, a variant of our method that selects data samples based on Shannon entropy (Equation 8);
- **Structured-Uncertainty**, which selects data samples based on both model uncertainty and data redundancy (our proposed Algorithm 1).

We note that Uncertainty is a method that has been investigated in image recognition [13]; however, to the best of our knowledge, we are the first to apply it to link prediction in knowledge graphs.

To investigate the effectiveness of our proposed incremental training method, we compare the following model training techniques for deep active learning:

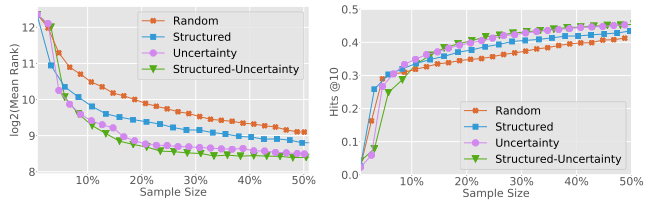
- **Retrain**, the conventional way of performing active learning, which trains the model from scratch at each new iteration;
- **Incremental** [29], the baseline incremental training method that combines newly and previously selected data to incrementally train the model from the last iteration;
- **Meta-Incremental**, our incremental training method that adopts meta-learning to get an unbiased estimate of the model parameters (Algorithm 2).

We evaluate the above model training methods in terms of both model performance and training efficiency.

Finally, to show the superiority of ActiveLink in model training over traditional supervised learning settings as well as to demonstrate the generalizability of ActiveLink on different neural link predictors, we apply both training settings to two state-of-the-art deep neural link predictors (see Section 3.1 for details):

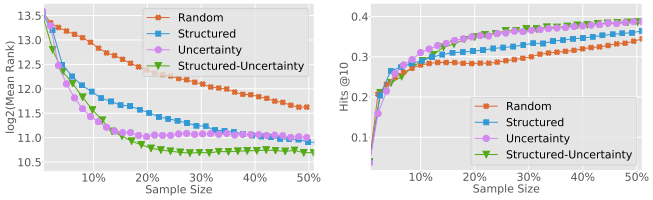
- **ConvE** [8], a model that uses two-dimensional convolutions over entity and relation embeddings for link prediction;
- **MLP** [9], a multi-perceptron model using fully-connected layers over entity and relation embeddings.

Parameter Settings for Link Predictors & ActiveLink. The parameters of the link predictors and ActiveLink are empirically set based on a held-out validation set that contains 10% of the original data. For the link predictors (i.e., ConvE and MLP), we apply grid search in {20, 50, 100, 200} for the dimension of the embeddings and in {0.1. 0.3, 0.5} for the dropout on different layers of the prediction model. We select learning rates from {0.0001, 0.001, 0.01, 0.1, 1} and batch size from {64, 128, 256}. In particular, we use 3×3 filters for the convolution in ConvE. For ActiveLink, the number of samples per iteration is selected from {500, 1000, 5000, 10000}. The number of clusters for the Structured-Uncertainty sampling method is selected from {10, 100, 1000, 10000}. The window size for our Meta-Incremental method is selected from {1, 5, 10, 20, inf}, where inf indicates that all preceding iterations are considered for meta-learning.



Evaluation Protocols. Evaluation is performed on a test set that contains 10% triples from the corresponding dataset; the remaining data is used as the training and validation sets. Following previous studies [5, 8, 21], we measure the performance using the following two metrics: 1) Mean Rank of correct entities, and 2) proportion of correct entities in the top-10 ranked entities (Hits@10). Lower Mean Rank and higher Hits@10 indicate better performance.

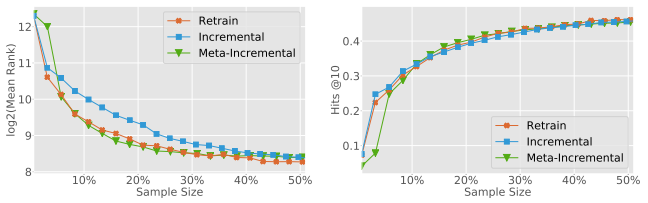
4.2 Comparative Results on Data Sampling (Q1)



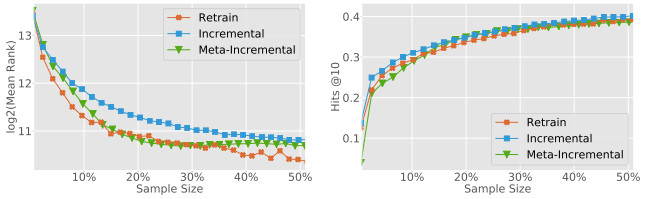
We start by investigating the effectiveness of our proposed sampling methods (Uncertainty, Structured, and Structured-Uncertainty) by comparing them against random sampling (Random). Results are reported in Figure 1, where performance is shown as a function of the fraction of training data (from zero to 50%) selected at different iterations of the active learning process.

From the figure, we observe that Random sampling is outperformed by Structured sampling and Uncertainty sampling across the two datasets and across the two performance metrics. This clearly demonstrates the effectiveness of model uncertainty and data redundancy in data sampling. Among Structured and Uncertainty sampling, we observe that Structured sampling generally performs better than Uncertainty sampling in the early iterations of the active learning process (before 5% samples are selected); however, in the late iterations, Structured sampling is outperformed by Uncertainty sampling. Such a pattern can be explained by the evolution of the size of the samples during the active learning process. In the early iterations of the active learning process, the size of the data being sampled is big as compared with the size of data samples already selected; it is, therefore, easy to select non-redundant data samples by considering the underlying data structure; when the size of selected data samples increases, the newly selected samples get increasingly more redundant with the selected samples, thus decreasing the effectiveness of Structured sampling. In comparison, model uncertainty is less affected by the size of the selected data samples. We note that, when the size of the selected data samples increases (30% to 40%), the performance gains of the link prediction model decreases even for Uncertainty sampling. This indicates the decreased utility of the data samples in the late iterations for improving model performance (see the next part of the results for additional evidence on that point).

Structured-Uncertainty sampling, which combines both model uncertainty and data redundancy in data sampling, achieves the best performance across the two datasets and the two performance metrics. The performance gains are most obvious for the WikiMovie-300K dataset measured by Mean Rank, as shown in Figure 1(c). We note that while not visually obvious in the other subfigures (due to the need for depicting the full range of the variations), Structured-Uncertainty consistently outperforms Uncertainty in every iteration as measured by both metrics: overall, the average improvements are 29.37 (Mean Rank) and 0.1% (Hits@10) for the FB15K-237 dataset when the sample size is between 40% and 50%; for the WikiMovie-300K dataset with the same sample sizes, the average improvements are 400.77 (Mean Rank) and 0.1% (Hits@10). These results highlight the difference between model uncertainty and data redundancy as data informativeness criterion and the effectiveness of combining both of them for data sampling.



(a) FB15K-237 - Mean Rank (b) FB15K-237 - Hits@10



(c) WikiMovie-300K - Mean Rank (d) WikiMovie-300K - Hits@10

Figure 1: Comparison between data sampling methods. Upper figures compare the performance of the data sampling methods measured by (a) Mean Rank (semi-log scale) and (b) Hits@10 on the FB15K-237 dataset; lower figures compare the performance by (c) Mean Rank (semi-log scale) and (d) Hits@10 on the WikiMovie-300K dataset.

(a) FB15K-237 - Mean Rank (b) FB15K-237 - Hits@10

(c) WikiMovie-300K - Mean Rank (d) WikiMovie-300K - Hits@10

Figure 2: Comparison between model training methods. Upper figures compare the performance of the model training methods measured by (a) Mean Rank (semi-log scale) and (b) Hits@10 on the FB15K-237 dataset; lower figures compare the performance by (c) Mean Rank (semi-log scale) and (d) Hits@10 on the WikiMovie-300K dataset.

Compared with Random sampling, Structured-Uncertainty improves link prediction performance by 250.13 (Mean Rank) and 4.5% (Hits@10) for the FB15K-237 dataset and by 1710.04 (Mean Rank) and 5.2% (Hits@10) for the WikiMovie-300K dataset when 50% data samples are selected in both datasets.

4.3 Comparative Results on Incremental Training (Q2)

We now compare our Meta-Incremental training method with Retrain and the Incremental training baseline. Among them, Retrain should perform best in terms of model performance as Retrain uses all data selected in the new and previous iterations to reach an unbiased estimate of model parameters. Figure 2 shows the results.

From the results by Mean Rank in Figures 2(a,c), we observe that both Retrain and our Meta-Incremental training method outperform the Incremental baseline, and importantly, that our method performs as well as Retrain. This indicates that our proposed incremental training method indeed succeeds in obtaining an unbiased estimate of model parameters and achieves optimal model generalizability. The performance difference between our method and the Incremental baseline highlights the importance of including an unbiased estimation of the model parameters. We note that all three methods converge when the size of the data used in active learning reaches 50% of the size of the original training data, which also verifies the decreased utility of data selected in late iterations.

The above trends are not obvious from the results measured by Hits@10 in Figure 2(b,d): no clear difference is observed between the three model training methods. The different results measured by Mean Rank and Hits@10 implies that Hits@10 is a less sensitive metric in evaluating data sampling methods. This is likely due to the fact that Hits@10 is a set-based metric that does not take into account the ranking position of true positives in the *top-10* results, thus it is less sensitive in differentiating model performance, especially given the large number of entities in the experimental datasets.

Table 2: Model training time (in minutes).

	Retrain	Meta-Incremental
FB15K-237	499	177
WikiMovie-300K	945	334

Model Training Efficiency. In order to evaluate the runtime performance of our proposed Meta-Incremental training method, we investigate the model training time with up to 50% of the data samples selected using our test server[3], for both the Retrain method and our Meta-Incremental training method (both achieve optimal model performance). Table 2 reports the results. As shown by the table, our Meta-Incremental method requires a much shorter training time on both FB15K-237 and WikiMovie-300K: it speeds up model training by 2.8x in both cases.

In summary, our Meta-Incremental training method not only achieves optimal model generalizability, but also dramatically reduces the model training time.

4.4 ActiveLink vs. Non-active Learning (Q3)

To evaluate the effectiveness of ActiveLink as a whole, we compare the performance of neural link predictors trained with ActiveLink and those trained with a traditional supervised learning setting

[3] An Ubuntu 14.4 machine with a GeForce GTX TITAN X and 3.3 GHz CPU.

Table 3: Performance of ConvE and MLP trained by ActiveLink and the non-active learning setting on a varying fraction of the FB15K-237 and WikiMovie-300K datasets, measured by both Mean Rank and Hits@10.

Predictor	Fraction	FB15K-237				WikiMovie-300K			
		Mean Rank		Hits@10		Mean Rank		Hits@10	
		Non-Act.	ActiveLink	Non-Act.	ActiveLink	Non-Act.	ActiveLink	Non-Act.	ActiveLink
ConvE	10%	1325.26	409.14	0.255	0.403	6857.77	2150.08	0.219	0.329
	20%	822.88	351.98	0.282	0.440	5253.15	1641.98	0.259	0.365
	30%	605.79	339.48	0.301	0.450	4317.67	1673.97	0.271	0.379
	40%	537.12	329.21	0.326	0.459	3406.10	1658.99	0.296	0.388
	50%	458.91	318.18	0.349	0.464	2832.33	1628.06	0.314	0.396
MLP	10%	1386.80	487.64	0.248	0.395	7094.62	2520.71	0.216	0.300
	20%	848.21	374.75	0.283	0.440	5613.55	1536.02	0.248	0.357
	30%	663.18	346.94	0.314	0.457	4463.22	1379.29	0.274	0.376
	40%	547.16	326.11	0.332	0.467	3370.01	1326.25	0.298	0.389
	50%	458.51	322.40	0.354	0.470	2680.69	1372.14	0.325	0.398

using varying fractions of the experimental datasets. To demonstrate the generalizability of ActiveLink on different neural link predictors, we experimented with two neural link predictors, i.e., ConvE and MLP, and report the results in Table 3.

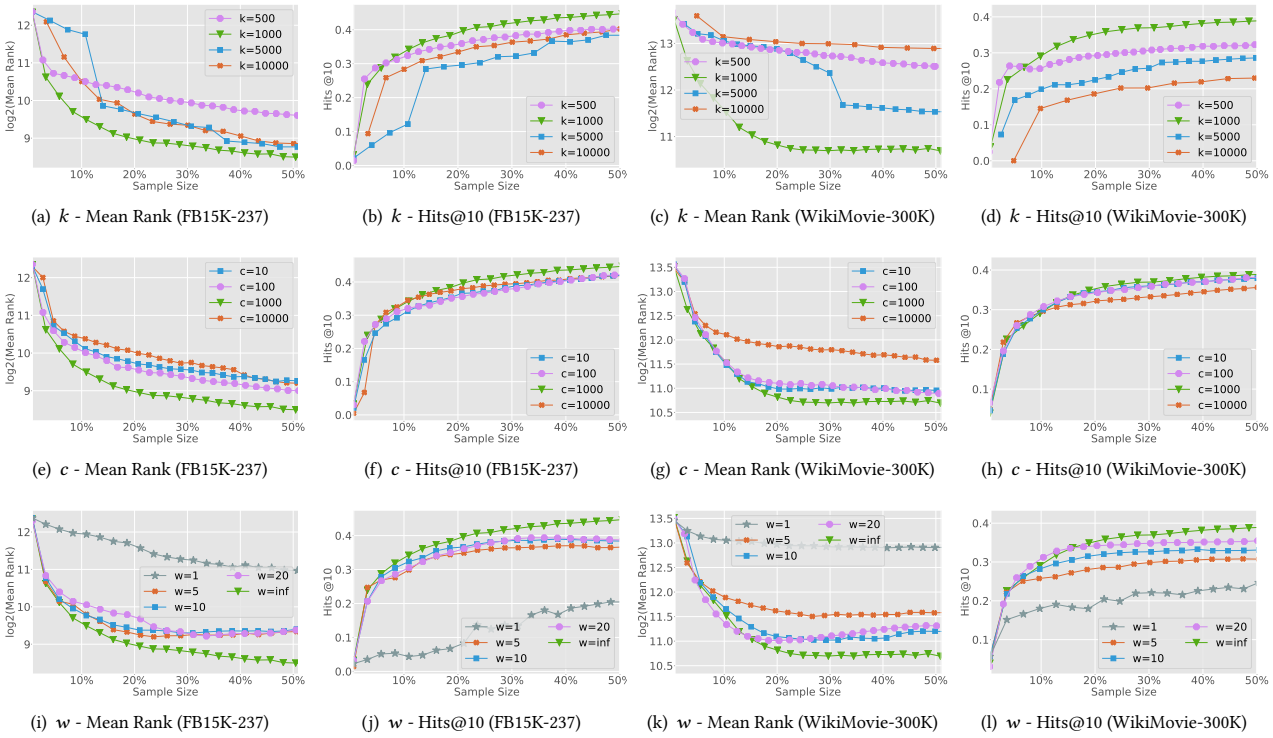
We observe that as the size of the training samples increases, the performance of ConvE and MLP also increases in both active learning and non-active learning settings. Importantly, ActiveLink consistently outperforms the traditional supervised learning setting across all experimental configurations in terms of the neural link predictor, the dataset, the fraction of the dataset for model training, and the performance metric. Such a result clearly indicates the superiority of ActiveLink in training neural link predictors when only a fraction of the dataset is used for model training. The performance gains achieved by ActiveLink flatten in the long run when most data samples are used for model training; this implies that the training set can no longer offer new informative data samples for improving model performance. Comparing the results on the two datasets, we observe that the performance gains through ActiveLink are larger for WikiMovie-300K than for FB15K-237, as measured by Mean Rank. Recalling that WikiMovie-300K contains 2.5x more entities than FB15K-237 does, these results suggest that ActiveLink brings more performance gains for sparse knowledge graphs.

We further compare the performance of ConvE and MLP trained by ActiveLink using a fraction of the dataset and by the supervised learning setting with the *full* dataset. Our experiments show that ActiveLink achieves nearly state-of-the-art results with only half of the data: for the FB15K-237 dataset, ActiveLink reaches 99.6% in Mean Rank and 96.4% in Hits@10 for ConvE, and 99.4% in Mean Rank and 94.6% in Hits@10 for MLP; for the WikiMovie-300K dataset, ActiveLink reaches 98.6% in Mean Rank and 97% in Hits@10 for ConvE, and 99.1% in Mean Rank and 97.4% in Hits@10 for MLP. These results strongly demonstrate the effectiveness of ActiveLink in data utilization when training neural link predictors.

Scalability for Large Datasets. In order to evaluate the performance of ActiveLink on large knowledge graphs, we compare it against a non-active learning setting on the WikiMovie-1M dataset. Results with ConvE as the neural link predictor are shown in Table 4 (similar results are observed with MLP). Overall, ActiveLink reaches 99% in MeanRank and 91% in Hits@10 with only **20%** of the data used for training. Compared with the previous results on the smaller datasets (FB15K-237 and WikiMovie-300K), these results show that ActiveLink is more effective in reducing the amount of training data required for large knowledge graphs.

Table 4: Performance of ConvE trained by ActiveLink using 20% of the WikiMovie-1M dataset and by the non-active learning setting using the full dataset.

	Mean Rank	Hits@10
ActiveLink	3356	0.337
Non-active learning	2341	0.371



As a remark, we note that ActiveLink is less time efficient compared to the non-active learning setting due to the multiple training iterations. This, however, comes as a necessity to reduce the amount of data required for model training.

4.5 Parameter Sensitivity (Q4)

We now investigate the impact of parameters on the performance of ActiveLink. Figure 3 shows the performance of ActiveLink with different values for the number of samples per iteration (k), the number of clusters (c) and the window size w on the FB15K-237 and WikiMovie-300K datasets.

Impact of k. Due to the high requirement in terms of training data by deep models, the sample size k of individual iterations is supposed to be bigger in deep active learning settings than in traditional active learning settings. However, when the sample size gets too large, the benefits of increased data samples might be less significant than the benefits of training a better prediction model using fewer data samples and using that model to select new data samples for the next iteration. Figures 3(a-d) confirm this hypothesis: as the sample size increases, the performance first increases then decreases. The optimal performance is achieved when k is set to 1000.

Impact of c. The number of clusters c in our proposed Structured-Uncertainty sampling method controls the strength of the influence

(a) k - Mean Rank (FB15K-237) (b) k - Hits@10 (FB15K-237) (c) k - Mean Rank (WikiMovie-300K) (d) k - Hits@10 (WikiMovie-300K)

(e) c - Mean Rank (FB15K-237) (f) c - Hits@10 (FB15K-237) (g) c - Mean Rank (WikiMovie-300K) (h) c - Hits@10 (WikiMovie-300K)

(i) w - Mean Rank (FB15K-237) (j) w - Hits@10 (FB15K-237) (k) w - Mean Rank (WikiMovie-300K) (l) w - Hits@10 (WikiMovie-300K)

Figure 3: Impact of (a) #samples per iteration k, (b) #clusters c and (c) window size w on the performance of ActiveLink on both FB15K-237 and WikiMovie-300K datasets, measured by Mean Rank (shown in semi-log scale) and Hits@10.

of the knowledge graph data structure on sampling. Structured-Uncertainty sampling with a small c relies more on the model's uncertainty when selecting data samples, while a large c relies more on the data structure of the knowledge graph. Figures 3(e-h) show that as the value of c increases, the performance first increases then decreases. The best performance is achieved when c is set to 1000, with a significant margin over the other settings. This result suggests that with an appropriate setting for the number of clusters, our proposed data sampling method can ideally combine model uncertainty with the underlying structure of the knowledge graph.

Impact of w. In the Meta-Incremental training approach, the window size w controls the size of the selected data samples for optimizing the generalizability of the incrementally trained model. A larger window will include more data from previous iterations when updating the model parameters, thereby better approximating the model's generalizability for future predictions. This intuition is confirmed in Figures 3(i-l). We observe that the performance of ActiveLink increases along with the increase of the window size. The model is biased to the latest iterations when the window size is too small (shown by the result of $w = 1$). The best performance is achieved when pieces of data from all preceding iterations are used for incremental learning. However, training with bigger window sizes takes more time. Therefore, in real applications, the selected window size would need to strike a balance between model generalizability and training efficiency. Interestingly, $w = 1$ (i.e., only data in the most recent iteration is used together with the current iteration for meta-learning of model parameters) is outperformed by all the other configurations by a large margin. Such low generalizability indicates that the model is biased to the latest iterations when the window size is too small.

5 CONCLUSION

We presented ActiveLink, a deep active learning framework for neural link prediction with optimized data sampling and model training. By taking a Bayesian view on neural link predictors, ActiveLink enables to use uncertainty sampling for deep active learning of link predictors. ActiveLink extends uncertainty sampling by taking advantage of the underlying data structure of the knowledge graph to improve sampling effectiveness. In addition, it adopts a meta-learning approach to incrementally train neural link predictors with high generalizability. We extensively evaluated our framework on three real-world datasets and showed that it can drastically reduce the amount of data needed to train a neural link predictor while reaching state-of-the-art performance. As future work, we plan to apply ActiveLink to solicit high-quality data from a crowd of annotators to further improve neural link prediction.

ABSTRACT

We provide a framework for modeling social network formation through conditional multinomial logit models from discrete choice and random utility theory, in which each new edge is viewed as a "choice" made by a node to connect to another node, based on (generic) features of the other nodes available to make a connection. This perspective on network formation unifies existing models such as preferential attachment, triadic closure, and node fitness, which are all special cases, and thereby provides a flexible means for conceptualizing, estimating, and comparing models. The lens of discrete choice theory also provides several new tools for analyzing social network formation; for example, the significance of node features can be evaluated in a statistically rigorous manner, and mixtures of existing models can be estimated by adapting known expectation-maximization algorithms. We demonstrate the flexibility of our framework through examples that analyze a number of synthetic and real-world datasets. For example, we provide rigorous methods for estimating preferential attachment models and show how to separate the effects of preferential attachment and triadic closure. Non-parametric estimates of the importance of degree show a highly linear trend, and we expose the importance of looking carefully at nodes with degree zero. Examining the formation of a large citation graph, we find evidence for an increased role of degree when accounting for age.

1 INTRODUCTION

Understanding how networks form and evolve is an essential component of understanding their structure, which in turn underlies the basis for understanding the broad range of processes that occur *on* networks. Models of social network formation can largely be decomposed into node formation and edge formation. In this work, we argue that edge formation can be effectively modeled as a *choice* made by an actor (or actors) in the network to instantiate a connection to another node. The diverse research on network formation has led to many models and mechanisms of edge formation, including preferential attachment [2], uniform attachment [12], triadic closure [31], random walks [65, 78], homophily [55], copying edges from existing nodes [35, 39], latent space structures [22, 41, 55], inherent node fitness [7, 11], and combinations of all of these [28, 40, 43]. Here, we frame edge formation as a discrete choice process and derive a family of discrete choice models [47, 74] that subsume a wide range of existing models in a unified framework and also naturally opens up a host of powerful extensions.

Discrete choice models are commonly employed in economics, social psychology, and statistics as a way to model how individuals make choices from a slate of discrete alternatives [1]. Typically, the alternatives have associated features, and statistical models of discrete choice make it possible to estimate the relative importance of such features. Such models have been used to answer questions such as how consumers choose goods [67], how people choose where they live [46], how students choose what college to attend [21], and how commuters choose between different modes of transportation [75]. Discrete choice analysis is also used to understand how choices vary depending on the context in which they are framed: in online commerce, this could be how web layouts lead to different purchasing priorities [26]; for choosing colleges, this could be incorporating the effect of the national economy. In this paper, we demonstrate how discrete choice models can similarly help us understand the factors driving social network evolution.

The starting point for the present work is the observation that edge formation events in social networks are naturally viewed as discrete choices. For simplicity, consider a directed graph where edges are formed one by one, where we can think of the formation of a directed edge (i, j) as i "choosing" to connect with j, where the set of alternatives available to i is the set of all other nodes. (While undirected graph models are common in social network analysis, the underlying formation procedure is almost always asymmetric. For example, the Facebook friendship graph is typically modeled as an undirected graph [77], but the friendships are proposed by one of the two nodes in an edge.) The key modeling question is easy to state: why did i choose j? This question has long been the informal subject of network formation modeling and at the same time the exact question that discrete choice models and analysis have been designed to answer. However, up to this point, network formation models have largely been decoupled from discrete choice theory.

In employing discrete choice analysis, we focus on the conditional multinomial logit model, commonly called the conditional logit model for short, which is a foundational workhorse of discrete

choice modeling. The model belongs to the family of random utility models, where choices are interpretable as those of a rational actor selecting the alternative with the largest "utility" sampled from random variables that decompose into the inherent utility of the alternative and a noise term. With the conditional logit model, we can use existing optimization routines to estimate model parameters and existing statistical methods to asses the uncertainty of the estimates. Discrete choice models can also easily restrict the set of available alternatives, where it might not be reasonable to assume that the *entire* set of nodes is available for friendship. For example, sometimes only "friends of friends" are considered [24, 28, 40].

In this paper, we first show that many popular network formation mechanisms can be rewritten as conditional logit models, including preferential attachment, uniform attachment, node fitness, latent space models, and models of homophily. However, the real power of discrete choice models for social network analysis is the ability to combine different features (e.g., node degree and node age), as well as different mechanisms (e.g., triadic closure and preferential attachment) and estimate their relative roles. Social networks are enormously varied in their structure [27], but existing methods often do a poor job at modeling this diversity. Thus, beyond unifying the network formation and discrete choice literature, we also develop several new tools for social network analysis. For example, we show how to estimate models to distinguish the effects of preferential attachment and triadic closure. We demonstrate these tools by analyzing the formation of the Flickr social network and the formation of a citation network. We find on Flickr that accounting for triadic closure greatly reduces the estimated role of degree in choosing who to connect to, and that nodes with degree zero have a remarkably high utility. Our estimates of preferential attachment in the citation network are similar to those observed in prior studies. When accounting for the age of a paper, we find evidence for linear preferential attachment. However, for a fixed degree, we find that age is *negatively* correlated with the likelihood of a new citation (i.e., older papers are less likely to be cited).

The key assumption underlying our framework is that the available data actually captures edge formation events (either through edge timestamps or other sequential information). In contrast, many existing approaches to understanding network formation focus on observing only the structural properties of a network at a single point of observation, e.g., its degree distribution, and initiating a deductive process to try and understand how variations in edge formation would lead to different outcomes [2, 7, 28, 43]. This approach leads to tidy analyses and easy-to-characterize asymptotic properties, but model selection in this context is strongly dependent on what properties are compared. Different underlying formation processes can lead to graphs with indistinguishable properties. For example, many different formation processes result in the same heavy-tailed degree distributions [52]. Thus, when "fitting" outcome measurements in this way, one has to know (or posit), e.g., the relative rates of node formation and edge formation. However, when temporal or sequential data is available [25, 56], our framework overcomes these limitations by incorporating this structure.

Additional related work. There is a strong connection between our work and work on link prediction and missing data methods using network features to predict edges [15, 42]. A network formation model implicitly makes claims about what edges are most likely to form next, and thus can be evaluated by the same metrics as link prediction algorithms [44]. We use predictive accuracy as a measure of goodness of fit, but our primary concern is interpretability of the model and estimates, which is one of the advantages of the conditional logit model.

In sociology, stochastic actor-oriented models (SAOMs) employ a similar logit choice [69, 70]; however, these models are targeted towards data collected as a few snapshots rather than edge-by-edge formation. SAOMs also model the rate at which nodes form new relationships, whereas we condition on the node initiating the new edge, providing better estimates of model parameters. There are also sociological models such as relational event models [10] and dynamic network actor models [71] that use fine-grained temporal information, yet these also do not condition on the initiator node as we do. While these sociological models can incorporate notions of network formation (e.g., preferential attachment), our conditional logit framework actually cleanly *subsumes* a wide range of models as special cases.

Finally, estimating the parameters that drive edge formation is different from identifying the factors that could have lead to the observed graph. The latter question is often pursued with so-called exponential random graph models (ERGMs) [63, 79, 81]. However, these models do not consider individual edge events, are hard to estimate, and have known pathologies [13, 66].

2 DISCRETE CHOICE AND EDGE FORMATION

We now develop network formation through the lens of discrete choice. Throughout this paper, we assume that the networks are directed. Again, while undirected graphs are common in social network analysis, the actual edge formation process often has directed initiation. In the common setting of "growing graphs," nodes arrive one at a time and form edges when arriving in a network. In these cases, the newly arriving node is considered to be the node initiating the connection; such analysis is standard with, e.g., classical preferential attachment models [2].

When modeling the directed formation of an edge (i, j), two processes need to be distinguished, roughly corresponding to the questions "who is i?" (the chooser) and "who is j?" (the chosen). In this paper, we focus on understanding the latter, i.e., the formation of (i, j) as the selection of j conditional on knowing that i is ready to form an edge. Thus, our discrete choice models of edge formation can be readily estimated from data that implicitly or explicitly contains a record of initiating i nodes and used for subsequent analysis, as we show in Sections 3 and 4. Beyond the scope of this work, our model of "j conditional on i" can be paired with a model of "initiations by i" for a full generative model of network formation.

2.1 Background on discrete choice models

We now review discrete choice models generically, which we will then translate to the context of edge formation in Section 2.2. Consider a universe of alternatives $\mathcal{X}$ and a dataset consisting of n different choices, indexed by $k = 1, \ldots, n$. Each choice (j, C) consists of a choice set $C \subseteq \mathcal{X}$ and a chosen item $j \in C$. The elements in C are mutually exclusive choice alternatives, and exactly one

element from C is chosen. We consider each element $j \in C$ to be represented by a vector of features x_j (for example, in our analysis in Section 2.2, x_j will be the feature vector of a node in the graph, and C will represent a set of nodes). We let $\mathcal{D} = \{(j_k, C_k)\}_{k=1}^n$ denote the choice data.

A broad family of discrete choice models is the family of random utility models (RUMs), of which the conditional logit is an important special case. Each alternative j has some inherent utility to the agent i making the choice; with the conditional logit, we model this utility as a linear function of j's features x_j:

$$u_{i,j} = \theta^T x_j,$$

for some (latent) parameter vector θ that is fixed across individuals i. Random utility models assume that agents make "rational" choices by maximizing random utilities centered on these inherent utilities. More formally, the utility $U_{i,j}$ observed by the actor is given by $U_{i,j} = u_{i,j} + \varepsilon_{i,j}$, where $\varepsilon_{i,j}$ is a noise term. The probability $P_i(j, C)$ of i choosing option j from the choice set C is

$$P_i(j, C) = \Pr(j = \arg\max_{\ell \in C} U_{i,\ell}).$$

When the $\varepsilon_{i,j}$ are i.i.d. standard Gumbel, the probability of choosing each alternative is proportional to the exponentiated inherent utility [1]:

$$P_i(j, C) = \frac{\exp \theta^T x_j}{\sum_{\ell \in C} \exp \theta^T x_\ell}. \tag{1}$$

The above model is the conditional multinomial logit model of discrete choice, though it is often referred to simply as the conditional logit or multinomial logit (MNL) model. If the noise terms $\varepsilon_{i,j}$ are distributed i.i.d. Normal, then the model is the independent multinomial probit. In probit models, the choice probabilities are no longer proportional to utilities as in Equation (1). The Gumbel assumption is common in discrete choice theory and will facilitate our connections to a variety of network formation mechanisms. There are more complex random utility models that can impose dependence between noise terms [74] and there also is a growing literature of flexible choice models [4, 60, 76] designed to model context effects and other varied violations of the *independence of irrelevant alternatives* [45] (a storied axiom satisfied by the conditional multinomial logit model). We leave the relationships of these models to network formation as avenues for future research.

2.2 Edge formation as discrete choice

With the above formalisms in place, we now develop network formation from a discrete choice perspective. We begin by showing how several well-known models can be conveniently expressed as conditional logit models, with a summary given in Table 1. All models are designed to grow simple graphs (i.e., without multi-edges), and the choice set C excludes any nodes to which the chooser i is already connected. Every item is represented by its features that, importantly, can evolve over time. The features $x_{j,t}$ of node j at time t are thus always time-indexed, but we often suppress the t to reduce notational clutter.

Preferential attachment. We start with the generalized Barabási-Albert model [2, 8, 36], also known as the generalized Price model [59], one of the most studied models in the network formation literature. It is typically stated as a growth model of a time-evolving graph $G_t = (V_t, E_t)$, $t = 1, 2, 3, \ldots$, and when a new node arrives it connects to m distinct existing nodes j with a probability proportional to a power of their degree $d_{j,t}$ at time t,

$$P(j, V_t) = \frac{d_{j,t}^\alpha}{\sum_{\ell \in V_t} d_{\ell,t}^\alpha}. \tag{2}$$

The exponent parameter α controls the relative importance of degree [36]. The case where $\alpha = 1$ is called linear preferential attachment, and produces networks that can mimic a range of structural properties observed in empirical networks. If we represent each potential neighbor j with the time-indexed one-dimensional "feature vector" $x_{j,t} = \log d_{j,t}$ and employ a conditional logit model as in Equation (1), we obtain a utility of j for i at time t of $u_{i,j,t} = \theta \log d_{j,t}$. Here the choice model parameter θ plays the exact role of α, since $e^{\theta \log d_{j,t}} = d_{j,t}^\theta$.

Given a growing network G_t, we can construct a choice dataset $\mathcal{D}$ from this network by extracting the node j_t, node sets V_t, and degree sequence $(d_{1,t}, \ldots, d_{|V_t|,t})$ at each time-step. The preferential attachment model has only one parameter, $\theta = \alpha$. The log-likelihood for that parameter given a dataset is then:

$$\begin{aligned} l(\alpha; \mathcal{D}) &= \sum_{(j,C) \in \mathcal{D}} \log \frac{\exp(\alpha \log d_j)}{\sum_{\ell \in C} \exp(\alpha \log d_\ell)} \\ &= \sum_{(j,C) \in \mathcal{D}} \left(\alpha \log d_j - \log \sum_{\ell \in C} \exp(\alpha \log d_\ell) \right). \end{aligned}$$

We've suppressed the time-index t from the features $\log d_\ell$ to reduce clutter, but emphasize that d_ℓ is the degree at the time of the choice.

Non-parametric preferential attachment. The above model assumes an attachment kernel of a particular parametric form. From a discrete choice perspective, one can also estimate the role of degree in edge formation non-parametrically by estimating a coefficient θ_k for each degree $k = 0, \ldots, n-1$ individually. This approach has the added benefit of being able to assign positive probability to choosing nodes with degree zero. Under this model, the log-likelihood of the parameters $\theta = (\theta_0, \ldots, \theta_{n-1})$ given the dataset is:

$$\begin{aligned} l(\theta; \mathcal{D}) &= \sum_{(j,C) \in \mathcal{D}} \log \frac{\exp \theta_{d_j}}{\sum_{\ell \in C} \exp \theta_{d_\ell}} \\ &= \sum_{(j,C) \in \mathcal{D}} \left(\theta_{d_j} - \log \sum_{\ell \in C} \exp \theta_{d_\ell} \right). \end{aligned}$$

Again we've suppressed time-indexing to simplify the presentation. Pham et al. [58] previously described a version of the above likelihood as a means of measuring the attachment kernel using maximum likelihood, albeit without making the connection to discrete choice.

Uniform attachment. A simple edge formation model is to sample a new neighbor uniformly at random from all nodes [12]. There are no parameters in this model, but we can still write down the likelihood of the model given a dataset, which will be useful when we later combine this model with others within a mixture model:

$$l(\mathcal{D}) = \sum_{(j,C) \in \mathcal{D}} \log \frac{\exp(1)}{\sum_{\ell \in C} \exp(1)} = \sum_{(j,C) \in \mathcal{D}} -\log |C|.$$

Table 1: Network formation models framed as utility functions for a conditional logit. Where appropriate, we use the traditional notation for the parameters of each process.

Process	$u_{i,j}$	C
Uniform attachment [12]	1	V
Preferential attachment [2, 36]	$\alpha \log d_j$	V
Non-parametric PA [54, 58, 62]	θ_{d_j}	V
Triadic closure [61]	1	$\{j : FoF_{i,j}\}$
FoF attachment [31, 65, 78]	$\alpha \log \eta_{i,j}$	V
PA, FoFs only	$\alpha \log d_j$	$\{j : FoF_{i,j}\}$
Individual node fitness [11]	θ_j	V
PA with fitness [6, 53]	$\alpha \log d_j + \theta_j$	V
Latent space [22, 41, 55]	$\beta \cdot d(i,j)$	V
Stochastic block model [33]	ω_{g_i,g_j}	V
Homophily [48]	$h \cdot \mathbb{1}\{g_i = g_j\}$	V

Triadic closure. A variant of uniform attachment is for i to attach to new neighbors uniformly at random from the set of their friends-of-friends, as opposed to the set of all nodes. This process effectively models triadic closure [61]. It has the same simple functional form of the uniform model, but now the *choice set* C varies with each choice, namely, the choice set is restricted to be only the friends of friends of node i (the chooser) to which i is not already connected. This change in choice set can also be achieved by assuming the utility of j to i at time t is $u_{i,j,t} = \log(\mathbb{1}\{FoF_{i,j,t}\})$, where $\mathbb{1}\{FoF_{i,j,t}\}$ is a boolean indicating whether i and j are friends of friends at time t, and then letting the choice set revert to the full node set.

An additional model that naturally combines the ideas of preferential attachment and befriending friends-of-friends takes the *number* of friends in common between i and j as a feature. We could define this feature as $\eta_{i,j,t} = |\{k : e_{i,k,t} \wedge e_{k,j,t}\}|$, where $e_{i,k,t}$ indicates whether there is an edge between i and k at time t. The corresponding utility would be $u_{i,j,t} = \alpha \log \eta_{i,j,t}$. This model is similar (but not equivalent) to random walk-based formation models [31, 65, 78], which emphasize formation within a local neighborhood.

Node fitness. Another line of formation models that is subsumed by the discrete choice framework are those involving fitness. In this work, nodes choose to connect to others based on some intrinsic latent fitness score. Certain distributions of fitness values lead to a scale-free degree distribution [11], providing an alternative explanation to preferential attachment for modeling such degree distributions. We can express the node fitness model by a conditional logit model with separate fixed effect θ_j for each node j (so the feature of a node is an indicator vector of its identity). The likelihood of the fitness parameters θ given the data is then:

$$l(\theta; \mathcal{D}) = \sum_{(j,C)\in\mathcal{D}} \log \frac{\exp \theta_j}{\sum_{\ell \in C} \exp \theta_\ell}$$
$$= \sum_{(j,C)\in\mathcal{D}} \left(\theta_j - \log \sum_{\ell \in C} \exp \theta_\ell \right).$$

This formation model is equivalent to the classic Bradley-Terry-Luce model of discrete choice for estimating the quality of alternatives [45]. Alternatively, one could replace the individual fixed effects with surrogate features of node fitness such as an auxiliary measure of gregariousness (in the case of social networks), or the impact factor of a paper's journal (in the case of citations networks).

A related model proposes selection probabilities proportional to the product of node fitness and degree [6, 53]. This model can be written as a conditional logit model with $u_{i,j,t} = \alpha \log d_{j,t} + \theta_j$.

Latent space models. Another class of network formation models postulates the existence of a latent space that drives connections between nodes. Examples of latent spaces include Euclidean space [22], hyperbolic space [37], a tree [41], a circle [55], or a set of discrete classes [23]. While the conditional logit model in the form that we describe it does not facilitate finding the best-fitting latent space assignment to explain the data, it can be used to estimate the relative importance of a known latent space given a distance function $d(i,j)$. As one example from the family of latent space models, in the community-guided attachment (CGA) model [41] all nodes have a distance derived from the height $h(i,j)$ of common parents in a latent tree structure situating all nodes i and j. Given this tree as known, a node connects to another proportionally to $c^{-h(i,j)}$ for some scalar $c > 0$. As a conditional logit model, the corresponding utility function is $u_{i,j} = -h(i,j) \cdot \log(c)$. The parameter vector $\theta = \log c$ can be retrieved by fitting a conditional logit with a known $h(i,j)$ as the only variable and transforming the estimated parameter with $c = \exp(\theta)$. Assuming that the latent space representation is given is a strong assumption, and fitting such a model while estimating the latent space representation (e.g. as done by Hoff et al. [22] in Euclidean space) is much more difficult.

Additional models. Conditional logit models are very flexible and can deal with multiple features and interactions between them. Any number of features can be added, including node covariates and structural features like a node's clustering coefficient [3] or age [12, 40]. Conditional logit models can also be used to investigate the role of homophily [48] in edge formation, by adding a binary feature indicating whether nodes i and j are part of the same class.

Table 1 summarizes how several network formation models fit within the discrete choice framework via their corresponding utility functions and choice sets. A major advantage of this framework is that different features can easily be combined into a single model and jointly estimated. Or, when suitable, one can employ a mixture of conditional logit models, as we show in the next section.

2.3 Combining modes using Mixed Logit

So far we have written a range of existing and new edge formation models as conditional logit models, a specific type of discrete choice model. But several existing edge formation models that do not fit neatly into the conditional logit framework, meanwhile, align exactly with the use of mixture models in discrete choice modeling. Following our success formulating edge formation models as conditional logit models, in this subsection we develop mixed conditional logit formulations of several additional models.

A common proposal to make network formation models more flexible is to augment an existing model by allowing nodes to pick neighbors uniformly at random with some probability $1 - p$, while running the ordinary model with probability p [17, 35, 39, 43]. This augmentation increases flexibility because it enables the model to explain edge events that may otherwise have probability zero.

Within discrete choice, this approach is precisely a mixed logit model where one of the mixture modes is uniform attachment.

While the conditional logit estimates a single parameter vector representing average preferences as shared by all agents, the *mixed logit* model is often used to account for differences in preferences across various types of agents. In its most general form, the mixed logit is expressed using a probability distribution f over different instantiations of the parameter vector θ:

$$P_i(j, C) = \int \frac{\exp \theta^T x_j}{\sum_{l \in C} \exp \theta^T x_l} f(\theta)\, d\theta.$$

In this work, we will only consider discrete mixtures of M logits, also called a latent class model [32]:

$$P_i(j, C) = \sum_{m=1}^{M} \pi_m \frac{\exp \theta_m^T x_j}{\sum_{l \in C} \exp \theta_m^T x_l},$$

where $\sum_{m=1}^{M} \pi_m = 1$ and the weights $\pi_1, \ldots, \pi_M$ model the relative prevalence of each mode.

Copy model. The copy model is a classic formation process that can be written as a mixed logit with two modes. In the first mode, new edges connect proportional to degree with probability p, while in the second mode they connect uniformly at random with probability $1 - p$ [17, 43]. As a conditional logit model, the utilities of the two modes are $u_x^{(1)} = \log d_x$ and $u_x^{(2)} = 1$, respectively, and the class probabilities are $(\pi_1, \pi_2) = (p, 1 - p)$. (This is a special case of the original copy model where d edges are copied from a sampled vertex [39]; the model here is when $d = 1$, which is often used for analysis [19].) The connection between relaxations of preferential attachment and mixture models was also recently observed by Medina et al. [49].

Local search model. Another example of a model with multiple modes is the Jackson-Rogers model of edge formation as a mixture of uniform attachment and triadic closure [24, 28]. The original model is based on a relative rate r^* between edges forming at random and edges formed locally. It also has edges form based on respective acceptance probabilities. We describe a simplified version of this model, which we'll call the local search model, where edges connect to nodes selected uniformly at random from the full node set with probability r and uniformly at random from the set of friends-of-friends with probability $1 - r$.[1] We can represent this simplified process with a two-mode mixed logit model. In this case the mixture parameters are $(\pi_1, \pi_2) = (r, 1 - r)$ and both modes have the same utility function $u_x = 1$ but their *choice sets* differ so that the second mode only considers friends-of-friends.[2]

Table 2 overviews the mixture model formulations described above, as well as a new model—the (r, p)-model—that we use in Section 4.2 to analyze preferential attachment effects.

3 ESTIMATION AND INFERENCE

To learn a discrete choice model of network formation from data, we assume that we have access to a sequence of directed edges, in chronological order. This sequence of edges needs to be recast as choice data in order to fit a choice model. For every formed edge (i, j), we create a data point consisting of the choice j, the choice set of candidates nodes at the time, and the features of each candidate node at the time.

Table 2: Network formation models framed as mixed logits. Each mixture component is a mode. FoF refers to friend-of-friending, also called local search or triadic closure. We define a new (r, p)-model as a natural generalization of prior ideas once we put network formation models in the language of discrete choice.

Process	Modes
Copy model [35]	Uniform, PA
Node types [38]	New node, PA, none
Local search [24, 28]	Uniform, Uniform FoF
(r, p)-model	Uniform, PA, Uniform FoF, PA FoF

Given a data set and a conditional logit model, one can write out the log-likelihood, as shown in Section 2.2. For any conditional logit model with a linear utility $u_{i,j} = \theta^T x_j$, the likelihood function is convex with respect to the variables θ and can be efficiently maximized using standard gradient-based optimization (e.g., BFGS). The functional form of the logit leads to straightforward gradients. For example, for preferential attachment, the gradient is

$$\frac{\partial}{\partial \alpha} l(\alpha; \mathcal{D}) = \sum_{(x, C) \in \mathcal{D}} \left(\log d_x - \frac{\sum_{y \in C} \log d_y \cdot \exp(\alpha \log d_y)}{\sum_{y \in C} \exp(\alpha \log d_y)} \right),$$

where the time-dependence of the features (degrees) have been suppressed to reduce clutter. Gradients for the other choice models in Section 2.2 are omitted but straightforward.

One advantage of likelihood-based model fitting is that we can compute standard errors and confidence intervals of the parameters. In particular, the standard errors can be computed with $\sqrt{\mathbf{H}^{-1}}$ [74], where $\mathbf{H}$ is the Hessian matrix of second derivatives of the log-likelihood at the parameters.

Mixture models and expectation-maximization. For mixed conditional logit models, the log-likelihood is no longer convex in general, making optimization more difficult. To maximize the likelihood of mixed models we turn to expectation maximization (EM) techniques [18, 73]. We briefly summarize the procedure described in Train's book [74, Chapter 14.3.2]. Assume that we have a model with M modes (i.e., mixture components), where every mode starts with initial parameter values $\vec{\theta}^m$ (usually initiated at 1). Choices $(x_k, C_k) \in \mathcal{D}$ are again indexed with k, so that $k \in \{1, \ldots, n\}$ and $n = |\mathcal{D}|$. The EM algorithm runs through the following steps:

(1) Initiate class probabilities uniformly with $\pi_m = 1/M$ and initial class responsibilities $\gamma_k^m = 1/M$ for each data point.
(2) For every data point k and every mode m, compute the class responsibility given by the relative individual likelihood:

$$\gamma_k^m = \frac{\pi_m \cdot \mathcal{L}^m(\theta^m; (x_k, C_k))}{\sum_{\ell=1}^{M} \pi_\ell \cdot \mathcal{L}^\ell(\theta^\ell; (x_k, C_k))}.$$

(3) For every mode m, update the total class probability with $\pi_m = \frac{1}{N} \sum_{k=1}^{N} \gamma_k^m$.

[1] Since the r^* parameter in the original presentation is actually the *rate* of uniform attachment, we can relate it to our r through $r = \frac{r^*}{1+r^*}$. For example, if the rate between random and friend-of-friend edges is one to one ($r^* = 1$), then $r = 0.5$.
[2] A model with a restricted choice set, for example to only friends-of-friends, gives a likelihood of zero to choices outside the choice set.

(4) For every mode m, update the parameters $\vec{\theta}^m$ using standard optimization for fitting a single model, weighing each choice set with its class responsibility γ_k^m.
(5) Repeat steps 2–4 until some convergence or stopping criteria.

The total likelihood of the parameters and class probabilities is:

$$l(\theta; \mathcal{D}) = \sum_{m=1}^{M} l^m(\theta^m; \pi_m; \mathcal{D}) = \sum_{m=1}^{M} \sum_{k=1}^{N} \log \mathcal{L}^m(\theta^m; (x_k, C_k)) \cdot \pi_m$$

We monitor the convergence of the iterative procedure using the change in this total likelihood between iterations.

Even though EM is theoretically an efficient estimator [82], there are cases when alternatives are appropriate. For example, if one has reasonable bounds or priors on the parameter values, then direct likelihood maximization could be used, and if the search space is low-dimensional, a grid search might be appropriate. Recent theoretical work has also developed algorithms for learning mixtures of two multinomial logit modes with theoretical guarantees assuming a separation between the modes [14].

Negative sampling. Every time an edge is formed by some node i, each node not yet connected to i is a candidate choice. For large sparse graphs, the full choice set of all nodes can become large and the gradients of the log-likelihood expensive to compute. To speed up this computation, s negative/non-chosen examples can be *sampled* uniformly at random to create a (random) reduced dataset with smaller choice sets. For each choice (j, C), one forms a smaller random choice set out of the positive choice and the negative samples, $\tilde{C} \subset C$ with $|\tilde{C}| = s + 1$, and replaces the original choice data with $(j, \tilde{C})$. As long as the negative examples are sampled uniformly at random, parameter estimates on a dataset with negatively sampled choice sets are unbiased and consistent for the estimates on the on the full set [29, 46, 74]. Practically, there is a trade-off between feature computation and storage on the one hand, and the ability to estimate coefficients for rare features on the other.

Typical likelihood surface. In Figure 1 we show the representative likelihood surface of a copy model to illustrate its properties. We generated a synthetic graph on $n = 10,000$ nodes according to the copy model with $m = 4$ edges per node and degree-attachment probability $\pi_1 = 0.5$. We fit a two-mode mixed logit model to this data with $u_j^{(1)} = \alpha \log d_{j,t}$ and $u_j^{(2)} = 1$. We use $s = 10$ negative samples. There are two free parameters in this model: the degree exponent α and the mixture probability π_1. We plot the log-likelihood across a reasonable range of values to show that surface is generally well behaved. We see that it is hard to distinguish between data generated under a copy model ($\alpha = 1$) with probability $\pi_1 = 0.5$ from data generated from no-mixture ($\pi_1 = 0$) preferential attachment with $\alpha = 0.5$, and there is a general trade-off between the exponent α and the mixture probability π_1.

Model comparison and the likelihood-ratio test. Another advantage of our discrete choice framework is that we can employ standard statistical methods for model selection. Specifically, when one model is a special case of another, their relative quality can be compared using the likelihood ratio test. In the case of the conditional logit, a model with additional features can be compared to one without them because the latter is a special case of the former with the coefficients of the additional features being set to 0. Or, in the case of the mixed logit, one can define a model with multiple modes and manually set some of their class probabilities to zero.

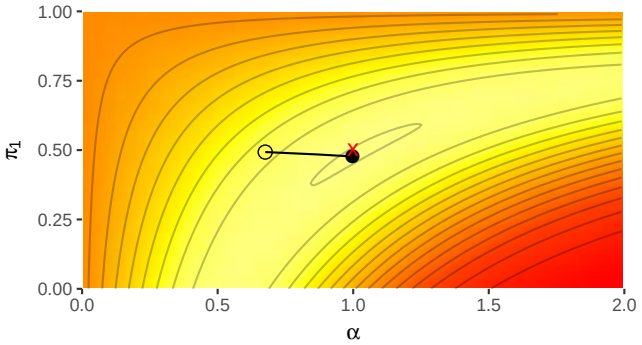

Figure 1: The log-likelihood surface of the copy model for a graph of $n = 10,000$ nodes generated with $\pi_1 = 0.5$ (marked as x). The line tracks the iterations of the EM algorithm, from open to closed dot. There is a trade-off between the degree coefficient α and the mixture probability π_1, but there are large regions with similar likelihoods.

As a concrete example, suppose we wanted to know whether including the age of a node in a preferential attachment model results in a statistically significantly better model. To do so, we would first estimate the parameters θ_1 of the more complex model, $u_j^{(1)} = \theta_{1,1} \log(d_j) + \theta_{1,2} \log(\text{age})$. We would then estimate the parameters θ_0 of the simpler model $u_j^{(0)} = \theta_{0,1} \log(d_j)$. Let $\mathcal{L}_1$ and $\mathcal{L}_0$ be the likelihoods of the two models with parameters $\hat{\theta}_1$ and $\hat{\theta}_0$. We can compute the likelihood ratio $\lambda = \mathcal{L}_0 / \mathcal{L}_1$. Under the null hypothesis of the simpler model, with some regularity conditions, $-2 \log \lambda$ is asymptotically distributed χ_1^2 (χ_k^2 where k is the number of additional degrees of freedom in the more complex model) [80], a standard test in the finite regime [74, Chapter 3.8.2].

4 APPLICATIONS

We now demonstrate how to use our conditional logit framework to analyze network formation processes. We first consider synthetic data and show how our tools can be used to better analyze preferential attachment mechanisms. We then analyze two empirical datasets that demonstrate how to integrate different structural features of the network or integrate node covariates. In both cases, our framework provides novel insights into the network formation processes. We provide code for processing data (converting edge lists to choice data) and for model fitting (with negative sampling), available here: https://github.com/janovergoor/choose2grow/.

4.1 Measuring preferential attachment

The question of whether and when preferential attachment is an important driver of network formation is widely debated [2, 3, 9, 11, 12, 24, 28, 54, 54, 65, 78]. Most prior research focuses on estimating the shape of the attachment kernel by comparing the degree of chosen nodes to the distribution of available degrees [30, 54, 62]. However, recent work by Pham et al. shows that previous measures are biased [58]. In particular, the bias comes from the assumption

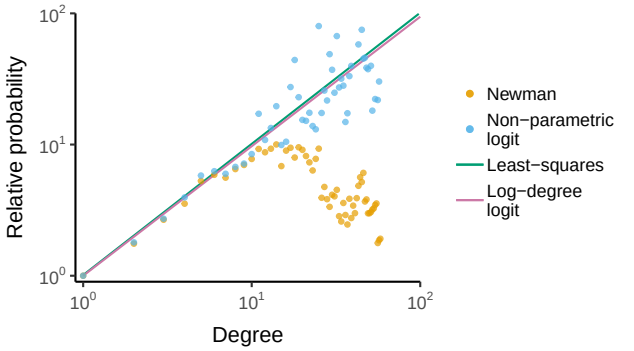

Figure 2: Attachment kernel fits for a synthetic preferential attachment graph. The Newman measure computes the relative likelihood of selecting a node of that degree, as compared to the likelihood of selecting the lowest degree, but it is biased for higher degrees. The non-parametric logit is consistent but noisy for higher degrees.

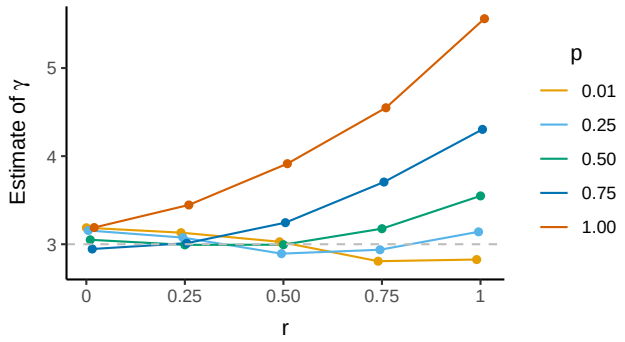

Figure 3: Estimating the power-law exponent γ from the degree distributions of graphs formed under the (r, p)-model with $n = 20,000$ nodes. Under the local search model with significant triadic closure ($p = 1$, small r), the exponent looks like it would under the copy model ($p \to 0$, $r = 1$).

that the distribution of available nodes of varying degrees is constant throughout the formation process, but this distribution clearly changes as the network grows.

To estimate the exponent α of an attachment kernel, Pham et al. propose fitting something akin to a conditional logit with a separate coefficient for each degree, and then estimating α via a weighted least squares fit over the degree coefficients [58]. Compared to this method, fitting a log-degree logit directly is much simpler. In fact, it is the maximum likelihood estimator for α, and thus consistent and efficient.

To illustrate, we generate a graph with pure preferential attachment ($n = 2,000$, $m = 1$ edges per node, $\alpha = 1$) and estimate the attachment kernel by the methods of Newman [54] and Pham et al. [58]. The maximum degree of this graph was 102, and the results of the different estimation procedures are shown in Figure 2. The non-parametric estimates are similar for lower degrees, but for higher degrees the Newman measure incorrectly drops, illustrating the bias that Pham et al. have previously documented. Fitting α directly using a log-degree conditional logit gives an estimate of $\hat{\alpha} = 0.987$. The Pham et al. least squares fit, $\hat{\alpha}_{LS} = 1.012$, is close to the MLE but may deviate considerably in more difficult instances.

4.2 Disentangling preferential attachment from triadic closure

Many models exhibit similar outcomes to preferential attachment [11, 24, 28, 36, 52, 78], but there are few principled ways to rigorously test the relative validity of these models. In this section, we show how to use the discrete choice framework to estimate the relative importance of preferential attachment while accounting for other dynamics. To this end, we generate data according to a known generative process and fit various (possibly mis-specified) formation models. Our generative process is a hybrid between the copy model of preferential attachment (i.e., choose nodes proportional to degree) and the Jackson-Rogers local search model (i.e., connecting to friends-of-friends). The process, which we call the (r, p)-model, is parametrized by $r \in (0, 1]$ and $p \in (0, 1]$. When a new edge is formed, with probability p it is formed uniformly at random and with probability $1 - p$ it is formed with linear preferential attachment ($\alpha = 1$). Meanwhile, the *choice set* is determined by the second parameter r: with probability r, the choice set is all nodes not yet connected to i, while with probability $1 - r$, the choice set is limited to available friends-of-friends of i. With $r = 1$ this model reduces to the copy-model and with $p = 1$ it reduces to the simplified local search model; the (r, p)-model thus subsumes two popular models in a single, simple discrete choice framework. For a growth process on directed graphs, it is necessary that $p > 0$ and $r > 0$, otherwise new nodes will never be selected.

With this general model, we investigate how estimating parameters of one of the more specific models goes awry when the true data generating process in fact comes from an instance of the more general model. For a range of values of p and r, we generated graphs using the following growth process. New nodes arrive, each creating $m = 4$ edges. For every edge, we sample the mode of the model (according to r and p) independently. If an edge is supposed to be a friend-of-friend edge, but no friends-of-friends are available (for example, i's first edge), then the process reverts to uniformly random formation across the full node set.[3] Sweeping through combination of p and r parameter values, for each set of parameters we generated 10 *undirected* graphs with $n = 20,000$ nodes each.

Degree distributions. The local search and copy models both produce graphs with power-law degree distributions. Therefore, fitting a mis-specified model on a degree distribution can lead to misleading results. To illustrate, we fit a power-law distribution $p(x) \propto x^{-\gamma}$ to the degree distribution of graphs generated from (r, p)-models using maximum likelihood estimation [16], with estimates for γ in Figure 3. In theory, an undirected graph formed with the copy model process with probability parameter p leads to a degree distribution with power law exponent $\gamma = (3 - p)/(1 - p)$ [8, 52] (for directed graphs, $\gamma = (2 - p)/(1 - p)$). As p increases, the degree distribution looks more like a random graph without preferential attachment. However, as r goes down (increasing the relative role of friend-of-friends), the parameter estimate looks like the estimates for the copy model, even when $p = 1$.

[3] This creates a slight bias towards uniform at random modes. This reversion to uniform attachment happens for every first edge with probability $1 - r$.

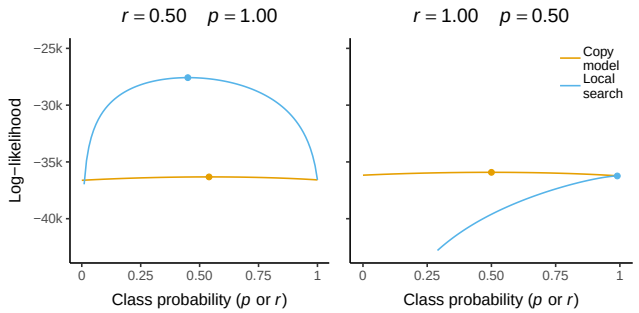

Figure 4: The log-likelihood of varying the class probabilities of the copy model ($r = 1$, p free) or the local search model (r free, $p = 1$) for two different synthetic graphs. In both cases the true model is the most likely. On the left we see a large difference in the log-likelihood between optima, while on the right we see a smaller difference. In both cases a likelihood ratio test is highly significant (P-values $< 10^{-16}$).

To summarize, it is not recommended to estimate a formation model from an observed degree distribution. The parameter estimates are sensitive to small deviations in the generative process.

Discrete choice modeling. Beyond degree distributions, in Figure 4 we look at how the two subsumed models (the copy model and the Jackson-Rogers local search model) fare when estimated from formation data generated by the (r, p)-model. We look at two cases. As a first case, we generate graphs with $r = 0.5$ and $p = 1$, so half the edges are formed to friends-of-friends with no utility from degree. The likelihood under a local search model (r free, $p = 1$) as a mixed logit is maximized at $r = 0.45$, while for the copy model ($r = 1$, p free) it is maximized at $p = 0.54$. The former is a much better fit than the latter (P-value $< 10^{-16}$), and the copy model erroneously thinks that preferential attachment is driving 45% of the edges. As a second case, we look at a graph generated with $r = 1$ and $p = 0.5$, so half the edges are due to preferential attachment, and friend-of-friending plays no role. In this case, both models are correctly maximized at their relative values. Again, the correct model has a higher likelihood (P-value $< 10^{-16}$).

4.3 Choosing to follow on Flickr

We now apply our framework to examine a real-world network formation dataset capturing the growth of the Flickr social network. We find that incorporating a Friend-of-Friend feature beyond preferential attachment and link-reciprocation features substantially improves both likelihood and test accuracy and furthermore that the inclusion of this feature significantly reduces preference for degree-based attachment. However, omitting preferential attachment entirely leads to a worse model. We also find a preference for nodes with zero degree over low degree nodes. This hints that such nodes play a special role in the network formation process, even though they would be ignored in preferential attachment models.

Data. We use a scrape of the Flickr social network collected daily between October 2006 and May 2007 [50, 51]. Users of Flickr can choose to follow other users and the "following" (but not the "followed by") connections are publicly accessible. The data was gathered using a breadth-first search crawl, which means that only the connected components reachable from the seed profiles are represented in the data. Since a full crawl was performed daily, the timing of new edges can be identified at the granularity of a day. The graph contains 3.2 million nodes and 33.1 million edges.

As described in the original papers, this data is consistent with both preferential attachment, as inferred from the in-degree distribution, and local search, as inferred from the over-representation of edges to nodes that are close to the linking node [50]. Fitting a power law to the distribution of *in*-degrees gives $\hat{\gamma} = 1.741$, which would indicate super-linear preferential attachment. We can test the relative importance of triadic closure by fitting a Jackson-Rogers model using the degree distribution matching procedure described in [28]. This results in $\hat{r} = 0.252$, estimating that three out of four edges are formed through triadic closure.

Table 3: Conditional logit model fits for Flickr data. Standard errors of the estimates are given in parentheses. Evaluation statistics are computed over 2,000 sampled examples excluded from the training data.

Discrete choice analysis. We fit a series of conditional logit models to further investigate the network formation process. We isolated a sample of 20,000 edge formation events occurring around the same date,[4] to avoid time heterogeneity affecting the estimates. We fit several models, displayed in Table 3. Not-chosen alternatives are negatively sampled with $s = 24$. We log-transform in-degree

[4]We enumerated edges starting November 5, 2006 and included new edges with probability 0.01 until reaching the desired sample size. We excluded edge events originating from nodes seen for the first time in a given day (the timing of these edge events are uncertain due to the original data collection process). The same analysis starting on March 3, 2007 led to virtually identical results.

(representing the number of followers), but in order to account for nodes with degree zero, we add a "has degree" feature for having a positive degree and use a modified version of log that returns 0 for input 0.[5] In the first column, we fit a model using just these two degree-related features, and a reciprocity feature capturing whether the target node is already following the chooser. Reciprocity is a common phenomenon, with 60% of edges being followed back [50]. The estimate $\hat{\alpha}$ (the coefficient for "log Followers") for this model is significantly larger than 1, again consistent with super-linear preferential attachment.

In the second model, we test the effect of the target node being a friend-of-friend of the choosing node. In the case of Flickr, this means that the choosing user already follows someone that follows the target user, which evidently is strongly correlated with following that user. However, combining these two features in a third model (column 3) leads to both estimated parameters dropping substantially. Most remarkable is the 40% drop in the estimate of α, which paints a very different picture about the role of degree.

In the fourth model, we measure network proximity as in the original paper, by counting the number of "hops" (path length) from i to the target before an edge was made. We integrate the hops as categorical variables to show the relative impact of each additional "hop". Being two hops away is equivalent to being a friend-of-friend, and thus has strongly positive coefficient. Every additional hop corresponds to a sharp decrease in choosing that node. Being five hops away is slightly worse than there not being a path at all. This could be an artifact of the way the data was gathered, so that new regions of the graph only get "discovered" when there is at least one link to them, or this could be due to path length not being an accurate measure of distance for newer nodes. Since the number of hops is co-linear with being a friend-of-friend, we can't test them both at the same time.

In Figure 5 we visually show the effect of different specifications on the estimate of $\hat{\alpha}$. The first model of the Flickr data looks like super-linear preferential attachment, while the role of degree in the other two is significantly reduced. However, fitting a non-parametric model shows that the estimated coefficients for individual degrees are remarkably linear, suggesting that the functional form of d_j^{α} is a good fit for this network. One important point is the role of zero-degree nodes. In most descriptions of preferential attachment, nodes with degree zero are not considered. However, in the Flickr data set, zero-degree nodes have a higher utility than positive low degree nodes, which could again be an artifact of the data collection process, or point to the special role of new nodes in the network. Either way, our framework allows one to find these kinds of patterns, and investigate them further.

4.4 Choosing to cite

We now turn to citation network data to show how a discrete choice framework facilitates the testing of network formation hypotheses. Previous analyses of citation networks have observed linear preferential attachment with respect to degree [62] and bias towards citing more recent work [62]. Here, we find consistent results that

[5]This solution is better than using $\log d + \epsilon$, or giving degree-zero nodes the same utility as degree-one nodes. Either of those solutions will give substantially different results, especially when there are many degree-zero nodes.

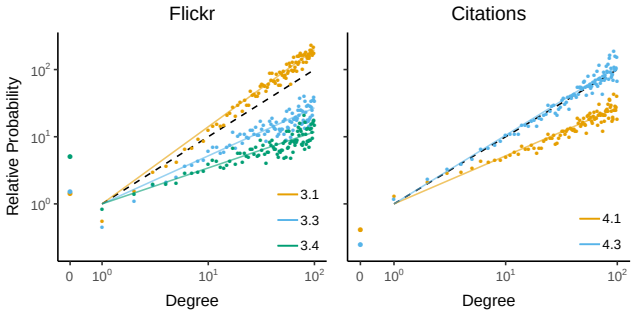

Figure 5: The probability of being chosen by degree, as compared to a node with degree 1. We show the fits of parametric (lines) and non-parametric (points) conditional logit models of the Flickr and citation networks. The legend references model numbers in Table 3 and Table 4. The estimate for degree 0 is inserted for comparison. Dashed reference lines illustrate what exact linear preferential attachment ($\alpha = 1$) would look like.

older papers are less likely to be cited but that accounting for age actually *increases* the importance of degree (i.e., after accounting for age, higher degree nodes are more likely to be cited).

Data. We use the Microsoft Academic Graph[6] dataset and focus on a representative subgraph of 459,000 "Climatology" papers. We focus on the subgraph of a single field to simplify the analysis since citations are predominantly within the same field of study (our analysis was similar on other subgraphs). We construct a graph out of this data by adding an edge each time a paper in our dataset cites another paper in our dataset. For our analysis of Climatology publications, 45% of edges are within the domain and citations to papers that are not labeled are excluded, leaving 3 million edges. We sample 10,000 citation events uniformly at random from papers published after 2010 and apply negative sampling ($s = 24$). This processing results in 10,000 choices with 25 alternatives in each choice set. For each possible choice, we compute four features: the number of citations at the time of citation, whether the paper shares authors with the citing paper, the age of the paper in years at the time of citation, and the maximum number of publications by any one of the authors at the time of publication. This last feature is a proxy for node fitness [11].

Discrete choice analysis. We fit conditional logit choice models relating these features to the likelihood of citation (Table 4). The first model (first column) is a simple log-degree model. We find that the estimate $\hat{\alpha}$ (the coefficient for "log Citations") is substantially lower than one, consistent with sub-linear preferential attachment. Apart from the log-likelihood of the models, we also report the predictive accuracy (defined as the share of instances predicted correctly) on a holdout test set of 2,000 examples. Just relying on prior degree already gives an accuracy of 36%, which is high for a classification task with 25 classes. In model two (second column), we add a covariate for whether a paper shares an author with the citing paper. As expected, this has a strongly positive coefficient.

For the third model we add a covariate for the age of the paper in log years (years is always at least one). Older papers are

Test accuracy	0.358	0.484	0.533	0.534
Note:				*p<0.01

less likely to get cited (accounting for degree), but accounting for age *increases* the relative importance of degree significantly. This expanded model also increases the accuracy to 53%, indicating that these feature weights do capture substantially more predictive power. Finally, in model four we add the "max papers by authors" feature as a proxy for fitness. The coefficient is small but positive. Accounting for fitness slightly reduces the estimated relative importance of degree, but the $\hat{\alpha}$ estimate is still close to 1. Adding this feature does not improve the log-likelihood or predictive accuracy; a better proxy for fitness may explain the data better. Looking back to the visual display of α for the citation models in Figure 5, the non-parametric coefficients are highly linear. In this data, zero-degree nodes are significantly *less* attractive than nodes with degree one.

As with any regression, the identifying causal effects from model fit depends on the design of the study. The estimates we provide here, as is the case with most analyses of observational data, are descriptive and not meant to describe causal processes. The point is that discrete choice models provide a flexible framework to easily test and compare different hypotheses around network formation.

5 DISCUSSION

When modeling network formation, the majority of the literature analyzes networks that grow "externally," with new nodes arriving and choosing who to connect to, and this setting has also been our main focus here. External growth leads to convenient models that are relatively easy to analyze, with citation networks and patent networks as examples of empirical networks that follow this generative process reasonably closely. However, in many (especially social) networks, pairs of older nodes often form edges as well, edges that are "internal" to the existing set of nodes. An extreme example is the social networks of schools or classrooms, which have a fixed node population and "grow" purely through an internal growth process. A major advantage of modeling network formation as discrete choice is that it does not require any model of edge event initiation and simply conditions on the sequence of decisions to initiate, focusing the modeling on the choices made by the initiator. Discrete choice can therefore easily be used to model internal growth as well.

Another major advantage of discrete choice modeling is that it connects the analysis of large-scale network datasets to statistical methods (fitting generalized linear models) that are tremendously scalable. As we show in this work, additional techniques (e.g., negative sampling) makes it possible to efficiently scale the estimation process to very large network datasets.

Since the conditional logit model of discrete choice is a random utility model, the estimated parameters can be interpreted as the marginal utility of each feature. This allows one to question the functional form of features. For example, we show that preferential attachment is equivalent to the logarithmic utility of degree. Given that degree is commonly heavy-tailed, this is a natural functional form, but we point out that the conditional logit allows one to flexibly compare different specifications.

Our discrete choice perspective has implications for how network data is best collected and analyzed. It is useful to consider and record notions of directionality, even if edges can otherwise be considered to be undirected. With information about the choice set associated with each choice, we can see what each node j looked like at the time the choice was made. Datasets that record the exact time of all edge formation events, as opposed to lumping edge events at the granularity of days or years, makes it possible to further analyze the formation process in more detail.

There are a couple limitations to our proposed methodology. First, we cannot model purely undirected edges without some notion of direction. Second, even though the conditional logit and mixed logit models allow one to model similar mechanisms, the interpretations of their estimates are different. The estimates of a conditional logit are more akin to those of a linear regression model, where one estimates the expected change in an outcome from varying a covariate. A mixture model is a probabilistic combination of constituent modes, so the class probabilities indicate the relative importance to each mode, which makes it harder to compare the roles of individual features within or across modes. However, many traditional models of network formation are equivalent to mixture models, which motivated our consideration of them in this work.

By making foundational connections between network formation and discrete choice, we are hopeful that many further tools from discrete choice theory can be applied to the study of network formation. For example, there can be bias in network formation, e.g., men are more likely to cite themselves than women [34]. Our discrete choice framework can help study these cases more rigorously. For another example, discrete choice models of subset selection [5, 20] could be applied to understand possible substitution and complementarity effects in network formation. And discrete choice interpretations of machine learning embeddings techniques [64] can likely help unpack the behavior of recent embedding-based network representation methods such as DeepWalk [57]. Networks fundamentally represent interactions between discrete entities, and

it is therefore natural that methods for modeling and analyzing discrete choice should enable many contributions.

ABSTRACT

Decision making is a challenging task in online recommender systems. The decision maker often needs to choose a contextual item at each step from a set of candidates. Contextual bandit algorithms have been successfully deployed to such applications, for the trade-off between exploration and exploitation and the state-of-art performance on minimizing online costs. However, the applicability of existing contextual bandit methods is limited by the over-simplified assumptions of the problem, such as assuming a simple form of the reward function or assuming a static environment where the states are not affected by previous actions.

In this work, we put forward *Policy Gradients for Contextual Recommendations (PGCR)* to solve the problem without those unrealistic assumptions. It optimizes over a restricted class of policies where the marginal probability of choosing an item (in expectation of other items) has a simple closed form, and the gradient of the expected return over the policy in this class is in a succinct form. Moreover, PGCR leverages two useful heuristic techniques called Time-Dependent Greed and Actor-Dropout. The former ensures PGCR to be empirically greedy in the limit, and the latter addresses the trade-off between exploration and exploitation by using the policy network with Dropout as a Bayesian approximation.

PGCR can solve the standard contextual bandits as well as its Markov Decision Process generalization. Therefore it can be applied to a wide range of realistic settings of recommendations, such as personalized advertising. We evaluate PGCR on toy datasets as well as a real-world dataset of personalized music recommendations. Experiments show that PGCR enables fast convergence and low regret, and outperforms both classic contextual-bandits and vanilla policy gradient methods.

1 INTRODUCTION

Decision making in online recommender systems and advertising systems are challenging because the recommender needs to find the policy that maximizes its revenue by interacting with the world. A typical decision-making problem is to select a featured item from a finite set of candidates, for example, to select an advertisement from a set of ads that relate to the user's query in a search engine, or to recommend a song from the user's playlist in a music streaming service. After making the decision, the recommender will receive a reward together with some state transition. In such settings, each item has a so-called *context* (which includes features and attributes) that carries all the necessary information for making the choice. Since it is often the case that the reward, as well as the state dynamic of choosing each item, are related to its context, the recommender system must try to learn how to make the choice given the contexts of all the candidates.

To solve such contextual recommendation problems, algorithms based on *contextual-bandits* have been successfully deployed in a number of industrial level applications over the past decade, such as personalized recommender systems [17, 27, 28], advertisement personalization [6, 29], and learning-to-rank [22]. Contextual-bandit algorithms are preferred if one needs to minimize the cumulative cost during online-learning because they aim to address the trade-off between exploitation and exploration.

The standard contextual bandit problem can be seen as a repeated game between nature and the player [16]. Nature defines a reward function mapping contexts (a set of features) to real-valued rewards, which is unknown to the player. At each step, nature gives a set of items, each with a context. The player observes the contextual items, selects one, and then receives a reward. The payoff of the player is to minimize the cumulative regret or to maximize the cumulative reward.

The main challenge of solving contextual bandits lies in the trade-off between exploration and exploitation. The most well-known approaches are arguably value-based methods including Upper Confidence Bounds (UCB) [5], Thompson Sampling (TS) [30], and their variants. These value-based methods try to estimate the expected reward of choosing each item, so they are especially effective when the form of reward function is known explicitly. For example, when the expected reward is linear in the context, [1, 9, 17] proposed Lin-UCB, which is applied successfully to the online news recommendation of Yahoo, and [4, 8, 19] also proposed TS to solve the linear contextual bandits. Similarly, [10] proposed GLM-UCB using generalized linear models, [15, 23] used Gaussian Processes, to model the reward functions. These variants of UCB and TS have been known to achieve sub-linear regrets [1, 2, 4, 5, 8–10, 15, 17, 23]. Similar ideas have also been applied to reinforcement learning algorithm such as the UCRL algorithm with regret bounds [13].

However, the applicability of these approaches in real-world applications is heavily limited, especially for large-scale and high-dimensional problems, due to the following reasons:

- First, these methods tend to over-simplify the form of the reward function, which is unrealistic in real-world cases. For example, for sponsored search advertising via real-time bidding, the reward of showing an ad (cost per click) is often the click-through rate multiplied by the bidding price, so it can be understood as a mixture of binary and linear outcomes. Moreover, the reward can often be a high-order non-linear function of features in the contexts.
- Second, the overall formulations of contextual-bandit problems are sometimes over-simplified comparing to real-world applications. It is often assumed that the reward is determined by the context of the currently chosen item, and the distribution of contexts is independent of the agent's action. However, it may not be true in real-world recommender systems where the behaviors of users heavily depend on not only the current contexts but the history, i.e., the items that he/she viewed in previous rounds. Also, the set of candidate items can relate to the user's previous preferences as well. These dependencies are not well exploited in existing models.
- Last but not least, these methods are value-based, so they are meant to find deterministic policies. A subtle change in the value estimation may cause a discontinuous jump in the resulting policy, which makes convergence difficult for these [25]. On the other hand, stochastic policies are sometimes preferred in online recommender systems.

In light of these observations, we propose Policy Gradients for Contextual Recommendations (PGCR), which uses the policy gradient method to solve general contextual recommendations. Our approach model the contextual recommendation problem without unrealistic assumptions or prior knowledge. By optimizing directly over the parameters of stochastic policies, it naturally fits the problems that require randomized actions as well as addresses the trade-off between exploration and exploitation.

Since we design PGCR specifically for contextual recommendations, we would like to specify the performance objective first and see if it is different from the one in standard reinforcement learning. We find that the objective over policies depends on the marginal expected probability of choosing each item (in expectation of other items). So PGCR restricts the search space to a class of policies in which the expected probabilities of choosing an item has a simple closed form and can be estimated efficiently. Therefore, the search space for PGCR is dramatically reduced.

Then, in order to estimate the marginal probability of choosing each item, we extend Experience Replay, the popular technique in off-policy reinforcement learning [3, 12], to a finer-grained sampling procedure. By doing so, the variance of estimating policy gradients can be much smaller than the variance of the vanilla policy gradient algorithm. The resulted algorithm is also computationally efficient by stochastic gradient descent with mini-batch training.

To address the trade-off of exploration and exploitation, our proposed PGCR empirically has the property of Greedy in the Limit with Infinite Exploration (GLIE), which is an essential property for contextual bandits [19]. The property is guaranteed by two useful heuristics named *Time-Dependent Greed* and *Actor-Dropout*. Time-Dependent Greed is to schedule the level of greed to increase over time, so the resulted stochastic policy will explore a lot in the early stage and then gradually converge to a greedy policy. Actor-Dropout is to use dropout on the policy network while training and inferring, thus the feed-forward network outputs policies with randomness. It has been known that such a stochastic feed-forward neural network can be seen as a Bayesian approximation [11], so it can provide with directed exploration for PGCR.

Furthermore, with the mentioned techniques, PGCR can directly apply to contextual recommendations in a Markov Decision Process (MDP) setting, i.e. with states and state transitions. We propose this generalized setting for the reason that the i.i.d. assumption on contexts in the standard contextual bandit setting is unrealistic for real-world applications. On the other hand, we suppose that at each step, the contexts are drawn i.i.d. from a distribution conditional on the current state. Furthermore, when an item is chosen, the immediate reward is determined by both the state and the selected item. The state is then transitioned into the next state. Such a model is tailored for a wide range of important realistic applications such as personalized recommender systems where users' preferences are regarded as states and items are regarded as items with contexts [20, 26], and e-commerce where the private information (e.g., cost, reputation) of sellers can be viewed as states and different commercial strategies are regarded as contexts [7].

We evaluate PGCR on toy datasets and a real-world dataset of music recommendation. By comparing with several common baselines including Lin-UCB, GLM-UCB, Thompson Sampling, ϵ-greedy, and vanilla policy gradients, it shows that PGCR converges quickly and achieves the lowest cumulative regret and the highest average reward in various standard contextual-bandits settings. Moreover, when state dynamics are included in the real-world recommendation environments, we find that GLM-UCB and TS fail to incorporate information from the states, while PGCR consistently outperforms other baselines.

2 PROBLEM FORMULATION

2.1 One-step Contextual Recommendations

We first introduce the simplified setting of contextual recommendation as a standard contextual-bandits problem. At each step, we have a set of contexts $\mathbf{c} = (c_1, \ldots, c_m)^T$ that corresponds to m items, where c_i is the context of the i^{th} item. The contexts $c_1, \ldots, c_m$ are independently and identically distributed random variables with outcome space C. The action is to select an item from the candidates, $a \in \{1, ..., m\}$.

For the ease of notation, we use $\mathbf{c}$ to denote the concatenation of all m contexts and use c_a to denote the context of the selected item a. We write the random variable of immediate reward as $R(c_a)$ to note that in this setting it depends only on the chosen context vector c_a. The dependency is not known to the decision-maker. So the target is to learn the dependency and choose the item with the largest expected reward.

A stochastic policy π is a function that maps the observations (the set of contexts $\mathbf{c}$) to a distribution of actions. Let the random variable $a \sim \pi(\mathbf{c})$ denote the action determined by policy π. The performance of a policy is measured as the expected reward of the chosen item over all possible contexts, i.e.,

$$J(\pi) = \mathbb{E}_{\mathbf{c}}\Big[R(c_a) \mid a \sim \pi(\mathbf{c})\Big], \tag{1}$$

where c_a is short for the context of the chosen action a.

When the policy π is parameterized as π_θ where θ is the trainable parameters, our goal is to find the optimal choice of θ that maximizes the objective $J(\pi_\theta)$.

However, there is an obvious drawback for this simplified setting: in real-world recommendations, it cannot be assumed that the contexts are always drawn i.i.d from some global probability distribution. For example, when recommending items (goods) to a customer given the searching query in an e-commerce platform, we can only select items from a candidate pool related to the query. This non-i.i.d nature motivates us to put forward a more general setting, which involves the states.

2.2 Sequential State-aware Contextual Recommendations

In this part, we introduce the generalized setting as a Markov Decision Process (MDP) with states and state transitions for contextual recommendations, which is referred to as MDP-CR.

At each step t, the decision maker observes its state s_t as well as a set of contexts correlated to that state $\mathbf{c_t} = \{c_{t1}, \ldots, c_{tm}\}$. When an action (one of the items) $a_t = \pi(s_t, \mathbf{c_t})$ is selected, a reward $R(s_t, c_{ta_t})$ is received, and the state is transitioned to the next state by a Markovian state transition probability $s_{t+1} \sim T(s_{t+1} \mid s_t, c_{ta_t})$. Note that the setting in this paper is different from other existing generalized bandits with transitions such as Restless bandits [31].

In this setting, we assume that the contexts are independently distributed conditioning on the state: $c_{ti} \sim g^{s_t}(c)$ for all i, where $g^{s_t}(c)$ is the probability density of contexts given state s_t. For example, if the state is the search query or the attribute vector of a user, we assume that the contexts of items in the candidate pool are drawn from a distribution that reflects the search query or the user preference.

The goal is to find a policy that maximizes the expected cumulative discounted reward, so the objective is

$$J(\pi) = \mathbb{E}\Big[\sum_{t=0}^{\infty} \gamma^t R(s_t, c_{ta_t}) \mid a_t \sim \pi(s_t, \mathbf{c_t})\Big], \tag{2}$$

where $0 < \gamma < 1$ is a discount factor that balances short and long term rewards, just like in standard reinforcement learning. We also define the action value function

$$Q^\pi(s, c) = \mathbb{E}\Big[\sum_{t=0}^{\infty} \gamma^t R(s_t, c_{ta_t}) \mid s_0 = s, c_{0a_0} = c, \pi\Big]. \tag{3}$$

Same as previous works [21, 25] on policy gradients, we denote the discounted state density by $\rho^\pi(s) = \int_{\mathcal{S}} \sum_{t=0}^{\infty} \gamma^t P_0(s_0) P(s_0 \to s, t, \pi) \mathrm{d}s_0$, where $P_0(s_0)$ is the probability density of initial states, and $P(s \to s', t, \pi)$ is the probability density at state s' after transitioning for t time steps from state s.

Thus we can rewrite the objective as

$$J(\pi) = \mathbb{E}_{s\sim\rho^\pi, \mathbf{c}\sim g^s, a\sim\pi(s,\mathbf{c})}\Big[R(s, c_a)\Big]. \tag{4}$$

3 POLICY GRADIENTS FOR ONE-STEP CONTEXTUAL RECOMMENDATIONS

In this section we investigate several key features of our purposed PGCR method. For readability, we first discuss the one-step contextual recommendation case (corresponding to section 2.1), which can be modeled as the standard contextual-bandits. Later in the next section, we will show how to extend to the generalized multi-step recommendation which can be modeled as MDP-CR.

3.1 Marginal probability for choosing an item

Due to the assumption of the problem setting that the reward only depends on the selected context, we claim that for any policy π, there exists a *permutation invariant policy* that obtains at least its performance.

Definition 1 (Permutation invariant policy). *A policy $\pi(\mathbf{c})$ is said to be permutation invariant if for all $\mathbf{c} \in C^m$ and any its permutation $\mathbf{c}' := P(\mathbf{c})$, it has*

$$c'_{a'} \overset{dist}{=} c_a \tag{5}$$

where $a' \sim \pi(\mathbf{c}')$ and $a \sim \pi(\mathbf{c})$ denote for the actions chosen by the policy π, $c'_{a'}$ and c_a is the their corresponding contexts respectively, and $\overset{dist}{=}$ means the probability distribution of the expressions on two sides are the same.

Lemma 1. *For any policy π, there exists a permutation invariant policy π' s.t. $J(\pi') \geq J(\pi)$.*

Proof. Let us suppose, for the sake of contradiction, that there exists a policy π such that

(i) it is not permutation invariant, i.e. there exists $\mathbf{c} \in C^m$ and some permutation operator $P \in \mathcal{P}$ that $c_a \neq c'_{a'}$ where $\mathbf{c}' = P(\mathbf{c})$ and $a' \sim \pi(\mathbf{c}')$;

(ii) The expected reward following π is larger than all permutation invariant policies $\tilde{\pi}$ that $J(\pi) > J(\tilde{\pi})$.

Then it follows that $\mathbb{E}_{\mathbf{c}}\Big[R(\mathbf{c}_{\pi(\mathbf{c})})\Big] > \mathbb{E}_{\mathbf{c}}\Big[R(\mathbf{c}_{\tilde{\pi}(\mathbf{c})})\Big]$ for all permutation invariant $\tilde{\pi}$, where the expectation is over all sets of contexts.

Recall that the contexts are drawn i.i.d. from the same distribution, so we have

$$\mathbb{E}_{\mathbf{c}}\Big[R(\mathbf{c}_{\pi(c)})\Big] \equiv \mathbb{E}_{\mathbf{c}}\Big[\frac{1}{|\mathcal{P}|}\sum_{P\in\mathcal{P}} R(P(\mathbf{c})_{\pi(P(\mathbf{c}))})\Big] > \mathbb{E}_{\mathbf{c}}\Big[R(\mathbf{c}_{\tilde{\pi}(c)})\Big], \tag{6}$$

so there exists at least one $\mathbf{c}$ that

$$\frac{1}{|\mathcal{P}|}\sum_{P\in\mathcal{P}} R(P(\mathbf{c})_{\pi(P(\mathbf{c}))}) > R(\mathbf{c}_{\tilde{\pi}(c)}) \text{ for all } \tilde{\pi}. \tag{7}$$

But because π is not permutation invariant, we find a policy $\pi^*(P(\mathbf{c})) = \pi((P^*P^TP)(\mathbf{c}))$ that is permutation invariant, where

$$P^* = \arg\max_{P\in\mathcal{P}} R(P(\mathbf{c})_{\pi(P(\mathbf{c}))}),$$

then

$$R(\mathbf{c}_{\pi^*(c)}) = R(P^*(\mathbf{c})_{\pi(P^*(\mathbf{c}))}) > \frac{1}{|\mathcal{P}|}\sum_{P\in\mathcal{P}} R(P(\mathbf{c})_{\pi(P(\mathbf{c}))}), \tag{8}$$

which leads to a contradictory to (6) and (7). So it must be that Lemma 1 holds. □

Lemma 1 states that, without loss of generality, we can focus on permutation invariant policies. The objective in then becomes

$$\begin{aligned} J(\pi) &= \mathbb{E}_{\mathbf{c}}\Big[R(c_a) \mid a\sim\pi(\mathbf{c})\Big] \\ &= \mathbb{E}_{\mathbf{c}}\Big[\sum_{i=1}^{m} R(c_i)I_{(a=i)}\,\Big|\, a\sim\pi(\mathbf{c})\Big] \\ &= \sum_{i=1}^{m}\mathbb{E}_{\mathbf{c}}\Big[R(c_i)I_{(a=i)}\,\Big|\, a\sim\pi(\mathbf{c})\Big] \\ &= \sum_{i=1}^{m}\mathbb{E}_{c_1}\Big[R(c_1)\mathbb{E}_{c_{-1}}\Big[I_{(a=1)} \mid a\sim\pi(c,c_{-1})\Big]\Big] \\ &= m\,\mathbb{E}_c\Big[R(c)p(c)\Big], \end{aligned} \tag{9}$$

where $p(c)$ is the marginal probability of choosing an item with context c (in expectation of randomness of the other $m-1$ items, denoted as c_{-1}), by a permutation invariant policy:

$$p(c) = \mathbb{E}_{c_{-1}}\Big[I_{(a=1)} \mid a\sim\pi(c,c_{-1})\Big]. \tag{10}$$

Suppose we have a score function μ_θ which takes the context as inputs and outputs a score, where θ are the parameters. We can construct a class $\mathcal{M}$ of permutation invariant policies with the score function:

$$\pi_\theta(\mathbf{c}) \overset{\text{dist}}{=} g\big(\mu_\theta(c_1),\ldots,\mu_\theta(c_m)\big), \tag{11}$$

where g is an operator that satisfies permutation invariance, for example, a family of probability distributions, and $\overset{\text{dist}}{=}$ means the two sides are equivalent in the sense of probability distribution.

Note that this class of policies include policies of most well-known value-based bandit algorithms. For example, if the score function is the estimation of the reward, and the operator $g(\cdot)$ chooses the item with the maximum estimated reward with probability $1-\epsilon$ and chooses randomly with probability ϵ, the policy is exactly the well-known ϵ-greedy policy [24]. If the score function is a summation of the reward estimation and the upper confidence bound, and $g(\cdot)$ chooses the item with the maximum score, it results in a similar policy to the upper confidence bound (UCB) policy [5, 17].

The policy gradient $\nabla_\theta J(\pi_\theta)$ for the standard one-step recommendations can be directly derived from (9)

$$\nabla_\theta J(\pi_\theta) = m\,\mathbb{E}_c\Big[R(c)\nabla_\theta p_\theta(c)\Big]. \tag{12}$$

So it involves computing the marginal probabilities of choosing an item $p(c)$ which is not explicitly parameterized or tractable given an arbitrary policy π_θ. To this end, we put forward a restricted family of stochastic policies that allows us to have $p(c)$ in closed-form so as to estimate the gradient of $J(\pi_\theta)$ efficiently.

3.2 A simple but powerful class of policies

Now we propose a class of policies for our PGCR algorithm. For the standard one-step contextual-bandits, following the form of a policy described in (11), we define a class of stochastic policies denoted by $\mathcal{N}$ as

$$\pi_\theta(\mathbf{c}) = \text{Multinoulli}\Big\{\sigma\big(\mu_\theta(c_1),\ldots,\mu_\theta(c_m)\big)\Big\}, \tag{13}$$

where $\mu_\theta(c)$ is any positive continuous function of c and θ, σ is a normalization $\sigma(\mathbf{x}) := \Big(\frac{x_1}{\sum_i x_i},\ldots,\frac{x_m}{\sum_i x_i}\Big)$ and Multinoulli$(\cdot)$ returns a multinoulli random variable (the multinoulli distribution is also known as categorical distribution).

The form of our policy (13) generalizes several important policies in reinforcement learning. For example, when $\mu_\theta(c_i)$ is an exponential function $e^{-\beta f_\theta(c_i)}$, it reduces to the well-known *softmax policy*. If β approaches to infinity, it converges to the greedy policy that chooses the item with highest score.

For any policy $\pi_\theta \in \mathcal{N}$, the marginal probability of choosing an item can be easily derived as

$$p_\theta(c_i) = \mathbb{E}_{c_{-i}}\Big[\frac{\mu_\theta(c_i)}{\mu_\theta(c_i)+\sum_{j\neq i}\mu_\theta(c_j)}\Big], \tag{14}$$

which is a continuous and positive function of parameters θ. So it is straightforward to estimate $p_\theta(c)$ by sampling c_{-i} from the contexts that the player have seen before. We denote by D_t the contexts that have appeared up to step t. The estimation of $p(c)$ is unbiased because as assumed all contexts in D_t are i.i.d from the context space.

4 POLICY GRADIENTS FOR SEQUENTIAL CONTEXTUAL RECOMMENDATIONS

In this section we extend this approach to MDP-CR. We first use $\tilde{c}$ to denote the *augmented context* by pairing together a state s and the context c for a certain item, i.e., $\tilde{c} = (s,c)$. For example, in a personalized recommender system, the state s consists of the user feature, c contains the item feature. Their concatenation $\tilde{c} = (s,c)$ is often used in ordinary tasks such as the prediction of click-through rate.

Given a policy π, the states can be roughly thought of as drawn from the discounted stationary distribution $\rho^\pi(s)$. As we already defined the density of contexts given the state as $g^s(c)$, we have the discounted density of the augmented context $\tilde{c}$ by the axiom of probability

$$\xi^\pi(\tilde{c}) = \rho^\pi(s)\,g^s(c).$$

Since we assume the state distribution $\rho^\pi(s)$ is stationary, it is natural that $\xi^\pi(\tilde{c})$ is also stationary.

Then by applying the same technique as we derive the marginal probability, we derive the performance objective as follows:

$$J(\pi) = m\,\mathbb{E}_{\tilde{c}\sim\xi^{\pi}}\Big[R(\tilde{c})\cdot p(\tilde{c})\Big], \tag{15}$$

where $p(\tilde{c}) = \mathbb{E}_{c_{-1}\sim g^{s}}[I(a=1)\mid\pi]$ is the marginal probability of choosing c given s.

Now we derive the gradients of $J(\pi)$ similar to the result in [25]. Surprisingly, it only replaces $R(c)$ in (12) by $Q(\tilde{c})$.

Theorem 2. *Assuming the policy π leads to stationary distributions for states and contexts, the unbiased policy gradient is*

$$\nabla_{\theta}J(\pi_{\theta}) = m\,\mathbb{E}_{\tilde{c}\sim\xi}\Big[\nabla_{\theta}p_{\theta}(\tilde{c})\,Q(\tilde{c})\Big], \tag{16}$$

where $Q^{\pi}(\tilde{c}) := Q^{\pi}(s,c)$ as defined in (3), and $\xi^{\pi}(\tilde{c})$ is the discounted density of $\tilde{c}$.

Proof. We denote the state-value for state s under policy π as

$$V^{\pi}(s) = m\int_{c} p_{\theta}(s,c)Q^{\pi}(s,c)g^{s}(c)\mathrm{d}c,$$

it follows that

$$\begin{aligned}\nabla_{\theta}V^{\pi}(s) &= \nabla_{\theta}m\int_{c} p_{\theta}(s,c)Q^{\pi}(s,c)g^{s}(c)\mathrm{d}c\\ &= m\int_{c}\nabla_{\theta}p_{\theta}(s,c)Q^{\pi}(s,c)g^{s}(c)\mathrm{d}c\\ &\quad+\gamma m\int_{s'}P(s\to s',1,\pi)\nabla_{\theta}V^{\pi}(s')\mathrm{d}s',\end{aligned}$$

By repeatedly unrolling the equation, we have

$$\nabla_{\theta}V^{\pi}(s) = m\int_{s'}\sum_{t=0}^{\infty}\gamma^{t}P(s\to s',t,\pi)\int_{c}\nabla_{\theta}p_{\theta}(\tilde{c})Q(\tilde{c})g^{s'}(c)\mathrm{d}c\mathrm{d}s'.$$

Integrating both side over the start-state and recalling the discounted state density $\rho^{\pi}(s)$ and discounted augmented context density $\xi^{\pi}(\tilde{c})$, we get the policy gradient as

$$\begin{aligned}\nabla_{\theta}J(\pi) &= m\int_{s}P_{0}(s)\nabla_{\theta}V^{\pi}(s)ds\\ &= m\int_{s}\rho^{\pi}(s)\int_{c}\nabla_{\theta}p_{\theta}(\tilde{c})Q(\tilde{c})g^{s}(c)\,\mathrm{d}c\mathrm{d}s\\ &= m\int_{\tilde{c}}\nabla_{\theta}p_{\theta}(\tilde{c})Q(\tilde{c})\xi^{\pi}(\tilde{c})\mathrm{d}\tilde{c}.\end{aligned}$$

□

Again we can find the restricted class of policies to perform efficient estimation of the gradient. For MDP-CR, it is straightforward to extend (13) to introduce states by replacing c as the augmented context $\tilde{c}$.

5 ACTOR-CRITIC WITH FUNCTION APPROXIMATIONS

In this section, we deliver the practical algorithm to estimate the policy gradient using function approximations. In the sample-based approximations, we write collected the reward feedback as $r(c)$ for the one-step recommendation case, and $r(\tilde{c})$ for the sequential recommendation case, as the realizations of the reward random variable $R(\cdot)$.

In conventional methods based on contextual-bandits, the most direct way to estimate the reward function is to directly apply supervised learning methods to find an estimator f_{ϕ} with parameter ϕ minimizing the mean squared error, i.e.,

$$\min_{\phi}\frac{1}{|D_{t}^{(1)}|}\sum_{c\in D_{t}^{(1)}}\Big(r(c)-f_{\phi}(c)\Big)^{2}, \tag{17}$$

where $D_{t}^{(1)}\subset D_{t}$ is the set of chosen contexts and $r(c)$ is the received reward for choosing context c. It is common for most value-based contextual bandit algorithms, such as ϵ-greedy, LinUCB and Thompson Sampling.

However, we argue that in a policy-based perspective, this kind of off-policy supervised learning brings bias. Since our goal is to maximize the expected reward $J(\pi_{\theta})$ rather than minimizing the empirical loss as in supervised learning, the marginal probabilities of choosing an item must be taken into consideration, and the form of $f_{\phi}(c)$ cannot be chosen arbitrarily.

Similarly, when states and state transitions are involved in MDP-CR, we also need to find an approriate $f_{\phi}(\tilde{c})$ to approximate $Q(\tilde{c})$. Since we have noted that the standard one-step contextual-bandits can be seen as a special case of the generalized MDP-CR, from now we will use the notations of MDP-CR by default to deliver the main results and algorithms.

We take similar spirit to [21, 25] and define the following *compatible* conditions, to assure that the policy gradient is orthogonal to the error in value approximation.

Theorem 3. *The policy gradient using function approximation*

$$\nabla_{\theta}J(\pi_{\theta}) = m\int_{\tilde{c}}\nabla_{\theta}p_{\theta}(\tilde{c})\cdot f_{\phi}(\tilde{c})\xi^{\pi}(\tilde{c})d\tilde{c} \tag{18}$$

is unbiased to (16) if the following conditions are satisfied:

(i) the gradients for the value function and the policy are compatible,

$$\nabla_{\phi}f_{\phi}(\tilde{c}) = \nabla_{\theta}\,log\,p_{\theta}(\tilde{c}), \tag{19}$$

(ii) the value function parameters ϕ reach a local minimum of the mean squared error over the stationary context distribution such that

$$\nabla_{\phi}\,\mathbb{E}_{\tilde{c}\sim\xi^{\pi}}\Big[p_{\theta}(\tilde{c})\Big(f_{\phi}(\tilde{c})-Q^{\pi}(\tilde{c})\Big)^{2}\Big] = 0. \tag{20}$$

Proof. By condition (ii), as we assumed the distribution of contexts ξ^{π} is stationary with respect to the policy π, it is easy to see when the conditions hold,

$$m\int_{\tilde{c}}\xi^{\pi}(\tilde{c})p_{\theta}(\tilde{c})[Q^{\pi}(\tilde{c})-f_{\phi}(\tilde{c})\Big]\nabla_{\phi}f_{\phi}(\tilde{c}) = 0.$$

Then by condition (i) we have

$$m\int_{\tilde{c}}\nabla_{\theta}p_{\theta}(\tilde{c})\Big[Q^{\pi}(\tilde{c})-f_{\phi}(\tilde{c})]\xi^{\pi}(\tilde{c})\mathrm{d}\tilde{c} = 0,$$

which is the difference between (16) and (18). □

5.1 The basic PGCR algorithm

We now formally propose the policy gradients algorithm for general contextual recommendations, coined by PGCR. Recall that our policy returns a Multinoulli random variable that chooses a_t by

$$a_t \sim \text{Multinoulli}\Big\{\sigma\Big(\mu_{\theta}(s_t,c_{t1}),\ldots,\mu_{\theta}(s_t,c_{tm})\Big)\Big\}.$$

The key is to estimate the marginal expected probabilities for each item. When estimating it for some context, say c_{ti}, at some state s_t,

we resample from all the previously observed contexts at the same state to get another $m-1$ contexts.

$$\hat{p}_\theta(s_t, c_{ti}) = \frac{1}{N}\sum_{n}^{N} \frac{\mu_\theta(s_t, c_{ti})}{\mu_\theta(s_t, c_{ti}) + \sum_c \mu_\theta(s_t, c)} \tag{21}$$

where N ($N \geq 1$) is the number of resampling times, and c in the denominator are another $m-1$ sampled contexts from the same state to s_t.

Similar to previous actor-critic algorithms [18], we can use Sarsa updates [24] to estimate the action-value function and then update the policy parameters respectively by the following *policy gradients for contextual-bandits* algorithm,

$$\delta_t = r_t + \gamma f_{\phi_t}(s_{t+1}, c_{(t+1)a}) - f_{\phi_t}(s_t, c_{ta}) \tag{22}$$

$$\Delta^{\text{PGCR}}_{\phi,t} = \hat{p}_\theta(s_t, c_{ta})\delta_t \nabla_\phi f_{\phi_t}(s_t, c_{ta}) \tag{23}$$

$$\phi_{t+1} = \phi_t + \alpha_\phi \Delta^{\text{PGCR}}_{\phi,t} \tag{24}$$

$$\Delta^{\text{PGCR}}_{\theta,t} = \sum_{i=1}^{m} \nabla_\theta \hat{p}_{\theta_t}(s_t, c_{ti}) f_{\phi_{t+1}}(s_t, c_{ti}) \tag{25}$$

$$\theta_{t+1} = \theta_t + \alpha_\theta \Delta^{\text{PGCR}}_{\theta,t}. \tag{26}$$

In practice, the gradients can be updated on mini-batches by modern optimizers such as the Adam optimizer [14] which we already used for experiments. PGCR naturally fits to deep Reinforcement Learning and Online Learning, and techniques from these area may also be applied. Note that the algorithm can also be apply to the standard contextual bandit setting without states.

5.2 Two useful heuristics

5.2.1 Time-Dependent Greed. Greedy in the Limit with Infinite Exploration (GLIE), is the basic criteria desired for bandit algorithms. GLIE is to explore all the actions infinite times and then to converge to a greedy policy that reaches the global optimal reward if it runs for enough time. Value-based methods can satisfy GLIE if a positive but diminishing *exploration value* is given to all the actions. But for policy-based methods, it is not straightforward, because one cannot explicitly show the exploration level of a stochastic policy.

For PGCR, on the contrary, it is easy to have GLIE by *Time-Dependent Greed*, which applies a Time-Dependent Greed factor to the scoring function $\mu(c)$. A straightforward usage is to let $\mu_{\text{greedy}}(c; t) := \mu^{\alpha t}(c)$ where α is a pre-determined positive constant value and t is the current time-step. When $t \to \infty$, the policy tends to choose only the item with the largest score. Also the marginal probability $p_{\text{greedy}}(c; t)$ remains positive with the assumption that $\mu(c) \in (0, +\infty)$ for all context c, so any item gets an infinite chance to be explored if it runs for enough time. This technique can also apply to other policy-based RL methods as well.

5.2.2 Actor-Dropout. Directed exploration is also desired. UCB and TS methods are well-known to have directed exploration so that they automatically trade-offs between exploration and exploitation and get sub-linear total regrets. The basic insight of UCB and TS is to learn the model uncertainty during the online decision-making process and to explore the items with larger uncertainty (or higher potential to get a large reward). Often a Bayesian framework is used to model the uncertainty by estimating the posterior. However, the limitation of these methods is that assumptions and prior knowledge of reward functions are required, otherwise the posterior cannot be estimated correctly.

In light of these observations, we propose *Actor-Dropout* for PGCR to achieve directed exploration. The method is simple: to use dropout on the policy network while training and inferring. We do so because it has been theoretically and empirically justified that a neural network with dropout is mathematically equivalent to a Bayesian approximation [11]. So Actor-Dropout naturally learns the uncertainty of policies and does Monte Carlo sampling when making decisions. Since Actor-Dropout needs no prior knowledge, it can apply to more general and complex cases than UCB and TS.

To use Actor-Dropout, in practice it is good enough for exploration to add dropout to just one layer of weights. For example, for a fully-connected actor-network, one can use dropout to the weights before the output layer, with a dropout ratio of 0.5 or 0.67. It can be understood as to train several actors and to randomly pick one at each step, so it trade-offs between exploration and exploitation since each actor learns something different from each other. We also found Actor-Dropout worth trying for other RL or Online Learning tasks in the exploration phase.

5.3 Lower variance of the gradients of PGCR than vanilla PG

We prove that the variance of updating the actor and the critic of PGCR is less than that of vanilla PG.

Since the concept of *context* does not exist in the classic formulation of reinforcement learning, it is often regarded as part of the state. Given a stochastic policy $\pi_\theta(s, \mathbf{c})$, PG has policy gradients

$$\nabla_\theta J(\pi_\theta) = m \sum_s \rho^\pi_s \sum_{i=1}^{m} \nabla_\theta [e_i^T \pi_\theta(s, \mathbf{c})] \cdot f_\phi(\tilde{c}_i), \tag{27}$$

where e_i denotes a unit vector and $e_i^T \pi_\theta(s, \mathbf{c})$ is the probability for choosing the i^{th} item. For simplicity, we write $v_i := e_i^T \pi_\theta(s, \mathbf{c})$. Since we focus on policy gradients, we assume that PG has a critic function $f_\phi(\tilde{c})$ with the same form as PGCR. The corresponding update steps for PG is

$$\Delta^{\text{PG}}_{\phi_t} = v_{ta}\delta_t \nabla_\phi f_\phi(s_t, c_{ta}) \tag{28}$$

$$\Delta^{\text{PG}}_{\theta_t} = \sum_{i}^{m} \nabla_\theta v_{ti} f_{\phi_{t+1}}(s_t, c_{ti}). \tag{29}$$

Our PGCR can achieve lower estimation variance comparing to classic stochastic policy gradient methods such as [25], the reasons are two-fold. Firstly, by Lemma 1 we know permutation invariant policies are sufficient for contextual-bandits problems, so PGCR adopts the restricted class of policies. On the contrary, in vanilla policy gradients, one should treat a state s and the whole contexts $\mathbf{c}$ altogether as the input of the policy function, so the sample space can be much larger, which results in lower sample efficiency. Secondly, even if with the same form of policy, vanilla policy gradients tend to converge slower than PGCR because they do not take the marginal expected probabilities of choosing an item into consideration.

In a formal way, we can have the following conclusion.

Lemma 4. *Given a policy $\pi_\theta \in \mathcal{N}$ and a value approximation f_ϕ, both $\Delta_{\phi_t}^{PGCR}$ and $\Delta_{\phi_t}^{PG}$ are unbiased estimators for the true gradients of action-value approximation*

$$\Delta_{\phi_t} = p(s_t, c_{ta})\delta_t \nabla_\phi f_\phi(s_t, c_{ta}). \tag{30}$$

And $Var\left[\Delta_{\phi_t}^{PGCR}\right] \leq Var\left[\Delta_{\phi_t}^{PG}\right]$. Additionally if PGCR uses a fixed N, as $t \to +\infty$, with probability 1 we have

$$Var\left[\Delta_{\phi_t}^{PGCR}\right] \to \frac{1}{N} Var\left[\Delta_{\phi_t}^{PG}\right]. \tag{31}$$

Proof. It is obvious that both v_{ta} in $\Delta_{\phi_t}^{PG}$ and $\hat{p}(s_t, c_{ta})$ in $\Delta_{\phi_t}^{PGCR}$ are unbiased to $p(s_t, c_{ta})$. So both $\Delta_{\phi_t}^{PGCR}$ and $\Delta_{\phi_t}^{PG}$ are unbiased to Δ_{ϕ_t}. To analyze the variance, we focus on the estimations of the probability of choosing an item: v_{ta} and $\hat{p}(s_t, c_{ta})$. Let $V := \mathrm{Var}\left[v_{ta}\right]$. Then for PGCR,

$$\mathrm{Var}\left[\hat{p}(s_t, c_{ta})\right] = \mathrm{Var}\left[\frac{1}{N}\sum_{n=1}^{N} v_{ta}^{(n)}\right], \tag{32}$$

where $v_{ta}^{(n)}$ denotes the probability of choosing c_{ta} at the n^{th} time of sampling. In the worst case, it samples exactly the same set of $m-1$ items every time, then $\mathrm{Var}\left[\hat{p}(s_t, c_{ta})\right] = V$. Otherwise if there exists n_1 and n_2 that the samples are different such that $v_{ta}^{(n_1)} \neq v_{ta}^{(n_2)}$, then the correlation is strictly less than 1 and we have $\mathrm{Var}\left[\Delta_{\phi_t}^{PGCR}\right] < \mathrm{Var}\left[\Delta_{\phi_t}^{PG}\right]$ in this case. Finally when enough time steps passed, for N is a fixed positive integer, the probability of each item being sampled at most once is

$$\binom{mt}{(m-1)N}(mt)^{-(m-1)N} \to 1 \quad \text{as} \quad t \to +\infty.$$

So with probability 1 the sampled contexts are all different to each other so the estimated probabilities of choosing an item are i.i.d., then $\mathrm{Var}\left[\Delta_{\phi_t}^{PGCR}\right] \to V/N$. □

We get the following theorem applying the similar technique to Lemma 4. We claim that Policy gradients (18) has no higher variance than gradients in PG.

Theorem 5. $Var\left[\Delta_\theta^{\mathrm{PGCR}}\right] \leq Var\left[\Delta_\theta^{\mathrm{PG}}\right]$.

Proof. Similar to the proof of Lemma 4, we denote the variance of $\Delta_\theta^{\mathrm{PG}}$ by V_θ.

$$V_\theta := \mathrm{Var}\left[\Delta_\theta^{\mathrm{PG}}\right] = \mathrm{Var}\left[\sum_{i}^{m} \nabla_\theta v_{ti} f_{\phi_{t+1}}(s_t, c_{ti})\right] \tag{33}$$

By the update rules (25) of PGCR, the variance of $\Delta_\theta^{\mathrm{PGCR}}$ is

$$\begin{aligned}
\mathrm{Var}\left[\Delta_{\theta_t}^{\mathrm{PGCR}}\right] &= \mathrm{Var}\left[\sum_{i=1}^{m} \nabla_\theta \hat{p}_\theta(s_t, c_{ti}) f_{\phi_{t+1}}(s_t, c_{ti})\right] \\
&= \mathrm{Var}\left[\frac{1}{N}\sum_{n=1}^{N}\sum_{i=1}^{m} \nabla_\theta v_{ti}^{(n)} f_{\phi_{t+1}}(s_t, c_{ti})\right] \\
&\leq \mathrm{Var}\left[\sum_{i=1}^{m} \nabla_\theta v_{ti}^{(n)} f_{\phi_{t+1}}(s_t, c_{ti})\right], \quad \forall\, n = 1, \ldots, N.
\end{aligned}$$

Because of the assumption that the sampled contexts in each sampling procedure are independent and identical distributed, we have $\mathrm{Var}\left[\sum_{i=1}^{m} \nabla_\theta v_{ti}^{(n)} f_{\phi_{t+1}}(s_t, c_{ti})\right] = V_\theta$ for all $n = 1, \ldots, N$ and the theorem is proved. □

Note that, in practice, PGCR does not necessarily set N to a large integer since it is naturally a finer-grained experience replay [3]. Surprisingly, when $N = 1$, PGCR can have a better performance than *PG* even in the simplest setting. In the next section, we will demonstrate experimental results that show that PGCR with $N = 1$ achieves better performance in various settings compared to other baseline methods including PG.

The results can be interpreted as follows. From a statistical point of view, PGCR takes advantage from a resampling technique so the estimations have lower variances. From an optimization perspective, PGCR reduces the correlation of estimating probabilities of choosing the m items within the same time step, so it has less chance to suffer from exploiting and over-fitting, while vanilla PG cannot. For example, when the estimated values of m contexts are given, an optimizer for PG would simultaneously increase one item's chosen probability and reduce other $m-1$ ones', which results in training the policy into a deterministic one: the item with the largest estimated value will get a chosen probability close to 1, and others get arbitrary small probabilities close to 0. Afterward, the items with 0 chosen probabilities will hardly have any influence to further updates. So eventually, vanilla PG is likely to over-fit the existing data. On the contrary, when PGCR estimates the gradients, even if an item cannot beat against the other $m-1$ competitors at its own time step, it can still help because it outranked some items from other time steps. Therefore, PGCR tends to be more robust and explores better than vanilla PG.

6 EXPERIMENTS

6.1 Datasets and simulation details

We test our proposed PGCR and other baseline methods on several simulated contextual recommendation environments. To start with, we would like to describe the details of our simulations.

- **Toy environments:** The first set of experiments are done with a generated toy dataset to simulate the standard contextual bandit settings. We simulate a contextual bandit environment with 5 items at each step, where each item is represented by a 40-dimensional context vector that is i.i.d. sampled from a uniform distribution in a unit cube $c \sim \mathrm{U}(C)$, $C = (0,1)^{40}$. Once an item with context c is chosen by the player, the environment returns a random reward $R(c)$. We test three types of reward functions: (a) the linear reward with Gaussian noise, as $R(c) := w_r^T c + e_r$; (b) the Bernoulli reward, as $R(c) \sim \mathrm{Bernoulli}(\beta(c))$ where $\beta(c) := w_\beta^T c + e_\beta \in [0,1]$ is the probability to return reward 1 for choosing c; (c) the mixed reward, which first returns a random linear reward $w_r^T c + e_r$ with probability $\beta(c)$ and returns a zero reward with probability $1-\beta(c)$, as a mixture of binary and linear rewards. w_r and w_β are coefficients unknown to the player. e_r and e_β are white noises to introduce some randomness.

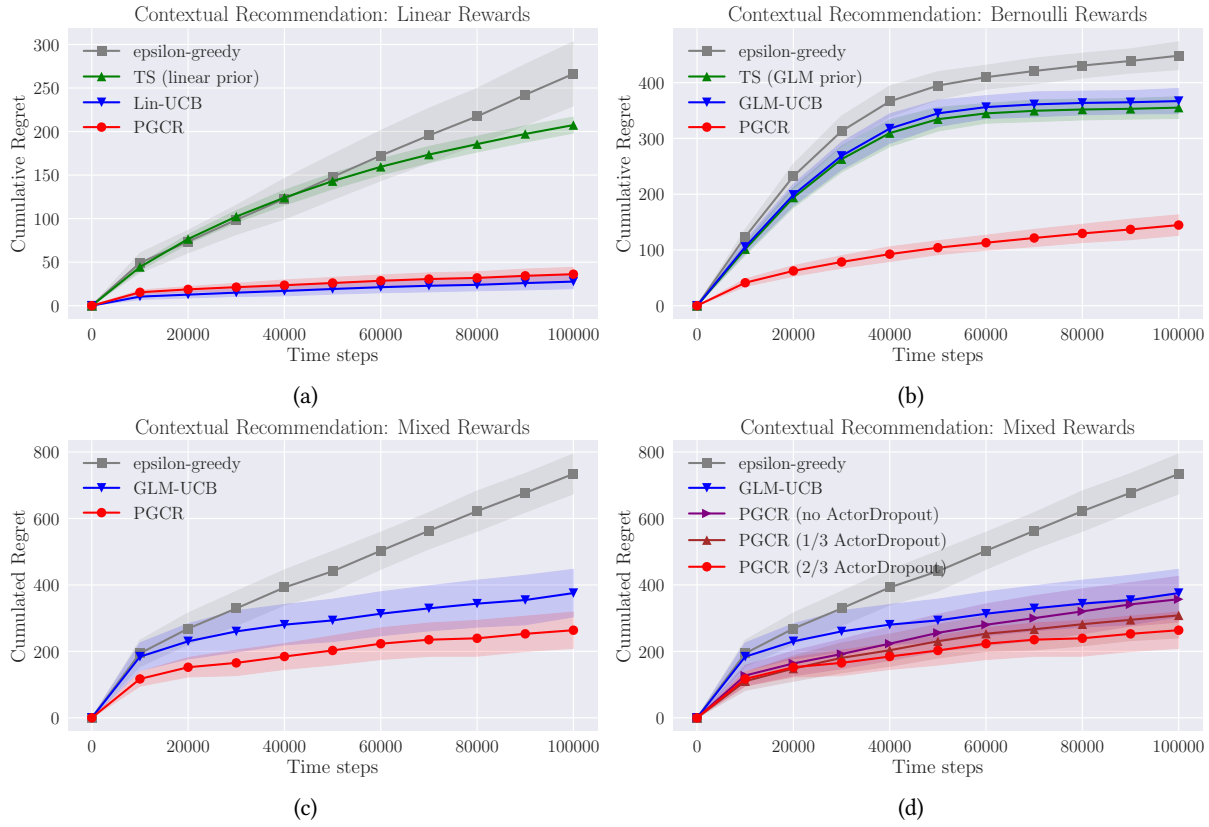

Figure 1: Experiments on toy data. The solid lines are averaged cumulative regrets over 20 runs, and the shaded areas stand for the standard deviations. (a) Linear rewards: PGCR perform comparably to Lin-UCB and is much better than the other two. (b) Bernoulli rewards: PGCR outperforms the others with large margins. (c) Mixed-rewards: PGCR outperforms the others. (d) Testing PGCR with different level of Actor-Dropout. It shows that, without Actor-Dropout, PGCR tends to have linear regret like ϵ-greedy and fail to converge. But when using Actor-Dropout, PGCR empirically converges which is similar to UCB, yet gets even lower regret than UCB.

- **Music recommendation environments:** We use a real-world dataset of music recommendation provided by *KKBox* and open-sourced on *Kaggle.com*[1]. The challenge is to predict the chances of a user listening to a song repeatedly. So we construct simulation environments to simulate the online contextual recommendations to test our methods.
  We construct two simulators based on the distributions of the dataset with different settings: one simplified setting without explicit states and one general setting with states and state transitions. At each round, a user comes, which is randomly picked from the users in the dataset. For the state-aware setting, the state is set as the last 3 songs the system recommended previously to this user, together with the corresponding feedbacks (listened or not). Then the simulator randomly samples a set of 10 candidate songs from the user's listening history. Finally, the recommender makes a decision to recommends one to the user. If the user listens to it again (which is the original target for the supervised learning dataset), the system gets a reward of 1, otherwise, it gets 0. Each song has 94 fields of features in the context vector, including discrete attributes and numerical features about the song's genre, artists, composers, language, etc. The simulation consists of 5 million time steps and is repeated for 5 runs. Since the optimal policy is unknown in this problem, we will use the average reward as the performance metric.

[1]https://www.kaggle.com/c/kkbox-music-recommendation-challenge/

6.2 Experiments on toy datasets

For the three standard contextual-bandit problems, we use the cumulative regret as the evaluation metric. The cumulative regret is defined as the cumulative difference between the received reward and the reward of the optimal item.

For PGCR, we use the multi-layer perceptron (MLP) as the policy and value networks. The MLPs have one fully-connected hidden layer with 10 units and the ReLU activation. As for the training details, at each step, we sample a batch of 64 history samples for efficient experience replay. The loss is minimized by the gradient-based Adam optimizer [14].

We compare PGCR with the following algorithms:

- **ϵ-greedy**: It chooses the item with the largest estimated value with a probability of $1-\epsilon$ and chooses randomly otherwise. Specifically, it estimates the expected reward by a value network with the same structure of PGCR.
- **Lin-UCB**: The widely studied version of UCB for contextual bandits with linear rewards [1, 9, 17], which uses a linear function to approximate the reward, and chooses the item with the maximum sum of the estimated reward and the estimated confidence bound.
- **GLM-UCB**: The UCB method for generalized linear rewards, proposed in [10], which can solve non-linear rewards if the reward function can be fitted by a generalized linear model of contexts, such as Bernoulli rewards and Poisson rewards.
- **Thompson Sampling**: It samples from the posterior distribution of parameters, estimates each item's value, and chooses the item with the maximum estimation [4, 8]. Specifically, it uses the same function approximation as Lin-UCB or GLM-UCB for linear and non-linear rewards.

For Lin-UCB, GLM-UCB and Thompson Sampling, we use the same training procedures as suggested in [17]. For ϵ-greedy, ϵ is set as a constant value, e.g. 0.1 or 0.3.

For each method, in order to reduce the randomness of experiments, we run the simulation for 20 times and report their averaged cumulative regrets. The results are shown in Figure 1.

From Figure 1(a), (b) and (c), it sees that PGCR converges more quickly and has lower regrets in most cases. For the linear bandits, Lin-UCB is, theoretically, one of the best choice if the linearity is known. Even though PGCR does not know the form of reward function apriori, the performance is comparable with Lin-UCB. Thompson Sampling converges slower and ϵ-greedy obviously fails to converge. For the generalized linear case, PGCR achieves much lower regret than other baselines. For the mixed reward case, we see that PGCR learns faster than GLM-UCB and empirically converges after a long run.

We further did an ablation study to test the improvements induced by the proposed heuristic, Actor-Dropout. See Figure 1(d) for the comparisons. It shows that Actor-Dropout significantly helps PGCR to converge. The growth rate of cumulative regret for PGCR without Actor-Dropout is similar to ϵ-greedy, indicating that the original algorithm fails to converge and has linear regrets. But when equipped with Actor-Dropout, the regrets are smaller. When the dropout rate is set to 0.67, the growth rate of PGCR's regret is similar to that of GLM-UCB which can theoretically achieve sub-linear regrets. So empirically we remark that Actor-Dropout is a strong weapon for PGCR in order to get a convergence guarantee, even with almost no assumptions on the problem.

6.3 Experiments on music recommendations

6.3.1 Simplified setting without explicit states. The experimental setup in the setting without states is as follows: PGCR uses MLPs as policy and value networks. Each MLP has two hidden layers of sizes 60 and 20 respectively and uses the ReLU nonlinearity. ϵ-greedy has exactly the same value network like the one in PGCR. All these methods are trained with Adam algorithm with the same learning rates. The batch-size is set as 256. We also test GLM-UCB here as another baseline because the reward is binary thus can be learned by a logistic regression model.

As is shown in Figure 2(a), PGCR performs the best. It is interesting to see that traditional contextual-bandits methods learn fast from the beginning, which indicates that they are good at exploration, but their average rewards stop increasing rapidly due to the limitation of the fitting power of general linear models. ϵ-greedy learns slowly at the early stage, but it outperforms GLM-UCB and TS after a long run. Comparing with these algorithms, PGCR has the best performance from the beginning to the end of the learning process.

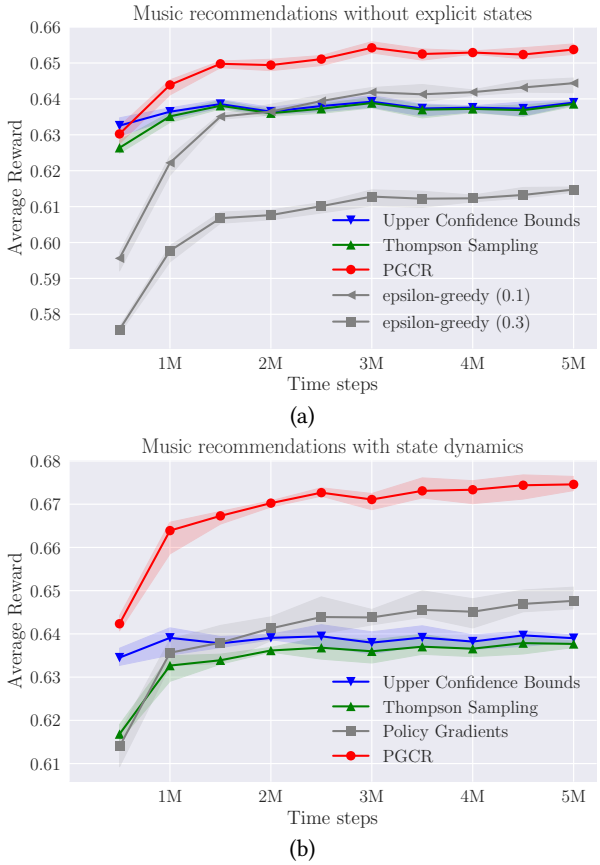

Figure 2: Average rewards of episodes for (a) music recommender without explicit states; (b) music recommender with states and state transitions. The solid lines are averaged from 5 runs, and the shaded areas are standard deviations.

6.3.2 Simulation with states and transitions. The experimental setup for this experiment with states is as follows. We enlarge the size of the first hidden layer of the MLPs from 60 to 90 because there are more inputs (including the contexts and the states). UCB and TS here take the augmented contexts as input. They keep the same general linear modeled priors as the previous part.

The result of the experiment is shown in figure 2(b). PGCR outperforms other algorithms with larger map comparing with the previous experiment. An interesting fact is that both UCB and TS

can only get almost the same return as in the previous experiment, which indicates that they can hardly make any use of the information from the states. PGCR learns faster and gets state-of-the-art performance in this task.

Since there are states and transitions, we also test the vanilla Policy Gradient method [25] as another baseline, with the same MLP neural networks as actor and critic as PGCR. From the result, it shows that vanilla PG can outperform classic bandits methods, which is not surprising because it can make use of the state dynamics and maximize the long-term return. However, it is still much worse than our purposed PGCR, for the reason that PGCR has a smaller search space and smaller variance when estimating the policy gradients. So the experimental results verified that PGCR is more sample efficient than the vanilla policy gradient method.

These simulation experiment results indicate that PGCR provides an alternative to conventional methods by using stochastic policies which can address the trade-off between exploration and exploitation well. The fast learning in the beginning phase and the stable performance over the entire training period of PGCR show that it is reliable to apply for real-world recommender systems.

7 CONCLUSION AND DISCUSSION

This paper has studied how to use the actor-critic algorithm with neural networks for general contextual recommendations, without unrealistic assumptions or prior knowledge to the problem. We first show that the class of permutation invariant policies is sufficient for this problem, and then derive the expected return of a policy which depends on its marginal expected probability of choosing each item. We next propose a restricted class of policies in which the objective has a simple closed form and is differentiable to parameters. When using such policies, the gradient can be computed in closed-form. Furthermore, we propose Time-Dependent Greed and Actor-Dropout to improve the performance and to guarantee the convergence. Eventually, it comes to our proposed PGCR algorithm. It can be applied to standard contextual bandits as well as generalized sequential decision-making problems with state dynamics.

By testing on a toy dataset and a recommendation dataset, we showed that PGCR indeed achieves state-of-the-art performance for both classic one-step recommendations and MDP-CR with state transitions in a real-world scenario.

It is a promising direction to extend our results to a variant of realistic recommendation settings, i.e, online advertising systems that choose multiple items at each round, or learning-to-rank that carries out diverse recommendation.

ABSTRACT

User data is the primary input of digital advertising, fueling the free Internet as we know it. As a result, web companies invest a lot in elaborate tracking mechanisms to acquire user data that can sell to data markets and advertisers. However, with same-origin policy and cookies as a primary identification mechanism on the web, each tracker knows the same user with a different ID. To mitigate this, Cookie Synchronization (CSync) came to the rescue, facilitating an information sharing channel between 3rd-parties that may or not have direct access to the website the user visits. In the background, with CSync, they merge user data they own, but also reconstruct a user's browsing history, bypassing the same origin policy.

In this paper, we perform a first to our knowledge in-depth study of CSync in the wild, using a year-long weblog from 850 real mobile users. Through our study, we aim to understand the characteristics of the CSync protocol and the impact it has on web users' privacy. For this, we design and implement CONRAD, a holistic mechanism to detect CSync events at real time, and the privacy loss on the user side, even when the synced IDs are obfuscated. Using CONRAD, we find that 97% of the regular web users are exposed to CSync: most of them within the first week of their browsing, and the median userID gets leaked, on average, to 3.5 different domains. Finally, we see that CSync increases the number of domains that track the user by a factor of 6.75.

1 INTRODUCTION

In the online era, where behavioural advertising fuels the majority of Internet, user privacy has become a commodity that is being bought and sold in a complex, and often ad-hoc, data ecosystem [17, 24, 35, 38]. Users' personal data collected by IT companies constitute a valuable asset, whose quality and quantity significantly affect each company's overall market value [40]. As a consequence, it is of no doubt that in order to gain advantage over their competitors, web companies such as advertisers and trackers participate in a user data collecting spree, aiming to retrieve as much information as possible and form user profiles. These detailed profiles contain personal data [12] such as interests, preferences, personal identifying information, geolocations, etc. [5, 31, 44], and could be sold to 3rd-parties for advertising or other purposes beyond the control of the user [30, 36, 37].

Highlighting the importance of this data collection, web companies have invested a lot in elaborate user tracking mechanisms. The most traditional one includes the use of cookies: they have been commonly used in the Web to save and maintain some kind of state on the web client's side. This state has been used as an identifier to authenticate users across different sessions and domains. Initially, *1st-party* cookies were used to track users when they repeatedly visited the same site, and later, *3rd-party* cookies were invented to track users when they move from one website to another. The same-origin policy (SOP) was invented a few years later [45] to restrict the potential amount of information trackers can collect about a user and share with other 3rd-party platforms.

To overcome this restriction, and create unified identifiers for each user, the ad-industry invented the Cookie Synchronization (CSync) process [19]: a mechanism that can practically "circumvent" the same-origin policy, and allow web companies to share (synchronize) cookies, and match the different IDs they assign for the same user while they browse the web. Sadly, recent results show that most of the 3rd-parties are involved in CSync: 157 of top 200 websites (i.e. 78%) have 3rd-parties which synchronize cookies with at least one other party, and they can reconstruct 62-73% of a user's browsing history [11]. Furthermore, 95% of pages visited contain 3rd-party requests to potential trackers and 78% attempt to transfer unsafe data [46]. Finally, a mechanism for respawing cookies has been identified, with consequences in the reconstruction of users' browsing history, even if they delete their cookies [1].

Although past works highlight the use of CSync across the most popular sites worldwide, they avoid diving into the details and fail to thoroughly explore this increasingly popular technique. In fact, the majority of related works perform their analysis using crawled data by fetching the top Alexa websites. Consequently, little is known on how CSync works in the wild, how many of real users' cookies are getting synced during their everyday browsing,

and to what extend it affects the end users' privacy. Importantly, existing studies focus solely on desktop web; however, today more than 52.2% of all web traffic is generated through mobile phones (up from 50.3% in the previous year [42]). This traffic points to a whole new, unexplored ecosystem of mobile Web, where users browse through their very personal devices, while employing a variety of sensors to experience a highly personalized content, but always at the expense of privacy. Thus, what is the impact of CSync in this new mobile ecosystem? *Which are the basic characteristics of CSync, and the mechanics used? How does CSync impact the user's privacy and anonymity on the mobile web?*

In this paper, we aim to answer these questions, by studying Cookie Synchronization using a large, year-long dataset of 850 real mobile users, and exploring in depth its use and growth through time, dominant companies, along with its side-effects on user privacy. The contributions of this work are as follows:

- We design and implement CONRAD: (COokie syNchRonizAtion Detector) a holistic mechanism to detect at real time CSync events and the privacy loss on the user side, even when synced IDs are concealed or obfuscated by participating companies aiming to reduce identifiability from traditional, heuristic-based detection algorithms. In such cases, when non-ID related features are used, our approach achieves high accuracy (84%-90%) and AUC (0.89-0.97).
- We perform the first of its kind, large-scale, longitudinal study of Cookie Synchronization on mobile users in the wild. We perform a passive data collection of the activity of 850 volunteering mobile users, lasting an entire year. This means that the data collected are not crawled, like in past studies, and therefore do not capture a distorted or biased picture of CSync on the Web. Instead, these data provide a rare glimpse of CSync in the mobile space, and an opportunity to study CSync and its impact on real mobile users' privacy and anonymity.
- Using the proposed detection mechanism, we conduct an in-depth privacy analysis of CSync. Our results show that 97% of regular web users are exposed to CSync. In addition, the average user receives ~1 synchronization per 68 HTTP requests, and the median userID gets leaked, on average, to 3.5 different domains. Furthermore, CSync increases the number of domains that track the user by a factor of 6.75. Finally, we detect CSync involved in different scenarios such as breaking-off an SSL session, and exposing userIDs and other personal data in cleartext.

2 COOKIE SYNCHRONIZATION

2.1 How does Cookie Synchronization work?

Figure 1 presents a simple example to understand in practice what is CSync and how it works. Let us assume a user browsing several domains like `website1.com` and `website2.com`, in which there are 3rd-parties like `tracker.com` and `advertiser.com`, respectively. Consequently, these two 3rd-parties have the chance to set their own cookies on the user's browser, in order to re-identify the user in the future. Hence, tracker.com knows the user with the ID `user123`, and advertiser.com knows the same user with the ID `userABC`. Now let us assume that the user lands on a website (say `website3.com`), which includes some JavaScript code from

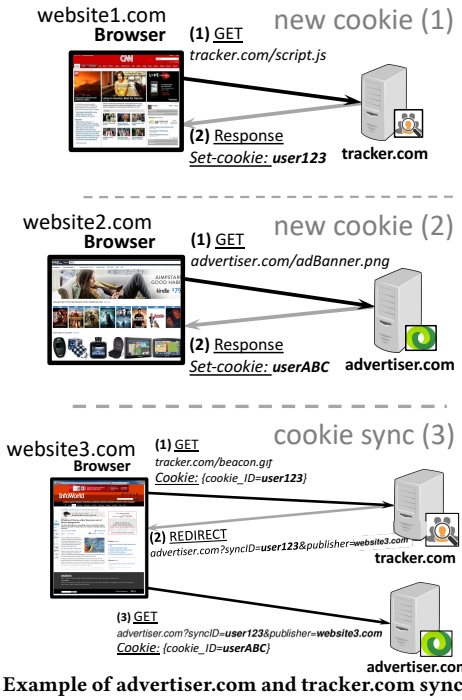

Figure 1: Example of advertiser.com and tracker.com synchronizing their cookieIDs. Interestingly, and without having any code in website3, advertiser.com learns that: (i) cookieIDs userABC==user123 and (ii) userABC has just visited the given website. Finally, both domains can conduct server-to-server user data merges.

tracker.com but not from advertiser.com. Thus, advertiser.com **does not (and cannot) know which users visit website3.com**. However, as soon as the code of tracker.com is called, a GET request is issued by the browser to tracker.com (step 1), and it responds back with a REDIRECT request (step 2), instructing the user's browser to issue another GET request to its collaborator advertiser.com this time, using a specifically crafted URL (step 3):

GET *advertiser.com?syncID=**user123**&publisher=**website3.com***
Cookie: {cookie_ID=**userABC**}

When advertiser.com receives the above request along with the cookie ID `userABC`, it finds out that `userABC` visited website3.com. To make matters worse, advertiser.com also learns that the user whom tracker.com knows as `user123`, and the user `userABC` is basically one and the same user. Effectively, CSync enabled advertiser.com to collaborate with tracker.com, in order to: (i) find out which users visit website3.com, and (ii) synchronize (i.e., join) two different identities (cookies) of the same user on the web.

2.2 Cookie Synchronization, Personalized Advertising & Privacy Implications

Digital advertising has moved towards a more personalized model, where ad-slots are purchased programmatically (e.g., Real Time Bidding (RTB) based auctions) in auctions, based on how well the profile of the visitor matches the advertised product. Consequently, advertisers need to obtain user data (e.g., interests, behavioral patterns) to use as input in their sophisticated decision engines. The core component for this data purchasing/sharing includes CSync [16].

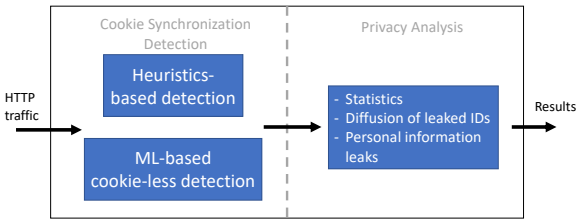

Figure 2: High-level overview of CONRAD's internal components.

It allows trackers and advertisers to perform common user identification and by participating in data markets enrich their knowledge base with user information from several data sources.

There are several privacy implications for the online users who access websites planted with such sophisticated tracking technologies. Using CSync, in practice, advertiser.com learns that: (i) what it knew as `userABC` is also `user123`, and (ii) this user has just visited website3.com. This enables advertiser.com to track a user to a much larger number of websites than was initially thought. Indeed, by collaborating with several trackers, advertiser.com is able to track users across a wide spectrum of websites, even if those websites do not have any collaboration with advertiser.com.

To make matters worse, the ill effects of CSync may reach way back in the past - even up to the time before the invention of CSync. Assume, for example, that someone manages to get access to all data collected by tracker.com, and all the data collected by advertiser.com (e.g., by acquisition [30, 36], merging or hacking of companies [22]). In the absence of CSync, in those two datasets, our user has two different names: `user123` and `userABC`. However, after one single CSync, those two different names can be joined into a single user profile, effectively merging all data in the two datasets. Nowadays, such cases of *server-to-server user data merges* are taking place at a massive scale [11], with the different web companies conducting mutual agreements for data exchanges or purchases, in order to enrich the quality and quantity of their user data warehouses [6, 30].

As if these threats to user privacy were not enough, CSync can rob users of the right to erase their cookies. Indeed, when coupled with other tracking technologies (i.e. evercookie [39], or user fingerprinting [9]), CSync may re-identify web users even after they delete their cookies. Specifically, when a user erases her browser state and restarts browsing, trackers usually place and sync a new set of userIDs, and eventually reconstruct a new browsing history. But if one of them manages to respawn [1] its cookie (e.g. through evercookie [39]), then through CSync, all of them can link the user's browsing histories from before and after her state erasure. Consequently: (i) users are not able to abolish their assigned userIDs even after carefully erasing their set cookies, and (ii) trackers are enabled to link user's history across state resets.

3 COOKIE SYNCHRONIZATION DETECTION

In this paper, we design CONRAD, a holistic methodology to detect CSync events in real time, on the user side. CONRAD monitors the HTTP(S) traffic of the user on the browser level and detects userIDs when shared from one domain to the other. To achieve that, it uses a (i) Heuristics-based (stateful) detection mechanism (Section 3.1), where the IDs from cookies are tainted and alert is raised when they are exfiltrated to a domain other than the owner

Table 1: Examples of userIDs synchronized among various domains.

URLs of Cookie Synchronization HTTP Requests
1. a.atemda.com/id/csync?s=**L2zaWQvMS9lkLzMxOUwOTUw**
2. bidtheater.com/UserMatch.ashx?bidderid=23& bidderuid=**L2zaWQvMS9lkLzMxOUwOTUw**&expiration=1426598931
3. d.turn.com/r/id/**L2zaWQvMS9lkLzMxOUwOTUw**/mpid/

of the cookie. However, as also presented in past studies [2], more and more companies include encryption (or cryptographic hashing) in the CSync-related APIs, thus concealing the synced IDs. To deal with these cases, CONRAD uses a (ii) ML-based (stateless) detection mechanism (Section 3.2) capable of classifying with high accuracy such possible concealed synchronizations, without relying on any previously stored cookie IDs, but only using characteristics from the connections themselves. Figure 2, provides a high level overview of CONRAD's internal components.

For each CSync detection method, CONRAD extracts its information flow: the chain of domains that share the synced ID, the domain that triggered the CSync event, the domains that (without having access to the website) used this sync request to set and sync their own userIDs (see Section 5.1). This way, our tool is able to measure the diffusion of anonymity loss for the given user by analysing what number of their overall userIDs budget got synced, and to how many 3rd-party domains. In addition, by using a simple pattern matching technique, CONRAD extracts possible personal information leaks tailored with the synced ID (see Section 5.5).

Although there are several existing techniques for detecting ID-sharing events even when cookies are encrypted, accurate CSync detection in real time is a hard task. The main advantages of our approach, contrary to existing detection mechanisms [1, 2, 11] are as follows: (i) It offers the ability to detect synchronizations when the userID is embedded not only in the URL's parameter, but also in its path (either in case of request/response URL or Location URL of the referrer). (ii) By filtering-out domains of the same provider, our approach can discriminate between intentional CSync and unequivocally legitimate cases of internal ID sharing, thus avoiding false positives. (iii) It is capable of detecting Cookie Synchronization *at real time*, even when shared IDs are encrypted.

3.1 Heuristics-based detection

Technically, as we see in Table 1, CSync is nothing more than a request from the user's browser to a 3rd-party domain carrying (at least one) parameter that constitutes a unique ID set by the calling domain. However, what CSync typically enables is a multiple, back-to-back operation with several 3rd-party domains getting updated with one particular ID. This multiple synchronization happens by utilizing URLs of HTTP requests (i.e., the Location HTTP header), in which the cookie ID (i.e., the userID) of the triggering domain is embedded. The userID may be embedded in the: (i) parameters of the URL, (ii) URL path, or (iii) referrer field. In some cases, detection may be straightforward: one can simply look for specific parameter names (e.g., syncid, user_id, uuid). However, different companies use different APIs and parameter naming; relying only on string matching for Cookie Synchronization detection will lead to a large number of false negatives in case of newcomer syncing domains. To remedy this, by extending previous work [29], we design a stateful heuristics-based detection algorithm, which relies on the previously set cookies to taint userIDs that may get synced with

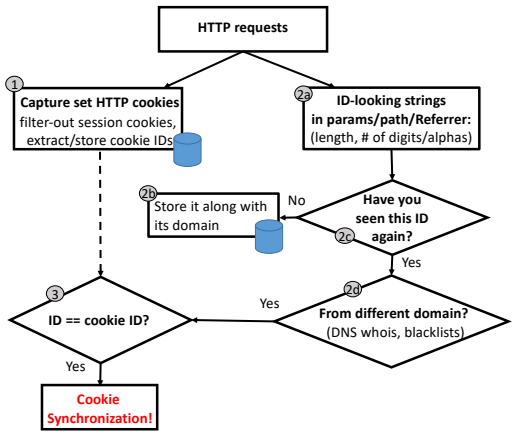

Figure 3: Heuristics-based CSync detection mechanism.

domains different than the cookie setter[1]. In particular, our Cookie Synchronization detection methodology includes the following steps, which are also illustrated in Figure 3:

(1) We extract all cookies set on the user's browser. To accomplish that, we parse all HTTP requests in our dataset and extract all *Set-Cookie* requests.
   (a) We filter out all session cookies. These are cookies without expiration date, that get deleted after the end of a session.
   (b) We parse the cookie value strings using common delimiters (i.e. ":", "&"). By extracting potentially identifying strings (cookie IDs), we create a list with the cookie IDs that could uniquely identify the user in the future.
(2) We detect possible ID-sharing events in the HTTP requests:
   (a) We identify ID-looking strings that are unique per user, carried either (i) as parameters in the URL, (ii) in URL path, or (iii) in the referrer field. As ID-looking strings, we define strings with specific length (> 10 characters) – false positives do not matter at this point.
   (b) If this ID is seen for the first time, it is stored in a hashtable along with the URL's domain (receiver of the ID).
   (c) If this ID has already been seen, we consider it as a shared ID and the requests carrying it as *ID-sharing requests*.
   (d) To check if the above ID-sharing requests regard different domains, we use several external sources (DNS whois, blacklists etc.) to filter-out cases where the IDs are shared among domains owned by the same provider (e.g., amazon.com and amazonaws.com) [25]. This way, our approach can discriminate between intentional ID leaking and legitimate cases of internal ID-sharing, thus avoiding false positives.
(3) Finally, to verify if the detected shared ID is a userID able to uniquely identify a user, we search this ID within the list of cookie IDs extracted in the first step. If there is a match, then we consider this request as CSync.

[1]A known limitation of this approach is its inability of capturing a small portion of 1st-party cookies set by javascript[7]

Table 2: Examples of Cookie Synchronization between 3rd-parties with plaintext and encrypted cookie IDs.

ID syncs beyond the 1-1 of source domain (plaintext):
Domain syncs ID with Tracker1 ID1; → ID1=ID;
Domain syncs ID with Tracker2 ID2; → ID2=ID;
Tracker1 syncs ID1 with Tracker2 ID2; → ID2=ID1=ID;
ID syncs beyond the 1-1 of source domain (encrypted):
Domain syncs h(ID,A) with Tracker1 ID1; → ID1=h(ID,A);
Domain syncs h(ID,B) with Tracker2 ID2; → ID2=h(ID,B);
Tracker1 syncs ID1 with Tracker2 ID2; → h(ID,A)!=h(ID,B), i.e., ID1!=ID2;

3.2 Cookie-less detection

It is apparent that in order for the above methodology to be a viable CSync detection method, cookie IDs need to be shared in plaintext. However, major web companies such as DoubleClick [19] have started encrypting the cookie ID in an attempt to protect the actual cookie from being revealed to unwanted parties that may snoop the user's traffic (plugins or even ISPs).

While the former case is obvious why companies would want to block such snooping, the latter case may not be clear why and, thus, we discuss this case further. In particular, under the traditional, plaintext case of cookie ID syncing, the same source company can sync independently with multiple 3rd-parties for the same user cookie ID. Thus, no-one forbids these other 3rd-parties from syncing their IDs with each other, and find out that they have information about the same user, something that goes beyond what the source company intended to do (top example of Table 2). With hashing or encryption of the cookie ID, these 3rd-parties are unable to do this syncing (bottom example of Table 2). As a consequence of this encryption, CSync events can proceed undetected, if the previously used detection method is employed.

To address this scenario, in this paper, we propose a novel method for identifying CSync which is oblivious to the IDs shared. This mechanism is able to identify with high accuracy CSync events in web traffic, even when the leaked IDs are protected and cannot be matched. To build this mechanism, we employ machine learning methods, which we train on the ground truth datasets created with the previous, heuristic-based technique. In particular, we analyze various features extracted from the web traffic due to CSync, and train a machine learning classifier to automatically classify a new HTTP connection as being a CSync event or not. Here, we make the assumption that the various features used to characterize, and eventually detect, CSync with plaintext IDs, are equally used, and have the same distributions and variability as in the CSync with encrypted IDs. We believe this is a reasonable assumption, since the companies employing encrypted IDs are not expected to change the rest of their mechanism which delivers these IDs and triggers CSync with their partners; these companies only want to obfuscate the IDs to avoid further, and unwanted, CSync.

For training the classifier, we extract various relevant features from the network traces. As ground truth, we use confirmed CSync events which were detected with the heuristics-based method described earlier. Beyond these confirmed events, there are *id-sharing* events which were first selected by the method as potential CSync events, but eventually were rejected as *non-CSync*, as they did not match cookie IDs already seen by the method (step 1 in Figure 3).

The features available for these network events can be several; we constrain the learning algorithm to use only features available at run time, and during the user's browsing to various websites:

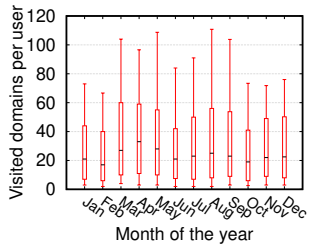

Figure 4: Distribution of number of unique domains visited per user, per month. The median user in our dataset visits 20 - 30 different domains per month.

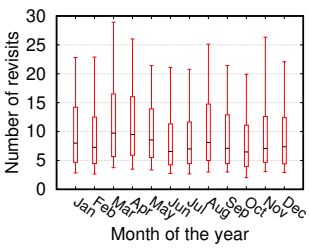

Figure 5: Distribution of number of times a user revisits the same domain per month. The median user revisits a domain around 7-10 times per month.

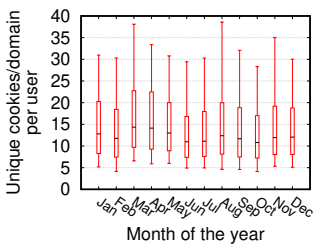

Figure 6: Number of (first and 3rd-party) cookies per domain per user. We see that the median user receives 12.25 cookies, on average, per visited website.

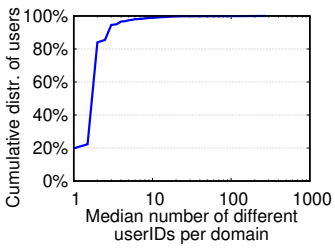

Figure 7: Unique userIDs set per domain, across the year. 80% of users are known to a single domain with only ~2 aliases, on average.

Table 3: Summary of contents in our dataset.

Description	#	Description	#
Total mobile users	850	Unique shared IDs (S)	68215
Requests captured	179M	Unique userIDs synced ($C \cap S$)	22329
Unique Cookies (C)	8.97M	CSync requests	263635
ID sharing requests	412805		

- EntityName: {domain of recipient company}
- TypeOfEntity: {Content, Social, Advertising, Analytics, Other}
- ParamName: {aid, u, guidm, subuid, tuid, etc.}
- WhereFound: {parameter in URL, parameter in Referrer, in the URL path}
- StatusCode: {200, 201, 202, 204, etc.}
- Browser: {Firefox, Chrome, Internet Explorer, etc.}
- NoOfParams: {0, 1, 2, ..., etc.}

Various machine learning algorithms can be applied: Random Forest, Support Vector Machines, Naive Bayes, and even more advanced methods such as Neural Networks. However, a balance must be found between training the given algorithm to reach a good accuracy, the computation cost for this training, as well as the capability of the algorithm to be used at real time on the user device.

This method aims to address two possible scenarios that can arise while IDs are being shared: First, we consider the realistic scenario that an already identified set of id-sharings are candidate CSync events (as found by the heuristics-based method), but cannot be validated as CSyncs because of the cookie ID being encrypted or unavailable, and therefore not matching the repository of IDs. Second, we consider the scenario where various HTTP connections are ingested by the method, and it needs to decide at run-time which are CSync events and which are not. This case is a more generalized version of the previous scenario, and attempts to detect CSync events, as an alternative method to the heuristic-based approach. In either of the two cases, we follow a generally accepted methodology (e.g., [34]) that separates training such a machine learning model, from applying it at real-time. The training can be performed offline, on an existing dataset (e.g., the one we collected, or from anonymous user network traffic donations), and the model trained can be distributed accordingly with the tool at hand. Then, the tool can apply the classifier on each network connection under question, for real-time classification.

4 DATASET

In this section, we describe the data collection process and our year long dataset. In order to collect data from real users, we set a group of proxies fronted by a load balancer, and gathered 850 volunteering users residing in the same country. These users agreed to strip their browsers from any previous state (i.e., cookies, cache, webStorage) and have their devices to continuously redirect their network traffic through our proxies for 12 consecutive months (2015-2016). They signed a consent form allowing us to collect and analyze their data during this period, and publish any anonymized results. They were well-aware of the purposes of the data collection, and were compensated with free data plan, as long as they were using the proxies. Before the analysis was performed, all data were anonymized and never shared with any other domains.

Given the long duration of the experiment, and in order not to jeopardize the confidentiality of the volunteering users' secure sessions, we capture only their HTTP mobile traffic (same method can be applied for HTTPS). On the server-side and based on the user agent of each request, we filtered out any possible app-related traffic. Overall, we collected a dataset containing a total of 179M requests, spanning an entire year. Table 3 summarizes the contents and CSync findings in our dataset.

Users: To analyse our dataset, we create a simple weblog parser. As noted earlier, this dataset consists of web browser traffic from the mobile devices of 850 users. After separating the flows of each one of them, we produced their timelines, and in Figure 4, we present the number of different domains each user visits per month. As we see from the distribution (Percentiles: 10th, 25th, 50th, 75th, 90th), the median user in our dataset visits 20-30 different domains depending on the month (we observe a seasonal phenomenon with increases during spring break and summer holidays).

Similarly, in Figure 5, we present the number of times each of these domains gets revisited by the median user in our dataset. In every revisit, there is a new request that asks the user's browser if there is a previously set cookie. If this *Get-Cookie* request regards a previously set cookie, this means that the domain already knows the user and we consider it as a revisit. We observe that the median user revisits around 7-10 times the same domain from their mobile browser. Again, we observe the seasonal phenomenon as earlier, when users tend to have more time to browse the web. Also, the 75th percentile of the users may revisit the same website more than 15 times (March, August).

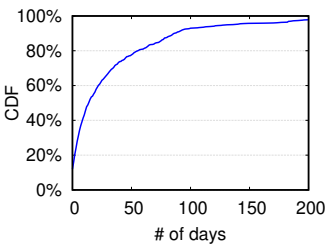

Figure 8: Distribution of time taken for first CSync to appear per user. 20% of users get their first userID synced in 1 day or less.

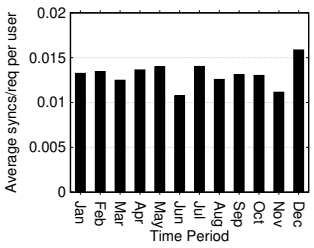

Figure 9: CSyncs per request for the average user across the year. The average user receives 1 synchronization every 68 requests.

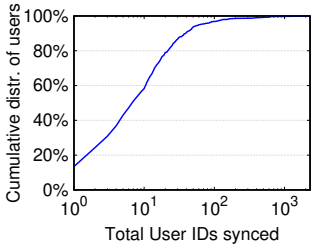

Figure 10: Distribution of the synced userIDs per user. The median user has 7 userIDs synced, when 3% of users has up to 100.

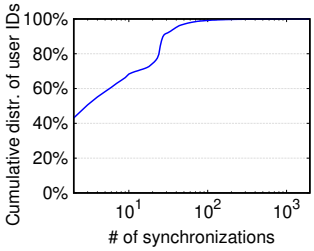

Figure 11: Distribution of synchronizations per userID. The median userID gets synced with 3.5 different domains.

Table 4: Breakdown of the CSync triggering factors.

	Initiator	Portion
(i)	Publisher syncs its userID	2.692%
(ii)	Embedded 3rd-party triggers syncing of its own set userID	49.668%
(iii)	3rd-party uses sync request to share its own set userID	45.697%
(iv)	3rd-party uses sync request to share with other domains the publisher's set userID	0.2658%

Cookies: To have a good view of the cookie activity of users, we extract all (1st & 3rd-party) cookies set in users' browsers across the year, and in Figure 6, we plot the distribution of number of cookies per visited website. The median user receives a fairly constant number of 12.25 cookies per visited website per month, on average.

Next, we extract the unique identifiers (i.e., cookie ID) set in these cookies. A cookie ID constitutes a unique string of characters that websites and servers associate with the browser and, thus, the user who stored the cookie. Thereby, here, we consider a cookie ID as a unique user identifier called userID. As it can be seen in Table 3, in our dataset, there are almost 9 million such unique IDs.

In Figure 7, we plot the distribution of the number of unique userIDs assigned to the users per domain. The vast majority of the users (80%) receive, on average, only 2.2 userIDs per domain, across the year. This means that users tend not to erase their cookies frequently, thus, allowing web domains to accurately identify them through time and during the users' browsing. Only 1.13% of users erase their cookies (either manually or by browsing with Private/Incognito Browsing), receiving more than 9.5 different userIDs per domain, on average. This means that it is very rare for a domain to meet a previously known user with a different alias.

5 PRIVACY ANALYSIS

By applying CONRAD in our dataset, we find several IDs passed from one domain to another. We detect 68215 such unique shared IDs. From these IDs, 22329 were actually cookie IDs from previously set cookies that were synced among different domains. In total, these cookie IDs were found in 263635 synchronization events (see Table 3 for a summary). From the CSyncs detected in our dataset, userIDs were found in 91.996% of the cases inside the URL parameters, 3.705% in the Referrer URL, and in 3.771% of the cases in the URL path. Thus, CONRAD was able to detect 3.771% more cases of CSyncs than existing detection methods [1, 29, 32].

5.1 Initiation of Cookie Synchronization

First, we correlate the cookie domain (the setter), the synchronizing request's Referrer field, and the publisher that the user visited, in order to extract the domain that triggered the CSync on the user's browser. As seen in Table 4, there are 4 distinct cases: (i) the CSync was initiated by the publisher who syncs the userID he assigned for the user: we find 2.692% of these cases in our dataset, (ii) the synchronization was initiated from a publisher's iframe, by the guest 3rd-party which syncs its own userID (49.668%), (iii) a 3rd-party which participated in a previous synchronization (case (i) or (ii) above) and uses the sync request to share its own userID (45.697%). Lastly, there is a rare case (iv), where a 3rd-party participating in a previous synchronization of the publisher's userID (case (i)) initiates a new round of syncs while it continues to share the publisher's userID (0.2658%). Obviously, in case (iv), the initiating 3rd-party shares with its 3rd-party affiliates, a userID assigned by a domain (the publisher) beyond its control, and possibly awareness.[2]

5.2 How are users exposed to CSync?

CSync impacts users' privacy by leaking assigned userIDs, and sharing them with 3rd-parties. In our dataset, we see that for users with regular activity on the web (> 10 requests per day), **97% were exposed to CSync at least once**. This means that CSync constitutes a phenomenon affecting the totality of online users. Next, we study how long it takes for the first synchronization to happen, or in effect, how quickly a user gets exposed to CSync after she starts browsing. Recall that as mentioned in Section 4, all participating users, during bootstrapping phase, had all state from their browsers erased. This means that our proxy was able to capture the very first cookie that was set during the user's monitoring period. Of course, the time depends on the browsing patterns of each user, however, as we see in Figure 8, a median user experiences at least one CSync within the first week of browsing. In fact, a significant **20% of users get their first userIDs synced in 1 day or less**. It is worth noting that users tend to browse the same top websites repeatedly (e.g., facebook.com, twitter.com, cnn.com), so the set cookies are already shared and no sync is fired.

Next, we investigate if the synchronizations the users are exposed to, change over time. Hence, we extract CSyncs per user, and normalize with the user's total number of requests. In Figure 9, we plot the average synchronizations per request across the year. As

[2]We reported all such cases and notified the respected publishers.

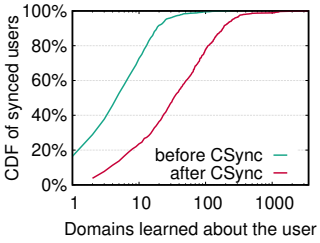

Figure 12: Distribution of domains learning at least a userID of a user (with/without the effect of CSync). After syncing, the domains that learned about the median user grew by 6.75×.

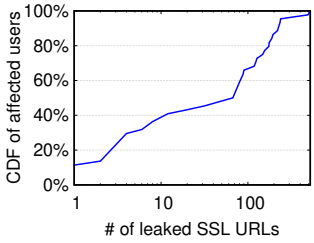

Figure 13: Distribution of the leaked TLS URLs per affected user. The median user has 70 TLS URLs leaked through Cookie Synchronization, when the 90th percentile has up to 226 TLS URLs leaked.

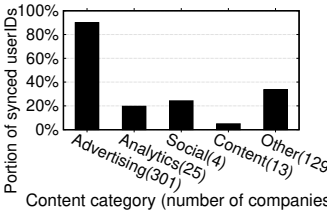

Figure 14: Portion of synced userIDs learned per content category. As expected, ad-related companies learned the vast majority (90%) of the total synced userIDs in our dataset.

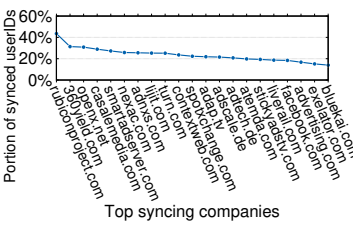

Figure 15: Portion of synced userIDs learned per tracker: 3 trackers learn more than 30% of the total userIDs in our dataset; 14 trackers learn more than 20% of userIDs each.

shown, CSync is persistent through the duration of an entire year, with the user being exposed to a steady number of synchronizations across time. Specifically, we see that **the average user receives around 1 synchronization per 68 requests**.

Considering the different userIDs that trackers may assign to a user, in Figure 10, we measure the number of unique userIDs that got synced per user. Evidently, **a median user gets up to 6.5 userIDs synced**, and 3% of users has up to 100 userIDs synced. It becomes apparent that the IDs of a user may leak to multiple 3rd-party domains through CSync. To measure the userID leak diffusion, in Figure 11, we plot the distribution of synchronizing requests per userID. As we see, **the median userID gets leaked, on average, to 3.5 different domains**. There is also a significant 14% that gets leaked to up to 28 different 3rd-parties.

To better understand the effect of CSync on the diffusion of the overall user privacy, we measure for each user the number of domains that learned about them (i.e., learned at least one of their userID) before and after CSyncs. From the distribution in Figure 12, **the domains that learned about the median user after CSyncs grew by a factor of 6.75**, and for 22% of users this factor becomes > 10. This means that before the rise of CSync, when the user visited a website, the domains that could track them were only the publisher and the included 3rd-parties, but in an independent fashion. However, with the introduction of CSync, the number of domains that can track the user drastically increased (6.75x for median user), severely decreasing their online anonymity.

Table 5: Example of an *ID Summary* stored on the user's browser. It includes userIDs and expiration dates used for the particular user by 4 different domains.

ID Summary stored in cookie by adap.tv
"key=**valueclickinc**:value=708b532c-5128-4b00-a4f2-2b1fac03de81:expiresat=wed apr 01 15:03:42 pdt 2015,key=**mediamathinc**:value=60e05435-9357-4b00-8135-273a46820ef2:expiresat=thu mar 19 01:09:47 pst 2015,key=**turn**:value=2684830505759170345:expiresat=fri mar 06 16:43:34 pst 2015,key=**rocketfuelinc**:value=639511149771413484:expiresat=sun mar 29 15:43:36 pst 2015"

5.3 Buy 1 - Get 4 for free: ID bundling and Universal IDs

We find **63 cases of domains which set on the users' browsers cookies with userIDs previously set by other domains**. For example, we see the popular `baidu.com`, the world's eighth-largest Internet company by revenue, storing a cookie with an ID *baiduid* = {*idA*}, and more than 5 different domains after this incident setting their own cookie using the same ID *baiduid* = {*idA*}. This by-product of CSync, enables trackers to use *universal IDs*, thus, bluntly violating the same-origin policy and merging directly (without background matching) the data they own about particular users.

In addition, we find **131 cases of domains storing in cookies the results of their CSyncs, thus composing *ID Summaries***. In these summaries, we see the userIDs that other domains use for the particular user previously obtained by CSyncs. An example of such summaries in JSON is shown in Table 5. As one can see, the cookie set by `adap.tv` includes the userIDs and cookie expiration dates of `valueclick.com`, `mediamath.com`, `turn.com` and `rocketfuel.com`. In our dataset, we find at least 3 such companies providing *ID Summaries* to other collaborating domains. This user-side info allows (i) the synchronizing domains to learn more userIDs through a single synchronization request, and (ii) `adap.tv` to re-spawn any deleted or expired cookies of the participating domains at any time, just by launching another CSync.

5.4 Spilling userIDs out of TLS

It is well-known that mixing encrypted and non encrypted sessions in TLS is a bad tactic [10]. Using TLS, everything except IPs and ports is encrypted [15] in a HTTP connection. As a result, although there are sophisticated estimation techniques [18], no observer can monitor what the user is actually browsing over TLS, or the IDs assigned to her. Given that our proxy is monitoring only HTTP traffic (see Section 4), one would expect that no information from secure TLS sessions would be captured. To our surprise, and as already found in [33], in our dataset we see userIDs that originated from TLS sessions getting leaked over plain HTTP to plain 3rd parties. As a result, *any curious, in-path observer (e.g., a snooping ISP) can eavesdrop the leaked userIDs*[3]. To make matters worse, we see

[3]As soon as we verified this leak, we notified publishers and also our volunteering users who updated their signed consent.

Table 6: Example of ID-spill from SSL in our dataset.

Role	Domain
Visited website:	https://financialexpress.com
Cookie setter: SetCookie:	https://tapad.com **D0821FA0-8A80-4D9E-BC85-C40EAC4E4FF5**
Cookie syncer:	http://delivery.swid.switchadhub.com/adserver/user_sync.php?SWID=cf43265166a9ccf5f6fd0472f23776fa&sKey=PM2&sVal=**D0821FA0-8A80-4D9E-BC85-C40EAC4E4FF5** referrer: **financialexpress.com** Get-cookie: {cf43265166a9ccf5f6fd0472f23776fa}
Cookie syncer:	http://tags.bluekai.com/site/3096?id=**D0821FA0-8A80-4D9E-BC85-C40EAC4E4FF5** referrer: **financialexpress.com** Get-cookie: {c57b29d1-f8e2-11e7-ac1b-0242ac110005}

that the same ID leaking requests have referrer fields[4], which leak the particular webpage the user visited over TLS (e.g., the particular article of the news site she read), thus leaking her interests.

To reproduce this leak, we manually visit the TLS protected websites where ID-spilling was found and we see it is caused by CSync events that sync a userID from a TLS cookie with non-TLS 3rd parties. In Table 6, we present one such real case we observe. As shown, while visiting over TLS the page *https://financialexpress.com*, two CSyncs are performed: *https://tapad.com* advertiser shares with *http://switchadhub.com* and *http://bluekai.com* the ID it assigned to the user. This way, the latter two tracking domains sync their set-cookies with the one of *https://tapad.com*. However, by doing that over plain HTTP, the visited webpage gets leaked through the referrer field to a monitoring entity, even when users browse through proxies or VPN, or even Tor. In addition, this entity from now on can re-identify the user in the web, just by monitoring the userIDs of cookies in requests destined to *http://switchadhub.com* and *http://bluekai.com*, even if the user's IP address is frequently changed. Obviously, the more 3rd-parties were participating in the Cookie Synchronization, the easier it would be for the monitoring entity to capture HTTP requests loaded with these synced cookies and, thus, re-identify the user using a secure VPN.

We measured such cases in our dataset and found **44 users (5%) affected by the ID-spilling of CSync**. The majority of leaked domains regard popular content providers, where an eavesdropper from the referrer field, apart from the domain, can also see sensitive information. From Figure 13, the median (90th percentile) user has 70 (226) TLS URLs leaked through CSync.

5.5 Sensitive information leaked with userIDs

The websites a user browses can easily leak through the referrer field during a CSync. Moving beyond this type of basic leak, in our dataset we find several cases of privacy-sensitive information passed to the syncing domain regarding the particular user with the particular synced ID. By deploying a simple string matching script, we look for keywords (e.g., gender, age, name, etc.) and find:

- 13 syncs leaking the user's city level location
- 2 syncs leaking the user's registered phone number
- 10 syncs leaking the user's gender
- 9 syncs leaking the exact user's age
- 3 syncs leaking the user's full birth date
- 2 syncs leaking the user's first and last name
- 16 syncs leaking the user's email address
- 4 syncs leaking user login credentials: username/password

[4]There are specific directives [23] for Referrer field hiding when referring over TLS visited domains.

The above information constitutes not only a severe privacy threat for the user, but can also enables potential impersonation attacks.

5.6 Who are the dominant CSync players?

In order to assess the content that CSync parties provide, we extract all domains involved in CSync, and using EasyList, EasyPrivacy [14] and the blacklist of the Disconnect browser extension [8] (enriched with our additions after manual inspection), we categorize them according to the content delivered. This way, we create five categories of domains related with: (i) Advertising, (ii) Analytics, (iii) Social, (iv) 3rd-party content (e.g., CDNs, widgets, etc.), and (v) Other.

As we saw in Figure 11, the median userID gets shared with more than one domains. We find that **ad-related domains participate in more than 75% of the overall CSyncs through the year**. Consequently, as we can also observe in Figure 14, **ad-related domains have learned as much as 90% of all userIDs that got synced**, with Social and Analytics -related domains following with 24% and 20% respectively. In Figure 15, we plot the top 20 companies[5] that learned the biggest portion of the total userIDs through CSyncs in our dataset. Interestingly, the top 3 companies (i.e., rubiconproject.com, 360yield.com and openx.net) learned more than 30% of all userIDs in our dataset each. There is also a significant number (14) of companies that learn more than 20% of userIDs.

6 COOKIE-LESS DETECTION

In this section, we explore two different scenarios outlined in Section 3.2 regarding the detection of CSync via ID sharing, while such IDs may be obfuscated to remove the possibility of matching them with past IDs shared between entities. First, we explore the scenario where IDs have been shared, detected by the heuristic-based approach, but have not yet been confirmed as CSync events. That is, we consider an already identified set of id-sharings, which are candidate CSync events, but cannot be validated as CSyncs because of the cookie ID being encrypted or unavailable (Section 6.1). Second, we take a step back and consider the more general case where various HTTP connections are ingested by the method, and it needs to decide at run-time which are CSync events and which are not based on given features (Section 6.2).

Towards this end, we train and test the classifier in these two experiments. We remind the reader of the assumption made earlier: the distributions of the features describing the CSync events with unencrypted IDs, have the same variability in the cases of encrypted IDs, and therefore can be used for the detection of such cases. This assumption allows us to handle the problem as an out-of-sample estimation, leaving as future work the final validation with a set of ground-truth data of encrypted IDs that we also know their unencrypted versions.

Data and Features: Based on the ground truth data presented earlier with the heuristic-based technique, we have 412.8k *id-sharing* events, from which 263.6k are confirmed CSync, and 149.2k are identified as *non-CSync*. The features available for these events can be various, as already explained in 3.2. The ones we use are features available at run time, and during the user's browsing to websites.

[5]In a dataset with both HTTP and HTTPS traffic, market shares may differ since there are companies operating over SSL only (e.g., DoubleClick)

Table 7: Performance of decision tree model trained on different subsets of features available at runtime for classification, given already identified id-sharing entries, and 10 cross-fold validation.

Algorithms: The final machine learning classifier used is decision tree-based. Others like Random Forest, Support Vector Machines and Naive Bayes were tested, but the decision tree algorithm outperformed them, with significantly less computation and memory overhead. Indeed, more advanced methods can be used, such as Neural Networks, but since the decision tree-based algorithm works very well, we leave this exploration for the future.

Metrics: To evaluate the performance of the classifier on the different classes and available features (F), standard machine learning metrics were used such as Precision (PR), Recall (RC), F-measure (FM), True Positive rate (TPR), False Positive rate (FPR), and area under the receiver operating curve (AUC).

6.1 CSync in ID-sharing HTTP

In this experiment, we assume there is already in place an existing technique for analysis of the HTTP traffic of the user, similar to the method outlined in Figure 3. However, there are candidate CSync events that cannot be confirmed, as the IDs cannot be matched with SET cookie IDs, either because these actions are not available to the method, or because the IDs are encrypted.

In this case, a machine learning classifier can be trained to detect if an id-sharing HTTP request is a true CSync event, by matching its pattern to past verified CSync events. For this experiment, we use two classes: the CSync events and the *id-sharing but non-CSync* events, to train and test a decision tree classifier under different subsets of features. The training and testing was performed using 10 cross-fold validation process. The results are shown in Table 7. We observe that independently, each of the features considered have some predictive power, except from the *NoOfParams* feature. When the most important features (using information gain as metric) are combined, a weighted AUC of 0.919 is achieved. When we select non-ID related features, a weighted AUC=0.887 is reached, and with all features the classifier can reach a weighted AUC=0.946.

Table 9: Detailed performance of decision tree model trained on different subsets of features in a balanced dataset, and tested on an unseen, and unbalanced test set, which maintains the original ratio of classes (last row of Table 8). C: CSync, ICS: *id-sharing but non-CSync*, O: Other, WA: weighted average.

Class	TPR	FPR	PR	RC	FM	AUC
CS	0.988	0.014	0.534	0.988	0.693	0.998
ICS	0.603	0.005	0.458	0.603	0.521	0.990
O	0.984	0.004	1.000	0.984	0.992	0.999
WA	0.981	0.004	0.989	0.981	0.984	0.999

6.2 CSync in HTTP with ID looking strings

In this setup, we assume there is a simple HTTP pre-filter, keeping connections with ID looking strings for further investigation. This is a necessary step to reduce the run-time workload of the classifier, as connections relevant to the task are only ~20% of the overall HTTP workload. Then, the classifier has to decide which of the 3 classes match for each of the selected HTTP requests: 1) CSync, 2) *id-sharing but non-CSync*, 3) other. In this case, *other* refers to HTTP entries containing an ID-looking string, but are *not id-sharing*.

We perform two rounds of tests on one month's data: 1) train and test the algorithm using balanced data from the three classes, in a 10 cross-fold validation process. 2) train the algorithm on balanced data from the three classes (as in (1)), but test it on an unseen and unbalanced dataset which maintains the ratio of the three classes: CSync: 1.6%, *id-sharing but non-CSync*: 0.73% other: 97.67%.

As seen from the classification results (Table 8), the company name and parameter used are among the most important features; number of parameters is the worst. Non-ID related features allow the classifier to reach weighted AUC = 0.973, with a high weighted Precision and Recall across all classes. When all features are used, a weighted AUC = 0.978 is reached, similarly to the high importance feature set that disregards the number of parameters. Interestingly, when the classifier is trained on the balanced dataset, and tested on the unbalanced test set (last row of Table 8), the classifier can distinguish very well the three classes, with low error rates across all three classes, even though there is high imbalance in the classes. These results are further validated by the breakdown of performance per class, demonstrated in Table 9, which show high TP rate and low FP rate for all three classes independently.

Overall, the results show that it is possible to understand and model the patterns of CSync, as they are driven by particular types of companies, using specific parameters, etc. Therefore, an online classifier could be trained to provide insights as to what each HTTP connection is and how likely it is to be performing CSync, without the need to match the IDs to SET cookie actions.

7 RELATED WORK

CSync has become a commonplace on the Web. One of the first works to discuss this mechanism [29] studies programmatic auctions from a privacy perspective and presents CSync as an integral part of communication between the participating entities. The study identified over 100 CSync events while crawling the top 100 sites. In our study, we extend their detection mechanism to detect CSync when cookieID is piggybacked in either URL parameters or path.

In [1], authors conduct a CSync privacy analysis by studying a small dataset of 3000 crawled sites, in conjunction with re-spawning cookies and how, together, they affect the reconstruction of user's browsing history by trackers. In [32] they measure the advertising ecosystem cost to users. Focusing on user privacy and targeted advertising, they use CSync as a metric for anonymity loss, showing that users receive 3.4 CSyncs per ad-impression.

Papadopoulos et al. [33] present how CSync can wreck a secure browsing session. They show cases where 3rd-parties may leak a user's cookie IDs and browsing history, thus increasing the identifiability of the user to a snooping ISP. By probing the top 12k Alexa sites they find 1 out of 13 websites exposing their users to these privacy leaks even when they use TLS and secure VPN services. In a recent census by Englehardt et al. [11], authors measure CSync and its adoption in a small subset of 100,000 crawled sites, before highlighting the need of further investigation given its increased privacy implications. Their results show that 157 of top 200 (i.e. 78%) 3rd parties synchronize cookies with at least one other party.

In [16] they study the economics and the revenue implications of CSync from the point of view of an informed seller of advertising space, uncovering a trade-off between targeting and information leakage. Similarly, in [4], authors explore the role of data providers on the price and allocation of consumer-level information and develop a simple model of data pricing that captures the key trade-offs involved in selling information encoded in 3rd-party cookies. In [13] they investigate tracking groups that share user-specific identifiers in a dataset collected after recording the browsing history of 100 users for two weeks. In this dataset, they detect 660 ID-sharing groups and found domains with sensitive content (such as health-related) that shared IDs with domains related to ad-trackers.

In [2] they aim to enhance the transparency in ad ecosystem with regards to information sharing, developing a content-agnostic methodology to detect client- and server-side flows of information between ad exchanges by leveraging retargeted ads. By using crawled data, authors collected 35448 ad impressions and identified 4 different kinds of information sharing behaviour between ad exchanges. In [3], they study the diffusion of user tracking caused by RTB-based programmatic ad-auctions, considering CSync as the core component of such auctions and the primary factor of the diffusion of privacy leaks. Results of their study show that under specific assumptions, no less than 52 tracking companies can observe at least 91% of an average user's browsing history.

Contrary to these works, we conduct a first of its kind, full-scale study of CSync by analysing a year-long dataset of 850 real users, thus avoiding any biases from crawling websites using artificial personas. Additionally, since nowadays mobile drives the majority of the network traffic, our work is the first to study CSync in the growing ecosystem of mobile devices.

8 SUMMARY AND DISCUSSION

One of the most popular techniques for trackers to share the IDs they assign to users today is Cookie Synchronization, with which different domains can merge their databases in the background. However, syncing userIDs of a given user increases the user identifiability while browsing, thus reducing their overall anonymity on the Web. In this paper, we build CONRAD: a holistic system to detect CSync events, either when the synced IDs are available in plaintext, or even when they are obfuscated (i.e., hashed, encrypted). Using our detection mechanism, we are the first to explore CSync in the mobile ecosystem and the first to analyze it in depth, using a year-long dataset of real mobile users. CONRAD is able to capture 3.771% more CSync cases than related work.

Results: Our analysis of $263k$ CSync requests, syncing $22.3k$ unique userIDs, led to the following findings:

- 97% of users are exposed to CSync at least once. The median user is synced at least once within the first week of browsing.
- Ad-related domains participate in more than 75% of all CSync through the year, learning as much as 90% of all synced userIDs.
- Three companies learn more than 30% of all userIDs, each.
- The median userID gets leaked to 3.5 domains, on average.
- The average user receives around 1 synchronization per 68 HTTP requests, and gets up to 6.5 of their userIDs synced.
- The number of domains that learn about the median user after CSyncs grows by a factor of 6.75.
- We find 63 cases, where domains set cookies on the users' browsers with userIDs previously set by other domains. This universal identification model enables collaborating domains to share data without background database merges.
- We find 131 cases of domains storing in cookies their CSyncs results forming ID Summaries.
- 5% of users suffer from ID-spilling in their secure TLS traffic.
- several sensitive information (e.g., gender, birth dates) is passed to the syncing domain along with the userID.

In addition to the classic, heuristics-based method applied to collect the above findings, in this work, we proposed a novel, CSync detection mechanism able to detect at real time CSync events, even if the synced IDs are obfuscated. In particular, this online, machine learning classifier can be trained to provide insights as to what each HTTP connection is, and how likely it is to be performing CSync, without the need to match the IDs to SET cookie actions. We use the set of detected CSyncs from the heuristics-based method as ground truth, to train our machine learning, cookie-less detection algorithm. We were able to achieve high accuracy (84%-90%) and high AUC (0.89-0.97), when non-ID related features were used.

Countermeasures: Nowadays, the most popular defence mechanism of CSync is the use of the traditional ad-blockers. Indeed, since the vast majority (75%) of CSync takes place among ad-related domains (see Figure 14), it is easy to anticipate that by blocking ad-related requests, one can eliminate a large portion of the privacy leak that CSync causes. However, the all-out approach of ad-blockers causes significant harm on publishers' content monetization models, forcing some of them to deploy anti-adblocking mechanisms [21, 27, 28] and deny serving ad-blocking users [26, 41, 43].

Mitigating mechanisms against CSync require a more targeted blocking strategy, that would not blindly harm the current ad-ecosystem. Instead, by applying detection techniques such as CONRAD, and blocking the specific traffic which has been found to facilitate CSync, we believe that the harmful privacy leakage and loss of anonymity of users due to CSync can be avoided, without the dire consequences on publishers' business models.

Impact: User data collection and sharing activities done without users' explicit consent can be illegal with hefty penalties imposed to

companies involved, as described in the new EU regulations for protecting user personal data and online privacy (GDPR and e-Privacy). Thus, it is important to design practical web transparency tools such as CONRAD, readily available to privacy researchers, regulators and end-users to investigate personal data leakage and anonymity on the Web, due to 3rd parties' activities such as CSync [20].

ABSTRACT

Ad-hoc retrieval models with implicit feedback often have problems, *e.g.*, the imbalanced classes in the data set. Too few clicked documents may hurt generalization ability of the models, whereas too many non-clicked documents may harm effectiveness of the models and efficiency of training. In addition, recent neural network-based models are vulnerable to adversarial examples due to the linear nature in them. To solve the problems at the same time, we propose an adversarial sampling and training framework to learn ad-hoc retrieval models with implicit feedback. Our key idea is (i) to augment clicked examples by adversarial training for better generalization and (ii) to obtain very informational non-clicked examples by adversarial sampling and training. Experiments are performed on benchmark data sets for common ad-hoc retrieval tasks such as Web search, item recommendation, and question answering. Experimental results indicate that the proposed approaches significantly outperform strong baselines especially for high-ranked documents, and they outperform IRGAN in NDCG@5 using only 5% of labeled data for the Web search task.

1 INTRODUCTION

Ad-hoc retrieval systems provide a ranked list of documents given a query, in which a user's information need is expressed. Such ad-hoc retrieval systems prevail in our daily lives, from Web search and question answering to product recommendation, which can be regarded as ad-hoc retrieval with users being queries and products being documents. Modern ad-hoc retrieval models are usually supervised or semi-supervised with training data to learn the relevance of documents to a query, because of its outstanding performance over unsupervised models.

Generally speaking, the training data are obtained for (semi-)supervised ad-hoc retrieval models in two ways. Annotators can explicitly label documents with their relevance to a query, and such labels are called explicit feedback. It is, however, often too expensive to obtain enough explicit feedback, and the labels may contain bias from a few annotators. Instead, labels can be inferred from the user's reactions (*e.g.*, clicks and views) on the given documents, and such reactions are called implicit feedback. Implicit feedback is cheap and reflects preference of actual users, so it has been widely studied [17, 26, 32] and adopted in the industry. Typically, there are much more non-clicked documents than clicked ones. Too few clicked documents can be problematic for generalization of the learned models. On the other hand, too many non-clicked documents can slow down the training and harm effectiveness of the trained model. Especially for ad-hoc retrieval tasks, the majority of the non-clicked documents is often not informational, sampling informational non-clicked documents is important for efficiency and effectiveness [28, 42].

Meanwhile, ad-hoc retrieval models often have a problem in themselves; their structures are vulnerable to adversarial examples. That is, due to the linearity in many models, the output can be dramatically changed by infinitesimal changes in input dimensions [8]. Traditional models such as logistic regression and matrix factorization work in a very linear way, and even recent deep neural networks are also designed to work in a quite linear way [9] (*e.g.*, ReLU [7] and LSTMs [15]).

To solve the aforementioned problems in implicit feedback and ad-hoc retrieval models, we propose an adversarial sampling-based adversarial training framework. On one hand, we generate adversarial positive examples to augment labeled (or clicked) documents with informational ones. On the other hand, to obtain informational negative examples, we first sample difficult examples adversarially from unlabeled (or non-clicked) documents. Then, we further generate adversarial negative examples, which are even more informational, on top of the sampled negative examples. The generated adversarial examples are supposed to be informational and to remove the weakness in the model's linearity. We also propose virtual adversarial training-based approach, which does not require labels to generate adversarial examples and thus suitable

for semi-supervised learning, and its variant that is more efficient and effective.

We perform experiments on benchmark data sets for three popular tasks: Web search, item recommendation, and question answering. Our proposed approaches are mainly compared with a strong baseline, IRGAN [36], which adopts a different kind of adversarial training to sample negative documents. Experimental results indicate that our proposed approaches are very effective on ad-hoc retrieval tasks and significantly outperform baselines especially on Web search and item recommendation. Moreover, our proposed approaches outperform IRGAN in NDCG@5 with only 5% of the labeled data for Web search.

Our contributions in this paper include:

- We propose a novel framework for learning ad-hoc retrieval models with implicit feedback. We generate very informational training examples by adversarial sampling and training. To the best of our knowledge, there has been no research work that incorporates adversarial sampling with adversarial training for ad-hoc retrieval models.
- We also propose virtual adversarial training and its variation for ad-hoc retrieval models. They can generate adversarial examples without labels, which may be ideal for noisy implicit feedback.
- We perform experiments on benchmark data sets for popular tasks. Experimental results indicate the proposed approaches significantly outperform strong baselines. The proposed approaches are empirically shown to be data-efficient.

2 RELATED WORK

2.1 Adversarial Training

It was found in [34] that several machine learning models, including modern state-of-the-art neural networks, fail with adversarial examples. A slight adversarial perturbation in the original input was enough to fake the models, meaning that the models classify the adversarial example into a wrong class with high confidence. Then, Goodfellow *et al.* hypothesized that the vulnerability of the models come from the linear nature in the models [9]. That is, the adversarial perturbation in each dimension adds up to a great change in the output due to some extent of linearity in the models. Goodfellow *et al.* also suggested to train a model by learning adversarial examples as well as original examples, where the adversarial examples were generated with the proposed *fast gradient sign method*. The trained model was reported more robust to adversarial examples. Adversarial examples and adversarial training are surveyed in [37]. Meanwhile, the earlier adversarial training approaches required labels of examples, and this is not ideal for semi-supervised learning where there are much more unlabeled data than labeled data. Miyato *et al.* [23] proposed virtual adversarial training, where labels are not required to generate adversarial examples. With its strength in semi-supervised learning, it has been applied to semi-supervised text classification [21] and image classification [22].

We adopt the ideas of adversarial training and virtual adversarial training in our approaches. However, there are several differences between our approaches and them. In our task, we assume that training data in implicit feedback consist of relatively fewer single-class labeled data and much more unlabeled data, where there exist many non-informational unlabeled examples. Such informativeness of unlabeled examples is not studied in the original works. We pay attention to it in this paper, especially for ad-hoc retrieval with implicit feedback. We further combine adversarial sampling with adversarial training to boost the informativeness of unlabeled examples. Meanwhile, virtual adversarial training iterates over all unlabeled examples and thus may not be efficient and effective for implicit feedback. Hence, we propose selective virtual adversarial training that iterates over only labeled examples and adversarially sampled unlabeled examples. Our problem, ad-hoc retrieval, also makes our approaches different from original ones. In our problem, there can be two input variables, queries and documents, instead of one single variable. In addition, we apply adversarial training to a pair-wise learning-to-rank framework.

2.2 Adversarial Training for Ad-hoc Retrieval

Recently, deep neural networks-based approaches have been successfully adopted in information retrieval tasks such as Web search [11, 16], click modeling [1], and query suggestion and auto-completion [24, 33]. Adversarial training has recently gained popularity with neural networks, and a few adversarial training-based approaches have been proposed for ad-hoc retrieval tasks. For example, an idea of generative adversarial networks (GAN) [8] has been adopted to unify generative and discriminative information retrieval models by IRGAN [36]. Its goal is indeed similar to ours, which is to build effective ad-hoc retrieval models through difficult examples. The generator of IRGAN tries to fool the discriminator by providing adversarial negative examples while the discriminator tries to distinguish them from true positive examples so that the generator and the discriminator can mutually enhance. Through dynamically sampling more and more difficult examples by the evolving generator, IRGAN achieves outstanding performance. However, IRGAN is different from our approaches in many aspects. Although it contains a generator, IRGAN does not really generate negative examples but samples them from unlabeled data according to the generator model. On the other hand, our approach *generates* difficult examples on top of existing examples by adding adversarial perturbation to them. Incorporating adversarial sampling with adversarial training, our approaches can generate even more difficult negative examples based on the adversarially sampled negative examples. Also, our approaches require one single model whereas IRGAN consists of two models: a generator and a discriminator; this means the required number of parameters and hyperparameters can double, and training both models at the same time can be more difficult. Furthermore, IRGAN requires a pre-trained model to ensure stability during training, unlike our stand-alone model. [39] extends IRGAN with a different neural network architecture for question answering.

More recently, a simultaneous work but independent from ours has proposed adversarial training for item recommendation [13]. It employs adversarial perturbation to build a robust model, and the experiment results show that it is superior to existing models. Despite its novel approach, our work is different from it in several aspects. Their approach adds adversarial perturbation to the model parameters while we add it to the input. Also, they do not have the same assumption on data as ours, *i.e.*, single-class labeled data

and much more unlabeled data, so they do not focus on sampling difficult negative examples from unlabeled data. Their focus is on item recommendation, but our focus is on ad-hoc retrieval with implicit feedback. Lastly, we further explore virtual adversarial training that can be promising for semi-supervised learning, which is not in their scope.

2.3 Negative Sampling for Ad-hoc Retrieval

Negative example sampling techniques have been adopted for information retrieval tasks as well as natural language processing tasks. Word embedding models have sampled negative examples by their frequency [10, 20], and [27] employs "max sampling" that samples negative examples that are most similar to positive examples for question answering. Generative Adversarial Networks-based negative sampling also has been proposed for ad-hoc retrieval tasks [36].

Negative sampling techniques have been studied more extensively for item recommendation. To train a model efficiently, negative sampling techniques have been employed. Traditional models including Bayesian Personalized Ranking [29] rely on uniform sampling for negative examples. Dynamic negative sampling techniques [28, 42] that sample informational negative examples for the current model also have been proposed. Recently, negative sampling by leveraging view information has been proposed and empirically shown to be effective for e-commerce data sets [5]. Hidasi and Karatzoglou [14] recently proposed a BPR-max loss function that assigns larger weights to more informative negative examples. To the best of our knowledge, no previous ad-hoc retrieval models adversarially generate negative examples on top of sampled negative examples in order to generate even more informational examples, as our approaches do.

3 PROBLEM DEFINITION

We study a typical ad-hoc retrieval problem. Given a query q that contains a user's information need and a set of documents $D = \{d_i\}_{i=1}^{M}$, the goal is to retrieve and rank documents based on their estimated relevance to q, where Probability Ranking Principle is assumed. Ad-hoc retrieval problems are not limited to document search, and q and D may be in other types. Item recommendation can be regarded as an ad-hoc retrieval problem where q is a user and D is a set of items. Question answering (retrieval-based) also can fall within ad-hoc retrieval where q is a question and D is a set of answer candidates.

We specifically study semi-supervised ad-hoc retrieval with implicit feedback, where for each q, we have a set of labeled (clicked) documents, which we assume relevant, and unlabeled (non-clicked) documents. We also assume the number of labeled documents is much less than that of unlabeled documents. Indeed, such configuration is common in the industry. When the retrieved documents are shown to users, the users usually click only a few of them while many documents are not clicked. The non-clicked documents are not necessarily irrelevant to q, so they are left unlabeled or sometimes labeled as *viewed*.

The labeled and unlabeled documents for q are given to a model as training data, whose example is in a form of triple (q, d, y), where y is a relevance of d to q, and $y = 1$ if a user clicked d for q. Non-relevant documents ($y = 0$) come from unlabeled documents. The ad-hoc retrieval model learns a function $f_{\boldsymbol{\theta}} : (q, d) \mapsto y$, where $\boldsymbol{\theta}$ is a set of model parameters. The learned function $f_{\boldsymbol{\theta}}$ is then employed to predict a relevance score of a test (q, d) pair.

There are challenges to learn ad-hoc retrieval models from implicit feedback. If the number of clicked documents is small, it can easily suffer from over-fitting. That means, the model will not generalize well on the test data. On the other hand, there are relatively too many unlabeled documents, and many of the unlabeled documents are either redundant or obviously irrelevant. That is, the unlabeled documents are not informational so that the model will not learn effectively with them. Therefore, careful utilization of the imbalanced data is desired to build an effective ad-hoc retrieval model.

4 ADVERSARIAL SAMPLING AND TRAINING FRAMEWORK FOR AD-HOC RETRIEVAL

In order to address the challenges in implicit feedback, we propose a framework of adversarial sampling and training that are applied differently for labeled and unlabeled documents. On one hand, we employ adversarial training to build a generalizable model with relatively few labeled documents. On the other hand, we first adversarially sample informational examples, and on top of them, we further generate even more informational examples by adversarial training. The generated adversarial examples for both labeled and unlabeled documents also help ad-hoc retrieval models cope with the weakness in linearity of the models.

In this section, we first explain how adversarial examples can cause a significant change in the output of models that have linearity. We then propose multiple adversarial training methods that can generate informational examples based on existing training examples. Then, adversarial sampling is incorporated with adversarial training in order to amplify informativeness of unlabeled examples. Pairwise learning is also proposed to effectively learn with implicit feedback.

4.1 Adversarial Examples for Ad-hoc Retrieval

An adversarial example is defined as an example that is slightly perturbed from the original example but greatly changes the activation and thus the output. Adversarial examples were first introduced for neural networks in [34] and later found that they occur due to linearity in models [9]. For an adversarial input $\tilde{\mathbf{x}} = \mathbf{x} + \boldsymbol{\eta}$, where $\mathbf{x}$ is an original input vector and $\boldsymbol{\eta}$ is an adversarial perturbation vector of the same shape, a dot product between $\tilde{\mathbf{x}}$ and a weight vector $\mathbf{w}$ becomes

$$\mathbf{w}^\intercal \tilde{\mathbf{x}} = \mathbf{w}^\intercal \mathbf{x} + \mathbf{w}^\intercal \boldsymbol{\eta}.$$

The change of the activation by adversarial perturbation is thus $\mathbf{w}^\intercal \boldsymbol{\eta}$. If the average magnitude of $\mathbf{w}$ and $\boldsymbol{\eta}$ are m and ϵ, respectively, then the maximum change caused by perturbation can grow linearly by ϵmn, where n is the number of dimensions in $\mathbf{x}$. (We explain how to approximate the optimal $\boldsymbol{\eta}$ in the next section.) Hence, small changes by perturbation can accumulate with dimensions to a great change. Such a great change can propagate to an output of more complicated models. For example, neural network activation

functions such as ReLUs [7] and sigmoid, which are widely used in modern neural networks, are piece-wise linear or almost linear (in non-saturating section); hence, the great change can easily propagate to the final output [9].

Such perturbations can also exist in ad-hoc retrieval systems. For example, let's assume $\mathbf{x}$ and $\mathbf{x}'$ are topic probabilities estimated by topic models for two semantically identical documents, where only $\mathbf{x}$ is in the training data. A slight word change from $\mathbf{x}$ to $\mathbf{x}'$ can cause slight difference in each dimension of $\mathbf{x}$ and $\mathbf{x}'$, and this may result in a large change in the output, yielding wrong prediction on $\mathbf{x}'$. Similarly, less processed features such as raw text and TF-IDF values can also cause such effect. For example, two semantically identical documents may have different raw text features, by synonyms of their words. Although their raw features are different, their latent vectors may still be similar, but the subtle difference in the latent vectors may eventually result in a great change in the output. This is because the latent vectors still need to go through activation functions that are linear or almost linear.

Unfortunately, recent ad-hoc retrieval models as well as several traditional models are often vulnerable to adversarial examples. Neural networks are recently employed for state-of-the-art performance, and modern neural networks behave in a linear way (*e.g.*, ReLUs) for more effective learning by avoiding vanishing gradients. Earlier models such as RankNet [2], or matrix factorization [18] also operate in a quite linear way.

4.2 Adversarial Training for Robust Ad-hoc Retrieval Models

4.2.1 Adversarial Training. We propose to train ad-hoc retrieval models with adversarial examples that can locate the weak points in the models. In general, ad-hoc retrieval models are trained by minimizing the following cost function

$$\mathbb{E}_{q,d,y\sim p_{\text{data}}}\mathrm{J}(\mathbf{q},\mathbf{d},y;\boldsymbol{\theta}) \tag{1}$$

where $\mathbf{q}$ and $\mathbf{d}$ are feature vectors for q and d, respectively, and $y \in \{0,1\}$ is a relevance label, and $\boldsymbol{\theta}$ is a set of model parameters.[1] J can be, for example, a cross entropy loss function. Hence, the goal is to learn a function $f_{\boldsymbol{\theta}} : (\mathbf{q},\mathbf{d}) \mapsto y$. Intuitively, in order to build a model that is robust to adversarial perturbation, we can generate adversarial perturbation and let the model learn from adversarial examples that are generated by adding adversarial perturbation to original training examples. That is, the adversarial examples still keep the original labels, but their $\mathbf{q}$ and $\mathbf{d}$ are modified to become more difficult (*i.e.*, yield greater losses). Learning with more difficult examples that attack the model's weaknesses, the model can become more robust to adversarial perturbation. Therefore, we can add a cost for adversarial examples to the objective as follows:

$$\mathbb{E}_{q,d,y\sim p_{\text{data}}}\mathrm{J}(\mathbf{q},\mathbf{d},y;\boldsymbol{\theta}) + \alpha\mathrm{J}(\mathbf{q}+\boldsymbol{\eta}_q,\mathbf{d}+\boldsymbol{\eta}_d,y;\boldsymbol{\theta}) \tag{2}$$

where $\boldsymbol{\eta}_q$ and $\boldsymbol{\eta}_d$ are adversarial perturbations for $\mathbf{q}$ and $\mathbf{d}$, respectively, and α is a hyperparameter, which is set to 1 in this work. This objective means that regardless of adversarial perturbation, the model should learn to predict the same relevance.

[1] If the given data consist of one input vector $\mathbf{x}$ instead of two vectors $\mathbf{q}$ and $\mathbf{d}$ for a query and a document as in Section 4.1, $\mathbf{x}$ can replace $\mathbf{q}$ and $\mathbf{d}$ accordingly.

4.2.2 Generating Adversarial Perturbation. When generating adversarial perturbation, the magnitudes of perturbation vectors need to be limited so that the adversarial examples do not become too similar to examples of the opposite classes. Thus, their magnitudes are limited by a hyperparameter ϵ such that $||\boldsymbol{\eta}||_p < \epsilon$. In order to build a model that is robust to perturbation, we need to generate a perturbation vector that can achieve the greatest loss within the limit of ϵ. In other words, a model trained with more difficult examples can be more effective for the unseen test examples. Such perturbation vectors are defined as

$$\boldsymbol{\eta}_q, \boldsymbol{\eta}_d = \underset{\boldsymbol{\eta}_q:||\boldsymbol{\eta}_q||_p<\epsilon,\ \boldsymbol{\eta}_d:||\boldsymbol{\eta}_d||_p<\epsilon}{\arg\max} \mathrm{J}(\mathbf{q}+\boldsymbol{\eta}_q,\mathbf{d}+\boldsymbol{\eta}_d,y;\hat{\boldsymbol{\theta}}). \tag{3}$$

We use the same ϵ for $\boldsymbol{\eta}_q$ and $\boldsymbol{\eta}_d$ in this paper, but different values can be used. Also, $\hat{\boldsymbol{\theta}}$ denotes a copy of $\boldsymbol{\theta}$, in order to avoid propagating gradients from this perturbation generation process to $\boldsymbol{\theta}$. Note that the objective in (2) with the equation (3) can be interpreted as a *minimax* game. Similar to the *fast gradient sign method* [9], with first-order Taylor series approximation, equation (3) is approximated as

$$\begin{aligned}\boldsymbol{\eta}_q &= \underset{\boldsymbol{\eta}_q:||\boldsymbol{\eta}_q||_p<\epsilon}{\arg\max}\ \mathrm{J}(\mathbf{q},\mathbf{d},y;\hat{\boldsymbol{\theta}}) + \boldsymbol{\eta}_q\nabla_{\mathbf{q}}\mathrm{J}(\mathbf{q},\mathbf{d},y;\hat{\boldsymbol{\theta}})\\ \boldsymbol{\eta}_d &= \underset{\boldsymbol{\eta}_d:||\boldsymbol{\eta}_d||_p<\epsilon}{\arg\max}\ \mathrm{J}(\mathbf{q},\mathbf{d},y;\hat{\boldsymbol{\theta}}) + \boldsymbol{\eta}_d\nabla_{\mathbf{d}}\mathrm{J}(\mathbf{q},\mathbf{d},y;\hat{\boldsymbol{\theta}}).\end{aligned} \tag{4}$$

Its solution depends on the value of p in the p-norm as follows

$$\boldsymbol{\eta}_q = \begin{cases}\epsilon\,\mathrm{sign}(\mathbf{g}_q) & \text{if } p=\infty\\ \epsilon\frac{\mathbf{g}_q}{||\mathbf{g}_q||_2} & \text{if } p=2\end{cases} \quad \text{where } \mathbf{g}_q = \nabla_{\mathbf{q}}\mathrm{J}(\mathbf{q},\mathbf{d},y;\hat{\boldsymbol{\theta}}) \tag{5}$$

where $\mathbf{g}_q$ can be efficiently computed by backpropagation while solving the first term of (2). That means, adversarial training requires only a few additional computations that can be done efficiently. $\boldsymbol{\eta}_d$ can be solved in the same way, so we do not include its solution here. Regarding the choice of p, a max norm ($p=\infty$) is used in [9] because the magnitudes of perturbation in image pixels are supposed to be small. However, we do not have such assumption for text; indeed, semantically similar documents can have very different text at least in their raw representation. Also, L2 norm can sometimes perform better than max norm for adversarial training [22], so we employ L2 norm in this work.

4.2.3 Virtual Adversarial Examples. The process for generating adversarial examples requires labels of query-document pairs. However, the number of unlabeled (non-clicked) documents is usually much greater than that of labeled (clicked) documents in implicit feedback. Even if we regard unlabeled ones as negative examples, the generated adversarial examples from the negative examples may not be ideal due to the uncertainty in the assumed labels. Virtual Adversarial Examples [23] may thus be useful in this case, which do not require labels to generate adversarial examples. The following cost function J_{KL} is added to the objective in (1) for both labeled and unlabeled data:

$$\begin{aligned}&\mathrm{J}_{\mathrm{KL}}(\mathbf{q},\mathbf{d};\boldsymbol{\theta}) = \mathrm{KL}\left[p(\cdot|\mathbf{q},\mathbf{d};\boldsymbol{\theta})||p(\cdot|\mathbf{q}+\boldsymbol{\eta}_q,\mathbf{d}+\boldsymbol{\eta}_d;\boldsymbol{\theta})\right], \text{ where}\\ &\boldsymbol{\eta}_q,\boldsymbol{\eta}_d = \underset{\boldsymbol{\eta}_q:||\boldsymbol{\eta}_q||<\epsilon,\ \boldsymbol{\eta}_d:||\boldsymbol{\eta}_d||<\epsilon}{\arg\max}\ \mathrm{KL}\left[p(\cdot|\mathbf{q},\mathbf{d};\hat{\boldsymbol{\theta}})||p(\cdot|\mathbf{q}+\boldsymbol{\eta}_q,\mathbf{d}+\boldsymbol{\eta}_d;\hat{\boldsymbol{\theta}})\right]\end{aligned} \tag{6}$$

where $\mathrm{KL}\left[p||p'\right]$ denotes KL divergence between conditional relevance distributions p and p'. Basically, minimizing the objective

including this cost function means that we want to reduce the distribution difference that is caused by adversarial perturbation. In other words, we want to enhance the model's local smoothness of conditional relevance distribution so that the model's output does not dramatically change by adversarial perturbation. The perturbation vector can be computed by a second-order Taylor series approximation and a single iteration of power method on the KL divergence function as in [23]. The solution thus can be approximated as

$$\begin{aligned} \boldsymbol{\eta}_q &= \epsilon \frac{\mathbf{g}_q}{||\mathbf{g}_q||_2} \ , \ \boldsymbol{\eta}_d = \epsilon \frac{\mathbf{g}_d}{||\mathbf{g}_d||_2}, \text{ where} \\ \mathbf{g}_q &= \nabla_{\mathbf{q}+\mathbf{e}_q} \mathrm{KL}\Big[p(\cdot|\mathbf{q}, \mathbf{d}; \hat{\boldsymbol{\theta}}) || p(\cdot|\mathbf{q}+\mathbf{e}_q, \mathbf{d}; \hat{\boldsymbol{\theta}})\Big] \\ \mathbf{g}_d &= \nabla_{\mathbf{d}+\mathbf{e}_d} \mathrm{KL}\Big[p(\cdot|\mathbf{q}, \mathbf{d}; \hat{\boldsymbol{\theta}}) || p(\cdot|\mathbf{q}, \mathbf{d}+\mathbf{e}_d; \hat{\boldsymbol{\theta}})\Big] \end{aligned} \tag{7}$$

where $\mathbf{e}_q$ and $\mathbf{e}_d$ are small random vectors. This process does not require labels, so the uncertainty of relevance in implicit feedback is not a problem to generate perturbations, and thus all non-clicked documents can be safely used for semi-supervised learning. However, training with all non-clicked documents can be very inefficient, so we discuss sampling approaches in Section 4.3.

4.2.4 Adversarial Examples for Discrete Input. If an input is a discrete value such as a word or an item ID, where the value is converted to a latent vector, one may consider to add a perturbation vector to the latent vector (or embedding vector). However, adding it to the perturbation vectors may be tricky because they may learn to increase their magnitudes so that the amount of perturbation ϵ becomes negligible. To avoid such phenomenon, it was proposed in [21] to normalize the latent vector after adding a perturbation vector to it. Meanwhile, ad-hoc retrieval models can have continuous input as well as discrete one, *e.g.,* TF-IDF features and other pre-processed features. To serve both discrete and continuous input, we employ another trick that adds adversarial perturbation to the input. When the input is continuous, we can add the perturbation vector as usual: $\tilde{\mathbf{x}} = \mathbf{x} + \boldsymbol{\eta}$. For discrete input, we are given $\mathbf{x}$ that is a length-v one-hot encoded input vector, where v is the cardinality. Instead of looking up the length-k embedding vector $\mathbf{z} \in \mathbb{R}^k$ from the embedding matrix $\mathbf{Z} \in \mathbb{R}^{v \times k}$, we multiply $\tilde{\mathbf{x}}$ and $\mathbf{Z}$ together to obtain the perturbed embedding vector of $\mathbf{x}$. That is, the perturbed embedding vector $\tilde{\mathbf{z}}$ is obtained by

$$\tilde{\mathbf{z}} = (\mathbf{x} + \boldsymbol{\eta})\mathbf{Z}. \tag{8}$$

That means, for example, we make a mixture of words to generate a perturbed embedding vector for the input word. The advantage of this approach is that it can be extended to accommodate the input that is combination of discrete values and continuous values. In addition, this approach may potentially provide more interpretable perturbation as it is engaged to the original input. For example, a perturbation by "`- man + woman`" for the input "`king`" will indicate that the perturbation changes the gender to generate the embedding vector of "`queen`". Such interpretability may be interesting since that of neural networks-based classifiers has been weak and has attracted attention [38, 41]. We do not explore these advantages in this paper as they are out of its scope, but they are left for our future work.

4.3 Adversarial Training with Adversarial Sampling

Adversarial training can be interpreted as learning with difficult examples that are generated to attack the current model's weakness. To amplify the effectiveness, we propose adversarial sampling-based adversarial training that generates even more difficult examples from already difficult examples. In ad-hoc retrieval systems with implicit feedback, labeled documents are mainly relevant but the number of documents is relatively small. On the other hand, unlabeled documents are more likely to be negative than positive while the number of documents is much greater. As many of the unlabeled examples may be either redundant or obviously irrelevant, finding informational examples may be the key to effective and efficient model.

Therefore, we use existing labeled documents as positive examples, but we adversarially sample negative examples from unlabeled documents. The optimization objective for adversarial training is thus defined as

$$\begin{aligned} \sum_q \Big(&\mathbb{E}_{d \sim p_{\text{data}}(d|q, y=1)} \Big[\mathrm{J}(\mathbf{q}, \mathbf{d}, y=1; \boldsymbol{\theta}) + \mathrm{J}(\mathbf{q}+\boldsymbol{\eta}_q, \mathbf{d}+\boldsymbol{\eta}_d, y=1; \boldsymbol{\theta}) \Big] + \\ &\mathbb{E}_{d \sim p_{\boldsymbol{\theta}}(d|q, y=1)} \Big[\mathrm{J}(\mathbf{q}, \mathbf{d}, y=0; \boldsymbol{\theta}) + \mathrm{J}(\mathbf{q}+\boldsymbol{\eta}_q, \mathbf{d}+\boldsymbol{\eta}_d, y=0; \boldsymbol{\theta}) \Big] \Big) \end{aligned} \tag{9}$$

where $\mathbf{q}$ and $\mathbf{d}$ are feature vectors for q and d, respectively, and the adversarial perturbation vectors $\boldsymbol{\eta}_q$ and $\boldsymbol{\eta}_d$ are computed as in Section 4.2 for each example. All positive examples are selected from labeled data by p_{data}, whose distribution is uniform, and the negative examples are selected from unlabeled data by p_θ. In practice, the model goes through all positive examples in the labeled data while it goes through the same number of negative examples that are sampled from unlabeled data. Negative examples are sampled by $p_{\boldsymbol{\theta}}(d|q, y=1)$ to ensure the examples are adversarial ($y=1$) so that they are difficult for the current model. Note that the negative examples are sampled dynamically for the current model, and more efficient sampling can be done by estimating $p_{\boldsymbol{\theta}}(d|q, y=1)$ for every K epochs or estimating it for only C document candidates. The conditional probability for sampling d can be estimated by the following softmax function:

$$p_{\boldsymbol{\theta}}(d|q, y=1) = \frac{\exp(f_{\boldsymbol{\theta}}(\mathbf{q}, \mathbf{d})/\tau)}{\sum_{d'} \exp(f_{\boldsymbol{\theta}}(\mathbf{q}, \mathbf{d}')/\tau)} \tag{10}$$

where τ is a temperature hyperparameter for controlling smoothness of the distribution. A lower temperature will assign most of the probability mass to a fewer documents while a higher temperature will make the distribution more uniform. We employ cross entropy loss for J, which is defined as

$$\begin{aligned} &\mathrm{J}(\mathbf{q}, \mathbf{d}, y; \boldsymbol{\theta}) = -\log p(y|q, d; \boldsymbol{\theta}) \ \ , \text{where} \\ &p(y=1|q, d; \boldsymbol{\theta}) = \sigma(f_{\boldsymbol{\theta}}(\mathbf{q}, \mathbf{d})) \ , \ p(y=0|q, d; \boldsymbol{\theta}) = 1 - \sigma(f_{\boldsymbol{\theta}}(\mathbf{q}, \mathbf{d})) \end{aligned} \tag{11}$$

where σ is a sigmoid function, and $f_{\boldsymbol{\theta}}$ is defined in Section 5 for each ad-hoc retrieval task.

The idea of adversarial sampling is not actually new. Dynamic negative sampling ideas have been proposed by [28, 42], which sample the most informational negative items at the moment. A generator model of IRGAN [36] also plays a similar role. It builds the generator that can adversarially fool the discriminator, and it

samples the negative examples according to the estimated generator. Our framework is different from theirs in that we further generate more difficult adversarial negative examples from the adversarially sampled negative examples, and in that we generate adversarial examples even for positive class for better generalization.

Selective Virtual Adversarial Training. Although the advantage of virtual adversarial training is that it can be used for all unlabeled documents, which is good for semi-supervised learning, it may not be effective and efficient to process many non-informational unlabeled documents. Therefore, we propose selective virtual adversarial training based on adversarial sampling. Instead of generating virtual adversarial perturbation for all unlabeled documents, we selectively generate them for difficult ones. The objective is defined as

$$\sum_q \Big(\mathbb{E}_{d\sim p_{\text{data}}(d|q,y=1)} \Big[\mathrm{J}(\mathbf{q},\mathbf{d},y=1;\boldsymbol{\theta}) + \mathrm{J}_{\mathrm{KL}}(\mathbf{q},\mathbf{d};\boldsymbol{\theta}) \Big] + \mathbb{E}_{d\sim p_{\boldsymbol{\theta}}(d|q,y=1)} \Big[\mathrm{J}(\mathbf{q},\mathbf{d},y=0;\boldsymbol{\theta}) + \mathrm{J}_{\mathrm{KL}}(\mathbf{q},\mathbf{d};\boldsymbol{\theta}) \Big] \Big) \tag{12}$$

where J_{KL} is defined in equation (6). Similar to equation (9), we sample one negative document from unlabeled data by $p_{\boldsymbol{\theta}}$ for each positive document. This is more efficient than the original virtual adversarial training [23] as it does not iterate over all unlabeled documents. In addition, it can also be more effective because only highly informational documents, which may result in a better decision boundary, are selected to train the model. Indeed, we empirically find that this approach is more effective than the original one in Section 6.

4.4 Pairwise Training

Instead of collecting relevance level for each query-document pair, it is often easier for ad-hoc retrieval systems to infer which documents are more preferred than other documents for a query, leveraging implicit feedback of users. In addition, users have biases, so one user's rating is often not compatible with another user, for example, in item recommendation. Hence, it has been studied how to exploit such relative preference instead of absolute relevance with pairwise or listwise learning algorithms [19, 29]. We thus extend our approaches to pairwise training.

There are several ways to form document pairs for pair-wise training. For example, for a query q, we can build document pairs such that $\{(d_i,d_j)|d_i \in D_c \wedge d_j \in D_{nc}\}$ where D_c is a set of documents clicked by users and D_{nc} is a set of documents that are not clicked. There exist better ways to form such pairs, but they are not within the scope of this work. The pairwise objective corresponding to equation (9) can be defined as

$$\sum_q \Big(\mathbb{E}_{d^+\sim p_{\text{data}}(d|q,y=1)} \Big[\mathbb{E}_{d^-\sim p_{\boldsymbol{\theta}}(d|q,y=1)} \Big[\mathrm{J}(\mathbf{q},\mathbf{d}^+,\mathbf{d}^-;\boldsymbol{\theta}) + \mathrm{J}(\mathbf{q}+\boldsymbol{\eta}_q,\mathbf{d}^+ + \boldsymbol{\eta}_{d^+},\mathbf{d}^- + \boldsymbol{\eta}_{d^-};\boldsymbol{\theta}) \Big] \Big] \Big) \tag{13}$$

where a preferred document d^+ is sampled from labeled data and the corresponding non-preferred document d^- is sampled from unlabeled data according to $p_{\boldsymbol{\theta}}$. The adversarial perturbations $\boldsymbol{\eta}_q$, $\boldsymbol{\eta}_{d^+}$, and $\boldsymbol{\eta}_{d^-}$ can be computed in the same way as in equation (4).

The cost function J for pairwise training is defined as

$$\mathrm{J}(\mathbf{q},\mathbf{d}^+,\mathbf{d}^-;\boldsymbol{\theta}) = -\log p(y^+ \rhd y^-|q,d^+,d^-;\boldsymbol{\theta}) \quad \text{where}$$
$$p(y^+ \rhd y^-|q,d^+,d^-;\boldsymbol{\theta}) = \sigma(f_{\boldsymbol{\theta}}(\mathbf{q},\mathbf{d}^+) - f_{\boldsymbol{\theta}}(\mathbf{q},\mathbf{d}^-)) \tag{14}$$

where $y^+ \rhd y^-$ means d^+ is preferred over d^-.

As in our solution, the pairwise perturbation is proposed for pairwise training as it assumes relative relevance between document pairs. However, virtual adversarial perturbation assumes no labels, so pointwise learning makes more sense than pairwise learning. Hence, we employ a hybrid learning whose objective is defined as

$$\sum_q \Big(\mathbb{E}_{d^+\sim p_{\text{data}}(d|q,y=1)} \Big[\mathbb{E}_{d^-\sim p_{\boldsymbol{\theta}}(d|q,y=1)} \Big[\mathrm{J}(\mathbf{q},\mathbf{d}^+,\mathbf{d}^-;\boldsymbol{\theta}) + \mathrm{J}_{\mathrm{KL}}(\mathbf{q},\mathbf{d}^+;\boldsymbol{\theta}) + \mathrm{J}_{\mathrm{KL}}(\mathbf{q},\mathbf{d}^-;\boldsymbol{\theta}) \Big] \Big] \Big) \tag{15}$$

where we sample one negative example from unlabeled data by $p_{\boldsymbol{\theta}}$ for each positive example in the labeled data. Here, we still learn from the pairwise loss with equation (14) while we also learn from pointwise virtual adversarial loss (equation (6)) for each of positive and negative examples.

5 APPLICATION TO AD-HOC RETRIEVAL TASKS

We apply the proposed approaches to ad-hoc retrieval tasks. Among various ad-hoc retrieval tasks, we chose three tasks: Web search, item recommendation, and question answering. These three tasks are specifically chosen because they are popular and actively studied, and they were also chosen by IRGAN [36], to which we mainly compare our approaches.

IRGAN is chosen as the main baseline because (i) it is based on a type of adversarial training too and it applies its unique negative sampling, (ii) it recently attracted a great deal of attention at ACM SIGIR 2017[2] with its novel approach and outstanding performance, and (iii) the source code and the pre-processed data sets are published[3] so that it provides an excellent benchmark environment. For a fair comparison, we apply our approaches to the same models as IRGAN does, except for a small change in Web search model. As the tasks and models are already described well in [36], we briefly describe them in this section.

5.1 Web Search

For Web search task, input vectors for (q,d) can be formed as a length-k vector $\mathbf{x}_{q,d} \in \mathbb{R}^k$, where each dimension represents a feature value of q and/or d. For example, TF-IDF scores of each document part and a query or PageRank scores of d can be such features. As in RankNet [2] and IRGAN[36], we adopt a two-layer neural network as the model of Web search:

$$f_{\boldsymbol{\theta}}(\mathbf{x}_{q,d}) = \mathbf{w}_2^{\mathsf{T}} f_1(\mathbf{W}_1\mathbf{x}_{q,d} + \mathbf{b}_1) + b_2 \tag{16}$$

where $\mathbf{W}_1 \in \mathbb{R}^{l\times k}$ is a weight matrix and l is the number of nodes in the hidden layer, $\mathbf{b}_1$ and b_2 are a bias vector and a constant, respectively, and $\mathbf{w}_2 \in \mathbb{R}^l$ is a weight vector for the output layer. For the activation function in f_1, the hyperbolic tangent was employed

[2] http://sigir.org/sigir2017/program/awards/

[3] Available at https://github.com/geek-ai/irgan except Netflix data for item recommendation.

in RankNet and IRGAN, but we replace it with ReLU since it can learn more effectively [7]. Although ReLU is quite linear so that it is more vulnerable to adversarial examples, adversarial training makes the model robust to them, so it is not a concern. We also experiment with ReLU version of IRGAN and compare the results. Our approach is originally defined for two separate input vectors $\mathbf{q}, \mathbf{d}$ of $f_{\boldsymbol{\theta}}$, but accommodating a single input vector instead is straightforward.

5.2 Item Recommendation

Item recommendation is a task where a ranked list of items are recommended for a user. Thus, it can be regarded as an ad-hoc retrieval task, where a query is a user, and a document is an item. One simple but popular approach is matrix factorization [18] for collaborative filtering. Given one-hot encoded vectors $\mathbf{u}$ and $\mathbf{i}$ for a user u and an item i, respectively, the model is defined as

$$f_{\boldsymbol{\theta}}(\mathbf{u}, \mathbf{i}) = \mathbf{v}_u^\intercal \mathbf{v}_i + b_i \tag{17}$$

where $\mathbf{v}_u, \mathbf{v}_i \in \mathbb{R}^k$ are latent vectors for u and i, respectively, and b_i is a bias for i. This model works in a linear way so that it is vulnerable to adversarial perturbation, so adversarial training is desired.

5.3 Question Answering

A retrieval-based question answering is a task where a ranked list of answers are retrieved for a question. We employ a deep learning-based end-to-end approach to estimate latent vectors $\mathbf{v}_q, \mathbf{v}_d \in \mathbb{R}^k$. Given one-hot encoded vectors $\mathbf{q}, \mathbf{d}$ for a question q and an answer d, respectively, the relevance of d to q is modeled by a cosine similarity between them:

$$f_{\boldsymbol{\theta}}(\mathbf{q}, \mathbf{d}) = \frac{\mathbf{v}_q^\intercal \mathbf{v}_d}{||\mathbf{v}_q||\,||\mathbf{v}_d||}. \tag{18}$$

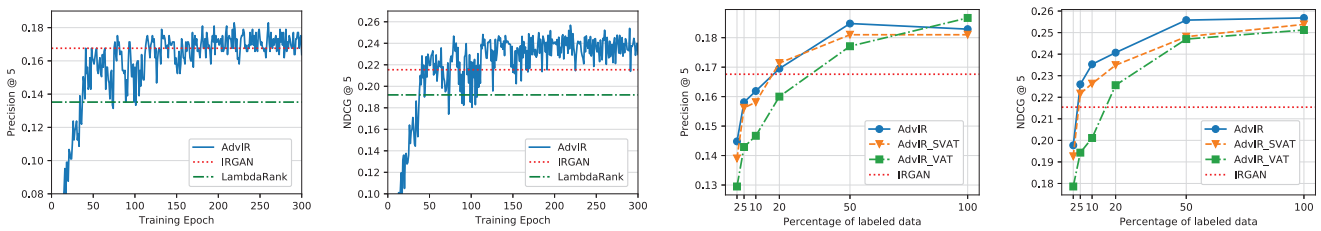
Recent successful approaches adopt convolutional neural network (CNN) [30, 31] or long short-term memory neural network (LSTM) [35] to obtain the latent vectors. Although such models can achieve great performances, they are vulnerable to adversarial perturbation as they can behave in a linear way. We thus apply our adversarial training to this model.

6 EXPERIMENTS ON THREE AD-HOC RETRIEVAL TASKS

We perform experiments with our pairwise approaches as they often perform better than pointwise approaches. The main approach uses the objective in equation (13), which is based on pairwise adversarial training, and we call it **AdvIR** (Adversarial training for Information Retrieval). We also experiment with selective virtual adversarial training (**AdvIR-SVAT**) in equation (15) and virtual adversarial training (**AdvIR-VAT**), which iterates over all unlabeled examples. The code is available online.[4]

Due to the complexity of experiments, we borrow some baseline results from [36]. In fact, the exact pre-processed data set is published by [36], so we regard it as a concrete benchmark data set, and we do not repeat experiments for some baselines that are clearly inferior to IRGAN at least on those data sets. Indeed, IRGAN is far superior to the baselines for Web search task. The strongest competitors for other tasks, which are LambdaFM [40] for item recommendation and LambdaCNN [42] for question answering, were actually proposed by some authors of IRGAN, so we can trust their results in [36]. For other settings, we follow the settings in [36].

6.1 Web Search



6.1.1 Experimental Design. The well-known benchmark data set LETOR 4.0 [25] provides MQ2008-semi (Million Query track), which is designed for semi-supervised learning. That is, it consists of a relatively small number of labeled data and a much larger number of unlabelled data. Specifically, a relevance in 4 levels (-1, 0, 1, or 2) is given to each query-document pair, where -1 means unlabeled and a greater number means more relevance. As we assume a single-class labeled data, we regard query-document pairs with relevance level 1 and 2 as 'relevant' and compile labeled data, and compile unlabeled data with all other pairs. As a result, there are 784 unique queries in total, and for each query, there are 5 labeled examples and 1,000 unlabeled examples on average. For each query-document pair, there is a 46-dimension feature vector, which consists of continuous features such as TF-IDF and language model values. The vector is given to the two-layer neural network in equation (16). The number of nodes in the hidden layer equals to the dimension size of the feature vector. We set the perturbation size to 300 unless otherwise specified.

Popular learning to rank approaches including RankNet [2], LambdaRank [4], and LambdaMART [3] as well as IRGAN [36] were employed as baselines. Note that a generator of IRGAN plays a role of negative example sampler. As our neural network employs ReLU [7] for an activation function instead of hyperbolic tangent, we also train IRGAN with ReLU on both generator and discriminator, and we report their best measures. We measure statistical significance of the improvement over this model with a paired t-test. We adopt precision at N and Normalized Discounted Cumulative Gain (NDCG) at N as performance metrics since they are standard in ad-hoc retrieval.

6.1.2 Result Analysis. The overall results are shown in Table 1. As described in [36], traditional learning to rank methods such as LambdaMART do not perform well since it is not specifically effective for semi-supervised learning. IRGAN_ReLU does not seem to differ much from IRGAN in terms of performance, but it performs better than IRGAN in NDCG measures. Our proposed approaches significantly outperform baselines in several measures. The improvement from our approaches except AdvIR_VAT is especially good for high-ranked documents. This is expected because our approaches train models with the generated very difficult examples, so they are especially beneficial for distinguishing top documents, who are more difficult to rank in general.

Among the proposed methods, AdvIR outperforms the other proposed methods in general. AdvIR_SVAT outperforms AdvIR_VAT especially for high-ranked documents, which can be identified by P@3 and N@3. Similar to the previous analysis, this is reasonable because it focuses on difficult unlabeled data so that it can affect more in the high-ranked documents. On the other hand, AdvIR_VAT learns from all unlabeled data, and the too easy examples may affect the model in a negative way.

(a) (b) (c) (d)

Figure 1: (a,b) Learning curves and (c,d) data efficiency on Web search

Table 1: Overall results on Web search. The best value for each metric is bold-faced. $*$ indicates statistical significance over IRGAN_ReLU. Relative improvement over IRGAN_ReLU is shown in parentheses.

	Prec@3	**Prec@5**	**Prec@10**
RankNet [2]	0.1619	0.1219	0.1010
LambdaRank [4]	0.1651	0.1352	0.1076
LambdaMART [3]	0.1368	0.1026	0.0846
IRGAN [36]	0.2000	0.1676	0.1248
IRGAN_ReLU	0.1937	0.1581	0.1286
AdvIR	**0.2349*** (21.3%)	0.1829* (15.7%)	**0.1305** (1.5%)
AdvIR_VAT	0.2000 (3.3%)	**0.1867*** (18.1%)	0.1248 (-3.0%)
AdvIR_SVAT	0.2222 (14.7%)	0.1810* (14.5%)	0.1238 (-3.7%)
	NDCG@3	**NDCG@5**	**NDCG@10**
RankNet [2]	0.1801	0.1709	0.1943
LambdaRank [4]	0.1926	0.1920	0.2093
LambdaMART [3]	0.1573	0.1456	0.1627
IRGAN [36]	0.2148	0.2154	0.2380
IRGAN_ReLU	0.2230	0.2185	0.2473
AdvIR	**0.2682*** (20.3%)	**0.2568*** (17.5%)	**0.2696*** (9.0%)
AdvIR_VAT	0.2390 (7.2%)	0.2512* (15.0%)	0.2527 (2.2%)
AdvIR_SVAT	0.2598* (16.9%)	0.2538* (16.2%)	0.2593* (4.9%)

The learning curves of AdvIR are depicted in Figure 1a and 1b. The dotted horizontal lines indicate the baseline methods' best measures among all training epochs. We can see that from the early part of the training (epoch=50), it already outperforms the baselines on test data. As more training is done, it easily outperforms the baselines.

In order to see how efficient the models are in terms of data, we randomly removed labeled data and recorded their performance in Figure 1c and 1d. Surprisingly, two of our models, AdvIR and AdvIR_SVAT can still outperform IRGAN in NDCG@5, using only 5% of labeled data. In Precision@5, they outperform IRGAN with only 20% of labeled data. Also, it is shown that AdvIR_SVAT consistently outperforms AdvIR_VAT especially when the number of labeled data is less. Our conjecture is that as there are fewer labeled data, it is more important to focus on difficult unlabeled data to place the relevant documents in the top.

The effect of negative sampling methods on our proposed approach is depicted in Figure 2. Even with uniform sampling for negative examples, AdvIR outperforms IRGAN, which has its own negative example sampling technique. Our approach "generates"

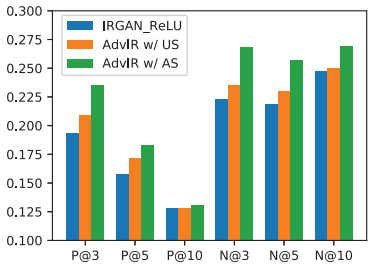

Figure 2: Effect of negative sampling methods for Web search. US stands for uniform sampling, and AS stands for adversarial sampling.

difficult negative examples instead of only "sampling" them, which is done by IRGAN. Through the dynamically generated difficult examples, AdvIR can learn from diverse difficult examples. In addition, IRGAN uses positive examples as they are whereas AdvIR generates difficult examples for even positive examples. These differences can explain the superiority of AdvIR to IRGAN even when uniform sampling is used for AdvIR. Switching from uniform sampling to adversarial sampling, AdvIR performs even better. This is reasonable because the difficult negative examples sampled by adversarial sampling serve as great basis for generating even more difficult negative examples by adversarial training.

6.2 Item Recommendation

6.2.1 Experimental Design. To perform experiments for the item recommendation task, we apply our approaches on a popular benchmark data set, Movielens (100k) [12]. It consists of 943 users, 1,683 items, and 100,000 user-item ratings, where ratings are in 5 levels. Following IRGAN [36], we regard the 4 and 5-star ratings as single-class labeled data[5] and all other entries as unlabeled data. We employ exactly the same data set as in [36] where a 4:1 random splitting is done for training/test data.

The input vectors, which are one-hot encoded vectors, for users and items thus have length 943 and 1,683, respectively. The input vectors are given to the matrix factorization model in equation (17). The size of latent vectors is 5. We set the perturbation size to 0.01 unless otherwise specified.

[5]It is described in [36] that only 5-star ratings are regarded as labeled data, but their published implementation regards both 4-star and 5-star ratings as labeled data.

Popular and state-of-the-art baselines are employed, including Bayesian Personalised Ranking (BPR) [29], LambdaRank-based collaborative filtering (LambdaFM) [40], and IRGAN [36]. Note that BPR samples negative items from uniform distribution while LambdaFM and IRGAN dynamically sample difficult negative items. To measure the statistical significance of our approach's improvement over IRGAN, we re-run IRGAN with their implementation and use the results to perform a paired t-test. Standard performance metrics such as precision at N and NDCG at N are employed.

Table 2: Overall results on item recommendation. $*$ indicates statistical significance over IRGAN_rerun.

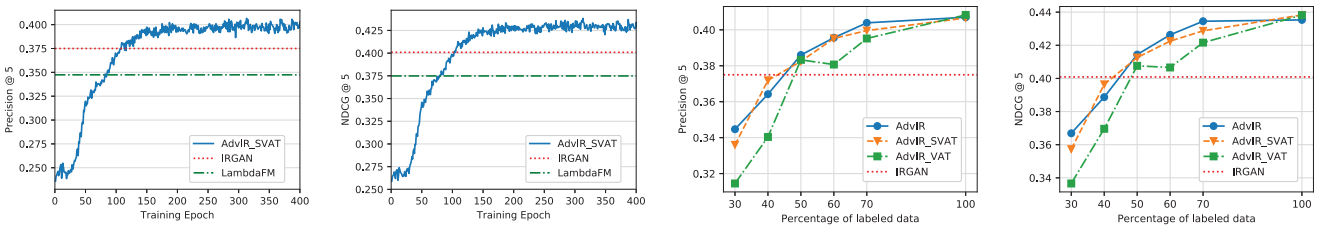
	Prec@3	**Prec@5**	**Prec@10**
BPR [29]	0.3289	0.3044	0.2656
LambdaFM [40]	0.3845	0.3474	0.2967
IRGAN [36]	0.4072	0.3750	0.3140
IRGAN_rerun	0.3999	0.3759	0.3217
AdvIR	0.4393* (9.9%)	0.4070* (8.3%)	0.3450* (7.2%)
AdvIR_VAT	0.4313* (7.9%)	**0.4083*** (8.6%)	0.3467* (7.8%)
AdvIR_SVAT	**0.4466*** (11.7%)	0.4066* (8.2%)	**0.3485*** (8.3%)
	NDCG@3	**NDCG@5**	**NDCG@10**
BPR [29]	0.3410	0.3245	0.3076
LambdaFM [40]	0.3986	0.3749	0.3518
IRGAN [36]	0.4222	0.4009	0.3723
IRGAN_rerun	0.4166	0.4010	0.3779
AdvIR	0.4563* (9.5%)	0.4353* (8.6%)	0.4079* (7.9%)
AdvIR_VAT	0.4539* (8.9%)	0.4382* (9.3%)	0.4108* (8.7%)
AdvIR_SVAT	**0.4641*** (11.4%)	**0.4383*** (9.3%)	**0.4183*** (10.7%)

6.2.2 Result Analysis. The overall results are shown in Table 2. The results indicate the dynamic negative item sampling approaches (LambdaFM, IRGAN, and AdvIR) outperform BPR, showing that negative item sampling is indeed important. Our proposed approaches significantly outperform baselines in all measures. Similar to the Web search task, our proposed approaches perform especially well for high-ranked documents in general; the very difficult examples generated by them are supposed to be beneficial for ranking top documents. Among our approaches, AdvIR_SVAT performs the best for this task, but the difference is small. Again, AdvIR and AdvIR_SVAT performs especially better for high-ranked items (P@3 and N@3) than AdvIR_VAT, with its focus on more difficult examples.

The learning curves of AdvIR_SVAT are depicted in Figure 3a and 3b. At around only 100 epochs, it starts to outperform the best measures of baselines. As more training is done, it shows better performance on the test data, and it gains little after 300 epochs. Different from Web search, the curves do not oscillate much for item recommendation.

The data efficiency is depicted in Figure 3c and 3d. Using only 50% of the labeled data, our proposed models outperform IRGAN in both Precision@5 and NDCG@5. Although our proposed approaches show significant improvements, its data efficiency for the item recommendation task is not as good as that for the Web search task. It is reasonable because it is more difficult to perform well for collaborative filtering when the number of labeled data is less; the information in transactions (user-item ratings) directly shrinks so that the models suffer from the cold-start problem. In other words, Web search can take advantage of text in the document when matching a document with a query, but a user does not have such information for collaborative filtering but has only user-item ratings; hence, it is much more difficult to perform well for item recommendation if there are fewer labeled data (user-item ratings). Similar to Web search results, it is shown that AdvIR_SVAT consistently outperforms AdvIR_VAT especially for fewer labeled data, with its focus on difficult unlabeled examples.

The effect of negative sampling methods is depicted in Figure 4. Similar to Web search results, AdvIR with uniform negative sampling still outperforms IRGAN, which has its own dynamic negative sampling mechanism. IRGAN only samples negative examples while AdvIR generates them on top of sampled negative examples. AdvIR also generates difficult examples for positive examples while IRGAN does not. These may have caused the superiority of AdvIR to IRGAN. Adversarial sampling again seems to play an important role in AdvIR for item recommendation. Adversarial sampling helps AdvIR to generate more difficult examples compared to uniform sampling, so AdvIR with adversarial sampling consistently outperforms that with uniform sampling.



6.3 Question Answering

6.3.1 Experimental Design. For question answering, we apply our approaches to one of the popular benchmark data sets, Insurance QA [6]. It consists of questions, which are submitted by users, and high-quality answers, which are written by domain experts. Training data consist of 12,887 (question, answer) pairs, and development data consist of 1,000 (question, answer) pairs. That is, a single-class labeled data (answer) is given for the task. We can thus regard the whole answer sets as unlabeled data to apply semi-supervised learning. There are two test sets (`test-1` and `test-2`), each of which consists of 1,800 (question, answer) pairs. The task is to retrieve the one and only correct answer from 500 candidate answers. Hence, we report precision @ 1 as the performance metric.

Both questions and answers are in raw text, so we apply the end-to-end model based on convolutional neural networks (CNN). The input vectors, which are one-hot encoded vectors, for questions and answers thus have length that is the vocabulary size, and the embedding vectors have 100 dimensions. We use the same CNN architecture as in IRGAN. The convolutional layer consists of 4 different kernels with sizes 1, 2, 3, and 5, and the feature maps after applying those kernels to the embedding are summarized by the max-pooling-over-time. Then, the resulting vectors for a question and an answer are given to equation (18) as $\mathbf{v}_q$ and $\mathbf{v}_d$, respectively. We set the perturbation size to 0.5 unless otherwise specified.

Strong baselines such as QA-CNN [30], LambdaCNN [30, 42] that enhances QA-CNN with dynamic negative sampling, and IRGAN [36] are employed. Note that uniform negative sampling is done by QA-CNN, and dynamic negative sampling is done in LambdaCNN and IRGAN. To measure the statistical significance of our approaches' improvement over IRGAN, we re-run IRGAN with their implementation and use the results to perform a paired t-test.

6.3.2 Result Analysis. The overall results on question answering are shown in Table 3. Approaches based on dynamic negative sampling techniques, including our approaches, IRGAN, and Lambda

(a) (b) (c) (d)

Figure 3: (a,b) Learning curves and (c,d) data efficiency on item recommendation

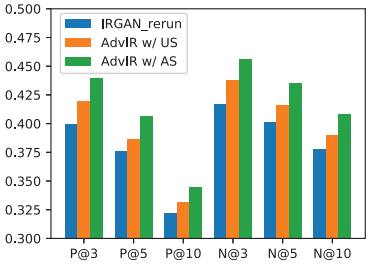


Figure 4: Effect of negative sampling methods for item recommendation. US stands for uniform sampling, and AS stands for adversarial sampling.

Table 3: Overall results on question answering. Precision@1 is reported.

	test-1	test-2
QA-CNN [30]	0.6133	0.5689
LambdaCNN [30, 42]	0.6294	0.6006
IRGAN [36]	0.6444	0.6111
IRGAN_rerun	0.6478	0.6028
AdvIR	0.6489 (0.2%)	**0.6150** (2.0%)
AdvIR_VAT	0.6450 (-0.4%)	0.6083 (0.9%)
AdvIR_SVAT	**0.6517** (0.6%)	0.6133 (1.7%)

CNN, outperform QA-CNN that is based on uniform negative sampling, but the difference in performance is not as big as that of Web search or item recommendation tasks. Although our proposed approaches outperform IRGAN in most measures, the improvements are not statistically significant. The performance difference among our proposed approaches is also small. There can be a couple of reasons for these. As the negative answers in the test data come from answers of other questions, the task is easier than other tasks. Thus, the advantage comes from learning with difficult examples may not be clearly shown in this data set. Indeed, the already high measures in Precision@1 tells the task is relatively easy. Also, there may not be negative examples that are difficult enough due to the data setting. A small improvement by dynamic negative sampling approaches compared to other tasks supports this.

The learning curves of AdvIR are depicted in Figure 5. Although it does not take advantage of pre-trained model as in IRGAN, AdvIR reaches high precision quickly (in 20 epochs). On the other hand, IRGAN, which starts with Precision@1 of 0.6 by pre-trained model, takes >30 epochs to reach Precision@1 >= 0.64 [36].

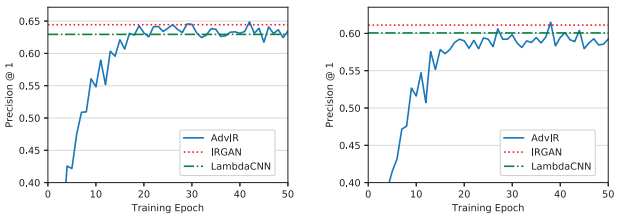

Figure 5: Learning curves on question answering for `test-1` (left) and `test-2` (right).

7 CONCLUSIONS

In this paper, we studied semi-supervised ad-hoc retrieval models with implicit feedback, where there are relatively fewer single-class labeled data and much more unlabeled data. We proposed an adversarial sampling and training framework that handles labeled data and unlabeled data differently. It adversarially generates informational examples for the positive class; on the other hand, it first adversarially samples informational examples for the negative class and further adversarially generates even more informational negative examples. We also proposed virtual adversarial training and selective virtual adversarial training that is more effective and efficient than the former, and they do not require labels to generate adversarial examples.

Experiments were performed on public benchmark data sets for three popular ad-hoc retrieval tasks such as Web search, item recommendation, and question answering. Experimental results show that (`i`) our proposed approaches are effective on ad-hoc retrieval tasks: they significantly outperform baselines on Web search and item recommendation and are on par with IRGAN on question answering, (`ii`) our proposed approaches perform especially well for high-ranked documents, (`iii`) our proposed approaches are data-efficient; (`iv`) adversarial sampling amplifies the effectiveness of adversarial training, and (`v`) our proposed selective virtual adversarial training is more effective and efficient than virtual adversarial training.

ABSTRACT

Invalid ad traffic is an inherent problem of programmatic advertising that has not been properly addressed so far. Traditionally, it has been considered that invalid ad traffic only harms the interests of advertisers, which pay for the cost of invalid ad impressions while other industry stakeholders earn revenue through commissions regardless of the quality of the impression. Our first contribution consists of providing evidence that shows how the Demand Side Platforms (DSPs), one of the most important intermediaries in the programmatic advertising supply chain, may be suffering from economic losses due to invalid ad traffic. Addressing the problem of invalid traffic at DSPs requires a highly scalable solution that can identify invalid traffic in real time at the individual bid request level. The second and main contribution is the design and implementation of a solution for the invalid traffic problem, a system that can be seamlessly integrated into the current programmatic ecosystem by the DSPs. Our system has been released under an open source license, becoming the first auditable solution for invalid ad traffic detection. The intrinsic transparency of our solution along with the good results obtained in industrial trials have led the World Federation of Advertisers to endorse it.

1 INTRODUCTION

Online advertising is a major social and economic driver of the so-called *Information Society*. First, online advertising sponsors free offerings of essential services to billions of users, such as Online Search Services, Map Services, and Social Media. Second, the market volume of online advertising reached, only in the US, $88 B in 2017 with an inter-annual growth rate of 21% [30]. Third, online advertising represents an important source of jobs. For instance, recent studies have estimated that 1 M direct and 6 M indirect jobs were associated with online advertising in the EU-28 workforce in 2015 [38]. Fourth, online advertising represents the fundamental source of income of the companies at the forefront of technological innovations such as Google or Facebook [2, 13]. Therefore, it is in the best interest of everyone (citizens, governments and the private sector) to guarantee the sustainable growth of this business. However, this sustainability is in jeopardy due to several factors. Arguably, the most important is the high volume of *invalid ad traffic*, i.e., delivered ads not shown to humans. It is estimated that every year trillions of delivered ad impressions are not watched by humans leading to losses of tens of billions of dollars for advertisers [18, 28].

Unfortunately, the identification and filtering of invalid ad traffic has not been properly addressed so far due to two fundamental reasons. First, a rapidly increasing fraction of ad transactions occur through a programmatic ecosystem, where a chain of intermediaries automatically connects advertisers willing to show ads and publishers owning the inventory (websites, mobile apps) to show those ads. This automatic process makes the detection of invalid traffic complex. Second, intermediaries in programmatic advertising receive a commission for each delivered ad, regardless if it is invalid or not. Then, it is well accepted the idea that invalid traffic only harms the interests of advertisers, which pay for the cost of the invalid ad impressions. Intermediaries in the supply chain get a commission for each served invalid impression and then they do not have direct monetary incentives to fight invalid traffic effectively.

Specialized companies referred to as verification vendors (e.g., IAS [20], DoubleVerify [11], White Ops [42]) have emerged offering opaque proprietary solutions for the identification of invalid traffic. Previous research has shown that even simple attack vectors can defeat these opaque defenses [8, 26]. These solutions do not properly address the concerns of advertisers, which have become

increasingly vocal about the uncertainty of the quality of programmatic media transactions [12, 39, 41] and the lack of transparency in the ecosystem [4, 9].

To meet the demands of advertisers, in this paper, we present the first open source (and thus auditable) solution for the detection of invalid ad traffic in programmatic advertising.

Prior to designing our solution, we have revisited the common idea that advertisers are the only stakeholders affected by invalid ad traffic in programmatic advertising. We present an economic model based on real financial reports of Demand Side Platforms (DSPs)–a key intermediary in the programmatic advertising ecosystem–and realistic assumptions on the operational set-up of DSPs, which provides initial evidence that invalid ad traffic seems to impact the business model of DSPs negatively. This finding suggests, contrary to the conventional wisdom, that DSPs may have strong incentives to filter invalid ad traffic. Our analysis concludes that post-bid (i.e., non real-time) detection of invalid traffic does not solve the problem for the DSPs. Instead, DSPs require a solution that can identify invalid traffic in real-time and at the level of individual ad transactions. Moreover, DSPs handle up to tens of billions of ad transactions per day, a factor imposing demanding computational performance constraints to the invalid traffic detection problem.

The main contribution of this paper is *Nameles*, an open source invalid ad traffic detection system that operates in real-time at the level of individual requests. Therefore, it meets the requirements of both advertisers and DSPs. Nameles identifies anomalous ad requests patterns of domains using an algorithm based on Shannon entropy. Nameles has been built in accord with the latest version of the OpenRTB specification [23] and is able to handle up to 500 k ad transactions per second, adding a total delay of less than 3 ms to each ad transaction. As a result, it can be seamlessly integrated into the programmatic supply-chain as a solution for the DSPs. We have applied Nameles on a stream of ~1.8 B daily bid request in two periods of two months separated one year from each other, observing that (on average) 20% of the daily ad traffic can be safely considered invalid.

Nameles' code is publicly available (under an open source license) and then auditable by anyone. This intrinsic transparency, along with the good detection performance shown by the system in extensive industry trials, has led the main global advertiser trade-body, the World Federation of Advertisers (WFA), to endorse Nameles.

2 BACKGROUND

In this section, we describe the process of serving an ad in programmatic advertising. We do it with an example of a user visiting a website, but the process is the same for ads shown in mobile apps.

A user connects to a website offering some ad spaces. Each ad space is typically leased by the website's publisher to an ad network or a Supply Side Platform (SSP), which upon the user's connection generates an ad request. This ad request may be forwarded through several intermediaries until it reaches the Ad Exchange. This part of the process is known as the *sell-side* and is represented by Step 1 in Figure 1. The ad request includes the domain name, IP address of the device, the User Agent, user's cookie(s), etc. Upon the reception of the ad request, the Ad Exchange initiates an auction which represents the *buy-side* of the programmatic process.

The bidding process of this auction is standardized by the OpenRTB protocol [23]. First, the Ad Exchange processes the information included in the ad request to generate a bid request whose format is specified by the OpenRTB standard [23]. For simplicity, in this paper, we will consider that a bid request includes the IP address receiving the ad and the domain name selling the ad space. Each bid request is sent to the Demand Side Platforms (DSPs) registered in the Ad Exchange. A DSP is an intermediary where advertisers, or their agencies, configure their programmatic advertising campaigns. Therefore, upon the reception of a bid request a DSP checks if the request meets the configuration parameters of any of its advertising campaigns and if so, it creates a bid response including, among other information, the price the advertiser is willing to pay for this ad space. Note that the bid responses to a given bid request have to be received by the Ad Exchange within 120 ms [15]. The Ad Exchange runs an auction based on the received bid responses and informs all the participant DSPs about the selected winner bid. The bidding process is represented by Steps 2-4 in Figure 1. To finalize the programmatic process the Ad Exchange coordinates the delivery of an URL from where to retrieve the ad, which is immediately downloaded by the browser and shown to the user. This is represented by step 5 in Figure 1.

From a business perspective, each bid event corresponds with an opportunity to place an online advertisement on a web page for the advertiser, and an opportunity to monetize an ad placement for the publisher. Based on their respective commission percentages (a reference of them obtained from insights from the industry is presented in Figure 1), the intermediaries are compensated every time a bid is successfully transacted, and an ad is displayed as a result. However, the advertiser only benefits when the traffic associated with the transaction is valid. This business model is open to fraudulent activity [18, 28, 29] (e.g., a publisher monetizing visits to a website coming from bots) whereas it seems not to offer the right incentives to intermediaries to identify and filter invalid ad traffic. Note that, according to various industry guidelines [14, 41], *invalid traffic is defined to correspond with those bid events where displaying an ad would not have any potential for advertising effect and the advertiser would lose its investment without getting anything in return.*

Verification companies (e.g., IAS, Double Verify or White Ops) have emerged recently offering proprietary opaque solutions for filtering invalid traffic. However, the lack of transparency on the used techniques makes it difficult to assess their actual capabilities. Indeed, recent works have demonstrated inefficiencies in these solutions [8, 26] and different studies attribute billions of dollars wasted in invalid traffic every year [18, 28, 29].

3 ECONOMIC IMPACT OF INVALID TRAFFIC IN DSP COMPANIES

In this section, we refute the argument that advertisers are the only stakeholders in the programmatic ecosystem negatively affected by invalid traffic [27]. To this end, we provide qualitative and quantitative economic analyses that support how, under realistic assumptions, invalid traffic negatively impacts the profitability of DSP companies.

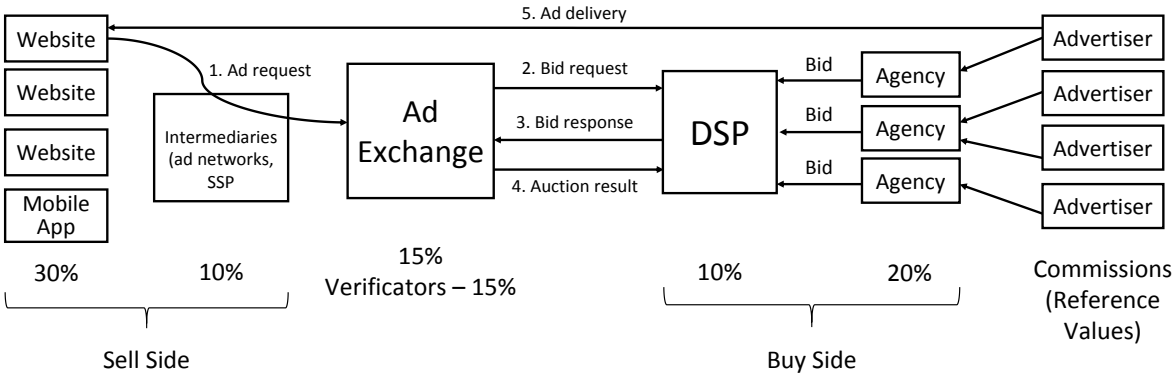

Figure 1: Overview of the programmatic advertising ecosystem operation.

-Qualitative Analysis: We investigated seven publicly listed DSP companies through their annual income statements and found that only one company had a positive net income. Moreover, depending on the DSP company, variable costs ranged from 30% to 50% of the revenue. Variable costs represent a proportion of total costs that vary as a function of revenue. These findings indicate that the low profitability of analyzed DSPs has a strong correlation with variable costs.

The DSP win-rate [9] is defined as the fraction of won bids out of all auctions. Regardless if an auction the DSP is hosting results in a win or not, the DSP bears the cost for facilitating that auction. Then, the inverse of the win-rate indicates how much a DSP company accumulated variable costs that yield no economic revenue. While valid bids represent a real opportunity for advertisers that provides an intangible value even to lost valid bids, in the case of invalid bids there is not a real opportunity and thus, lost invalid bids contribute exclusively to increase DSPs costs.

Based on interviews we conducted with DSP companies, we conclude that the DSP win-rate is typically between 5% to 20%. An individual advertiser win-rate has been shown to be in the range 0.1% to 1% [44], and ad exchanges (and ad networks) *fill-rate* (i.e., the fraction of successfully completed auctions) is commonly below 40% [35]. Consequently, we assert that there is an oversupply of programmatic ad inventory. This supports the economic viability of invalid traffic filtering so that even after removing the invalid ad traffic there will be still enough ad inventory available for DSPs.

In summary, all the above objective facts show that filtering invalid traffic would contribute to reducing the accumulated variable costs of DSPs without affecting the availability of ad inventory and as a result would lead to improving profitability and valuation of a DSP company.

Finally, to maximize the profitability of the DSP company, invalid bid requests should be identified in real time in the pre-bid stage, so that variable costs incurred by processing such invalid bids are minimized since the processing of the bid is stopped in the first step of the procedure.

-Quantitative Analysis: Net Present Value (NPV) model is the tool of choice for financial forecasting because it considers the time value of money, and provides a concrete metric to financial decision-makers, such as investors, for evaluating investment against the predicted return [3]. Finance theory endorses an investment if NPV is positive and higher than NPV of an alternative investment [3]. In addition to the NPV, we evaluated Enterprise Value (EV) [21], a useful variant of the NPV, that takes into account cash flows beyond the forecasted time window. Positive NPV and EV values are reached when the cash inflows exceed cash outflows [3]. NPV and EV are widely used as decision-making tools for planning purchases, mergers or acquisitions [3].

Table 1: Impact of invalid traffic filtering to economics of DSPs.

	Enterprise Value (EV)			Net Present Value (NPV)		
	No filtering	Filtering		No filtering	Filtering	
		Max [F=0,23; P=0]	Min [F=1; P=1]		Max [F=0,23; P=0]	Min [F=1; P=1]
DSP-1	10,544	19,002	-3,269	4,421	8,020	-1,979
DSP-2	2,516	5,194	-3,518	536	1,672	-2,213
DSP-3	3,254	3,833	-1,147	1,237	1,481	-706
DSP-4	1,184	2,973	-2,376	133	892	-1,498
DSP-5	1,702	2,648	-819	634	1,035	-506
DSP-6	1,354	2,342	-1,005	445	863	-628
DSP-7	1,595	2,262	-2,118	310	592	-1,337
Average	3,163	5,468	-2,036	1,101	2,079	-1,267

We compute NPV and EV for two scenarios; without invalid traffic filtering (Scenario A), and with filtering (Scenario B). The timeframe of the analysis is eight years. NPV and EV are computed based on five key factors:

1) Annual growth rates. In our analysis, they are based on the industry average of seven publicly listed DSPs' annual and quarterly income statements between 2012-2015 [16] and are the same for both scenarios.

2) Rate of return r. We use $r = 20\%$, which is a typical value for investments made into new products [3, 22], for both scenarios.

3) Invalid traffic filtering rate F. We consider $F = 0$ for Scenario A and F between 0 and 100% for Scenario B.

4) Revenue penalty P (as a dependent factor of F). We have selected the parameters of the penalty function to make the penalty increase in an exponential manner, such that the penalty is low until $F = 20 - 30\%$ and it spikes after this point until F reaches 100% where all traffic is filtered. This function has been carefully constructed so that a low penalty is imposed for filtering rates up to the average reported fraction of invalid traffic from different studies [10, 43].

5) Long-term cash flow growth rate G, which is set-up to 2% in both scenarios [25].

Our results show that there are NPV and EV gains for the DSP when the filtering rate increases from zero towards $F = 23\%$. Filtering invalid traffic beyond $F > 23\%$ first results in diminishing benefit and eventually drives a decline in revenue for the DSP. These results confirm our hypothesis that filtering invalid traffic (at a reasonable rate) improves DSPs profitability due to a reduction in variable costs. Table 1 shows the minimum and maximum values of NPV and EV, which correspond to [F;P] values of [0,23;0] and [1;1] in Scenario B, respectively. We observe that at the optimal filtering rate, NPV and EV in Scenario B increase (on average) 1,72 and 1,89 times in comparison with Scenario A, respectively.

Finally, we would like to note that the results obtained in this section represent a reference example based on realistic assumptions and should be interpreted as such.

4 DATASET

The dataset used in this paper includes a daily sample of incoming bid requests stream data collected in two different periods one year apart and each spanning two months between Dec 2016-Jan 2017 and Dec 2017-Jan 2018, respectively.

The data is from one of the largest DSPs with a significant global presence. The data consist of desktop and mobile bid events, for video, banner and in-app inventory. In particular, each daily sample includes between 1.7-1.9 Billion actual bid requests issued on that date from ~50 Ad Exchanges. These bid requests are associated (on average) to ~150 M IP addresses and ~900 k domains per day. The dataset includes the following information per bid request: a unique identifier, the IP address[1] and User Agent of the device initiating the ad request and the Web Domain or Mobile Application ID selling the ad space. For simplicity, we refer to both Web Domains and Mobile Apps as *Domains* along the paper.

5 SYSTEM REQUIREMENTS, DESIGN AND IMPLEMENTATION

In this section we describe *Nameles*, an open source system for the detection of invalid ad traffic that operates in real time and at the level of individual bid requests, thus meeting the requirements of DSPs and advertisers.

5.1 System's Functional Requirements

1. Scalability: DSPs typically handle tens of billions of bid requests per day. This maps into peaks of hundreds of thousands of bid request per second. Nameles must be capable of handling these high rates of bid requests.

2. Delay: The bid response to a given bid request has to be received by the Ad Exchange within 120 ms [15]. Hence, the delay introduced by Nameles should be limited to a few milliseconds in order to minimize the impact in the overall bidding process delay.

3. Accuracy in invalid traffic identification: Providing 100% guarantee that a bid request is invalid (or not) is not feasible. Instead, it is more reliable providing a score indicating the likelihood that a bid request is invalid. Therefore, our system must incorporate an accurate scoring algorithm.

[1]We anonymize the IP address before any processing.

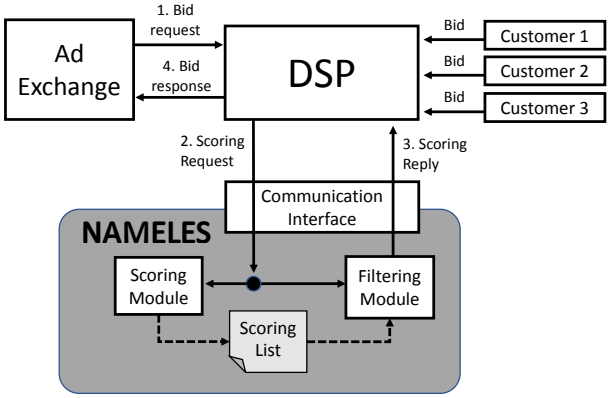

Figure 2: Programmatic Ecosystem Scheme with Nameles.

5.2 System Design

In this subsection, we present a brief overview of the system functionality and how it is integrated with the programmatic advertising ecosystem. Then, we describe in detail each of the functional blocks forming Nameles.

5.2.1 Overview. Figure 2 depicts a high-level representation of Nameles functional blocks. Moreover, the figure shows how Nameles could be integrated into the programmatic ad delivery chain as an auxiliary service for DSPs. The only difference with respect to the current operation of a DSP would be that, as part of the pre-bid phase, the DSP makes a request to Nameles to provide a Confidence Score per bid request. To this end, the DSP sends a *scoring request* to Nameles (step 2 in Figure 2). The scoring request includes the following fields: bid request id (to allow mapping Nameles result to the corresponding bid request), IP address of the device associated with the ad request and the domain offering the ad space. This information is included in the bid requests as defined in the OpenRTB protocol standard [23]. The *scoring request* is delivered to two independent modules of Nameles: the *Scoring* module and the *Filtering* module.

Because the DSP has limited information about a bid request to determine if it is invalid or not, we propose to aggregate all bid requests from a domain and use statistical analysis to determine the level of confidence of a domain. This approach provides statistically robust Confidence Scores for domains since they are computed from a sample of (at least) hundreds of bid requests. Then, Nameles assigns to the bid requests from a domain the Confidence Score of such domain. The *Scoring Module* is responsible for computing the Confidence Score for domains present in the bid requests received by the DSP. Moreover, it groups the domains in four different Confidence Classes. This information is summarized in the *Scoring List*.

The *Filtering* module is responsible for classifying in real-time each received *scoring request*. To this end, it retrieves the domain id from the *scoring request* and obtains the domain's Confidence Score and Confidence Class from the *Scoring List* introduced above.

After that, it creates a *scoring reply* to be sent to the DSP (Step 3 in Figure 2). This reply includes the following information: bid request id (extracted from the corresponding scoring request), the domain Confidence Score, and the domain Confidence Class.

Finally, the *Communication Interface Module* handles the communication between the DSP and Nameles.

5.2.2 Communication Interface Module. This module manages the delivery of scoring requests from the DSP to Nameles and scoring replies in the opposite direction. We have opted to use a parallel pipeline communication structure. In particular, the DSP creates two queues: a sending queue used for pushing scoring requests to Nameles and a receiving queue for pulling scoring replies from Nameles in return. Nameles sets up a number of worker processes, which connect to the sockets associated with both queues. These workers pull scoring requests from the sending queue and forward them to the Scoring and Filtering modules. The resulting scoring replies are pushed by the workers to the receiving queue of the DSP.

This parallel pipeline communication structure is highly scalable, being able to handle streams of hundreds of thousands of requests per second with processing delays below 3 ms (see Section 6.2).

5.2.3 Scoring Module. The goal of the scoring module is to produce a *Scoring List* of domains to be used by the *Filtering* module. This list is updated daily. Since Nameles operates in real-time, the list used at day d is obtained from a prediction algorithm applied on the historical *Confidence Score* values of domains at days $d-1$, $d-2$, $d-3$, ... This module implements three different algorithms to produce the *Scoring List*: one to compute the Confidence Score of each domain, a second to compute the Confidence Classes, and a third to derive the *Scoring list* to be used at day d based on historical information. Next, we describe each of these algorithms.

- Confidence Score computation: A DSP can reconstruct the traffic pattern associated with a given domain X by analyzing the distribution of a number of requests across the IP addresses included in the bid requests associated to X. This is the fundamental signal used by our algorithm. Skewed distributions, where most bid requests come from just a few IP addresses, are for obvious reasons suspicious[2] and thus domains presenting such traffic patterns should be assigned low Confidence Scores. Instead, legit traffic patterns correspond to more homogeneous distributions of bid requests across IPs and domains presenting such distributions should receive high Confidence Scores.

We compute the Shannon Entropy [33] of the distribution of bid requests across IP addresses for each domain. The Shannon Entropy summarizes in a single value the level of determinism of a distribution and ranges between 0 (all bid requests to a domain come from a single IP address) and $log_2(n)$ (the bid requests are homogeneously distributed across the n IP addresses making ad requests to the domain).

Shannon entropy has been successfully used in the field of anomaly detection [24, 40]. However, in our case, it has an important limitation because it does not consider the volume of bid requests, but just the shape of the distribution of bid requests. This limitation prevents the direct comparison of domains with different traffic volumes. For instance, a domain with 5 bid requests uniformly distributed across 5 IPs would have the same Entropy value (2.32) than a domain with 5000 bid requests homogeneously distributed across 5 IPs. While the first domain is just an unpopular domain, the second one is highly suspicious, having a high number of daily visits distributed evenly across a small number of IPs.

[2]For instance, a domain receiving most of its visits from scrapers or from other types of bots associated with fraudulent ad traffic.

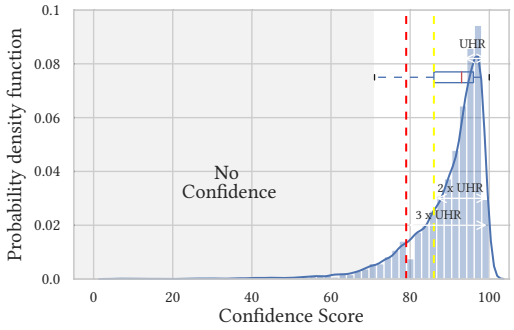

Figure 3: Distribution of Confidence Score (CS) values for domains with more than 500 bid requests at January 15, 2018.

To address this limitation, we propose a normalization process that takes into account the volume of bid requests associated with a domain X. In essence, we compute the ratio of the Shannon entropy and the binary logarithm of the total number of bid requests ($C(X)$) and scale the resulting value to a normalized range between 0 and 100. This normalized entropy score is the *Confidence Score* (CS) assigned to domains by Nameles, and its formal expression is:

$$CS(X) = 100\left(1 - \frac{\sum_{i=1}^{n} C(x_i)\, log_2(C(x_i))}{C(X)\, log_2(C(X))}\right) \quad (1)$$

To get an intuition on the effect of this normalization process, we can consider the toy example mentioned above. The domain with 5 bid requests from 5 IP addresses would have a high CS equal to 100 whereas the domain with 5000 bid requests would have a low CS equal to 19.

- Computation of the Confidence Classes: We first analyzed the probability distribution function of the CS values across domains in our daily datasets. Figure 3 shows this distribution for a specific day. Note that other days in our dataset showed similar distributions. We observed a skewed distribution concentrated in the high CS values with a long tail towards low CS values. This distribution indicates that most domains present homogeneous traffic patterns (represented by high CS) while as we move towards lower values of CS, we find domains with infrequent (i.e., statistically unlikely) traffic patterns offering lower confidence.

To define the Confidence Classes, we use two different unsupervised statistical methods that divide the distribution in 4 ranges each representing a single Confidence Class:

- *Outlier detection method*: This method identifies outlier CS values based on the definition of traditional outliers [31], i.e., $CS(X) < 25\ percentile - 1.5 \times IQR$. Nameles uses this expression to define the threshold for the *No Confidence* Class including domains with an extremely deterministic and infrequent traffic pattern.

- *Dispersion method*: We defined intermediate Confidence Classes between the one formed by outliers and the one composed by the mass of legit domains. To this end, we use the Upper Half Range[3] (UHR) of the distribution as our dispersion metric and define two new thresholds as $max\,(CS) - 2 \times UHR$ and $max\,(CS) - 3 \times UHR$. Based on these thresholds we defined the following Confidence Classes:

  - *Low Confidence Class*: formed by domains whose CS falls in the range $max\,(CS) - 3\,UHR > CS \geq 25\,percentile - 1.5\,IQR$.
  - *Moderate Confidence Class*: formed by domains whose CS falls in the range $max\,(CS) - 2\,UHR > CS \geq max\,(CS) - 3\,UHR$.
  - *High Confidence Class*: formed by domains whose CS falls in the range $CS \geq max\,(CS) - 2\,UHR$.

Figure 3 shows the defined Confidence Classes for the Confidence Score distribution of the dataset of Jan 15, 2018.

- Predicting the Scoring List: The Scoring list used at day d has to be inferred from a prediction algorithm applied to the historical Confidence Score values of domains at days $d-1$, $d-2$, $d-3$, ...We refer to the estimated CS value of a domain X included in this list as $CS^*_d\,(X)$. To define the prediction algorithm, we first studied the stationary properties of the temporal series of CS values of domains across the 62 days forming each of our datasets. This analysis revealed that CS values present high stationarity, with 40% of the domains in our dataset being strictly stationary (with a 90% confidence interval), as reported by the Augmented Dickey-Fuller test [32]. The analysis of the autocorrelation and partial autocorrelation functions for these domains revealed that in general, only the CS of the previous day ($CS_{d-1}\,(X)$) contributes significantly to the prediction of $CS\,(X)$ at day d. Then, the best predictor is $CS^*_d\,(X) = CS_{d-1}\,(X)$ and the Scoring List to be used at day d is formed by the $CS^*_d\,(X)$ of the different domains in our dataset.

As a result of the application of the three described algorithms, the Scoring Module produces each day a Scoring List that includes both the Confidence Score and the Confidence Class for each individual domain.

5.2.4 Filtering Module. This module processes in real-time each scoring request received from the Communication Interface module. In particular, it extracts the domain from the scoring request and searches for the $CS^*_d\,(X)$ and the Confidence Class associated with the domain in the Scoring list. As a result of this process, the Filtering Module generates a *scoring reply* message including the following information: Bid Request ID (obtained from the corresponding scoring request) and the domain's CS and Confidence Class. The scoring reply is sent to the DSP through the Communication Interface module. Note that if the domain extracted from the scoring request is not present in the Scoring list, the scoring reply has the following content <bid request id, NULL, NULL>.

5.3 System Implementation

In this subsection, we describe our implementation of Nameles that meets the performance and scalability requirements defined in Subsection 5.1.

[3]The UHR is measured as the distance between the median and the maximum value of the CS distribution.

5.3.1 The Communication Interface and Filtering module. The Communication Interface and the Filtering modules address different functional aspects of Nameles, and thus we have described them separately in Section 5.2. In our Nameles prototype, we use an integrated implementation of these two functional modules for efficiency purposes. We implement the parallel pipeline communication structure described in Section 5.2.2 on top of ZeroMQ [19] (a highly scalable distributed messaging system) using the existing Java bindings for this purpose. On the Nameles side, we use 6 workers that in addition to taking care of the pull and push communication functions, implement the filtering process. Each worker is an independent process, which has an independent copy of the Scoring List hash table produced by the Scoring Module allocated in RAM. Moreover, each worker pulls independently scoring requests from the DSP's sending queue. For each scoring request, it extracts the domain, obtains the CS and Confidence Class associated with the domain from the Scoring List hash table, creates the scoring reply and pushes it to the DSP's receiving queue.

5.3.2 The Scoring Module. The Scoring Module implements a temporary hash table including the number of bid requests associated with each pair <domain, IP>. For each new bid request, the counter of the tuple <domain, IP> included in the bid request is increased by 1. At the end of every day, the resulting hash table includes the needed information to compute the Confidence Score for each domain as well as the thresholds to define the different Confidence Classes. For this purpose, we store this temporary table into a PostgreSQL database and use different PostgreSQL functions and Java scripts to obtain the CS and the Confidence Class of each domain. The final result of the process is the Scoring List, which is stored in a hash table using as a key the domain id and as value the tuple <CS, Confidence Class>. This table is transferred to the "Communication Interface and Filtering" module to be used in the real-time filtering of bid requests.

6 PERFORMANCE EVALUATION OF THE SYSTEM

We have deployed a realistic experimental set-up to confirm that our Nameles prototype meets the requirements defined in Section 5.1.

6.1 Experimental Set-up

The experimental set-up replicates a production set-up used by a large-scale DSP. In particular, we use three servers in our setup for Nameles. The first server plays the role of the DSP. This server uses the real stream of bid requests from our dataset to produce a stream of scoring requests to Nameles. The rate of scoring requests is a configurable parameter so that we can perform stress tests by using significantly higher rates of bids per second than the ones reflected in our dataset. The second server deploys the "Communication Interface and Filtering" module of our Nameles prototype. It receives the stream of scoring requests from the DSP server and processes it to obtain the scoring replies. In addition, this server forwards the scoring requests to a third server, which implements the "Scoring" module.

The server emulating the DSP is a Dell PowerEdge R710 with 16 cores and 48 GB of RAM. The servers implementing the "Communication and Filtering" and the "Scoring" modules are similar,

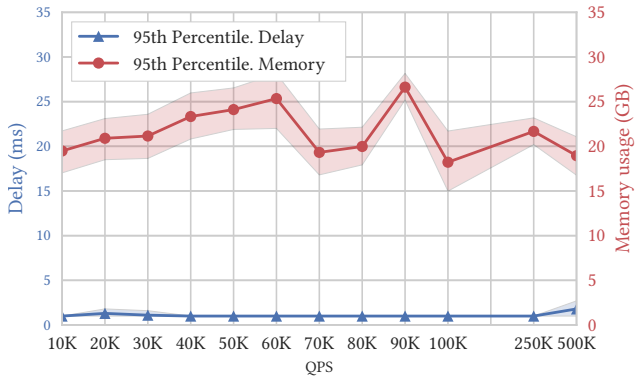

Figure 4: 95 percentile of delay and memory consumption for the filtering process at different input request rates.

a Dell PowerEdge R730xd with 24 cores and 64 GB of RAM. The servers are connected to a conventional 1 Gbps Ethernet switch. In the context of common use in the Adtech industry, the resources employed in our prototype can be considered commodity hardware.

6.2 Scalability and Processing Delay

6.2.1 Scoring List computation time. A critical aspect of the scalability of Nameles resides in its ability to produce the Scoring List in a short time. Specifically, given that the Scoring List is updated daily, the computation process must guarantee that the new list is ready before the expiration of the previous one, i.e., in less than 24 h. We have measured the computation time for every daily dataset, including between 1.7-1.9 B bid requests, and confirmed that it is always shorter than 4 hours. Hence, Nameles meets the scalability requirements for this critical process.

6.2.2 Delay and memory consumption of the filtering process. From the DSP's perspective, the filtering process starts when it sends a Scoring Request and finishes when it receives the corresponding Scoring Reply. The analysis of our dataset reveals an average and a peak rate of 22 k and 26 k requests per second, respectively. Then, our prototype must meet the next two requirements while processing scoring requests streams at the observed peak rate: not overflowing the memory of the server and offering a small delay to minimize its impact on the overall delay of the real-time bidding process.

We have evaluated the performance of our prototype for scoring request streams ranging from 10 k to 500 k queries per second (QPS). For each of the analyzed rates, we run stress tests of 5 minutes. During the tests, we measure the individual delay associated with the filtering process of each scoring request as well as the overall memory consumption of the filtering process. Figure 4 summarizes the performance of our Nameles prototype. The x-axis shows the different tested scoring request rates. The left y-axis and right y-axis show the 95-percentile filtering delay and 95-percentile memory consumption measured during the experiment for the different scoring request rates (QPS), respectively. Note that each stress test has been run 5 times. The line in the figure represents the average of 95-percentile values across the five experiments whereas the lighter color area shows the max and min 95-percentile values.

First of all, we observe that the system performance is quite stable across the different experiments and the observed variability in memory consumption is due to the instantaneous load of the server at the measurement moment rather than the QPS of the experiment. The results of the stress tests demonstrate that our Nameles prototype offers very high scalability performance. In particular, the 95 percentile of memory consumption and delay is lower than 28 GB and 3 ms for any of the considered QPS. These results prove that our filtering process scales to handle more than 20 B bid requests per day with a modest infrastructure, meeting the requirements of the largest DSPs such as Google, The Trading Desk and MediaMath.

6.3 Scoring Accuracy

In this subsection, we assess both the accuracy of our prediction algorithm and the accuracy of the Confidence Scores assigned to domains.

6.3.1 Accuracy of the prediction algorithm. For each daily dataset, we have computed the Root Mean Square Error (RMSE) of the difference between the predicted CS ($CS^*_d(X)$) and the actual CS ($CS_d(X)$) across all domains. The results indicate that the RMSE is smaller than 3 points in every case.

In addition, we have evaluated the misclassification rate of domains among Confidence Classes. We observe that the average misclassification rates across all days in our dataset are below 3% between any pair of classes. A careful analysis of the misclassified domains indicates that the classification errors are mainly associated with domains having a CS close to the threshold that separates two contiguous classes. This is also coherent with the fact that misclassifications between non-contiguous classes are negligible (< 0.3%).

6.3.2 Assessment of Confidence Score accuracy. The accuracy of the Confidence Score cannot be objectively evaluated. There are various continuously changing factors related to the invalid traffic problem; attack vectors, domain traffic profiles, and others. As a result, ground truth datasets for evaluating invalid traffic filtering solutions do not exist. Indeed, to the best of the authors' knowledge, previous related academic works [6, 37] rely on manual validation whereas proprietary commercial solutions do not offer any publicly available accuracy evaluation analysis.

In this subsection, we present for the first time an objective approach to (at least partially) assess the accuracy of invalid ad traffic detection tools. While we acknowledge our approach is far from ideal, it does not suffer from the severe limitations associated with manual validation such as: 1) limited scalability since only a handful of domains can be manually evaluated; 2) it suffers from human errors due to the lack of sufficient knowledge, lack of motivation, distractions, etc.

In particular, we propose a two-fold approach to validate the classification accuracy of Nameles:

(1) We compare the result of Nameles scoring with the following widely used ad tech metrics:

- **Bounce Rate:** This metric measures the fraction of sessions that only visit a single page in a domain. A low bounce rate is a strong indication of low-quality traffic.

Table 2: Value of external quality metrics associated with domains in each of the defined Confidence Classes in our dataset.

		No Conf.		Low Conf.		Moderate Conf.		High Conf.
Alexa Upstream traffic from Google and Facebook (%)	median	20	(-41%)	18.5	(-45%)	23.7	(-30%)	33.7
	IQR	21.05		20.19		24.19		32.84
Alexa Bounce rate (%)	median	41.8	(-27%)	40.9	(-29%)	35.3	(-39%)	57.5
	IQR	32.4		25.6		27.7		28.7
Alexa Search traffic (%)	median	8.1	(-35%)	7.7	(-38%)	5.5	(-56%)	12.5
	IQR	19.7		15.9		16.1		16.9
Alexa Total sites linking to the domain	median	9.2	(-75%)	131	(-62%)	256	(-27%)	348
	IQR	616		371		800		1,198
SimilarWeb Bounce rate (%)	median	51.5	(-12%)	38.8	(-34%)	34.9	(-40%)	58.6
	IQR	24.97		20.84		24.8		24.0
SimilarWeb Direct traffic (%)	median	43.1	(68%)	34.2	(34%)	38.1	(49%)	25.6
	IQR	39.5		37.0		34.6		27.8
SimilarWeb Search traffic (%)	median	21.2	(-31%)	29.3	(-5%)	19.5	(-37%)	30.9
	IQR	39.3		46.5		39.5		39.8

- **Traffic from popular publishers:** This metric represents the percentage of upstream traffic coming to the domain from popular publishers. In particular, the two publishers contributing a larger fraction of traffic to domains are Google and Facebook. Then, for our validation, we will compute the fraction of upstream traffic coming from Google and Facebook to a domain. A very low fraction of traffic coming from them may reveal the presence of low-quality traffic.

- **Search Traffic:** This metric measures the percentage of traffic coming to the domain from search engines. A very low search traffic percentage is often an indication of low-quality traffic.

- **Direct Traffic:** This metric measures the percentage of traffic that reaches the domain directly without being redirected from other websites. In this case, a large fraction of direct traffic is usually linked to low-quality traffic.

- **Number of sites linking to a domain:** An interesting domain attracting high-quality traffic would typically be linked from a large number of other sites. Contrary to this, domains associated with ad fraud or other malicious practices would typically be linked from a lower number of sites.

To obtain these metrics, we have queried two well-known services, Alexa [1] and SimilarWeb [34]. Table 2 presents the median and IQR values for the distribution of each one of these metrics for each Confidence Class. In addition, the table shows the relative difference of the median values of these metrics for the "No", "Low" and "Moderate" Confidence Classes in comparison to the "High" Confidence Class. We observed substantial differences (up to 75% in some cases) between the "High Confidence" Class and the rest.

(2) Low-quality domains and thus their ad inventory are likely to have a short-term lifetime (i.e., being more volatile) in the online advertising ecosystem for multiple reasons: they might be committing fraud and being detected and blacklisted or removed by fraudsters after short periods of times to avoid detection; they provide poor KPIs and thus the bidding prices for their inventory dramatically decrease making them no longer profitable, etc. We have measured the volatility associated with the domains of each of the confidence classes defined by Nameles. In particular, we have computed the fraction of domains of each class in our oldest dataset that are still present one year later in our most recent dataset. The result shows that (4.5; 1.2; 6.4; 35.0)% of domains within the ("No", "Low", "Moderate" and "High") confidence classes in our 16-17 dataset are still present in our 17-18 dataset. We observe that the volatility of the "High" Confidence Class is one order of magnitude smaller than in other classes[4].

The results from our two-fold objective validation suggest that our scoring mechanism accurately identifies legitimate domains and thus it is suitable for adoption by DSPs. Finally, it is also worth noting that we have worked together with experts from the Ad Tech industry over a period of 18 months to let them subjectively evaluate the results provided by Nameles in extensive trials. The satisfactory results obtained during these tests have led the World Federation of Advertisers to endorse Nameles.

7 RESULTS OBTAINED FROM NAMELES' EXECUTION

In this section, we present the results obtained from applying Nameles to our large-scale dataset. First, we analyze the distribution of domains and traffic across the defined Confidence Classes. Then, we quantify the positive impact that Nameles may have in the profitability of DSPs using as reference the economic model described in Section 3.

-Longitudinal Analysis of domains' confidence level: Figure 5 shows the fraction of domains and ad traffic (i.e., bid requests) belonging to each of the defined Confidence Classes in our 16-17 and 17-18 datasets, respectively. The main bar shows the average, and the error bar shows the 95% confidence interval across the days in the dataset.

On average, in our 16-17 dataset (11.2; 8.8; 33.3; 46.7)% of the traffic is associated with ("No", "Low", "Moderate" and "High") Confidence Classes. Whereas in our 17-18 dataset (7.0; 13.9; 36.3; 42.8)% of the traffic belong to the ("No", "Low", "Moderate" and "High") classes. We find an overall stable behavior across time. In particular, there exists ~20% low-quality traffic (belonging to the "No" and "Low" confidence classes) in both datasets. These results imply that, for instance, a DSP handling 50 B bid request per day using a policy that filters traffic belonging to "No" and "Low" classes would

[4]There is an apparent systemic volatility since even in the high confidence class only 35.0% of the domains remain in the 17-18 dataset. While there exists such systemic volatility, the reported one is likely to be inflated because our datasets represent a subsample of the overall ad inventory available at the measurement time.

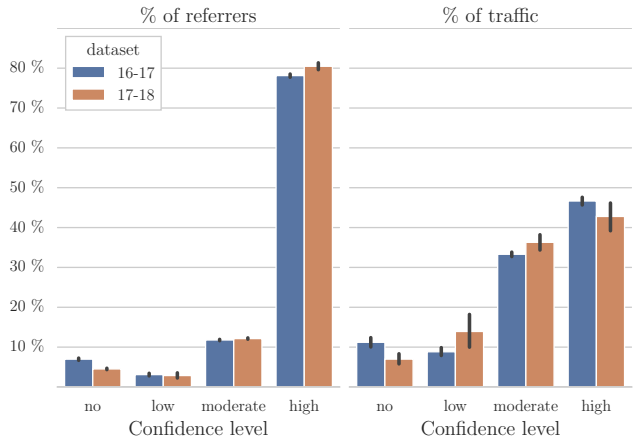

Figure 5: Percentage of domains and ad traffic in each of the Confidence Classes across the 62 days of the dataset. The main bar presents the average value whereas the error bars show the confidence interval at the 95%.

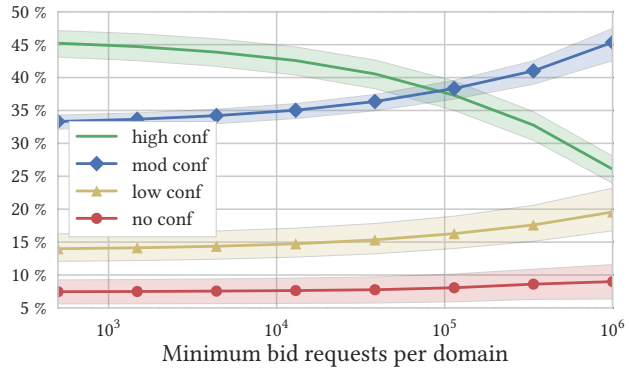

Figure 6: Percentage of ad traffic in each Confidence Class as function of the popularity (i.e., bid requests) of domains.

eliminate (on average) around 10 B (20%) bid requests every day. However, it is worth mentioning that there seems to be a transfer of ~5% traffic from the "No" to the "Low" confidence class between the 16-17 and 17-18 datasets, this may be interpreted as a slight improvement in the behavior of the ecosystem for DSPs filtering traffic at the "No" confidence level. Contrary, a transfer of ~4% traffic is observed from the "High" to the "Moderate" confidence class, which may likewise be interpreted as a slight worsening of the ecosystem behavior for DSPs accepting traffic exclusively from the "High" confidence class.

In addition, we analyzed how popularity relates to confidence. To this end, we computed the average (and standard deviation) fraction of traffic within each Confidence Class for domains with at least 500, 1 k, 10 k, 50 k, 100 k, and 1 M bid requests per day for our 16-17 dataset. Figure 6 shows the results. One may expect that as more popular domains are considered, the fraction of domains within the "High" Confidence Class would increase and the fraction in other groups would decrease. However, we observe the opposite trend between "Moderate" (which increases) and "High" (which decreases) classes. In the case of "Low" and "No" Classes we observe just a light increase after 100 k daily bid requests.

-Nameles' impact on DSPs' profitability: The results in the previous subsection provide specific figures on the filtering rates of Nameles at different confidence levels. For instance, in our 16-17 dataset, a filtering rate of 11.21% filters out traffic from domains with very rare traffic patterns that offer no confidence. A filtering rate of 20.04% eliminates traffic offering low or no confidence, and a filtering rate of 53.34% filters any domain that does not provide high confidence.

Using these filtering rates as input to the economic model presented in Section 3 gives us an estimation of the impact that Nameles is expected to have in the profitability of a DSP. The obtained results indicate that filtering at the "No Confidence", "Low Confidence" and "Moderate Confidence" level offer NPV (and EV) improvements in comparison to the scenario without filtering of 41, 54 and -204% (14, 19 and -71%). We observe that filtering at the "Moderate Confidence" level would not be recommended. On the other hand, filtering at the "No Confidence" or "Low Confidence" class leads to a strong positive economic impact. Note that results considering the 17-18 datasets are consistent.

8 NAMELES' APPLICABILITY AND EXTENSIBILITY

- **Applicability by other players:** In addition to DSPs, Nameles can be easily integrated with other players of the programmatic advertising supply chain such as Ad Exchanges or SSPs, which handle a representative fraction of the ad traffic of a given domain. Also, Publishers can integrate Nameles to self-generate the CS of their websites and mobile apps.

-Extensibility to other signals: The concept of entropy allows us to compute the CS considering different signals. In particular, in addition to the default signal used in this paper (CS of domains), we have computed the CS of individual IP addresses. To this end, we consider the traffic pattern generated by each IP address as the distribution of ad requests it sends across different domains. Having the CS for the IP and the domain within a bid request enriches the decision capacity of the DSP since such bid request can be dropped due to a low CS associated with the IP address as well. We have computed the CS for all IP addresses (with more than 500 entries) for every daily sample in our dataset and based on it, we have re-calculated the fraction of traffic belonging to the Confidence Classes more likely to be filtered by DSPs' policies (i.e., *None* and *Low* Confidence). Adding the information about the CS of IP addresses increases the fraction of traffic in these two categories in less than 0.5%. This result indicates that the application of Nameles at the level of domains suffices to identify more than 99% of low-quality ad traffic.

9 NAMELES' LIMITATIONS

In this section, we discuss the main limitations of Nameles and argue why despite them, Nameles is still an important contribution.

- **False Negatives:** They are represented by the invalid traffic not identified by Nameles. In the presence of Nameles, any attacker owning a domain d would be undetected if it is able to generate a normal (i.e., similar to the mass) traffic pattern for d. This is obviously doable, but it would require the attacker to increase the complexity of the attack. First, the attacker would need to infer the CS threshold over which it would not be detected. Second, an attacker performing n daily visits to its domain from m IPs leading to a low CS would need to either reduce n or increase m to increase its CS over the quality threshold defined by different DSPs. Both approaches lead to a revenue reduction.

To obtain a ballpark estimation of such reduction, we have computed the number of daily visits that all 8 K domains in the "No" and "Low" Confidence Classes in a given day of our dataset would need to remove in order to pass the threshold of the "Moderate" Class. We found that on average these domains would need to eliminate 38,5% visits leading to a roughly similar reduction in their revenue. Therefore, even when failing in the detection, Nameles contributes to reducing the profitability of possible attacks significantly.

-**False Positives:** They are represented by domains wrongly assigned a low CS. While false positives may have serious implications in other businesses, it is well-established in the programmatic advertising industry that false positives are not an issue for the buy-side, i.e., advertisers and DSPs, which are the target of our solution. The existing oversupply of ad spaces discussed in Section 3 guarantees that wrongly filtering a legitimate domain would not result in a lost opportunity of placing an ad that would be provided by other legitimate non-filtered domain. Therefore, we assert that false positives are not an important consideration in adopting Nameles.

- **Presence of NATs:** The widespread use of NATs may pollute the computation of a domain's CS since visits coming from different users behind a NATed IP address would be all assigned to that IP address, and thus Nameles could consider the traffic pattern of that domain more deterministic than it actually is. To analyze this potential limitation, we have re-computed the CS of all domains in our dataset using as input the visits coming from <IP, User Agent> pairs. The obtained results are similar to those presented in the paper. Given that the impact of NATs when considering <IP, User Agent> pairs as input is expected to be limited, we conclude that Nameles is minimally affected by the presence of NATs.

10 RELATED WORK

In addition to the abovementioned commercial proprietary solutions [11, 20, 42], the research community has also addressed the identification of invalid ad traffic. The proposed solutions focus on detecting invalid traffic at the sell side of the online advertising chain, i.e., publishers web pages [7] or delivered ads [5, 17]. These solutions analyze the interaction of the user with the web page or the served ad in order to identify commonly known attacks such as visits generated by bots [5] or redirection attacks [36]. None of these solutions are valid for DSPs. To the best of the author's knowledge, Stitelmant et al. [37] proposed the only alternative solution to Nameles able to operate at the DSP level. By analyzing the degree of overlapping in the IPs visiting two (or more) domains, their solution identifies potential invalid traffic. This is a complementary technique to our normalized entropy score, and thus both solutions can be used in parallel.

From a methodological perspective, there is a previous work that has used entropy to identify invalid video visits to a Chinese video portal [6]. The authors of this paper propose to use entropy as the final metric to assess the traffic quality and a semi-supervised classification that rely on manually labeled samples to differentiate between valid and invalid video traffic. However, as discussed in Section 5, the native Shannon entropy has an important drawback since its interpretation depends on the volume of associated events. To overcome this limitation, we use a Confidence Score based on a normalized version of entropy. Moreover, instead of using manual labeling of suspicious traffic, we define unsupervised statistically supported outlier detection method. Hence, Nameles clearly advance the state-of-the-art from a methodological perspective as well.

11 CONCLUSION

This paper introduces Nameles, a system for the detection of invalid ad traffic, which is one of the main problems faced by the online advertising industry. Nameles has been designed to meet the requirements of both advertisers and DSPs that together form the so-called buy-side of the programmatic advertising industry. On the one hand, Nameles is the first available open source solution for the identification of invalid traffic, responding to the advertisers' demand for transparency. On the other hand, the paper provides economic supported evidence that, contrary to conventional wisdom, show how DSPs may increase their profitability with invalid traffic filtering. For this, the applied solution needs to be highly scalable and operate in real time and at the level of individual bid requests. Nameles meets these requirements.

A Nameles prototype has been thoroughly tested in a realistic deployment. We demonstrate that even with modest resources, Nameles is able to process tens of billions of bid requests per day, with processing delays below 3ms per request and good detection accuracy. Moreover, applying Nameles on two datasets including each almost 2 B bid requests per day for a period of two months, we observe the presence of 20% invalid traffic. The evidenced performance of Nameles along with our open-source vision has led the World Federation of Advertisers to endorse Nameles as a solution to counter invalid traffic by the Adtech industry.

ABSTRACT

The curation of a knowledge base is a crucial but costly task. In this work, we propose to take advantage of the edit history of the knowledge base in order to learn how to correct constraint violations. Our method is based on rule mining, and uses the edits that solved some violations in the past to infer how to solve similar violations in the present. The experimental evaluation of our method on Wikidata shows significant improvements over baselines.

KEYWORDS

knowledge base; history; data cleaning; rule mining; Wikidata

1 INTRODUCTION

Knowledge bases (KBs) play a key role in many applications and lay at the core of the Semantic Web. They contain entities (such as persons, cities, etc.) and statements about them (such as relationships between persons, places of residence, etc.). In this work, we focus on RDFS-style KBs, such as Wikidata [38], YAGO [35] or DBpedia [7]. The data quality of a KB is crucial for its usability. However, it is usually very costly to check the correctness of the data, because KBs can be huge (Wikidata, e.g., contains about 50 millions entities). Moreover, KBs are often built using methods that are error-prone. For instance YAGO and DBpedia are automatically extracted from Wikipedia. Wikidata, for its part, is a collaborative KB that anyone can edit, with more than 18,000 active contributors.

A way of avoiding or at least detecting some of the flaws in the data is to impose *constraints* on the KB. Such constraints can enforce that some information must be present (e.g., imposing that every human being has a birth date), or that some statements may not occur (e.g., ensuring that a person is not also a city). Constraints are related to, but different from, ontological rules: A constraint imposes a certain condition, whereas an ontological rule infers certain statements. For example, consider a KB that contains the statement "Spinoza is a human being" without knowing any birth date for Spinoza, and consider a rule "All human beings have a birth date". If the rule is taken as an ontological rule, then it would just infer that Spinoza has some birth date. If the rule is taken as a constraint, in contrast, the KB would be considered incorrect. Constraints are thus similar in spirit to database integrity constraints. In practice, constraints often have exceptions. Therefore, it is useful to allow data that does not respect them (in Wikidata, e.g., constraint violations are simply flagged). Nonetheless, by design, most of the constraint violations are not exceptions but actual errors and proposing to repair them is a good starting point when it comes to improving KB quality.

In this paper, we aim at learning how to repair constraint violations. Our goal is to help a KB editor by suggesting how to clean the data locally (providing a solution to a particular constraint violation) or globally (providing rules that can be automatically applied to all constraint violations of a given form once validated by the editor). To do that, we take advantage of the *edit history* of the KB. We use it to mine *correction rules* that express how different kinds of constraint violations are usually solved. To the best of our knowledge, this is the first work that builds on past users corrections in order to infer possible new ones. We validate our framework experimentally on Wikidata, for which the whole edit history of more than 700 millions edits is available. Our experiments show substantial improvements over baselines. More concretely, our contributions are as follows:

- a formal definition of the problem of correction rule mining,
- a dataset of more than 67M past corrections for ten different kinds of Wikidata constraints (13k constraints in total),[1]
- a correction rule mining algorithm, together with an implementation for Wikidata, CorHist,[2]
- a suggestion tool for users to correct data based on our mined correction rules,[3]
- an experimental evaluation based both on the prediction of the corrections in the history and on user validation of the suggested local corrections.

2 RELATED WORK

We start with a brief discussion of works relevant to our problem along three axes: constraints for KBs, KB cleaning, and rule learning.

Constraints. Constraints have long been used in databases and KBs to express rules that the data should follow. Databases typically operate under the closed world assumption, where missing facts are considered to be false. This allows for "completeness" constraints such as tuple generating dependencies. KBs, in contrast, operate under the open world assumption, where missing

facts are not necessarily false. They thus classically have only "correctness" constraints, such as disjointness or functionality axioms (corresponding to special cases of denial constraints and equality generating dependencies in databases).

To express also completeness constraints, several works propose to use description logics, with varying semantics [28, 37]. Another possibility is to use queries that should or should not hold as constraints (see e.g., [24] for methods for writing constraint queries in SPARQL). Other approaches define constraint languages to specify conditions for RDF graph [9] validation, such as SHACL [22] or ShEx [8]. It has been argued in [30] that description logics under the closed world assumption are also suitable for constraint checking in RDF, which can then be implemented with SPARQL queries. In our work, we follow a similar path, using description logic axioms as constraints for RDFS KBs, because it corresponds best to what we observe in current real-world KBs.

Contrary to the above works, we do not aim at *expressing* constraints, but at *repairing* their violations. The correction rules we learn for this purpose are similar in spirit to active integrity constraints [11], which specify for each constraint a set of possible repair actions. This type of constraints has recently been applied to description logic KBs as well [32]. Conditioned active integrity constraints add conditions for choosing among the possible actions, and we propose, in a similar spirit, to take into account the context of the constraint violation to correct it. Different from the existing work [11, 32], our goal is to mine correction rules automatically from the edit history of the KB.

Knowledge base cleaning. Several recent approaches have dealt with the interactive cleaning of KBs. The proposed methods detect when a constraint is violated, compute the responsible facts, and then interact with the user to find out how to update the KB. The goal is then to minimize the number of questions the user has to answer. This is done in various ways, which include taking into account the dependencies among the facts to check or the interaction between several constraints violations to define heuristics to choose the best question to ask the user [2, 3, 5, 6].

Other approaches to improve the quality of a KB rely on statistics, clustering, or structural aspects of the KBs. The work of [31] uses statistics to add missing types to the KB, and to detect wrong statements. The work of [25] exploits the observation that cycles in the KB often contain wrong "IsA" relations. Again other approaches [1] use crowdsourcing to detect Linked Data quality issues. We refer the reader to Section 7.2 of [1] for a recent overview of approaches for data quality assessment.

Our method also exploits KB constraints. However, it differs from the above in that it *learns the corrections automatically* from the edit history. It thus taps a source of knowledge that has so far not been exploited.

Rule learning. Mining logical rules by finding correlations in a dataset is a well-established research topic. In particular, learning patterns in the data can be used for completing KBs [14, 36]. An algorithm for learning conjunctive patterns from a KB enriched with a set of rules is described in [20]. Methods similar to association rule mining have also been used for induction of new ontological rules from a KB [33]. A more recent trend is to use embedding-based models for KB completion. A comparison between these models and usual rule learning approaches is reported in [27] and significant recent works in this area include [19, 39, 40].

In this paper, we use a vanilla rule mining algorithm inspired by [14]. Our contribution is not the rule mining per se, but the application of rule mining to the edit history of a KB in order to mine correction rules. This avenue has, to the best of our knowledge, never been investigated.

3 PRELIMINARIES

In this work, we use description logics (DL) [4] as KB language and as constraint language, because they are the foundation of the Semantic Web standard OWL [16].

Syntax. We assume a set $\mathsf{N_C}$ of *concept names* (unary predicates, also called classes), a set $\mathsf{N_R}$ of *role names* (binary predicates, also called properties), and a set $\mathsf{N_I}$ of *individuals* (also called constants). An *ABox* (dataset) is a set of *concept or role assertions* of the form $A(a)$ or $R(a, b)$, where $A \in \mathsf{N_C}$, $R \in \mathsf{N_R}$, $a, b \in \mathsf{N_I}$. A *TBox* (ontology) is a set of axioms whose form depends on the DL $\mathcal{L}$ in question, and expresses relationships between concepts and roles (e.g., concept or role hierarchies, role domains and ranges...). A *knowledge base* (KB) $\mathcal{K} = \mathcal{T} \cup \mathcal{A}$ is the union of an ABox $\mathcal{A}$ and a TBox $\mathcal{T}$.

In this work, we assume that $\mathcal{T}$ is a *flat QL* TBox [23], i.e., that $\mathcal{L}$ differs from the standard *RDF Schema (RDFS)* [17] only by allowing inverse roles in role inclusions. More precisely, $\mathcal{T}$ can contain concept inclusions of the form $A_1 \sqsubseteq A_2$ (subclass), $\exists P \sqsubseteq A$ (domain or range), and role inclusions $P_1 \sqsubseteq P_2$ (subproperty), where $A_{(i)} \in \mathsf{N_C}$ and $P_{(i)} := R \mid R^-$ with $R \in \mathsf{N_R}$.

A KB can also be written as a set of *RDF triples* $\langle s, p, o\rangle$ where s is the *subject*, p is the *property*, and o the *object*, using special properties to translate concept membership and relationships between concepts and roles [29]. A concept assertion $A(a)$ is written as $\langle a, \texttt{rdf:type}, A\rangle$, and a role assertion $R(a, b)$ as $\langle a, R, b\rangle$. Flat QL TBox axioms can also be represented by single triples. For example, $A_1 \sqsubseteq A_2$ is written as $\langle A_1, \texttt{rdfs:subClassOf}, A_2\rangle$ and $\exists R^- \sqsubseteq A$ is written as $\langle R, \texttt{rdfs:range}, A\rangle$.

Semantics. We recall the standard semantics of DL KBs. An *interpretation* has the form $\mathcal{I} = (\Delta^\mathcal{I}, \cdot^\mathcal{I})$, where $\Delta^\mathcal{I}$ is a non-empty set and $\cdot^\mathcal{I}$ is a function that injectively maps each $a \in \mathsf{N_I}$ to $a^\mathcal{I} \in \Delta^\mathcal{I}$ (unique name assumption), $\top$ to $\Delta^\mathcal{I}$, each $A \in \mathsf{N_C}$ to $A^\mathcal{I} \subseteq \Delta^\mathcal{I}$, and each $R \in \mathsf{N_R}$ to $R^\mathcal{I} \subseteq \Delta^\mathcal{I} \times \Delta^\mathcal{I}$. The function $\cdot^\mathcal{I}$ is straightforwardly extended to general concepts and roles, e.g. $(\neg B)^\mathcal{I} = \Delta^\mathcal{I} \setminus B^\mathcal{I}$, $(R^-)^\mathcal{I} = \{(c, d) \mid (d, c) \in R^\mathcal{I}\}$, $\{a_1, \ldots, a_n\} = \{a_1^\mathcal{I}, \ldots, a_n^\mathcal{I}\}$, $(\exists P \cdot B)^\mathcal{I} = \{c \mid \exists d : (c, d) \in P^\mathcal{I}, d \in B^\mathcal{I}\}$, $(B_1 \sqcap B_2)^\mathcal{I} = B_1^\mathcal{I} \cap B_2^\mathcal{I}$, $(B_1 \sqcup B_2)^\mathcal{I} = B_1^\mathcal{I} \cup B_2^\mathcal{I}$. An interpretation $\mathcal{I}$ *satisfies* an inclusion $G \sqsubseteq H$, if $G^\mathcal{I} \subseteq H^\mathcal{I}$; it satisfies an axiom $(\text{func } P)$ if $P^\mathcal{I}$ is functional; it satisfies an axiom $(\text{trans } P)$ if $P^\mathcal{I}$ is transitive; and it satisfies $A(a)$ (resp. $R(a, b)$), if $a^\mathcal{I} \in A^\mathcal{I}$ (resp. $(a^\mathcal{I}, b^\mathcal{I}) \in R^\mathcal{I}$). We write $\mathcal{I} \models \alpha$ if $\mathcal{I}$ satisfies the DL axiom α.

An interpretation $\mathcal{I}$ is a *model* of $\mathcal{K} = \mathcal{T} \cup \mathcal{A}$ if $\mathcal{I}$ satisfies all axioms in $\mathcal{K}$. A KB is *consistent* if it has a model. A KB $\mathcal{K}$ *entails* a DL axiom α if $\mathcal{I} \models \alpha$ for every model $\mathcal{I}$ of $\mathcal{K}$.

Queries. A *conjunctive query* (CQ) takes the form $q(\vec{x}) = \exists \vec{y} \psi(\vec{x}, \vec{y})$, where ψ is a conjunction of atoms of the form $A(t)$ or $R(t, t')$ or of equalities $t = t'$, where t, t' are individual names or variables from

$\vec{x} \cup \vec{y}$. If $\vec{x} = \emptyset$, q is a Boolean CQ (BCQ). A BCQ q is *satisfied* by an interpretation $\mathcal{I}$, written $\mathcal{I} \models q$, if there is a homomorphism π mapping the variables and individual names of q into $\Delta^{\mathcal{I}}$ such that: $\pi(a) = a^{\mathcal{I}}$ for every $a \in \mathsf{N_I}$, $\pi(t) \in A^{\mathcal{I}}$ for every concept atom $A(t)$ in ψ, $(\pi(t), \pi(t')) \in R^{\mathcal{I}}$ for every role atom $R(t, t')$ in ψ, and $\pi(t) = \pi(t')$ for every $t = t'$ in ψ. We also consider as BCQs the queries true and false which are respectively always and never satisfied by an interpretation. A BCQ q is *entailed* from $\mathcal{K}$, written $\mathcal{K} \models q$, iff q is satisfied by every model of $\mathcal{K}$. A tuple of constants $\vec{a}$ is a (certain) *answer* to a CQ $q(\vec{x})$ if $\mathcal{K} \models q(\vec{a})$ where $q(\vec{a})$ is the BCQ obtained by replacing the variables from $\vec{x}$ by the constants $\vec{a}$. We denote by answers$(q(\vec{x}), \mathcal{K})$ the set of answers of $q(\vec{x})$ over $\mathcal{K}$. A *union of CQs* (UCQ) is a disjunction of CQs and has as answers the union of the answers of the CQs it contains.

Canonical model. It is well-known that a flat QL KB $\mathcal{K}$ has a *canonical model* $\mathcal{I}_{\mathcal{K}}$ such that for every BCQ q, $\mathcal{K} \models q$ iff $\mathcal{I}_{\mathcal{K}} \models q$. The domain of $\mathcal{I}_{\mathcal{K}}$ is the set of individual names that occur in $\mathcal{K}$ and $A^{\mathcal{I}_{\mathcal{K}}} = \{a \mid \mathcal{A} \models B(a), \mathcal{T} \models B \sqsubseteq A\}$ for every $A \in \mathsf{N_C}$ and $R^{\mathcal{I}_{\mathcal{K}}} = \{(a, b) \mid \mathcal{A} \models P(a, b), \mathcal{T} \models P \sqsubseteq R\}$ for every $R \in \mathsf{N_R}$ [23].

4 CONSTRAINTS

This section defines the constraints that can be imposed on a KB, and relates the problem of checking that a KB complies with these constraints to CQ answering over this KB.

Defining constraints. In this work, we consider two types of constraints: consistency constraints (which express that some statements are contradictory), and completeness constraints (which impose that certain statements should hold in the KB as soon as some others do). While violations of consistency constraints can only be solved by removing statements, those of completeness constraints can also be solved by adding statements.

Definition 1 (Constraint): *Constraints are built from complex concepts and roles defined by the following grammar rules:*

$P := R \mid R^-$

$B := \top \mid A \mid B \sqcap B \mid B \sqcup B \mid \exists P \cdot \{a_1, \ldots, a_n\} \mid \exists P \cdot B$

where $R \in \mathsf{N_R}$, $A \in \mathsf{N_C}$, $a_1, \ldots, a_n \in \mathsf{N_I}$.

A consistency constraint *is a concept inclusion of the form* $B_1 \sqsubseteq \neg B_2$ *or of the form* $B \sqsubseteq \{a_1, \ldots, a_n\}$*, a role inclusion of the form* $P_1 \sqsubseteq \neg P_2$*, or a functionality axiom of the form* (func P).

A completeness constraint *is a concept inclusion of the form* $B_1 \sqsubseteq B_2$*, a role inclusion of the form* $P_1 \sqsubseteq P_2$*, or a transitivity axiom of the form* (trans P).

This definition of constraints covers the "constraining" versions of the majority of the most popular DL axioms used on the Web of Data according to the ranking done by [15].

We assume without loss of generality that concepts of the form $B_1 \sqcup B_2$ or $\{a_1, \ldots, a_n\}$ with $n > 1$ appear only on the right side of inclusions, and not at all in negative inclusions of the form $B_1 \sqsubseteq \neg B_2$. For example, we assume that $\exists P \cdot (B_1 \sqcup B_2) \sqsubseteq C$ is rewritten as $\exists P \cdot B_1 \sqsubseteq C, \exists P \cdot B_2 \sqsubseteq C$, and $B \sqsubseteq \neg \exists P \cdot \{a_1, \ldots, a_n\}$ is rewritten as $B \sqsubseteq \neg \exists P \cdot \{a_1\}, \ldots, B \sqsubseteq \neg \exists P \cdot \{a_n\}$. As usual, we abbreviate $\exists P \cdot \top$ as $\exists P$.

Example 1: *As a running example, we consider the following KB* $\mathcal{K} = \mathcal{T} \cup \mathcal{A}$ *and set of constraints* $\mathcal{C}$ *inspired from Wikidata. Our TBox* $\mathcal{T}$ *expresses that human beings and deities are persons. Our ABox* $\mathcal{A}$ *provides information on several individuals. Our constraints* $\mathcal{C}$ *state that there are three possible genders (consistency constraint), that those who have a mother or are a mother must be persons or animals, that a mother must have gender female, and that if a has mother b, then b must have child a (completeness constraints).*

$\mathcal{T} = \{ \mathsf{Human} \sqsubseteq \mathsf{Person},\ \mathsf{Deity} \sqsubseteq \mathsf{Person} \}$

$\mathcal{A} = \{ \mathsf{Deity}(\mathit{Zeus}),\ \mathsf{Deity}(\mathit{Rhea}),\ \mathsf{hasGender}(\mathit{Zeus}, \mathit{masculine}),$
$\mathsf{hasGender}(\mathit{Rhea}, \mathit{female}),\ \mathsf{hasMother}(\mathit{Zeus}, \mathit{Rhea}),$
$\mathsf{hasChild}(\mathit{Rhea}, \mathit{Zeus}),\ \mathsf{Human}(\mathit{Spinoza}),$
$\mathsf{hasMother}(\mathit{Spinoza}, \mathit{Marques}) \}$

$\mathcal{C} = \{ \Gamma_0 = \exists \mathsf{hasGender}^- \sqsubseteq \{\mathit{male}, \mathit{female}, \mathit{nonbinary}\},$
$\Gamma_1 = \exists \mathsf{hasMother} \sqsubseteq \mathsf{Person} \sqcup \mathsf{Animal},$
$\Gamma_2 = \exists \mathsf{hasMother}^- \sqsubseteq \mathsf{Person} \sqcup \mathsf{Animal},$
$\Gamma_3 = \exists \mathsf{hasMother}^- \sqsubseteq \exists \mathsf{hasGender} \cdot \{\mathit{female}\},$
$\Gamma_4 = \mathsf{hasMother} \sqsubseteq \mathsf{hasChild}^- \}$ ◁

We say that a KB $\mathcal{K}$ *satisfies a constraint* $\Gamma \in \mathcal{C}$ if $\mathcal{I}_{\mathcal{K}} \models \Gamma$, where $\mathcal{I}_{\mathcal{K}}$ is the canonical model of $\mathcal{K}$. Otherwise, $\mathcal{K}$ *violates* Γ.

Example 2: *In our running example, the KB* $\mathcal{K}$ *satisfies* Γ_1 *since* $\exists \mathsf{hasMother}^{\mathcal{I}_{\mathcal{K}}} = \{\mathit{Zeus}, \mathit{Spinoza}\}$ *and* $\mathcal{I}_{\mathcal{K}} \models \mathsf{Person}(\mathit{Zeus})$ *and* $\mathcal{I}_{\mathcal{K}} \models \mathsf{Person}(\mathit{Spinoza})$*. However, it violates* Γ_2 *because* $\mathcal{I}_{\mathcal{K}} \not\models \mathsf{Person}(\mathit{Marques}) \vee \mathsf{Animal}(\mathit{Marques})$ *while* $\mathit{Marques} \in \exists \mathsf{hasMother}^{-\mathcal{I}_{\mathcal{K}}}$*. It violates* Γ_3 *and* Γ_4 *for similar reasons. Finally,* $\{\mathsf{hasGender}(\mathit{Zeus}, \mathit{masculine}), \Gamma_0\}$ *has no model because of the unique name assumption (which enforces that the interpretation of masculine differs from those of male, female and nonbinary). Hence,* $\mathcal{I}_{\mathcal{K}}$ *cannot be a model of* Γ_0*. Thus,* $\mathcal{K}$ *violates* Γ_0. ◁

Note the semantic difference between the constraints and the axioms of the TBox: The axiom (Human $\sqsubseteq$ Person) in the TBox makes every human an answer to the query asking for persons. In contrast, if we had put the axiom in the set of constraints, it would have required all human beings in the KB to be explicitly marked as persons. As another example, consider the axiom (func hasBirthdate) (which says that everyone can have at most one birth date). If this axiom appears in the TBox, it renders the KB inconsistent whenever a person is given two distinct dates of birth. This has severe consequences on the reasoning capabilities, since everything is entailed from an inconsistent KB. If this axiom is in the set of constraints, in contrast, then distinct dates of birth lead only to the violation of the constraint. This gives us relevant information without having any impact on the usability of the KB.

Checking constraints. We show that our setting allows us to check constraint satisfaction via CQ answering. For this purpose, we use a function π, which maps each constraint $\Gamma \in \mathcal{C}$ to a rule of the form $\exists \vec{y} \varphi(\vec{x}, \vec{y}) \rightarrow \exists \vec{z} \varphi'(\vec{x}, \vec{z})$. This function is defined recursively as shown in Table 1. The left side of the rule is called the *body* and its right side the *head*.

Example 3: *In our running example, we obtain the following rules:*

$\Gamma_0(x) : \exists y \mathsf{hasGender}(y, x) \rightarrow x = \mathit{male} \vee x = \mathit{female} \vee x = \mathit{nonbinary}$

$\Gamma_1(x) : \exists y \mathsf{hasMother}(x, y) \rightarrow \mathsf{Person}(x) \vee \mathsf{Animal}(x)$

$\Gamma_2(x) : \exists y \mathsf{hasMother}(y, x) \rightarrow \mathsf{Person}(x) \vee \mathsf{Animal}(x)$

$\Gamma_3(x) : \exists y \mathsf{hasMother}(y, x) \rightarrow \exists z (\mathsf{hasGender}(x, z) \wedge z = \mathit{female})$

$\Gamma_4(x, y) : \mathsf{hasMother}(x, y) \rightarrow \mathsf{hasChild}(y, x)$ ◁

Table 1: Translation of DL axioms into rules. Variables that appear in the right column and not in the left one are fresh.

$\pi(\top, x)$	=	true
$\pi(A, x)$	=	$A(x)$
$\pi(\{a_1, \ldots, a_n\}, x)$	=	$x = a_1 \vee \cdots \vee x = a_n$
$\pi(R, x, y)$	=	$R(x, y)$
$\pi(R^-, x, y)$	=	$\pi(R, y, x)$
$\pi(B_1 \sqcap B_2, x)$	=	$\pi(B_1, x) \wedge \pi(B_2, x)$
$\pi(B_1 \sqcup B_2, x)$	=	$\pi(B_1, x) \vee \pi(B_2, x)$
$\pi(\exists P \cdot B, x)$	=	$\exists y(\pi(P, x, y) \wedge \pi(B, y))$
$\pi(B \sqsubseteq C)$	=	$\pi(B, x) \rightarrow \pi(C, x)$
$\pi(P \sqsubseteq Q)$	=	$\pi(P, x, y) \rightarrow \pi(Q, x, y)$
$\pi(B \sqsubseteq \neg C)$	=	$\pi(B, x) \wedge \pi(C, x) \rightarrow$ false
$\pi(P \sqsubseteq \neg Q)$	=	$\pi(P, x, y) \wedge \pi(Q, x, y) \rightarrow$ false
$\pi(\text{func } P)$	=	$\pi(P, x, y) \wedge \pi(P, x, z) \rightarrow y = z$
$\pi(\text{trans } P)$	=	$\pi(P, x, y) \wedge \pi(P, y, z) \rightarrow \pi(P, x, z)$

The following proposition shows that this transformation is sound and that the rule body and head can be rewritten as CQ and UCQ.

Proposition 1: *For every constraint $\Gamma \in \mathcal{C}$, $\pi(\Gamma)$ can be rewritten as a rule $\Gamma(\vec{x}) : b(\vec{x}) \rightarrow h(\vec{x})$ where $b(\vec{x})$ is a CQ, $h(\vec{x})$ is a UCQ, and for every flat QL KB $\mathcal{K}$, $\mathcal{K}$ satisfies Γ iff* $\text{answers}(b(\vec{x}), \mathcal{K}) \subseteq \text{answers}(h(\vec{x}), \mathcal{K})$.

Proof. By our assumptions on the form of the concepts that occur in the left side of the inclusions or in the right side of a negative inclusion, $b(\vec{x}) := \exists \vec{y} \varphi(\vec{x}, \vec{y})$ is a CQ. It is easy to show by structural induction that for every concept B (resp. role P), $\pi(B, x)$ (resp. $\pi(P, x, y)$) can be written as a UCQ $q(x)$ (resp. $q(x, y)$) and that $\text{answers}(q(x), \mathcal{K}) = B^{\mathcal{I}_\mathcal{K}}$ (resp. $\text{answers}(q(x, y), \mathcal{K}) = P^{\mathcal{I}_\mathcal{K}}$). If Γ is a completeness constraint of the form $B_1 \sqsubseteq B_2$ (resp. $P_1 \sqsubseteq P_2$), or a consistency constraint of the form $B \sqsubseteq \{a_1, \ldots, a_n\}$, the result follows immediately since $\mathcal{K}$ satisfies Γ iff $\mathcal{I}_\mathcal{K} \models \Gamma$. If Γ is a consistency constraint of the form $B_1 \sqsubseteq \neg B_2$ (resp. $P_1 \sqsubseteq \neg P_2$), $\text{answers}(b(\vec{x}), \mathcal{K}) = B_1^{\mathcal{I}_\mathcal{K}} \cap B_2^{\mathcal{I}_\mathcal{K}}$ (resp. $\text{answers}(b(\vec{x}), \mathcal{K}) = P_1^{\mathcal{I}_\mathcal{K}} \cap P_2^{\mathcal{I}_\mathcal{K}}$) and is empty iff Γ is satisfied. Since in this case $h(\vec{x}) :=$ false, $\text{answers}(h(\vec{x}), \mathcal{K}) = \emptyset$, and the desired relation holds. If Γ is of the form (func P), since the answers of $h(x, y, z) := y = z$ over $\mathcal{K}$ are all possible tuples of the form (a, b, b), $P^{\mathcal{I}_\mathcal{K}}$ is functional iff $\text{answers}(b(x, y, z), \mathcal{K}) \subseteq \text{answers}(h(x, y, z), \mathcal{K})$. Finally, if Γ is of the form (trans P), $b(x, y, z) := \pi(P, x, y) \wedge \pi(P, y, z)$ and $h(x, y, z) := \pi(P, x, z)$, and it is easy to see that $P^{\mathcal{I}_\mathcal{K}}$ is transitive iff $\text{answers}(b(x, y, z), \mathcal{K}) \subseteq \text{answers}(h(x, y, z), \mathcal{K})$. □

Constraint violations. A *constraint instance* $\Gamma(\vec{a})$ of a constraint $\Gamma(\vec{x})$ is obtained by replacing the variables $\vec{x}$ by the individual names $\vec{a}$ in $\Gamma(\vec{x})$. This notion allows us to define constraint violations:

Definition 2 (Constraint violation): *A* violation of a constraint $\Gamma(\vec{x})$ *in $\mathcal{K}$ is a minimal subset $\mathcal{V} \subseteq \mathcal{K}$ such that there exists $\vec{a}$ such that $\mathcal{V}$ violates $\Gamma(\vec{a})$ and $\mathcal{K}$ violates $\Gamma(\vec{a})$. We denote by* $\text{Violations}(\mathcal{K}, \Gamma(\vec{x}))$ *the set of violations of $\Gamma(\vec{x})$.*

In this definition, the requirement that $\mathcal{K}$ violates $\Gamma(\vec{a})$ may seem superfluous. Yet, if Γ is a completeness constraint, it may be the case that some $\mathcal{V} \subseteq \mathcal{K}$ violates $\Gamma(\vec{a})$, while $\mathcal{K}$ satisfies it.

Example 4: *In our running example, it is easy to see that the subset $\mathcal{V}_0 = \{\text{hasGender}(Zeus, masculine)\}$ is a violation of Γ_0. Consider now $\mathcal{V} = \{\text{hasMother}(Spinoza, Marques)\}$. $\mathcal{V}$ is a violation of Γ_2, Γ_3 and Γ_4. Indeed, it violates $\Gamma_2(Marques)$, $\Gamma_3(Marques)$, and $\Gamma_4(Spinoza, Marques)$ and $\mathcal{K}$ does not satisfy any of these constraint instances. However, even if $\mathcal{V}$ violates $\Gamma_1(Spinoza)$, $\mathcal{V}$ is not a violation of Γ_1 because $\{\text{Human}(Spinoza), \text{Human} \sqsubseteq \text{Person}\} \subseteq \mathcal{K}$ satisfies the head of $\Gamma_1(Spinoza)$.* ◁

If a constraint instance $\Gamma(\vec{a})$ is violated, $\vec{a} \in \text{answers}(b(\vec{x}), \mathcal{K})$ and $\vec{a} \notin \text{answers}(h(\vec{x}), \mathcal{K})$, so its violations are the minimal subsets of $\mathcal{K}$ responsible for $\vec{a} \in \text{answers}(b(\vec{x}), \mathcal{K})$. The next proposition relates constraint violations and *justifications*. A justification (also known as an explanation, axiom pinpointing, or MinAs) for the entailment of a BCQ is a minimal subset of the KB that entails the BCQ [21, 34].

Proposition 2: *If $\mathcal{K}$ violates $\Gamma(\vec{a}) : b(\vec{a}) \rightarrow h(\vec{a})$, a subset $\mathcal{V} \subseteq \mathcal{K}$ is a violation of $\Gamma(\vec{a})$ iff $\mathcal{V}$ is a justification of $\mathcal{K} \models b(\vec{a})$.*

5 CORRECTIONS

We now turn to correcting constraint violations.

Solutions. We will make use of atomic modifications of the KB to define solutions to constraint violations.

Definition 3 (Atomic modification): *An* atomic modification *of a KB $\mathcal{K}$ is a pair $m = (\mathcal{M}^+, \mathcal{M}^-)$ of two sets of assertions or $\mathcal{L}$-axioms that takes one of the following forms:*
Addition: *$m = (\{\langle s, p, o\rangle\}, \emptyset)$, where $\langle s, p, o\rangle \notin \mathcal{K}$*
Deletion: *$m = (\emptyset, \{\langle s, p, o\rangle\})$, where $\langle s, p, o\rangle \in \mathcal{K}$*
Replacement: *$m = (\{\langle s, p, o\rangle\}, \{\langle s', p', o'\rangle\})$, where $\langle s, p, o\rangle \notin \mathcal{K}$, $\langle s', p', o'\rangle \in \mathcal{K}$, and $\langle s, p, o\rangle$ differs from $\langle s', p', o'\rangle$ in exactly one component.*

Thus, an atomic modification consists of two sets $\mathcal{M}^+$ and $\mathcal{M}^-$, each of which is either the empty set or a singleton set. $\mathcal{M}^+$ will be added to the KB, and $\mathcal{M}^-$ will be removed from the KB. Since the sets contain at most one triple, we slightly abuse the notation and identify the singletons with their elements (e.g., we will denote the addition of $\langle s, p, o\rangle$ simply by $(\langle s, p, o\rangle, \emptyset)$). A replacement is equivalent to a sequence of a deletion and an addition. We chose to keep it as an atomic modification because it corresponds to common knowledge base curation tasks, such as correcting an erroneous object for a given subject and predicate, or fixing a predicate misuse. Atomic modifications can be used to solve a constraint violation, as follows:

Definition 4 (Solution): *A* solution *to a violation $\mathcal{V}$ of a constraint instance $\Gamma(\vec{a})$ in $\mathcal{K}$ is an atomic modification $(\mathcal{M}^+, \mathcal{M}^-)$ such that there exists $\mathcal{K}' \subseteq \mathcal{K}$ such that $(\mathcal{V} \cup \mathcal{K}' \cup \mathcal{M}^+) \setminus \mathcal{M}^-$ satisfies $\Gamma(\vec{a})$. We call $(\mathcal{M}^+, \mathcal{M}^-)$ a solution to $\mathcal{V}$ for $\Gamma(\vec{a})$ in $\mathcal{K}$.*

Note that $\Gamma(\vec{a})$ can still be violated in $(\mathcal{K} \cup \mathcal{M}^+) \setminus \mathcal{M}^-$ if $\mathcal{K}$ contains other violations of $\Gamma(\vec{a})$ for which $(\mathcal{M}^+, \mathcal{M}^-)$ is not a solution. For example, if $\Gamma(a) : \exists x R(a, x) \wedge A(a) \rightarrow$ false, and $\mathcal{K} = \{R(a, b), R(a, c), A(a)\}$, the deletion of $R(a, b)$ is a solution to the violation $\{R(a, b), A(a)\}$, but $\{R(a, c), A(a)\}$ still violates $\Gamma(a)$. Note also that every constraint violation has at least one solution, which consists of the deletion of any of its elements. Solutions may also be additions or replacements, as in the following example:

Example 5: *In our running example, the deletion* $(\emptyset, \text{hasGender}(\textit{Zeus}, \textit{masculine}))$ *and the replacement* $(\text{hasGender}(\textit{Zeus}, \textit{male}), \text{hasGender}(\textit{Zeus}, \textit{masculine}))$ *are two possible solutions to* $\mathcal{V}_0$ *for* $\Gamma_0(\textit{masculine})$.

The deletion $(\emptyset, \text{hasMother}(\textit{Spinoza}, \textit{Marques}))$ *is a solution to* $\mathcal{V}$ *for the three constraint instances* $\Gamma_2(\textit{Marques})$, $\Gamma_3(\textit{Marques})$ *and* $\Gamma_4(\textit{Spinoza}, \textit{Marques})$. *The additions* $(\text{Human}(\textit{Marques}), \emptyset)$, $(\text{hasGender}(\textit{Marques}, \textit{female}), \emptyset)$ *and* $(\text{hasChild}(\textit{Marques}, \textit{Spinoza}), \emptyset)$ *are solutions to* $\mathcal{V}$ *for respectively* $\Gamma_2(\textit{Marques})$, $\Gamma_3(\textit{Marques})$ *and* $\Gamma_4(\textit{Spinoza}, \textit{Marques})$. ◁

Good solutions. Our goal is to find "good" solutions to constraint violations, i.e., solutions that make the KB as close to the real world as possible. The basic requirement for a "good" solution is that it deletes only erroneous facts, and that it adds only true facts. We also prefer replacements over deletions as long as they fulfill this condition. For instance, in our running example, the replacement $(\text{hasGender}(\textit{Zeus}, \textit{male}), \text{hasGender}(\textit{Zeus}, \textit{masculine}))$ is better than the deletion $(\emptyset, \text{hasGender}(\textit{Zeus}, \textit{masculine}))$, because it corrects erroneous information instead of simply erasing it.

In some cases, there may be no "good" solution that consists of a single atomic modification. Consider for example a completeness constraint of the form $A \sqsubseteq \exists P \cdot B$ violated by $\{A(a)\}$. If $A(a)$ is true, we should actually add both $P(a, b)$ and $B(b)$ for some b. We choose to define solutions as atomic modifications nevertheless to simplify the problem by reducing the size of possible solutions. This is a limitation of our approach since we will not be able to learn solutions that are not atomic. However, we will still be able to learn to add $B(b)$ to solve the aforementioned constraint violation in the case where $P(a, b)$ is already present.

The main difficulty in finding good solutions to constraint violations is that we do not have access to an oracle that knows the validity of all facts. This is the problem that all KB cleaning approaches face (cf. Section 2). Our idea is to exploit the history of the KB modifications to learn how to correct constraint violations.

Definition 5 (Edit history): *The* edit history *of a KB is a sequence of KBs* $(\mathcal{K}_i)_{0 \le i \le p} = (\mathcal{T}_i \cup \mathcal{A}_i)_{0 \le i \le p}$ *such that* $\mathcal{K}_{i+1} = (\mathcal{K}_i \cup \mathcal{M}_i^+) \setminus \mathcal{M}_i^-$, *where* $(\mathcal{M}_i^+, \mathcal{M}_i^-)$ *is an atomic modification.*

The edit history allows us to pinpoint how constraint violations have been corrected in the past. In order to avoid learning from vandalism or mistakes, we consider only those corrections that have not been reversed:

Definition 6 (Past correction): *A* past correction *is a solution* $(\mathcal{M}^+, \mathcal{M}^-)$ *to a violation* $\mathcal{V}$ *of a constraint instance* $\Gamma(\vec{a})$ *in* $\mathcal{K}_i$ *such that there exist* $\mathcal{B}$ *and* $\mathcal{D}$ *such that the current KB* $\mathcal{K}_p = (\mathcal{K}_i \cup \mathcal{B}) \setminus \mathcal{D}$ *with* $\mathcal{M}^+ \subseteq \mathcal{B}$, $\mathcal{M}^- \subseteq \mathcal{D}$, $\mathcal{M}^+ \cap \mathcal{D} = \emptyset$, $\mathcal{M}^- \cap \mathcal{B} = \emptyset$.

Intuitively, $(\mathcal{B}, \mathcal{D})$ corresponds to the sequence of additions and deletions that leads from $\mathcal{K}_i$ to the current state of the KB $\mathcal{K}_p$, that contains the solution, and that does not "undo" it.

Relevant past corrections. During the history of a KB, users can change not just the assertions of the KB, but also the TBox. However, the TBox is typically much smaller and more stable than the ABox. Therefore, the edit history of the TBox is not a rich ground for correction rule mining. Moreover, we are interested in learning solutions that correct constraint violations in the *current* KB $\mathcal{K}_p$. We thus consider only those past corrections that would have been corrections also under the current TBox. For example, assume that the TBox contained $C \sqsubseteq B$. Assume that $C(a)$ was added to correct a violation of the constraint $A \sqsubseteq B$. If, in the meantime, the inclusion $C \sqsubseteq B$ has been removed, we do not want to learn from this past correction. The following definition formalizes these requirements.

Definition 7 (Relevant Past Correction): *A* relevant past correction $(\mathcal{M}^+, \mathcal{M}^-)$ *to a violation* $\mathcal{V}$ *of a constraint instance* $\Gamma(\vec{a})$ *in* $\mathcal{K}_i$ *is a past correction such that (i)* $\mathcal{M}^+ \cup \mathcal{M}^-$ *contains only assertions, and (ii)* $(\mathcal{V} \cap \mathcal{A}_i) \cup \mathcal{T}_p$ *contains a violation* $\mathcal{V}'$ *of* $\Gamma(\vec{a})$ *such that* $(\mathcal{M}^+, \mathcal{M}^-)$ *is also a solution to* $\mathcal{V}'$ *in* $\mathcal{A}_i \cup \mathcal{T}_p$.

We will now see how we can use the relevant past corrections to mine correction rules.

6 FROM HISTORY TO CORRECTION RULES

In this section, we propose an approach based on rule mining to learn *correction rules* for building solutions to constraint violations.

6.1 Extraction of the Relevant Past Corrections

Algorithm 1 constructs the set of relevant past corrections from the KB history. It consists of three main steps. First, it constructs patterns to spot KB modifications that could be part of a relevant past correction. Then it uses these patterns to extract atomic modifications that solved some violation in the past. Finally, the relevant past corrections are obtained by pruning those that have been reversed.

Algorithm 1 Construction of PCDataset

Input: set of constraints C, current TBox $\mathcal{T}_p$, history $(\mathcal{K}_i)_{0 \le i \le p}$
Output: set of relevant past corrections PCDataset

```
// Construct correction seed patterns
for all Γ ∈ C such that Γ(x⃗) : b(x⃗) → h(x⃗) do
    Patterns(Γ) := {(_, A(x⃗)) | A(x⃗) ∈ b'(x⃗), b'(x⃗) ∈ rewrite(b(x⃗), T_p)}
    if Γ is a completeness constraint then
        Patterns(Γ) ∪= ({(A(x⃗), _) | A(x⃗) ∈ h'(x⃗),
                                      h'(x⃗) ∈ rewrite(h(x⃗), T_p)})
// Extract past corrections
for 0 ≤ i ≤ p − 1 do
    if (M_i^+, M_i^-) such that K_{i+1} = (K_i ∪ M_i^+) \ M_i^- matches
    some pattern in Patterns(Γ) then
        PCDataset ∪= {⟨(M_i^+, M_i^-), Γ(a⃗), V, i⟩ |
                V ∈ Violations(K_i, Γ(a⃗)) \ Violations(K_{i+1}, Γ(a⃗))}
// Remove reversed past corrections
for ⟨(M_i^+, M_i^-), Γ(a⃗), V, i⟩ ∈ PCDataset do
    if M_i^+ ⊈ K_p or M_i^- ∩ K_p ≠ ∅ then
        PCDataset \= {⟨(M_i^+, M_i^-), Γ(a⃗), V, i⟩}
```

Let us explain our algorithm with our running example. Consider the constraint $\Gamma_0(x) : \exists y \text{hasGender}(y, x) \rightarrow x = \textit{male} \vee x = \textit{female} \vee x = \textit{nonbinary}$. Assume that $\langle \textit{Zeus}, \text{hasGender}, \textit{masculine} \rangle$ was added between $\mathcal{K}_1$ and $\mathcal{K}_2$, but then replaced by $\langle \textit{Zeus}, \text{hasGender}, \textit{male} \rangle$ between $\mathcal{K}_{100}$ and $\mathcal{K}_{101}$.

The first goal of the algorithm is to find out that the removal of $\langle \textit{Zeus}, \text{hasGender}, \textit{masculine} \rangle$ between $\mathcal{K}_{100}$ and $\mathcal{K}_{101}$ (as part of the replacement) may be part of a relevant past correction. We

Table 2: Dataset PCDataset **of relevant past corrections extracted for our running example.**

Relevant past correction	Constraint instance	Violation	KB index
$(\{\langle Zeus, \text{hasGender}, male\rangle\}, \{\langle Zeus, \text{hasGender}, masculine\rangle\})$	$\Gamma_0(masculine)$	$\{\langle Zeus, \text{hasGender}, masculine\rangle\}$	100

call this deletion a *correction seed*. Formally, a correction seed is a deletion $(\emptyset, \mathcal{M}^-)$ or an addition $(\mathcal{M}^+, \emptyset)$ such that (i) there exists $0 \leq i \leq p-1$ such that $\mathcal{K}_{i+1} = (\mathcal{K}_i \cup \mathcal{M}_i^+) \setminus \mathcal{M}_i^-$ with $\mathcal{M}_i^- = \mathcal{M}^-$ (resp. $\mathcal{M}_i^+ = \mathcal{M}^+$) and (ii) there exists a KB $\mathcal{T}_p \cup \mathcal{D}$, where $\mathcal{D}$ is a set of assertions, such that $\mathcal{T}_p \cup \mathcal{D}$ contains a violation $\mathcal{V}$ of some constraint instance and $(\emptyset, \mathcal{M}^-)$ (resp. $(\mathcal{M}^+, \emptyset)$) is a solution to $\mathcal{V}$. Looking for correction seeds instead of computing the constraint violations for all constraints on all KB versions has the advantage of significantly reducing the search space.

To find such correction seeds efficiently, the first step of the algorithm precomputes for each constraint a set of atomic modification patterns that the possible correction seeds would match. In the example there would be only one pattern: the deletion pattern $(_, \langle ?, \text{hasGender}, ?\rangle)$, where _ can be anything so that it matches both the deletion of $\langle ?, \text{hasGender}, ?\rangle$ and its replacements. Since we only consider past corrections that involve assertions, and want them to be relevant for the current TBox, computing the correction seed patterns can be done via query rewriting of the CQs in the body $b(\vec{x})$ and the head $h(\vec{x})$ of the constraint w.r.t. $\mathcal{T}_p$. Indeed, if $\mathcal{T}$ is a flat QL TBox, any CQ $q(\vec{x})$ can be rewritten w.r.t. $\mathcal{T}$ into a UCQ $q'(\vec{x})$ such that for every ABox $\mathcal{A}$, answering $q(\vec{x})$ over $\mathcal{T} \cup \mathcal{A}$ amounts to answering $q'(\vec{x})$ over $\mathcal{A}$ [23]. Each atom that occurs in the rewriting of the body of a constraint corresponds to a deletion pattern, and each atom that occurs in the rewriting of the head of a completeness constraint corresponds to an addition pattern. We collect the patterns for the constraint Γ in the set Patterns(Γ). Note that it is not possible to solve a consistency constraint with an addition, which is why such constraints have only deletion patterns.

The second step of the algorithm verifies, for each correction seed, whether it solved some constraint violation in the past – i.e., whether $\mathcal{K}_i$ contains some violations of some constraint instances that are not in $\mathcal{K}_{i+1}$. If so, the modification between $\mathcal{K}_i$ and $\mathcal{K}_{i+1}$ is a solution that solved these violations in $\mathcal{K}_i$. In the example we would have found the violation $\{\langle Zeus, \text{hasGender}, masculine\rangle\}$ of $\Gamma_0(masculine)$ in $\mathcal{K}_{100}$, which is not in $\mathcal{K}_{101}$. So we would have extracted that $(\langle Zeus, \text{hasGender}, male\rangle, \langle Zeus, \text{hasGender}, masculine\rangle)$ is a solution that solved the violation $\{\langle Zeus, \text{hasGender}, masculine\rangle\}$ of $\Gamma_0(masculine)$ in $\mathcal{K}_{100}$. We store this information as a tuple in the relevant past corrections dataset (the PCDataset), as shown in Table 2. Finding the constraint instances violated in $\mathcal{K}_i$ or $\mathcal{K}_{i+1}$ is done via CQ answering (Proposition 1), and computing their violations amounts to computing BCQ justifications (Proposition 2).

The final step of the algorithm removes corrections that have been reversed. The result is thus the set of relevant past corrections.

6.2 Correction Rule Mining

Correction rules. The previous algorithm has given us a list of relevant past corrections (the PCDataset, exemplified in Table 2). We now present our approach to mine *correction rules* from this dataset and the KB history.

Definition 8 (Correction rule): *A* correction rule *is of the form*

$$r := [\Gamma(\vec{x})] : \mathcal{E}(\vec{x}, \vec{y}, \vec{z}) \rightarrow (\mathcal{M}^+(\vec{x}, \vec{y}), \mathcal{M}^-(\vec{x}, \vec{y})), \text{ where}$$

- $\Gamma(\vec{x})$ *is a constraint that can be partially instantiated, i.e., some of its variables have been replaced by constants,*
- $(\mathcal{M}^+(\vec{x}, \vec{y}), \mathcal{M}^-(\vec{x}, \vec{y}))$ *is a pair of sets of at most one triple,*
- $\mathcal{E}(\vec{x}, \vec{y}, \vec{z})$ *is a set of atoms called the* context *of the violation such that* $\mathcal{M}^-(\vec{x}, \vec{y}) \subseteq \mathcal{E}(\vec{x}, \vec{y}, \vec{z})$,

and both $(\mathcal{M}^+(\vec{x}, \vec{y}), \mathcal{M}^-(\vec{x}, \vec{y}))$ *and* $\mathcal{E}(\vec{x}, \vec{y}, \vec{z})$ *are built from* $\mathsf{N_C} \cup \mathsf{N_R} \cup \{\texttt{rdf:type}\} \cup \mathsf{N_I} \cup \vec{x} \cup \vec{y} \cup \vec{z}$.

A correction rule can be applied *to a KB* $\mathcal{K}$ *when there exist tuples of constants* $\vec{a}, \vec{b}$ *such that* $\mathcal{K}$ *violates* $\Gamma(\vec{a})$ *(recall that this can be decided via CQ answering by Proposition 1) and* $\mathcal{K} \models \exists \vec{z} \mathcal{E}(\vec{a}, \vec{b}, \vec{z})$. *The* result of the rule application *is then* $(\mathcal{M}^+(\vec{a}, \vec{b}), \mathcal{M}^-(\vec{a}, \vec{b}))$.

Note that while the variables from $\mathcal{E}(\vec{x}, \vec{y}, \vec{z})$ that do not appear in $\Gamma(\vec{x})$ or in the head of r can be existentially quantified, those that occur in the head of r have to be free: they have to be mapped to individuals occurring in the KB in order to construct the result.

Example 6: *In our running example, we would like to learn the following correction rules:*

$$r_1 := [\Gamma_0(masculine)] : \{\text{hasGender}(y, masculine)\} \rightarrow (\text{hasGender}(y, male), \text{hasGender}(y, masculine))$$

$$r_2 := [\Gamma_2(x)] : \{\text{hasMother}(y, x), \text{Human}(y)\} \rightarrow (\text{Human}(x), \emptyset)$$

The context of the second rule says that if x *is the mother of a human, then* x *must also be a human. The rule obtained by replacing* Human *by* Animal *would express how to solve a violation of* Γ_2 *in the context where* y *is an animal.* ◁

Mining correction rules. We mine correction rules with Algorithm 2. This algorithm is an adaptation of the algorithm in [13, 14] to our context, where we learn rules not from a KB but from the PCDataset and the KB history. We first adapt the definitions of the confidence and support from [13, 14] to our case. The *support of the body* of a correction rule r for a constraint Γ is the number of violations of Γ stored in the PCDataset that could have been corrected by applying r. Such violations are associated with an instance $\Gamma(\vec{a})$ of the partially instantiated $\Gamma(\vec{x})$ that appears in r and with an index i such that $\mathcal{K}_i \models \exists \vec{z} \mathcal{E}(\vec{a}, \vec{b}, \vec{z})$ for some $\vec{b}$. These two conditions imply that r could be applied to the KB $\mathcal{K}_i$. Moreover, we need to check that the result of applying r to $\mathcal{K}_i$ actually gives a solution to $\mathcal{V}$. For example, consider the case where PCDataset contains both $\langle(\emptyset, R(a,b))), \Gamma(a), \{R(a,b), A(a)\}, i\rangle$ and $\langle(\emptyset, R(a,c))), \Gamma(a), \{R(a,c), A(a)\}, j\rangle$ for $\Gamma(a) : \exists x R(a,x) \wedge A(a) \rightarrow \text{false}$. Both violations count for the support of the body of $[\Gamma(a)] : R(a,x) \rightarrow (\emptyset, R(a,x))$ but only the second one counts for the support of the body of $[\Gamma(a)] : R(a,c) \rightarrow (\emptyset, R(a,c))$, even in the case

where $\mathcal{K}_i \models R(a, c)$. Formally, $sup_{bod}(r) = |BSup|$ where

$$BSup = \{\mathcal{V} \mid \langle _, \Gamma(\vec{a}), \mathcal{V}, i\rangle \in \text{PCDataset}, \exists \vec{b}\, \mathcal{K}_i \models \exists \vec{z} \mathcal{E}(\vec{a}, \vec{b}, \vec{z})$$
and the result of the application of r to $\mathcal{K}_i$ is a solution to $\mathcal{V}\}$.

The *support of the rule r* measures when the past correction is exactly the result of the application of the rule in the cases where it could be applied. Formally, $sup_{rule}(r) = |RSup|$, where

$$RSup = \{\mathcal{V} \mid \langle (\mathcal{M}^+(\vec{a}, \vec{b}), \mathcal{M}^-(\vec{a}, \vec{b})), \Gamma(\vec{a}), \mathcal{V}, i\rangle \in \text{PCDataset},$$
$$\text{and } \mathcal{K}_i \models \exists \vec{z} \mathcal{E}(\vec{a}, \vec{b}, \vec{z})\}.$$

Finally, the *confidence of a correction rule r* is $conf(r) = \frac{sup_{rule}(r)}{sup_{bod}(r)}$.

Algorithm 2 Correction rule mining

Input: PCDataset, $(\mathcal{K}_i)_{0 \le i \le p}$, *minsup*, *minconf*, θ
Output: correction rules

```
// Generate basic rules
BasicR := ∅
for all ⟨(M⁺(a⃗, b⃗), M⁻(a⃗, b⃗)), Γ(a⃗), V, i⟩ ∈ PCDataset do
  r0 := [Γ(a⃗)] : M⁻(a⃗, b⃗) → (M⁺(a⃗, b⃗), M⁻(a⃗, b⃗))
  BasicR ∪= {σ(r0) | C ⊆ a⃗ ∪ b⃗, σ : C ↣ Var,
              sup_rule(σ(r0)) ≥ minsup, conf(σ(r0)) ≥ minconf}
// Refine the context part of the rules
q := [], q.enqueueAll(BasicR)
while q is not empty do
  r := q.dequeue()
  Output r
  for all operators op do
    for all r' ∈ op(r) do
      if sup_rule(r') ≥ minsup and conf(r') ≥ conf(r) + θ then
        q.enqueue(r')
```

Algorithm 2 shows our mining algorithm. It takes as input the PCDataset computed by Algorithm 1, the KB history, a minimum support threshold, a minimum confidence threshold, and a regularization threshold θ. These thresholds are chosen empirically (see Section 7.3). The algorithm produces correction rules (Definition 8). For this purpose, it first generates a trivial rule r_0 for each entry of the PCDataset. This rule has as context simply the deletion part of the constraint past correction. This trivial rule is then transformed into several more general rules, which we call *basic rules*, each of which is obtained from r_0 by replacing some of the constants by variables. Formally, the algorithm uses all partial substitutions σ from constants to distinct fresh variables. It retains only those basic rules that meet the minimum support and confidence thresholds.

In the second step, the algorithm incrementally refines each rule by building up its context part $\mathcal{E}(\vec{x}, \vec{y}, \vec{z})$. This works similarly to the mining algorithm of [14]: Each refinement step adds one atom built from the KB concept and role names and the variables and constants that appear in the rule, plus at most one fresh variable. For this purpose, the algorithm uses the operators defined in [14]. If the resulting rule meets the minimum support threshold, and improves the confidence by at least θ, the rule is retained.

Note that Algorithm 2 outputs only rules that would have been returned by the algorithm of [13, 14] if evaluated with our confidence function. It prunes more rules because of the use of the θ and the *minconf* thresholds that are also used to do an early pruning of the rules during the context construction. Algorithm 2 can be easily parallelized by running it independently on each constraint and/or having multiple workers working on the same queue.

Applying correction rules. When all rules have been mined, they are sorted by decreasing confidence, breaking ties by help of the support (as it is done in [26] to build classifiers from rules). This set of rules then forms a program that can be used to fix constraint violations as follows. Given a violation $\mathcal{V}$ of a constraint Γ in $\mathcal{K}$, choose the first rule r in the program that is relevant for Γ (i.e., that contains $[\Gamma(\vec{x})]$ where $\Gamma(\vec{x})$ is a partially instantiated version of Γ). Then check whether r can be applied to $\mathcal{V}$. The correction is the result of the rule application.

Example 7: *Assume we mined the rules r_1 and r_2 of the preceding example with confidence 0.9 and 0.8 respectively, and another rule $r_3 := [\Gamma_0(x)] : \{\text{hasGender}(x, y)\} \to (\emptyset, \text{hasGender}(x, y))$ with confidence 0.5. The correction program is (r_1, r_2, r_3). To correct a violation of Γ_0, i.e. a wrong value for the* hasGender *property, the program first checks whether r_1 is applicable. If so, it replaces masculine by male. Otherwise, it falls back to r_3 and removes the wrong value. To correct a violation of Γ_2, it ignores r_1 that is not related to Γ_2 and either applies r_2 if the context matches or does nothing.* ◁

7 EXPERIMENTS ON WIKIDATA

This section describes CorHist, which implements the framework introduced for Wikidata, and presents its experimental evaluation.

7.1 Wikidata

Wikidata is a generalist collaborative knowledge base. The project started in 2012, and as of July 2018, it has collected more than 500M statements about 50M entities. The data about each entity is stored in a versioned JSON blob, and there are more than 700M revisions. Wikidata encodes facts not in plain RDF triples but in a reified representation, in which each main $\langle s, p, o\rangle$ triple can be annotated with qualifiers and provenance information [38].

Wikidata knows the property instanceOf which is similar to `rdf:type`. It does not have a formally defined TBox, but knows properties such as subClassOf, subPropertyOf, and inverseOf. However, only the property subClassOf is used to flag the constraint violations. Therefore, we use only this property in our TBox, which thus contains simple concept inclusions.

We consider the set C of constraints built from ten types of Wikidata property constraints (see Table 3). They are the top Wikidata property constraints that can be expressed in DL, covering the majority of the most used constraints, as well as 71% of Wikidata property constraints. The remaining constraints are mainly about string format validation with regular expressions (52% of the remaining constraints) and about qualifiers (31% of them).

7.2 Dataset Construction

We stored the RDF version [10, 18] of the Wikidata edit history in an RDF quad store. We used named graphs for the global state of Wikidata after each revision, and for the triple additions and deletions. Our dataset stores 390M annotated triples about 49M items extracted from the July 1st, 2018 full database dump.

Table 3: Wikidata property constraints. R is the property for which the constraint is given. A constraint has several lines when it uses a property whose set of values may be specified or not. ♯constr. is the total number of constraints of the given type in Wikidata. ♯triples is the sum for all these constraints of the numbers of triples with the property R on which they apply. ♯violations is the number of violations for this constraint in Wikidata on July 1st, 2018. ♯past cor. is the number of past corrections we extracted from Wikidata history. t.o. indicates that we were not able to extract all past corrections because of timeout so that we sample them (we then indicate the number of corrections we extracted).

Name in Wikidata	DL form	Rule form	♯constr.	♯triples	♯violations	♯past cor.
Type [4]	$\exists R \sqsubseteq A_1 \sqcup \cdots \sqcup A_n$	$\exists y R(x,y) \rightarrow A_1(x) \vee \cdots \vee A_n(x)$	2575	249M	3465k	t.o.(>16M)
Value type [4]	$\exists R^- \sqsubseteq A_1 \sqcup \cdots \sqcup A_n$	$\exists y R(y,x) \rightarrow A_1(x) \vee \cdots \vee A_n(x)$	696	67M	3062k	t.o.(>19M)
One-of	$\exists R^- \sqsubseteq \{a_1, \ldots, a_n\}$	$\exists y R(y,x) \rightarrow x = a_1 \vee \cdots \vee x = a_n$	104	3.6M	4k	14k
Item requires	$\exists R \sqsubseteq \exists R' \cdot \{a_1, \ldots, a_n\}$	$\exists y R(x,y) \rightarrow R'(x,a_1) \vee \cdots \vee R'(x,a_n)$	3102	255M	3710k	t.o.(>15M)
statement	$\exists R \sqsubseteq \exists R'$	$\exists y R(x,y) \rightarrow \exists z R'(x,z)$				
Value requires	$\exists R^- \sqsubseteq \exists R' \cdot \{a_1, \ldots, a_n\}$	$\exists y R(y,x) \rightarrow R'(x,a_1) \vee \cdots \vee R'(x,a_n)$	243	85M	1345k	t.o.(>6M)
statement	$\exists R^- \sqsubseteq \exists R'$	$\exists y R(y,x) \rightarrow \exists z R'(x,z)$				
Conflict with	$\exists R \sqsubseteq \neg\exists R' \cdot \{a_1, \ldots, a_n\}$	$\exists y R(x,y) \wedge (R'(x,a_1) \vee \cdots \vee R'(x,a_n)) \rightarrow \text{false}$	601	449M	142k	465k
	$\exists R \sqsubseteq \neg\exists R'$	$\exists y z R(x,y) \wedge R'(x,z) \rightarrow \text{false}$				
Inverse/Symmetric[5]	$R \sqsubseteq R'^-$	$R(x,y) \rightarrow R'(y,x)$	146	6M	409k	2989k
Single value	$(\text{func } R)$	$R(x,y) \wedge R(x,z) \rightarrow y = z$	2772	85M	334k	389k
Distinct values	$(\text{func } R^-)$	$R(y,x) \wedge R(z,x) \rightarrow y = z$	2728	56M	189k	7432k

We extracted the relevant past corrections as explained in Section 6.1. Wikidata revisions do not correspond exactly to atomic modifications in our sense. For example, Wikidata bots are able to change multiple unrelated facts about the same entity at the same time. Wikidata users also sometimes prefer to delete a statement then add another one with the same property instead of directly modifying the value, in order to clear the existing qualifiers and references. Therefore, we artificially created a replacement modification for every deletion with a neighboring addition by the same user, which shares at least two components of the triple (analogously for additions). For example, if the correction seed is the deletion of ⟨*Zeus*, hasGender, *masculine*⟩, and if this revision or a neighboring one adds ⟨*Zeus*, hasGender, *male*⟩, then we consider this a replacement. However, if the same revision added the triple ⟨*Zeus*, hasMother, *Rhea*⟩, then we would not consider this a replacement, because it does not share two components with the first one.

Since the TBox consists of simple concept inclusions and the constraint bodies contain only roles, the deletion patterns for correction seeds correspond directly to the atoms of the constraint body. In the same vein, only atoms in the head of the *Type* or *Value type* constraints need to be rewritten. To find the constraint violations solved by a correction seed, we make use of the fact that the correction seed allows us to know the constraint instance $\Gamma(\vec{a})$, and we look for matches of the constraint instance body.

To speed up the execution for the four constraint types which have the highest numbers of past corrections, *Type*, *Value type*, *Item requires statement* and *Value requires statement*, we did not extract all the past corrections but sample them as follows. We compute only the relevant past corrections that where applied between $\mathcal{K}_i$ and $\mathcal{K}_{i+1}$ where i is a multiple of $s := max(1, N/10^6)$ with N the number of triples with the property R of the constraint at hand. This sampling allows us to get a sufficient ground for rule mining for each constraint. In practice, it affects only the most frequent 0.9% of *Type*, 2% of *Value type*, 0.5% of *Item requires statement*, and 3% of *Value requires statement* constraints.

7.3 Mining Rules

The output of our method is a set of correction rules that form a program (Section 6.2). To evaluate such a program, we apply it to each of the constraint violations stored in the PCDataset, using the associated stage of the KB to evaluate the part of the context which is not the deletion part of the correction. Then we check whether the correction we compute is exactly the same as the one associated to the constraint violation in the PCDataset. The *precision* p of the program is given by the fraction of the corrections computed by the program that are actually the same as those that have been applied. The *recall* r of the program is the fraction of the constraint violations stored in PCDataset for which the program gives some correction. The *F1 score* is $F_1 = 2\frac{p \cdot r}{p+r}$.

CorHist mines rules as explained in Section 6.2. In order to decrease the computation time, we only allow one atom $p(s,o)$ in $\mathcal{E}(\vec{x},\vec{y},\vec{z}) \setminus Body(\vec{x},\vec{y})$, where $Body(\vec{x},\vec{y})$ corresponds to the part of the context that matches part of the constraint body, such that s is a variable of $\vec{x} \cup \vec{y}$ and o is a fresh variable or a constant.

Rules were mined per constraint. For each constraint, we split the set of extracted past corrections into a 70% training set, a 10% cross-validation set, and a 20% test set. The training set is used to mine the rules, the cross-validation set is used to determine the confidence threshold that maximizes the F1 score of the obtained program, and the test set is used to evaluate the final program.

[4] The Wikidata constraint *Type* can be qualified to modify its meaning. We ignore these cases, which are marginal: they concern less than 6% of the *Type* constraints. The same goes analogously for *Value type*.

[5] *Inverse* and *Symetric* are two distinct kinds of constraints in Wikidata but we treat them together since *Symetric* is actually a special case of *Inverse*.

Table 4: Example of mined rules.

Constr. type	Constraint Γ	Correction rule
Type	$\exists$isAListOf $\sqsubseteq$ List	$[\Gamma(s)]$: isAListOf(s, o) $\wedge$ WikiDisambiguationPage(s) $\rightarrow$ ($\emptyset$, isAListOf(s, o))
Value type	$\exists$foundInTax$^-$ $\sqsubseteq$ Taxon	$[\Gamma(human)]$: foundInTax(s, *human*) $\wedge$ hasPart(s, v) $\rightarrow$ (foundInTax(s, *homoSapiens*), foundInTax(s, $human$))
One-of	$\exists$mannerDeath$^-$ $\sqsubseteq$ {. . . }	$[\Gamma(trafficAcc)]$: mannerDeath(s, *trafficAcc*) $\rightarrow$ (causeDeath(s, *trafficAcc*), mannerDeath(s, *trafficAcc*))
Item req. stm.	$\exists$heritageStatus $\sqsubseteq$ $\exists$country	$[\Gamma(s)]$: heritageStatus(s, *monumentInFornminnesregistret*) $\rightarrow$ (country(s, *Sweden*), $\emptyset$)
Val. req. stm.	$\exists$residence$^-$ $\sqsubseteq$ $\exists$country	$[\Gamma(s)]$: diplomaticRelation(s, v) $\rightarrow$ (country(s, s), $\emptyset$)
Conflict	$\exists$filmplID $\sqsubseteq$ $\neg\exists$filmplFilmID	$[\Gamma(s)]$: filmplID(s, o) $\rightarrow$ ($\emptyset$, filmplID(s, o))
Inv./Sym.	geneticAssoc $\sqsubseteq$ geneticAssoc$^-$	$[\Gamma(s, o)]$:$\rightarrow$ (geneticAssoc(o, s), $\emptyset$)
Single val.	(func sexOrGender)	$[\Gamma(s)]$: sexOrGender(s, *maleOrg*) $\wedge$ sportsTeam(s, v) $\rightarrow$ ($\emptyset$, sexOrGender(s, *maleOrg*))
Distinct val.	(func ncbiLocusTag$^-$)	$[\Gamma(s)]$: ncbiLocusTag(o, s) $\wedge$ molecularFunction(o, v) $\rightarrow$ ($\emptyset$, ncbiLocusTag(o, s))

Table 4 gives examples of rules mined by CorHist. Several of these rules show the crucial importance of the instantiation of the constraint and/or of the context to be able to choose the correction. For instance, the rule for the *Single value* constraint uses the fact that an entity involved in a property "member of sport team" is probably a human being, and thus that if it has several values for the functional property "sex or gender" and one of them is a value reserved for non-human organisms in Wikidata, this value is probably wrong. In the same vein, the rule for the *Item requires statement* constraint recognizes that an entity has a heritage designation that is specific to Sweden ("monument in Fornminnesregistret"), to conclude that its country is Sweden. The rules also propose fixes to misused predicates: in Wikidata, the property "manner of death" is intended for the general circumstances of a person's death (such as "accident"), while the property "cause of death" is intended to give more precise causes (such as "traffic accident").

7.4 Evaluation against the Test Set

Table 5 presents the results of the evaluation of the mined programs against the test set. We computed both the micro and macro average of the precision, recall and F1 score per kind of constraint. The micro average aggregates over the whole set of relevant past corrections for the given kind of constraint, whereas the macro average computes the scores for each constraint of this given kind, and then computes the average. Both numbers are important: The micro average gives more weight to correction rules that fix many violations. It thus measures the overall impact of the correction rules on the dataset. However, if few rules had a large impact, then it would be easier to formulate these rules by hand. Our method, in contrast, can also find rules that by themselves solve less violations, but together contribute a large mass of corrections. To illustrate this, we also report the macro average: It measures the average performance across different constraints.

We compare our approach with two baselines: The first one, called "delete", is the most basic one and uses the fact that all Wikidata constraint bodies contain an atom of the form $R(x, y)$ and the TBox contains only concept inclusions, so that all constraint violations contain an assertion that matches $R(x, y)$. The "delete" baseline simply deletes this assertion. For the completeness constraints we define an additional baseline, "add", which tries to add a new triple to solve the constraint violation. For *Inverse* and *Symmetric* constraints this baseline adds the missing reverse edge and performs very well. For *Item requires statement*, *Value requires statement*, *Type* and *Value type*, it adds the missing triple only if it is possible to know the expected value from the constraint rule. For example, for *Type* constraints of the form $\exists y R(x, y) \rightarrow A(x)$ it applies the correction $(A(x), \emptyset)$. *Value type* constraints are handled in the same way. However, this baseline is not able to figure out what is the relevant addition correction for a constraint of the form $\exists y R(x, y) \rightarrow A_1(x) \vee A_2(x)$ because there is no way to know a priori if A_1 or A_2 should be added. For *Item requires statement*

Table 5: Evaluation of the correction rules mined by CorHist with a minimal support of 10, a minimal confidence between 0.5 and 1 and a regularization threshold of 0.05, and comparison with the baselines. Best precision and F1 scores in bold.

Constraint type		Micro average Prec.	Rec.	F1	Macro average Prec.	Rec.	F1
Type[6]	add	0.35	0.33	0.34	0.29	0.55	0.38

[6]Computed from a sample of the set of relevant past corrections. One *Type* constraint, six *Value type* constraints and one *Val. req. stm* constraint were omitted due to time-out.
[7]The actual value is greater than 0.995 and rounded to 1 for consistency.

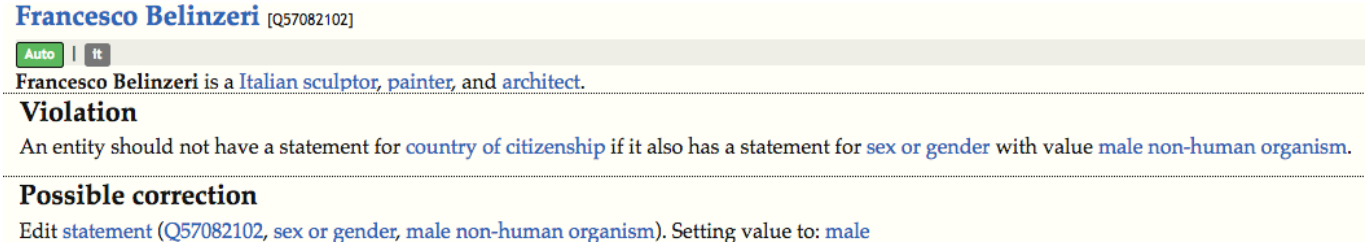

Figure 1: Example of a replacement correction suggested by CorHist for a violation of the constraint $\exists \text{countryOfCitizenship} \sqsubseteq \neg\exists \text{sexOrGender} \cdot \{maleOrg, femaleOrg\}$.

Table 6: Human evaluation of the suggested corrections.

Constraint type	Suggested	"Apply"	"Wrong"	Approval
Type	9908	252	312	0.45
Value type	2374	195	208	0.48
One-of	239	14	47	0.23
Item requires stm.	41	8	32	0.2
Value requires stm.	1024	790	178	0.82
Conflict with	3254	1717	203	0.89
Inverse/Symmetric	28138	20247	1720	0.92
Single value	3264	41	71	0.37
Distinct values	921	8	23	0.26

constraints of the form $\exists y R(x, y) \rightarrow R'(x, a)$, the "add" baseline applies $(R'(x, a), \emptyset)$ (similarly for *Value requires statement* constraints). However, it cannot find a correction if there are multiple a_i.

As shown in Table 5, the precision of our approach significantly outperforms the two baselines – often by a very high margin. Regarding the recall, we manage to keep a reasonable, and sometimes even good, recall (see best F1 scores in Table 5), except for *Single* and *Distinct value*. The very low recall obtained for these two kinds of constraints is easily explainable because they are mostly used on predicates that link Wikidata to other databases (91% of the *Single* and 95% of the *Distinct* constraints), and we cannot get meaningful information about the target database to mine corrections.

7.5 User Evaluation

To see whether our corrections are accepted by the community, we designed a user study. We created a tool that suggests our corrections to Wikidata users for validation (available at https://tools.wmflabs.org/wikidata-game/distributed/#game=43). The user can choose a constraint type, and the tool then suggests corrections for random violations of constraints of this type (Figure 1). The violations for which corrections are suggested are provided by `query.wikidata.org`, which limits their number for performance reasons. For each proposed correction, the user has to choose between three options: apply the proposed correction to Wikidata, tag it as wrong, or get another correction to review. We ran the experiment for 3 months and 47 Wikidata users participated.

Table 6 presents the results. The number of corrections reviewed is highly unbalanced between the kinds of constraints, mainly because a few users evaluate a lot of suggestions, and have a predilection for some kinds of constraints. It is thus difficult to draw conclusions for those kinds of constraints for which very few corrections have been evaluated. However, we can still make some interesting observations. In particular, the proposed corrections marked as wrong give us insights about possible weaknesses of our approach.

For the constraints which got a significant number of evaluations, our approach seems to perform well for *Inverse* and *Symmetric*, *Conflict with* and *Value requires statement* constraints, with approval rates above 80%. The other approval rates are lower. This is partly due to biases in the data. For example, when a gender is missing, our approach proposes the value "male" by default, because of the over-representation of men in Wikidata. Another issue is the quality of the constraints, which in Wikidata are sometimes questionable or difficult to understand (e.g., an incomplete set of possible types or values for completeness or *One-of* constraints).

However, even lower approval scores do not mean that our approach would be useless: Psychological research [12] shows that people find it much easier to choose from given options than to come up with an answer by themselves. The actual time needed to come up with an answer may vary, but if it takes just 3 times longer to come up with an answer than to accept or reject our proposed correction, then achieving a precision of 40% is already useful: If we have a precision of 40%, and if a free-form answer takes time t, then the expected answer time with our tool is $40\% \times \frac{1}{3} \times t + 60\% \times \frac{4}{3} \times t < t$.

8 CONCLUSION AND FUTURE WORK

We have introduced the problem of learning how to fix constraint violations from a KB history. We have also presented a method based on rule mining to this end. Our experimental evaluation on Wikidata shows significant improvement over baselines. Our tool is live on Wikidata and has already allowed users to correct more than 23k constraint violations. While our evaluation focused on Wikidata for which the whole edit history was available, we believe that our method can be applied in other settings, for example using edits done during the partial cleaning of an automatically extracted KB.

For future work, it would be interesting to evaluate the impact of parameters such as the size of the context part of the correction rule in terms of rule quality. We also plan to extend the learning dataset with external knowledge (such as other KBs), or with information extracted from other sources (for instance from Wikipedia). We believe that this will allow finding even more precise correction rules, thus making KBs ever more precise and more useful.

ABSTRACT

The ability to continuously discover domain-specific content from the Web is critical for many applications. While focused crawling strategies have been shown to be effective for discovery, configuring a focused crawler is difficult and time-consuming. Given a domain of interest *D*, subject-matter experts (SMEs) must search for relevant websites and collect a set of representative Web pages to serve as training examples for creating a classifier that recognizes pages in *D*, as well as a set of pages to seed the crawl. In this paper, we propose DISCO, an approach designed to bootstrap domain-specific search. Given a small set of websites , DISCO aims to discover a large collection of relevant websites . DISCO uses a ranking-based framework that mimics the way users search for information on the Web: it iteratively discovers new pages, distills, and ranks them. It also applies multiple discovery strategies, including keyword-based and related queries issued to search engines, backward and forward crawling. By systematically combining these strategies, DISCO is able to attain high harvest rates and coverage for a variety of domains. We perform extensive experiments in four social-good domains, using data gathered by SMEs in the respective domains, and show that our approach is effective and outperforms state-of-the-art methods.

CCS CONCEPTS

• **Information systems → Web searching and information discovery**; *Page and site ranking*; *Content ranking*; Rank aggregation.

1 INTRODUCTION

The ability to continuously discover content relevant to an information domain has many applications, from helping in the understanding of humanitarian crises to countering human and arms trafficking. It is estimated that tens to hundreds of thousands of escort ads are posted every day and about 75% of reported human-trafficking survivors were advertised online at some point [5]. Recently, the US law enforcement has shut down the sex marketplace website backpage.com due to its role in sex trafficking. Criminals also take advantage of online markets to avoid background checks and trade illegal weapons. According to an FBI report, hundreds of thousands of guns slip through the federal background-check system every year [30]. At the same time, many sites advertise weapons for sale – in armslist.com alone one can find hundreds of thousands of weapon-related ads.

By collecting and analyzing domain-specific content from the Web, we can better understand these illegal activities, generate leads, and obtain evidence for investigations. But doing so is challenging. Currently, subject matter experts (SMEs) (e.g., from non-governmental organizations and government agencies) must collaborate with computing experts and data scientists to construct specific solutions to their problems, which include (1) creating machine-learning models to recognize relevant content, and (2) configuring crawlers that retrieve the information at scale. Once these are available, it is possible to continuously discover relevant content by using re-crawling strategies [10, 23, 27]. However, both of these tasks require users to obtain a sufficiently large number of pages and finding these pages is difficult.

In this paper, we address this key problem in bootstrapping domain-specific search: how to effectively discover relevant websites given a small seed set provided by SMEs. A natural approach for discovering relevant websites is to use commercial search engines, such as Google and Bing, and issue keyword queries or search for similar sites using "related" search. This requires SMEs to go through an iterative process in which they search, distill the results, and use the information gathered to formulate additional queries. This process is cumbersome and inefficient for large-scale information gathering tasks. Different approaches have been proposed to tackle this problem. The Domain Discovery Tool (DDT) [15] aims to simplify the process of constructing classifiers for a given domain. To help users discover relevant pages and train a domain classifier, it provides an easy-to-use interface that summarizes search results and helps users formulate new search queries. While the tool is effective, it was designed with a user-in-the-loop philosophy and thus requires substantial user effort to perform the discovery operations and review the results. Methods such as forward and backward crawling [3] and DEXTER [24] have been be proposed to automate discovery. Because they rely on classifiers, they need to be adapted for different domains. Besides, these methods fall short of achieving high precision and recall in domains where relevant websites are not highly connected. To the best of our knowledge, there has been no systematic comparison of these methods for different domains, therefore whether they are effective for website discovery is still an open question.

Several focused crawling and discovery techniques could potentially be adapted for this problem. However, they all rely on the availability of an accurate domain-specific classifier [3, 13, 31]. This is an unrealistic assumption for the many application scenarios where experts must start with a small set of relevant websites , since a small sample is unlikely to be sufficient construct an accurate classifier. These techniques use the classifier to select discovered pages that are relevant, and use content of these pages to train other models that directly control future search, e.g., ordering unvisited URLs and generating search queries. Therefore, a weak classifier would gradually degrade the effectiveness of discovery.

To address this challenge, we propose DISCO, a new method for website discovery that does not depend on an accurate domain-specific classifier. Given a small number of sample pages, DISCO automatically discovers additional pages that can be used both to construct domain classifiers and to serve as seeds for focused crawlers. The strategy adopted by DISCO was inspired by how users follow the search process: it searches for pages on the Web and distills the results in an iterative fashion. Different operations can be used to discover new pages, including keyword-based and related queries issued to search engines, and backward and forward crawling. However, the effectiveness of an operation varies across domains. For example, in our experiments (Section 5), we observed that backlink search performs the best for human trafficking domain, but is much less effective for the others. Based on this observation, unlike previous works [3, 31], DISCO applies multiple search operations. To systematically select the search operation as the discovery progresses, we propose an algorithm that uses the multi-armed bandit strategy [1]. This makes DISCO adaptive both within and across domains, and leads to higher harvest rates and coverage compared to a fixed strategy.

To distill the results, in the absence of a model that recognizes relevant pages, DISCO approximates how users select relevant pages by ranking them. Given a set of discovered pages, it ranks higher pages that are more similar to the input sample set. The challenge here lies in designing a strategy that is effective. We carried out an empirical study of several ranking approaches and found that none of the approaches is uniformly better for all domains. We propose a new ranking function that, by combining the results of multiple functions, produces a robust ranking.

Contributions. Our contributions can be summarized as follows:

- We propose DISCO, a framework that automatically discovers relevant websites requiring only a small set of example websites . To the best of our knowledge, ours is the first approach that does not require an accurate classifier to bootstrap domain discovery.
- To distill results, we propose an ensemble ranking approach that combines multiple independent ranking functions, and show that it consistently attains higher precision than the independent functions.
- We incorporate different search operations in our framework and propose an algorithm that uses the multi-armed bandits strategy to select the best search operator at each iteration. We also perform a systematic evaluation of the performance of the different operations in multiple domains and show that, by using the multi-armed bandits-based algorithm, our method is able to attain high harvest rates.
- We perform extensive experiments in multiple social-good domains using real data provided by SMEs from the corresponding domains. We report experimental results which show that DISCO obtains 300% higher harvest rate and coverage compared to state-of-the-art techniques for domain discovery.

Outline. The remainder of this paper is structured as follows. We discuss related work in Section 2. In Section 3, we define the website discovery and ranking problems and give an overview of the DISCO framework. In Section 4 we describe the ranking and discovery components of the framework. We present the results of our experimental evaluation in Section 5, and conclude in Section 6, where we outline directions for future work.

2 RELATED WORK

Several techniques have been proposed to discover domain-specific web content. These can be categorized in the following two groups: *Search-based Discovery* techniques [24, 31, 32] which rely on search engine APIs (e.g., Google, Bing, and Alexa APIs) to find web pages similar to given keywords or web pages ; and *Crawling-based Discovery* techniques [2, 3, 21], which use the Web link structure to explore new content by automatically downloading and recursively following links extracted from the discovered web pages . Note that while some of these techniques were proposed to discover specific web pages , they can be extended to discover websites as well. To the best of our knowledge, as we discuss below, none of the prior work supports all different discovery techniques, and most require an accurate domain-specific classifier.

2.1 Search-Based Discovery

There are two main search-based discovery operators supported by search engine APIs: *keyword search* and *related search*. Most of the existing discovery techniques use keyword search since related search is only supported by two search engines, Google and Alexa.

Earlier work [11, 21] used both content and Web link structure to compute the relatedness between web pages . Vieira et. al. [31] proposed a system that uses relevance feedback to gather seeds to bootstrap focused crawlers. It submits keyword search queries to Bing; extracts keywords from the result pages classified as relevant for the focus domain; and uses these keywords to construct new search queries. Their system shares some of our goals and their findings support our design decisions. They show that submitting multiple short queries and retrieving a small list of results leads to more relevant pages than submitting long queries and extracting a large number of results. The major drawback of this approach is that, when the classifier is not accurate, the search results quickly diverge from the target domain. Furthermore, the system is specifically designed to use with keyword search, therefore, does not support other search techniques.

Disheng et. al. [24] presented a discovery pipeline that uses keyword search to find websites containing product specifications (e.g., cameras and computers). While they also utilize backward search, they showed that the relevant websites are mainly discovered by searching with product identifications extracted from previous discovery iterations. However, using product identifications as search keyword is specific to product search domain and therefore not applicable to other domains.

Wang et. al. [32] focused on the claim-relevance discovery problem that, if solved, can help to identify online misinformation. They proposed a system that extracts salient keywords from fact-checking articles and uses them to search for candidate documents. Unlike in our search strategy, their search phase is not iterative, since they do not aim to attain high coverage of relevant documents.

2.2 Crawling-Based Discovery

Forward and backward crawling are two types of crawling-based techniques explored in the literature. In forward-crawling, links are extracted from the discovered web pages . Several forward-crawling approaches been proposed to discover domain-specific web pages and websites [4, 7, 8, 13]. The most prominent approach in this group are the *focused crawling* methods that employ online learning policies [4, 7, 20]. They use two classifiers to focus the search: the critic, a classifier that categorizes web pages as relevant or irrelevant to the domain; and the apprentice, a classifier that learns to identify the most promising links in a domain-relevant page in an online fashion. Note that while the apprentice classifier is automatically learned, the critic is a classifier given as input to the system and requires a substantial number of positive and negative examples to be trained on. In contrast, our approach does not require an input classifier, just a small set of relevant pages. Compared to search-based techniques, forward crawling is more scalable, however, it works best for domains where relevant content is well-connected.

In contrast to forward crawling, backward crawling (or reverse crawling) discovers new pages through backlink search. Since the Web is unidirectional, it must be done through search engine APIs that expose results of previous large-scale crawls. Early work proposed the use of backlink search to discover Web content [6, 12]. More recently, Barbosa et. al. [3] proposed a crawling strategy that combines both backward-crawling and forward-crawling techniques to locate bilingual websites. It employs two link classifiers, trained with the content of visited pages and their relevance to the target domain, to determine the visiting orders of the links discovered by the two techniques. As a result, the efficiency of this strategy highly depends on the domain classifier. In addition, this approach has the same limitation we discussed above, in that the crawler becomes ineffective when the classifier is not accurate. In later work, Barbosa [2] proposed a similar crawling architecture for discovering forum websites .

Approaches that focus on real-time discovery [26, 29, 34] have taken advantage of social media platforms (e.g., Twitter) to monitor and track domain-specific content such as misinformation [29], activity related to natural disasters [26], and rumors [34]. Although these techniques mainly target social-media feeds, they could potentially be used to discover websites by extracting links present in the feeds. Discovery from social media could be integrated in our approach as an alternative discovery operation.

3 PROBLEM AND SOLUTION OVERVIEW

3.1 Problem Definition

Website Discovery Problem. Let D represent the domain of interest and w denote a website represented as one of more web pages

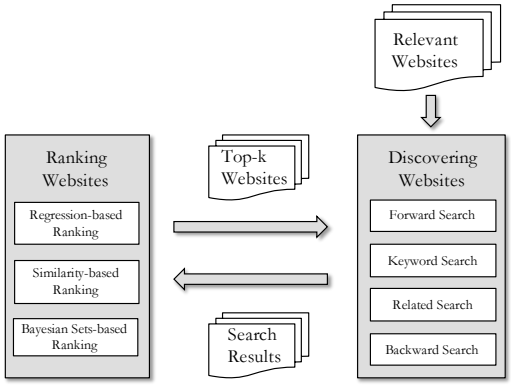

Figure 1: Architecture of DISCO.

. If w is relevant to the domain, we say that $w \in D$. Given a small set of websites $S \subset D$ (seeds), our goal is to efficiently expand S by finding additional websites w that belong to D.

Website Ranking Problem. In the absence of a model that recognizes pages in D, we approximate the problem to make it depend only on the set S of seeds by framing it as a ranking task: given S, the goal is to discover new websites that are *similar* to S. More formally, given set of discovered websites D_+, the problem consists of ranking each site w in D_+ according to its similarity with S – this is equivalent to the likelihood of w being in D. The intuition is that the closer w is to S, the more likely it is that $w \in D$.

By ranking the discovered websites based on their similarity with S, we help to reduce the SMEs effort in reviewing and labeling examples to build a domain-specific classifier and selecting important websites for the re-crawling process. A ranking strategy in this scenario should ideally have two important features: high precision in the top of the ranked list and low false negative in the tail of the ranked list. The former feature is important for the website discovery operation to be effective since the top-ranked websites are fed back into the discovery process. The latter is useful for reducing the SMEs effort of reviewing the final ranked list output by the system: the fewer relevant documents in the tail of the list, the fewer documents need to be reviewed by the SMEs. In our experimental evaluation in Section 5, we use metrics aligned with these desired features to evaluate different ranking functions.

3.2 Framework Overview

The design of DISCO was inspired by the iterative process that SMEs usually follow to discover domain-specific websites . They start by submitting queries to a search engine. Then, they review and evaluate the search results based on their knowledge about the domain. The new knowledge they acquire in this process is used to refine and formulate new search queries. In DISCO, we replace the manual evaluation with the website ranking component and use search engine APIs to automate the search operations. Figure 1 depicts the high-level architecture of the DISCO framework. It consists of two main components: *website ranking* and *website discovery*. To incorporate different search engine APIs and ranking techniques, we standardize the input and output of the two components. Specifically, the website discovery component takes a list of

Algorithm 1 Website Discovery

```
1:  procedure Discovery(seeds)
2:      results = ∅
3:      ranked_results = ∅
4:      topk = seeds
5:      while stop condition do
6:          op = select_discovery_operator()
7:          search_results = op.search(topk)
8:          results = results ∪ search_results
9:          ranked_results = rank(results)
10:         topk = get_top_k(ranked_results)
11:     end while
12:     return ranked_results
13: end procedure
```

relevant websites as input and returns a list of discovered websites after performing the search operations. Similarly, the input and output of the website ranking component consist of lists of discovered websites so far and the corresponding list of ranked websites , respectively. This design unifies multiple search operators in a single framework, and hence, it allows us to fairly compare their efficiency across different domains (see Section 5). Algorithm 1 outlines the discovery process carried out by DISCO. It starts with the seeds and iteratively searches, ranks and selects the top results. The *select_discovery_operator()* function in line 6 returns one of the four discovery operators: forward crawling, backward crawling, keyword search and related search.

4 RANKING AND DISCOVERY

In this section, we present the details of the website ranking and discovery components of DISCO. Then, we present a technique to efficiently select the discovery operator based on the multi-armed bandits algorithm.

4.1 Website Ranking

The website ranking problem can be cast as a conventional ranking problem in information retrieval, where S represents the query, and the goal is to rank the websites in D_+ according to its similarity to the query. The query here consists of a very long document containing all the websites in S, which makes the traditional ranking models (e.g., BM25 [25]) less effective. Furthermore, merging all the websites in S can potentially blur the distinct domain-specific features that exist in individual websites . To avoid this problem, we investigate other ranking approaches that consider websites in S individually. We then propose a new ranking function, inspired by ensemble learning methods, that combines the scores of the existing approaches.

Website Representation. The first step of any ranking function design is to represent the candidate documents, which are websites in our context. A website can be represented as a single or multiple web pages . We consider both options and selected the latter for several reasons. To use multiple pages to represent a site, we need to have an effective procedure to select representative pages in the sites. This task is challenging, especially when we do not have ground truth data. Random selection tends to result in a large number of web pages that are not good representative of the site and that lead to noise that negatively affects the ranking. The single-web page representation can help circumvent this issue if we rely on the assumption that every website contains at least one web page that can serve as an effective representative of the website content. As a result, the score of a website can depend only on the score of its most relevant web page discovered. Furthermore, the single-web page representation greatly simplifies the implementation of the framework and improves its performance. For this representation, we do not need a separate process to retrieve and manage additional pages for each newly discovered website , and discovered web pages can be processed independently. This makes the framework ready for parallelization.

In fact, we experimentally compared selection strategies using multiple web pages representation against the single-page representation, and the former led to better rankings than the latter for all domains we considered. We considered two different approaches for the multiple-page representation. One performs a breadth-first-search crawling starting from the home page, which leads to both relevant and irrelevant pages. The other uses in-site search via search engine APIs (i.e., using queries with the format "site:keyword"). This method, however, is keyword-sensitive and tends to retrieve false positive pages.

Several ranking function have been proposed in the literature. In what follows, we describe the ones we considered. Details about their performance are discussed in Section 5.

4.1.1 Regression-Based Ranking. This approach learns the ranking function using regression-based techniques and computes a score for each website in D_+. The challenge is that only positive examples (i.e., S) are given, and thus additional negative examples must be obtained or unconventional techniques such as PU learning [18] or novelty detection [28] must be applied. We investigate three regression techniques in this direction and describe how they can be applied in our scenario.

Binomial Regression. In order to use binomial regression (i.e., logistic regression), we need both positive and negative examples. Therefore, we obtain negative examples by randomly selecting web pages from a public Web corpus. Since the Web corpus is relatively large compared to the number of samples pages, there is only a very small chance of selecting a web page relevant to the domain. Given S and the unlabeled web pages as negative examples, we train a binomial regressor and use it to compute ranking scores.

Positive and Unlabeled Example Learning (PU Learning). A well-known alternative to binomial regression method, given positive and unlabeled examples, is PU learning [18]. Liu et al. [18] proposed biased SVM, a PU learning technique that frames the PU Learning problem as a constrained optimization problem. They experimentally showed that biased SVM outperforms other 2-steps PU learning approaches. Therefore, we choose this technique to learn the ranking function.

Novelty Detection. Another line of research that does not require negative examples is novelty detection [19, 28]. Scholkopf et. al. [28] extend SVM (support vector machine) to learn a function that is positive on the positive examples and negative on its complement.

Intuitively, it computes the minimal region in feature space that encloses the positive examples.

4.1.2 Similarity-Based Ranking. Similarity-based ranking, inspired by the k-nearest neighbors algorithm, computes the ranking score of a website according to the average of its similarities to all websites in S. Let $Sim(w_i, w_j)$ be a similarity function between the websites w_i and w_j, the score of a website $w \in D_+$ is computed as follows:

$$Score(w) = \frac{1}{|S|} \sum_{w_s \in S} Sim(w, w_s) \tag{1}$$

We consider Jaccard and Cosine as similarity functions. These are two well-known similarity measures for textual content that use distinct input representations, which might encapsulate different ranking advantages. We use the vector space model and binary vector to represent websites for computing Cosine and Jaccard similarity respectively. Since these similarity measures use different representations of the websites , they might expose different characteristics in the ranking task. Let x, y be the representation of websites w_x, w_y, the Jaccard index and Cosine similarity between them are computed as follows:

$$Jaccard(x, y) = \frac{x \cap y}{x \cup y} \tag{2}$$

$$Cosine(x, y) = \frac{\sum_{i=1}^{n} x_i y_i}{\sqrt{\sum_{i=1}^{n} x_i^2} \sqrt{\sum_{i=1}^{n} y_i^2}} \tag{3}$$

4.1.3 Bayesian-Sets-Based Ranking. Bayesian Sets (BS) is a Bayesian inference technique introduced by Ghahramani and Heller in [14] that performs set expansion – it generates high-precision sets of related items. Specifically, given a set of related items that belong to a class C, BS scores a new item by estimating its normalized marginal probability that the item belongs to C. By this definition, BS can be directly applied to our ranking problem by considering the related items as seeds S and class C as domain D. Accordingly, the score of a website w is computed as the probability of w given that S is observed:

$$Score(w) = \frac{P(w|S)}{P(w)} \tag{4}$$

4.1.4 Ensemble Ranking Function. While many alternatives are possible for ranking functions, none of them is uniformly better for all domains, as we experimentally show in Section 5. Thus, ideally, we should be able to combine them. Ensemble learning is a paradigm that combines multiple machine-learning models and has been shown to be effective at reducing their variance. In our context, each ranking function captures a different set of features, hence their combination has the potential to improve the robustness and reduce the variance of the ranking. Inspired by this, we propose a new ranking function that combines the results from multiple ranking functions. Specifically, let $F = \{f_i\}$ be the list of the ranking functions and $f_i(w)$ denote the position of w in the ranked list that w belongs to. The new ensemble score of w is computed as the mean of these position values:

$$Score(w) = \frac{\sum_{f_i \in F} f_i(w)}{|F|} \tag{5}$$

Another option could be to directly consider the similarity scores as $f_i(w)$. However, these scores must be calibrated for the ensemble function to be effective. Our similarity functions do not produce naturally calibrated scores (i.e., probabilities), hence, we decided to use rank positions for combining the results. We also considered using other rank combination methods that have been proposed in previous work, e.g., reciprocal rank fusion [9]. However, we found that the mean function performed comparably well in our case and at same time it was faster.

4.2 Website Discovery Operators

The goal of the discovery operators in our context is to discover new websites , therefore we make use of existing discovery methods in a way that maximizes this objective. We investigate four different discovery techniques: forward crawling, backward crawling, keyword search, and related search. To incorporate these discovery methods in our framework, we designed them in such a way that they take the same input, the top-k most relevant websites , and produce the same output, a list of new websites . In what follows, we describe in detail each of these methods.

Forward Crawling. The forward crawling operator discovers new websites through outlinks extracted from the HTML content of the input web pages . Since the objective is to maximize the number of relevant websites , the operator only returns the outlinks for websites have not been discovered in the previous iterations.

Backward Crawling. The backward crawling operator discovers new websites by performing two operations: backlink search and forward crawling. In backlink search, it calls search engine APIs to obtain backlinks for the input web pages . Since the input is relevant to the domain, the discovered backlinks are likely to serve as hubs pointing relevant pages. This phenomenon has been referred to as co-citation in the literature [16]. Then, we can discover additional relevant websites by extracting outlinks from the hubs and doing forward crawling.

Keyword Search. The keyword search makes use of search engine APIs to search for websites relevant to the keywords. The problem is how to obtain domain-specific keywords from the input websites that lead to more relevant websites . The body text extracted from the input pages contains good keywords that are representative of the domain, however, they often co-occur with terms that may not be representative. Our observation is that the keywords extracted from the metadata tags (i.e., description and keyword) are significantly less noisy than the ones extracted from the body text. For this reason, they are particularly effective for searching for relevant websites . For each page, we extract and tokenize the metadata from the description and keywords tags. We select the most frequent tokens as search keyword candidates. The problem is that, even though many keywords are relevant to the domain, do not comprise sufficient information to retrieve relevant websites . For example, the keywords *pistol*, *texas*, and *sale* are related to the *weapon forums* domain, but more contextual information is needed to build search queries that find additional relevant websites . To address this challenge, we combine these keywords with terms that are good descriptors of the domain. For example, in the *weapon forums* domain, given *gun forum* as seed keyword, the corresponding search terms of the previous keywords are *gun forum pistol*, *gun*

forum texas and *gun forum sale*. Note that we only need one seed keyword for each domain, so this should not add any burden to the SMEs.

Related Search. The related search operator takes a website URL as input and returns a list of related websites . To our knowledge, only Google Search APIs and Alexa APIs support this operation. Depending on the nature of the data that these search platforms possess and their underlying algorithms, the results can be vastly different. Nevertheless, it appears to be a natural fit for our objective of discovering relevant websites . Note also that different search providers can be easily included as different search operators.

4.3 Discovery Operator Selection

In the previous section, we have described four different operators for discovering relevant websites , the challenge now is how to select an operator at each iteration in Algorithm 1 that maximizes the rate of discovering new relevant websites .

This is a non-trivial task for several reasons. First, it is not clear which search operator performs the best across multiple domains. In our experiments, described in Section 5, backward crawling performs better than other operators for website discovery in the Human Trafficking domain, but it performs poorly in other domains. Furthermore, favoring only search operators that are known to be good can leave the discovery process stuck in a connected region of the Web. On the other hand, using different discovery operators can diversify the discovery process, and eventually improve the rate of harvesting relevant websites .

To address this problem, we propose a strategy to balance the trade-offs between different discovery operators using multi-armed bandits (MAB), particularly UCB1 algorithm [1]. MAB is known as an effective means to solve the exploitation and exploration problem. The goal of this strategy is to select bandit arms with the highest accumulated reward and to penalize the ones that were overly operated in the past. To accomplish this, we need to define two variables in the UCB1 algorithm: the bandit arm (*op*) and the reward of its operation (μ_{op}). We model each discovery operator as a bandit arm. Assume that each time t, when an arm *op* is selected, it discovers $n_{op,t}$ websites . According to the UCB1 algorithm, the score of *op* at time t is defined as:

$$Score_{op,t} = \overline{\mu_{op}} + \sqrt{\frac{2ln(n)}{n_{op,t}}} \tag{6}$$

In this equation, n is the total number of websites retrieved by all operators. At each iteration, the algorithm selects the operator with highest score to perform the discovery.

The remaining challenge is to define the reward of an operator so that it is proportional to the number of relevant websites it discovered. Although we do not know the relevance of the discovered websites , we can approximate them by their ranking scores computed by the website ranking component (Section 4.1). Let pos_i denote the position of a website i in the ranked list. The normalized reward of i is $1 - \frac{pos_i}{len}$, where len is length of the ranked list. By this definition, if i is ranked at the end or top of the list, its reward is 0 or 1 respectively. Since the goal is to maximize the number of new relevant websites , we assign 0 reward to a website that was already discovered in previous iterations, regardless of its position. As a result, the reward of i is redefined as $(1 - \frac{pos_i}{len}) * I_i$, where I_i takes binary values:

$$I_i = \begin{cases} 0 & \text{website } i \text{ was already discovered} \\ 1 & \text{otherwise} \end{cases} \tag{7}$$

If a discovery operator *op* returns k websites , its reward μ_{op} is defined as follows.

$$\mu_{op} = \frac{\sum_{i=1}^{k}(1 - \frac{pos_i}{len}) * I_i}{k} \tag{8}$$

We use this reward to compute the score of an operator at time t ($Score_{op,t}$) in the equation 6. After each round of search, we recompute this score and select the operator with highest score for the next round.

5 EXPERIMENTAL EVALUATION

In this section, we evaluate the effectiveness of our discovery framework and ranking functions through extensive experiments using real-world datasets. We use the following domains for the experiments:

- Human Trafficking (HT): classified ads and other escort-related websites which often contain adult ads. Prominent example websites in this domain are `backpage.com`, `craigslist.com`, and `adultsearch.com`.
- Weapon Forums (Forum): discussion forums about firearms and weapons.
- Weapon Marketplaces (Market): marketplace or classified ads websites for firearms and weapons.
- Stock Promotions (SEC): websites that post stock promotion alerts. This domain contains information that can support investigations of micro-cap fraud.

We selected these domains for the following reasons. First, since they are different in nature, they allow us to evaluate the robustness of our proposed techniques and baselines. Most importantly, we had access to the seed websites and the training examples manually labeled by SMEs in these domains. The SMEs were analysts from government agencies and worked with us in collecting and reviewing relevant content. The number of seed websites in HT, Forum, Market and SEC domains are 54, 103, 23, and 18 respectively. These are representative websites that contain a significant number of pages relevant to the domains. These seed websites are used for the evaluation of the ranking methods in 5.2 and for the input of the DISCO framework in Section 5.3. As training examples (described in Table 1), we used a bigger set of websites, labeled as relevant and non-relevant by SMEs in HT, Forum and Market domains. We use these examples to create ground-truth classifiers for the evaluation of the DISCO framework, which we present in Section 5.3.

It is worthy of note that although we were able to obtain ground-truth to train these classifiers, labeling the pages required a very time-consuming process. In addition, the labeling process was not a trivial task for the SMEs, who are familiar with the domain but not with the intricacies of learning. For example, they did not know the impact of labeling some confusing cases would have in the final model. An important motivation for this work is to devise an easier-to-use and less time-consuming process to solve this problem.

5.1 Evaluation Metrics

5.1.1 Website Ranking Metrics. Section 3.1 presented two desired characteristics of good ranking functions: high precision in the top of the ranked list and low false negative in its tail. In order to measure these qualities, we use the following metrics:

P@k: computes the percentage of the relevant websites in the top-k websites of the ranked list. This metric captures the quality at the top of the list.

Mean Rank: computes mean of the ranking positions of the relevant websites in the ranked list.

$$MR = \frac{1}{n} \sum_{w_i \in D_+^*} position(w_i) \tag{9}$$

We do not normalize the rank by the length of the ranked list because we want to keep the absolute values for easy interpretation. Also, in our experiment, the length of the ranked lists in the experimental domains are similar, therefore absolute values are still valid for cross-domain comparison.

Median Rank: position of the relevant website whose position after ranking is the midpoint of all the relevant websites .

5.1.2 Website Discovery Metrics. We measure the discovery efficiency using *Harvest Rate* and *Coverage* metrics. In the following metric definitions, let D_+^* be the set of discovered websites that are in the domain D.

Harvest Rate: the ratio between the size of D_+^* and the size of D_+. The Harvest Rate is a standard metric that has been widely used in literature to measure the efficiency of focused crawlers.

Coverage: we define coverage as the percentage of websites in D that are discovered.

5.2 Website Ranking Evaluation

For each domain, we randomly select 10,000 websites from DMOZ directory[1] as negative candidates. Since the domains are rare and the size of DMOZ is large (about 4M websites), there is only a small chance that the selected examples are relevant to the domain. Therefore, we can reliably consider these as negative candidates. For each domain, we split the seed websites into train and test sets randomly. We merge the test set into the set of negative examples, creating a new set named the *candidate set*. Then, we rank the candidate set using the ranking functions described in Section 4.1. We compute the evaluation metrics based on the positions of the test set in the ranked list.

JACCARD, COSINE: These ranking functions compute the similarity between two websites using JACCARD and COSINE similarity index, respectively.

BS: This ranking function uses Bayesian sets technique. We represent each website as a term-frequency vector as opposed to the binary vector used in [14].

ONECLASS: This ranking function uses novelty detection (i.e., one-class SVM [28]).

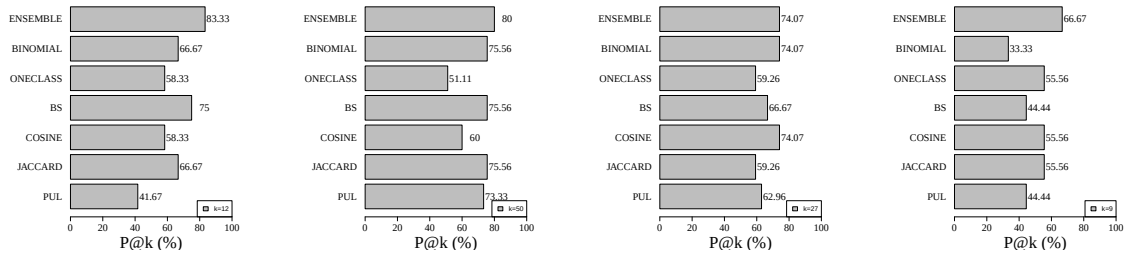
BINOMIAL: This ranking function uses binomial regression. We use logistic regression because it is fast and known for performing well on text data. To obtain the negative examples, we randomly select websites from DMOZ. The number of selected examples was equal to the number of positives examples. For the implementation of both *ONECLASS* and *BINOMIAL*, we used scikit-learn [22].

PUL: This ranking function uses biased SVM [18]. We use SVM light[2] as an implementation of biased SVM. We also use DMOZ to obtain the unlabeled examples for learning this function.

ENSEMBLE: This is our ranking function that combines all the above ranking functions, except *PUL*, whose performance showed a high variability across different domains.

Figures 2, 3, and 4 compare the ranking functions using different metrics: *P@k*, mean rank and median rank. Note that we select a k that is equal to the number of relevant websites (test set) in the candidate set. By doing this, we basically normalize the *P@k* values to range [0, 1]. The figure shows that the ENSEMBLE ranking function achieves better performance than the individual ranking functions do in most of the cases. This confirms that the combination of different ranking functions is able to reduce the variance and increase the robustness of the overall ranking. We also observe that *BS* consistently performs better than other individual ranking functions in median rank metric, i.e., it rarely places a relevant website to the end of the list, which is one of our desired features. Another observation is that the precision in SEC domain is relatively low (66.67%) compared to the others. This can be explained by the fact that in this domain, relevant websites might contain a mix of topics that are less distinguishable. Another reason is that this domain has smallest number of seeds among other domains.

Influence of the Number of Seed Websites . To understand how the number of seed websites impacts the effectiveness of the ranking, we conduct a ranking evaluation with different number of seed websites . Figure 5 shows the *P@k* corresponding to number of seed websites . We notice that the precision improves when we increase the number of seed websites up to 13 and stabilizes after that. This finding suggests that this number of seeds is sufficient to achieve a good ranking performance. It also reveals that probably there is still room to improve ranking performance, especially for cases in which a larger number of seed websites is available. Given recent advances in text representation using dense vector representations and document distance computation in the embedding space [17, 33], this is a promising area for future work. While this is a limitation of our ranking approach, it is still suitable for our context, where we assume to have only a small list of seeds as input.



5.3 Discovery Evaluation

In this section, we assess the effectiveness of DISCO and compare it to state-of-the-art discovery strategies [3, 4, 31] (baselines). Since the baselines require a page classifier to operate, we train one classifier for each domain using seed websites and unlabeled examples as training data. Specifically, we consider seed websites as positive examples, and randomly select pages from DMOZ to use as negative examples. For training the classifiers, we use an implementation of SVM from the scikit-learn library [22].

To compute the discovery metrics, we train one ground-truth page classifier for each domain using the positive and negative examples manually labeled by SMEs. Note that these classifiers are only used for evaluation purposes. Although not ideal, these classifiers are the closest to the real ground truth that we can possibly

	HT	Market	Forum
# of positive examples	968	68	103
# of negative examples	7117	169	256
Accuracy (5-fold CV)	0.97	0.96	0.84

obtain. Nevertheless, they provide a scalable and consistent way to evaluate the discovery results. Table 1 summarizes the training data and cross-validation accuracy of these classifiers. The accuracy ranges from 84% to 97%, which are sufficiently reliable for evaluating discovered websites . For each method, we stop the algorithm when it retrieves 50,000 web pages . In fact, all the baselines stop before reaching this limit. In the following, we describe baselines and different configurations of DISCO framework used in the evaluation.

We used the following approaches as baselines:

ACHE: ACHE is an adaptive focused crawler described in [4]. We used an open-source implementation available online.[3] This implementation uses an online-learning crawling policy [7] to prioritize the unvisited links. Since ACHE is designed to maximize the number of relevant web pages instead of relevant websites , we limit the number of crawled web pages per website to 10 to ensure it will visit more websites . While a smaller limit would yield higher rate of new websites , it would potentially lead to missing relevant websites that exist but would not have been discovered because some web pages would never been visited. Indeed, our experiment with a smaller limit results in a lower harvest rate and the crawler also stops earlier due to running out of links to crawl.

BIPARTITE: This crawling strategy was proposed by Barbosa et. al. [3] and, similar to ACHE, we set the page-per-site limit to 100.

SEEDFINDER: We implemented the SeedFinder algorithm proposed by Vieira et. al. [31]. SeedFinder uses the keyword search operator to discover new web pages . It then extracts new keywords from the content of the pages classified as relevant by the page classifier to derive new queries using relevance feedback.

We used the following search operators for DISCO:

KEYWORD: DISCO used with the keyword search operator. For a fair comparison, this method uses the same settings as SEEDFINDER (i.e., initial keywords and the number of search results returned by search APIs).

RELATED: DISCO used with the related search operator. Since the objective is to discover websites , we use host name of the input URL to form the search query. For example, given the URL `http://example.com/path.html`, the query is represented as `related:http://example.com`.

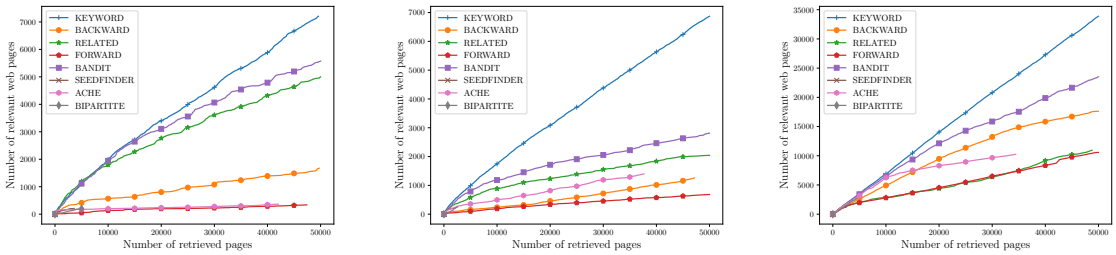
FORWARD: DISCO used with the forward crawling operator.

BACKWARD: DISCO used with the backward crawling operator.

BANDIT: DISCO used with the multi-armed bandits algorithm for selecting the discovery operator.

Implementation Details. For KEYWORD and SEEDFINDER methods, we use "gun classified", "gun forum" and "adult escort" as seed keywords for the Market, Forum and HT domains respectively. We selected these keywords since they represent well these domains and we observed highly relevant results by searching these keywords on Google. To obtain new keywords, we tokenize the textual content extracted from the description and keywords tag, then select the most frequent keywords to use in the next search iteration. In each iteration, we select at most 20 new keywords. All methods start with the seeds provided by SMEs (also used in the ranking experiment). We limit the number of results retrieved by keyword search, related search and backlink search to be 50, 50, 5, respectively. We set k in Algorithm 1 to 20. DISCO uses ENSEMBLE as the ranking function because it outperforms other ranking functions and is consistent across multiple domains. We use MOZ API[4] for backlink search, Bing Web Search API[5] for keyword search, and Google Custom Search API[6] for related search.

5.3.1 Comparing Harvest Rates. We use the ground-truth classifiers to classify the discovered web pages . A website is considered as relevant if it contains at least one relevant web page . Figure 6 and Figure 7 show the number of discovered relevant web pages and websites versus the number of discovered web pages over time. Overall, DISCO with the best configuration (BANDIT) obtains at least 300% higher harvest rate compared to other baselines. Also, BANDIT consistently outperforms other configurations in all the three domains in terms of discovered websites . However, if we measure the harvest rate by relevant web pages , ACHE performs closely to the DISCO strategies in the Market and Forum domains. The reason is that ACHE's objective is to maximize the number of relevant web pages by exploiting relevant websites that are already discovered. However, it quickly reaches a plateau when fewer relevant websites are found. Another reason that ACHE performs well in HT domain is that websites in this domain are highly connected. This also explains why backlink method performs better in this domain than the others. SEEDFINDER and BIPARTITE strategies stop early, before reaching 5,000 pages in all the domains, due to running out of links to crawl.



5.3.2 Comparing Coverage. Since it is impractical to obtain the real ground truth for each domain (i.e., all the relevant websites in the domain), we use the union of discovered websites from all discovery methods as an approximation for the ground truth. By doing this, while the estimated coverage can be largely different from the real value, it serves as reasonable relative measure to compare different methods. Figure 8 shows the coverage of all discovery methods in the considered domains. For each method, we compute the percentage of relevant websites that are also discovered by all other methods, which we denominate as *intersection* in the plots. The *complement* region represents the percentage of relevant websites that are discovered only by the corresponding method. The BANDIT strategy consistently attains the largest intersection among all methods. This suggests that each operator searches a different region of the Web, and by adaptively combining them, the BANDIT strategy is able to explore a broader portion of the Web.

6 CONCLUSION

In this paper, we propose DISCO, a new approach that helps bootstrap domain discovery: given a small number of sample sites in a domain, it automatically expands the set. DISCO employs an iterative crawling procedure that combines multiple search operators and, as proxy to select relevant pages, it ranks the search results based on their similarity to the sample sites. We perform extensive experiments using real-world data from different social-good domains and show that our framework is effective and attains significant gains in harvest rate compared with state-of-the-art methods. The experimental results suggest that DISCO can be effective at lowering the burden on users that need to create page classifiers and discover information on the Web at scale. For example, DISCO could be used to both automatically provide additional seed pages for DDT [15] and to rank the results of user-specified search operations.

While DISCO is effective for the domains we experimented with, it has limitations. Our ranking approach is only suitable for the domains for which using n-gram features are effective and the given seed websites are representative for the domains. Additionally, keyword search is very sensitive to the seed keywords, which can be hard to select for some domains. In future work, we would like to explore image-based search for this problem, which can be

potentially applied to image-rich domains, such as weapon ads and human trafficking.

ABSTRACT

Search engines play an important role on the Web, helping users find relevant resources and answers to their questions. At the same time, search logs can also be of great utility to researchers. For instance, a number of recent research efforts have relied on them to build prediction and inference models, for applications ranging from economics and marketing to public health surveillance. However, companies rarely release search logs, also due to the related privacy issues that ensue, as they are inherently hard to anonymize. As a result, it is very difficult for researchers to have access to search data, and even if they do, they are fully dependent on the company providing them. Aiming to overcome these issues, this paper presents Private Data Donor (PDD), a decentralized and private-by-design platform providing crowd-sourced Web searches to researchers. We build on a cryptographic protocol for privacy-preserving data aggregation, and address a few practical challenges to add reliability into the system with regards to users disconnecting or stopping using the platform. We discuss how PDD can be used to build a flu monitoring model, and evaluate the impact of the privacy-preserving layer on the quality of the results. Finally, we present the implementation of our platform, as a browser extension and a server, and report on a pilot deployment with real users.

1 INTRODUCTION

Over the past few years, researchers have demonstrated how online search data can be used to infer contextual information related to both individual users and populations, with examples ranging from consumer behavior modeling [19], macroeconomic statistics [14], and sales forecasting [8, 40], to early detection of cancers [30, 39] and disease monitoring at a national level [18, 21, 32].

Typically, individual-level studies rely on acquiring access to the (anonymized) search history of multiple users. However, this prompts significant ethical and privacy issues: search history often contains sensitive data on topics such as income, sexual orientation, religion, and health. Furthermore, anonymization has proven to be very difficult to guarantee [17]. A case in point is the AOL search logs, which were released in 2006: several users were easily de-anonymized, leading to a public outcry that resulted in the resignation of AOL's CTO [44]. Therefore, search engine providers seldom, if ever, provide such data, even for research purposes.

On the other hand, estimating properties of a population may be done over aggregate data, i.e., how many users have searched for specific keywords over a time frame, which is much less sensitive. In particular, in this paper, **we focus on inferring population health statistics from Web query data**, and experiment with a use-case related to estimating the prevalence of a disease such as influenza [18, 21]. Unless the population and/or region size is very small, or the queries contain many outliers, aggregates do not permit de-anonymization. One possible data source for search statistics is Google, which offers services like Google Trends and the Health Trends API (see Section 2). However, it is still quite possible that these products will not be maintained or may cease in the future. Moreover, they might not provide information on specific keywords, or sufficient geographic granularity. Also, and perhaps more importantly, since aggregation is performed by a third party, it actually provides no privacy with respect to that party.

Aiming to fill this gap, **this paper investigates how to privately crowd-source Web search data.** To this end, a number of challenges need to be addressed, including: (i) recruitment and retention, (ii) human-computer interaction, and (iii) privacy. This paper primarily focuses on a technical solution to the privacy issue. In theory, a straightforward implementation to collect users' Web search data, without the search engine's involvement, would attempt to anonymize the user and transmit data to a trusted third party, which would then aggregate data before releasing it to a researcher. However, both steps involve significant risks to individuals' privacy, with de-anonymization and security breaches of the third party being the most obvious.

By contrast, we propose a solution that does not require a fully trusted third party, and which only collects aggregate statistics on search behavior at a population level. More specifically, **we present the Private Data Donor (PDD) platform**: PDD consists of a lightweight Web browser extension, which users (data donors) install, and that monitors the searches performed by them. Users are assigned to groups, and each group uses a protocol based on homomorphic encryption to encrypt and transmit the number of times a user searched for specific queries to a server. For each user in the group, the server adds their encrypted count together. The resulting sum is an unencrypted value representing the aggregate count of the group. Data from each group is then aggregated to

determine the counts for the entire population, so that at no time is the server able to determine the query frequencies of an individual.

Contributions. Overall, we make the following contributions:

(1) We propose PDD, a new platform to handle privacy-preserving crowd-sourcing of Web search queries, decentralized, and scaling up to millions of users.
(2) We analyze the impact of different system parameters on the behavior of our platform, aiming to find the best balance between the privacy of users and the utility of collected results.
(3) We study how our platform can be applied to a real-life use case, i.e., building a flu monitoring model.
(4) We implement and deploy our platform, and use it for real-life data collection.

2 RELATED WORK

Studies using Web searches. Search engines such as Google, Bing, DuckDuckGo, etc. respond to billions of queries every day [37]. Users ask search engines a wide range of questions, and these often include personal and contextually rich information. In 2016, Google reported that at least 1% of their searches were related to symptoms, and started to provide structured information about the health conditions associated to those symptoms [31]. Overall, Web searches can often be a treasure trove for researchers, with notable examples including the applications mentioned earlier [8, 14, 19, 40].

Of particular interest to us is research relying on search data for health purposes [18, 21, 30, 32, 39], and more specifically based on crowd-sourced information [22, 36, 38, 42]. In this paper, we essentially aim to introduce a privacy-preserving layer on top of those studies, which might encourage users to donate their data, and help researchers comply with regulations, while removing the dependence on limited statistics given by search engines.

Aggregate search data. Popular search engines do not have incentives to share search data, as this information is of commercial value and, as discussed earlier, sensitive in nature. Google provides two ways to gain insights into the searches it receives, at an aggregate level: (1) Google Trends and (2) the Health Trends API. The former is a Web interface offering a global, longitudinal view of the interest for one or more queries, provided as a normalized number between 0 and 100. The latter is a service offered to researchers, with access to the interest of search queries related to health topics (see also [23, 46]). Here, the interest is provided as a frequency, i.e., the number of times the queries were searched during a time period normalized by the total number of searches in the same period. Note that this is only computed from a subset of all searches (10%-15%), and various anonymization measures are taken to remove low-count searches. With the former, the number of times a query was issued is not made available—only some normalized measure, which does not allow evaluation of the absolute popularity of a query. Moreover, statistics are only provided at a country-level or state-level granularity. Finally, relying on these two platforms means that the researchers are directly dependent on a third-party company, whereas, we envision a decentralized scenario where researchers could be autonomous in collecting the data they need.

Privacy-preserving data aggregation. Researchers have also studied the generic problem of collecting statistics from users in a privacy-preserving manner. To this end, cryptographic schemes have been proposed for privacy-preserving data aggregation, e.g., in the context of smart grids [20], wireless sensor networks [4], and streaming data [5, 26]. Our work builds on the homomorphic encryption protocol proposed in [26], which we review in Section 3.2; however, since it was originally designed for real-time applications like counting viewers of streaming videos, we need to address a number of challenges to adapt it to our setting (see Section 3.3).

An alternative approach is to add noise to the statistics so that they do not leak information about any particular individual, thus guaranteeing Differential Privacy (DP) [12]. Typically, this approach relies on a central curator, which receives raw data, aggregates it, applies a differentially-private algorithm, and releases the protected version of the data to researchers (see for example [25, 27]). However, this central entity needs to be a fully trusted entity and as such could be vulnerable to attacks or a subpoena. Another possible setup is known as local differential privacy, where noise is applied at the user-side before sending the data, thus preventing the entity collecting data from learning anything sensitive [13]. However, this requires very large numbers of users in order for the noise to cancel out and yield reasonably accurate results [16].

Privacy-preserving crowd-sourcing. Finally, prior work specific to crowd-sourcing data from users includes systems allowing third-parties to gather Web analytics [7, 15], location statistics [33], and surveys [10]. Some also provide DP guarantees [1, 6, 13]. As opposed to this line of work, we aim to provide a distributed platform that does not rely on: (i) a central anonymization server and, (ii) a persistent connection between the clients and the server.

3 PRIVACY-PRESERVING AGGREGATION

This section presents our approach to privacy-preserving collection of aggregate data, a key component of our PDD platform. After providing a high-level overview, we formalize the underlying protocol. We then discuss how to adapt it to build a large-scale system for crowd-sourcing Web searches; finally, we present the enhanced version, which we release, open-source, for public use.

3.1 Overview

Terminology. Throughout the paper, we use the following terms:

- *Server:* in PDD, the server is a piece of software running for an institution interested in gathering Web searches statistics.
- *Users:* people willing to contribute their searches (in aggregate form) to a research project. They install a *client*, i.e., a browser extension communicating with the server. We use the terms "users" and "clients" interchangeably in the rest of the paper.
- *Query:* a string that can interpreted by a search engine (e.g., Google, Bing, DuckDuckGo) to retrieve matching Web resources, e.g., "world cup odds," "will it rain today," etc.
- *Monitored query:* a query for which the server collects and provides statistics.
- *Search:* a query that was sent by a user to a search engine. A search is thus the association of a user, a query, and a timestamp.
- *Analyst:* a researcher having access to the data collected by PDD and using it for further analyses.

Data Aggregation. We build on an underlying privacy-preserving data collection protocol – specifically, the one presented by Melis

et al. [26] – to create a fully-fledged crowd-sourcing platform for Web searches. The protocol encompasses three steps:

(1) *Setup:* Users willing to contribute their searches (in aggregate form) install a browser extension; upon installation, the extension generates a pair of cryptographic keys, registers itself to the server with its public key, and is assigned a client identifier.
(2) *Reporting:* Clients regularly obtain the set of monitored queries and the public keys of the other clients. They generate a (secret) blinding factor for each query, in such a way that the sum of blinding factors of all users, for a given query, will equal zero. Using their browsing history, clients fill a vector of counts, where each value corresponds to the number of times a monitored query was searched in the previous day: the vector is encrypted using the blinding factors and sent to the server.
(3) *Aggregation:* Once the server has received the encrypted vectors of all clients, it can decrypt the encrypted counts by summing them up.

Adapting Melis et al.'s protocol to our setting immediately prompts two main challenges. A first issue is the impact of a client being unable to report his encrypted data to the server; in this case, the sum of all blinding factors is *not* equal to zero, and the encrypted data cannot be decrypted by the server. In other words, a single user failing to report his data on a given day will result in the inability to retrieve the statistics for a particular day, which is not acceptable. Our PDD platform introduces two measures to build more reliability into the protocol: (1) We organize clients into smaller groups, each one running its own instance of the protocol; (2) We introduce some additional delay before "giving up," leaving more time for clients to send their data.

Another issue is that [26] requires a persistent connection between the server and the clients. This allows the server to learn when users are online, which may introduce a new privacy threat, and also increases the load on the server. We remove this requirement by letting clients communicate with the server at most once a day, which significantly lowers the privacy threat.

3.2 Privacy-Preserving Aggregation

We now formally present Melis et al.'s protocol [26].

Notation. First, let us introduce notation, also summarized in Table 1. We use N to denote the numbers of clients in the system, and L the number of monitored queries. $C_i, i \in [1, N]$ denotes the i-th client, and $W_j, j \in [1, L]$ denotes the j-th monitored query. Let $\mathbb{G}$ be a cyclic group of prime order q for which the Computational Diffie-Hellman problem [11] is hard, and g be the generator of the same group. Also, we use a cryptographic hash function, $H : 0,1^* \rightarrow \mathbb{Z}_q$, mapping strings of arbitrary length to integers. Let "||" denote the string concatenation operator, and $a \in_r A$ indicate that a is sampled at random for A.

Algorithms. The protocol involves the following algorithms:

- *Initialization.* Each client C_i generates a private key $x_i \in_r \mathbb{G}$ and a public key $y_i = g^{x_i} \bmod q$, and then sends its public key along with its identifier i to the PDD server to be registered.
- *Encryption.* At each round s, client C_i holds a counts vector $V_{si} = (v_j \in \mathbb{N}, j \in [1, L])$, where v_j represents the number of times the query W_j was searched for. To encrypt this vector, client C_i first generates a blinding factors vector:

Symbol	Meaning
$\mathbb{G}$	Cyclic group of prime order q, whose generator is g
H	Hash function mapping strings to integers
$\|\|$	String concatenation operator
s	Current round number (0-based)
N	Total number of clients
C	Set of all clients
C_i	i-th client, $i \in [1, N]$
(x_i, y_i)	Private and public keys of client C_i
L	Total number of monitored queries
W_ℓ	ℓ-th monitored query, $j \in [1, L]$
K_{si}	Blinding factors of client C_i at round s
V_{si}	True counts vector of client C_i at round s
$\hat{V}_{si}$	Encrypted counts vector of client C_i at round s
$o_s : C \rightarrow \mathbb{B}$	Whether client C_i was online during round s

Table 1: Notation.

$$K_{si} = \left(\sum_{j=1, j\neq i}^{N} H(y_j^{x_i} || \ell || s) \times (-1)^{i>j} \bmod q, \ell \in [1, L] \right) \quad (1)$$

where $(-1)^{i>j} = -1$ for $i > j$ and 1 otherwise. Then, each C_i encrypts its counts vector V_{si} into an encrypted vector $\hat{V}_{si} = V_{si} + K_{si}$, which is then to be sent to the server.

- *Decryption.* Once the server has received the encrypted vectors for all clients at round s, it can decrypt it by summing them:

$$V_s = \sum_{i=1}^{N} \hat{V}_{si} = \sum_{i=1}^{N} V_{si} + \sum_{i=1}^{N} K_{si} = \sum_{i=1}^{N} V_{si} \,. \quad (2)$$

Indeed, the sum of all K_{si} is a zero vector:

$$\forall \ell \in [1, L], \sum_{i=1}^{N} K_{si_\ell} = \sum_{i=1}^{N} \sum_{\substack{j=1 \\ j\neq i}}^{N} H(y_j^{x_i} || \ell || s) \times (-1)^{i>j} = 0 \,. \quad (3)$$

3.3 Challenges

As mentioned above, using Melis et al.'s protocol [26] in our setting (i.e., crowd-sourcing Web searches) poses a few challenges, as it was designed for a different set of applications, namely, counting the viewers of streaming videos or the number of requests to Tor Hidden Service directories. In other words, [26] targets real-time data collection in a context where users are expected to all be online at the same time and the cryptographic code actually runs directly in the browser in Javascript (specifically, as a Node.js package). At some point, the server decides to gather statistics, issues a request to the clients to encrypt and send their counts, and decrypts/publishes the aggregate results after decrypting the clients' contributions.

However, if some clients disconnect during the process, e.g., the user goes offline or closes the browser tab, the server will not receive some of the encrypted counts, and cannot decrypt the aggregate counts since the blinding factors no longer sum up to zero. Also, the protocol requires a persistent connection between clients and server (e.g., via a web-socket or a regular ping). We discuss these two challenges in more detail next.

Disconnections. To mitigate the issue of disconnections, [26] proposes two solutions: (1) organizing users in smaller groups, and (2) running a recovery protocol. Specifically, the protocol can be applied independently on several groups, and the decrypted count vectors of each group summed to obtain the global decrypted count vector. In this setting, the size of each group becomes a critical parameter, impacting both privacy (i.e., among how many other

users is each user hidden) and utility (i.e., the likelihood the group's count vector can be decrypted). Put simply, the larger the group, the better the privacy, but the more at risk is utility. Another open question, which was not handled in [26], is how to organize users into groups. At the same time, the recovery protocol allows the users that are still online to compute a recovery factor, which will then be used to "reverse" the effect of the blinding factors of missing users. However, users might in turn disconnect during this recovery protocol, making the recovery protocol fail in turn.

Persistent connection. In our setting, the need for a permanent bi-directional connection between the server and its clients is very undesirable, for two main reasons. First, having a permanent connection between the server and every client requires non-negligible computing resources, while we need the platform to be as operationally simple as possible, allowing researchers to deploy it on a single server with limited computing power. Second, this also raises orthogonal privacy issues, as the server will know the times at which users are online, learning information about users' behavior which can potentially to be a side-channel for privacy attacks. In theory, privacy-preserving presence protocols have been proposed (e.g., [3]), but they rely on having multiple non-colluding servers, which we do not have.

Requirements. Overall, as mentioned, Melis et al.'s protocol [26] was designed for different applications, while we are interested in collecting Web searches. This distinction has two practical implications in the requirements of our platform: (1) Our client-side platform needs to access browsing history to collect the search queries (specifically, the monitored queries), thus, it needs to run as a browser extension (and not directly on a particular web page); (2) We do not need real-time statistics, but rather daily aggregates.

Next, we discuss how we modify the platform to accommodate our requirements and overcome these challenges.

3.4 Enhanced Aggregation Protocol

The main idea is that the server prepares itself at the beginning of every day to gather statistics about the past day. To do so, it precomputes, each night, groups of clients based on their past activity patterns. Then, throughout the day, when they come online, clients ask the server which groups they are part of, and retrieve the list of monitored queries. Each user is only part of at most one group each day, but the server may return several groups for the past few days, if necessary to recover from past days where the user was inactive. Clients then use their browsing history to compute the counts vector for each requested group, encrypt it using the public keys of the other members of the group, and send the encrypted counts vectors to the server. In this setup, the round number s becomes the number of days elapsed since the data collection began.

Handling disconnections. As proposed in [26], we organize clients into groups. However, as we only have at most one contact with each client per day, the challenge is to be able to pre-compute groups without knowing for sure which users will be active the next 24 hours. To this end, we leverage historical knowledge about past clients' activity. More specifically, at the beginning of day d, when statistics about day $d-1$ need to be gathered, the server knows which clients were active during day $d-1$. Therefore, the server includes only the clients active on day $d-1$ in the groups formed on day d, which reduces the number of clients actually involved in the protocol every day, and improves the reliability of the data collection. Indeed, the less users are involved in the protocol, the lower the probability that some of them will not be active on day d and hence the lower the probability to lose data.

Creating groups introduces, obviously, the need for setting a *group size*, which is a system parameter controlling the number of clients into each group. Concretely, groups formed at the beginning of day d are composed of only clients that were active on day $d-1$, and affected to groups in a round-robin fashion. All groups will hence have the same number of clients, except one group which may contain less clients. We will explore, in Section 4.4, a more advanced strategy, selecting users by their past activity, trying to maximize the probability for them to be online.

Nonetheless, the main drawback of pre-computing groups is that there is still a risk that some clients involved in the protocol will not be active the next day, which may prevent the encrypted data from some groups to be decrypted. For that reason, we introduce the notion of a *delay*, i.e., a number of days during which the server will wait for the encrypted counts to be sent by the clients. Waiting a few more days will allow the inactive clients to come online later on, thus improving the quality of the results.

Removing persistent connections. Because clients only contact the server at most once a day, the privacy threats are dramatically lowered as compared to having a persistent connection, because the server does not anymore know, in real-time, which users are active. It also significantly lowers the computational pressure on the server, which is only expected to handle a couple of requests from each client every day. (Rate limiting strategies should also be used to protect against DDoS attacks [43].)

Confidence. It might still happen that a client does not come online on day d, and neither in the additional delay that may be granted. In that case, it means that the encrypted data for this client, and for all this group, will never be decrypted and is considered as *lost*. Although lost data should be considered impossible to recover at that point, we can provide a *confidence* measure to the data analysts, computed as the ratio of successfully decrypted users. This adds transparency to the figures provided to them by the PDD platform.

Threat Model. The security of this approach relies on that of the aggregation scheme presented by Melis et al. [26], which is proven secure in the honest-but-curious (HbC) model under the Computational Diffie-Hellman assumption [2]. Here the HbC model means that both the clients and the server, although they may attempt to violate privacy of their counterparts, do not deviate from the protocol specification. For instance, malicious users could report fake values in order to invalidate the final aggregation values, while the server could maliciously manipulate the number and identity of clients in the same group. This is a common assumption in cryptography, which can be mitigated using verifiable tools such as zero-knowledge proofs, cryptographic commitments, and code attestation. We leave such extensions as part of future work, as they are orthogonal to the challenges we face in this work.

3.5 Example

To clarify how our platform works, we use an example, as pictured in Figure 1. We consider five clients (A, . . ., E), who participate in

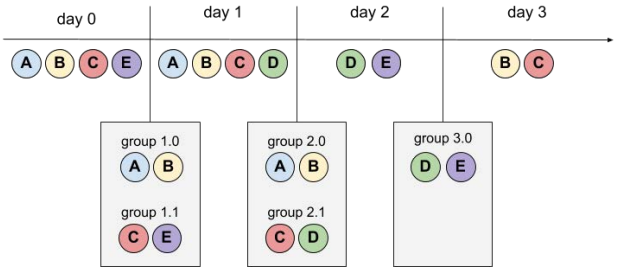

Figure 1: Example of how users can be added to groups based on their past activity.

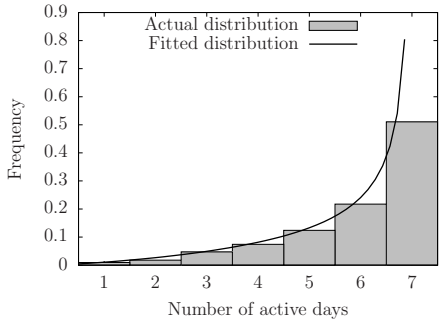

Figure 2: Distribution of users' activity.

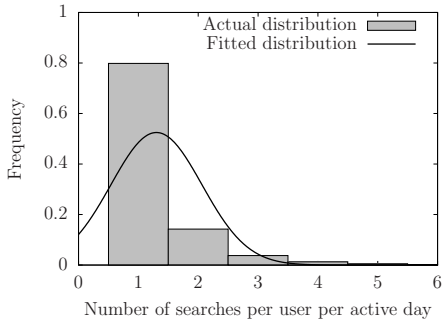

Figure 3: Distribution of search volume.

data collection, a group size of two, and a delay of one additional day. At the beginning of day 1, A, B, C and E, who were seen online on day 0, are put into two groups of two clients each. On day 1, A, B and C were seen online, as well as client D, who is not part of any group. Then, A, B and C will be tasked with sending their encrypted count vectors to the server, while D will not have any task to perform. At the end of day 1, data of group 1.0 has been decrypted, but data of group 1.1 is still missing E's counts vector.

At the beginning of day 2, A, B, C, D (who were seen online on day 1) are put into two groups. At the end of day 2, because E has eventually come online within the one additional day of delay, data of group 1.1 has been decrypted. However, groups 2.0 and 2.1 are still un-decrypted, because A, B and C were not online on day 2. At the end of day 3, group 2.1 has been decrypted within the one-day delay, but group 2.0 is lost since A was not active on days 2 and 3.

Eventually, data for day 0 has been made available at the end of day 2 (with a confidence of 100%), while data for day 1 has been made available at the end of day 3 (with a confidence of 50%). Overall, this simple example illustrates the usefulness of both dividing users into groups (allowing to decrypt half of the data for day 1) and the additional delay (allowing to decrypt all, instead of only half, of data for day 0).

4 CONFIGURING PDD THROUGH SIMULATION

We use extensive simulations to determine the configuration of the PDD platform. Specifically, we evaluate the impact of the two main system parameters (see Section 3.4): the group size and the delay. As PDD is a distributed system, potentially involving thousands or even millions of users, we use simulation to better understand its behavior and test different parameterizations.

4.1 The PDD Simulator

We now introduce the simulation environment used in our experiments. It involves two distinct modules, simulating: (1) user activity, and (2) the PDD protocol itself. The former simulates how users interact with their browser, while the latter simulates the interaction between clients and the server. The simulator is implemented in Python (for data pre-processing and analysis) and Scala (for the main workflow).

User activity module. The user activity module is made of three distinct parts, each simulating: (i) connectivity, i.e., which days users are active and using their browser, (ii) search volume, i.e., how many searches users are performing on active days, and (iii) search content, i.e., what are users actually looking for.

Overall, accurately simulating users' browsing activity is a very challenging task, mainly due to the lack of publicly available datasets. To overcome this challenge, we turn to the datasets released by Mozilla in 2010 to shed light on how users interact with their browsers [28]. We use the most complete dataset, which contains data for 4,802 users, collected over a week in December 2009. For each user, we have the number of browsing sessions (i.e., how many times each user started his browser during the week) and the average duration of those browsing sessions. We use the data to "replay" such sessions since, unfortunately, the dataset does not contain the *times* at which users were active. We obtain a distribution with the number of days (out of seven) during which the users have been effectively using their browser. Due to the randomness of this process, we run 100 iterations, and eventually select the Beta distribution with the lowest distance, according to a Kolmogoroc-Smirnov test [24]. More specifically, we end up with a Beta distribution with $\alpha = 2.2170$ and $\beta = 0.4634$.

The original frequencies and the fitted distribution are shown in Figure 2. Note that the fitted distribution has a mean of 82.7% – i.e., on average, users are using their browsers between 5 and 6 days every week. This is consistent with a more recent study from Mozilla [9], which reports how long Mozilla's data scientists have to wait for telemetry data to be available, estimating that, on average, 95% of telemetry data was received within a single day. For each user, we sample a number of active days from the Beta distribution, scaled to the total number of days considered in our experiments (rounded to the closest integer). Simulations in Section 4 involve 100k simulated users over 100 days.

Next, we simulate search volume using the Yahoo dataset [35], which provides search logs collected over a month (July 2010), featuring 29M users, 67k unique queries and 80M searches. From this dataset, we extract the daily number of queries performed by each user, and fit a normal distribution on it ($\mu = 1.3020$, $\sigma^2 = 0.7603$). Figure 3 reports the original data along with the fitted distribution. For every day a user is active, we sample a number of searches to be performed from the distribution (rounded to the closest integer). Finally, we simulate searches by extracting the frequency of each of query included in Yahoo's dataset, which spans over an entire month. Note that the data is truncated after more than 10k searches of a given query, which may limit the precision of the simulation for very frequent queries. However, it still allows us to capture that a few queries are searched very often (e.g., 2k queries more than 10k times), with a long tail of infrequent queries (e.g., 11k queries less than 10 times). We simulate searches by randomly sampling a query from this distribution, as a random choice weighted by the frequency of each query.

PDD protocol module. This module trivially simulates the behavior of the PDD server by implementing the protocol described in Section 3.4. We assume that network communication is reliable (using TCP), thus, we do not need to simulate network communications and failures. Because we rely on simulation instead of a real-life system, we also have access to the ground-truth data (i.e., the V_{si}'s, the counts vectors of each client at each round), which we can use to evaluate our solution. The simulation essentially produces as output, for every day, a report about the true count and estimated count (i.e., after decrypting data) of each query, the total number of searches and the confidence.

Evaluation metric. We use the mean relative error (MRE) of the decrypted counts as the main metric to evaluate the quality of the collected data, averaged out across all queries, all users, and all rounds. Formally, it is defined as:

$$\text{MRE} = \frac{1}{|\{V_{si_\ell} \neq 0\}|} \sum_{V_{si_\ell} \neq 0} \frac{V_{si_\ell} - \tilde{V}_{si_\ell}}{V_{si_\ell}}, \tag{4}$$

where $\tilde{V}_{si}$ is the estimated counts vector received by the server for client C_i at round s. In practice, $\tilde{V}_{si} = V_{si}$ if the data of client C_i was successfully decrypted at round s, or $\tilde{V}_{si} = (0, \ldots, 0)$ otherwise.

4.2 Group Size

We start by using simulations to study the impact of the group size. First, users are put into groups following the heuristic described in Section 3.4, considering only the users who were online the previous day, i.e., at day d, $\{C_i \in C | o_{d-1}(C_i)\}$.

Group size is inherently responsible for the trade-off between privacy and utility. Here the level of privacy provided to the users is akin to k-anonymity [12], meaning that every client part of an aggregate will be hidden among $k-1$ other clients being part of the same aggregate, whereas, utility is measured via MRE as discussed above. On the one hand, creating groups of very few clients would yield near-optimal utility, but at the cost of providing little or no privacy to the users. On the other hand, putting *all* clients into a single group would provide the best levels of privacy, but can dramatically decrease the utility, since even a single client not sending its data will prevent the decryption of everybody's data. It also means that system designers have no control on the impact that increasing/decreasing numbers of clients will have.

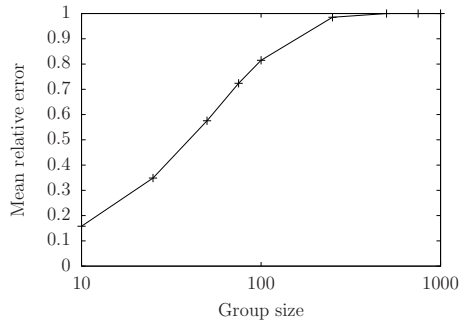

Figure 4: Impact of the group size on utility.

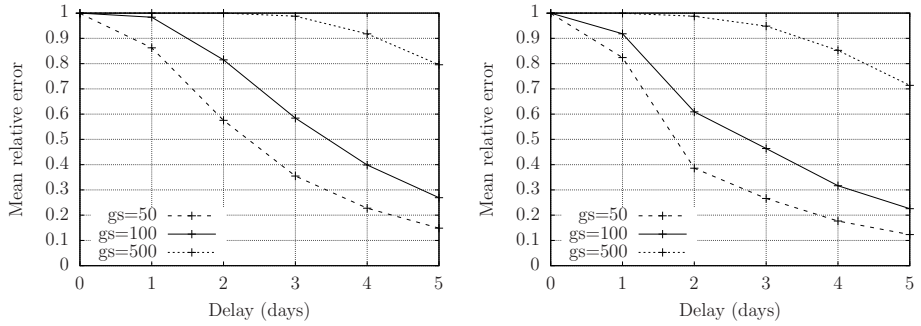
Therefore, we seek to find a middle ground, providing reasonable privacy guarantees, while still allowing reported counts to be accurate enough for data analysts to work with it. In Figure 4, we report the impact of the group size on the MRE of decrypted counts with a delay of two days. We report results with group sizes between 10 and 1000, as suggested in [26]. We note that MRE varies between 16% and 100%, increasing quite quickly: a group size of 100 already yields an 81% MRE. The privacy-utility trade-off is pretty clear: groups should not be too small because of privacy (in fact, we would not recommend less than 50 clients per group), however, large group sizes do not seem very practical, e.g., MRE is 100% with 750 users per group. Therefore, in Sections 4.3–4.5, we will experiment with group sizes between 50 and 500, and study how we can improve the utility without degrading privacy.

4.3 Delay



Next, we study the impact of utility when waiting for a few more days to provide aggregate counts to the analysts. As opposed to the group size, the delay does not play a central role in the privacy-utility trade-off, as it does not impact the privacy. Instead, it imposes a trade-off between utility and the availability of the results. Figure 5a shows the evolution of MRE with delay varying between 0 and 5 days, for group size $gs \in \{50, 100, 500\}$. We note a significant positive impact on MRE starting with a delay of two days.

Choosing the right delay is inherently application-dependent: some use-cases might accommodate well delays of a week, while others need near-real-time results. Nevertheless, Figure 5a shows that a group size of 500 is still not very practicable, because the MRE remains around 80% in the best case, while groups of 50 clients with 5 days of delay reduces MRE to 15%.

Our simulations also highlight that some errors are not recoverable, even while waiting up to five additional days. We believe this is due to the behavior of users, as shown in Figure 2, with a very small fraction of the users being active only once in a while. Next, we study how to mitigate the impact of inactive users on MRE.

4.4 Improving Client Selection

Aiming to improve the privacy-utility trade-off presented above, we present a novel approach to organize clients in groups. The basic idea is to only put into groups clients that are likely to be active the next few days, assuming that some additional delay is allowed.

(a) Naive approach. **(b) Improved selection algorithm.**

Figure 5: Impact of the delay on utility.

Indeed, we want to maximize the probability that all users inside groups will be active in the next days, even if it implies losing out on the data of some users that are generally not very active.

Ideally, one would rely on machine learning techniques to learn user behavior patterns. However, because of the lack of real-life browser usage traces, this approach is not viable since we would not be able to effectively train prediction models. Therefore, we set to improve our heuristic to select users to put into groups more effectively. As shown in Figure 2, while most users are active every day, there is a non-negligible tail of users that are much less active.

Basically, if we have a delay of δ days, we want to only select users that are active on average at least one out of δ days. More formally, at the beginning of day d, when the delay is configured to δ days, we only select users satisfying the following constraint:

$$\left\{ C_i \in C | o_{d-1}(C_i) \wedge \frac{|\{d' \in [0, d-2], o_{d'}(C_i)\}|}{d-1} \geq \frac{1}{\delta} \right\} . \quad (5)$$

The above criterion is applied when $\delta > 0$ and $d > \delta$, meaning that we effectively have some additional delay and have accumulated enough data about users' past behavior to decide whether it is worth including them into a group.

Figure 5b shows the impact of this new heuristic on MRE. When compared to Figure 5a, we observe a noticeable decrease in the error. For instance, with a group size of 100 and 2 days of delay, the MRE goes from 0.82 to 0.60 (a 26% improvement). In fact, the best improvements with the heuristic are obtained with 2 days of delay. With 1 day of delay, we do not have enough past activity history to yield enough impact, while further increasing the delay is sufficient to lower MRE without the need for our heuristic.

4.5 Building Confidence in the Platform

Finally, we set to provide a confidence metric to the analysts in order to capture the expected quality of the aggregate statistics. Essentially, we use the percentage of users that were successfully involved in the data collection process. That is, we define confidence as the ratio of clients whose data was successfully decrypted and the total number of clients who were active on the target day. For example, a confidence of 60% for day d means that we were able to decrypt data for 60% out of all clients who were active that day. Recall that the missing counts can be due to clients that never sent their encrypted counts to the server, or by clients who were part of a group where a client never sent their data.

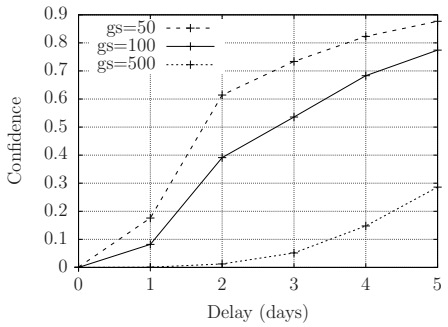


Figure 6: Confidence levels, i.e., ratio of clients whose data was successfully decrypted, for increasing delay.

In Figure 6, we plot the evolution of the confidence depending on the delay and the group size. Unsurprisingly, this is closely related to MRE (cf. Figure 5b), i.e., a high MRE is associated to low confidence. However, while MRE can only be computed through simulation (since it relies on the ground truth), confidence can actually be computed in real production environments. Therefore, we believe it can constitute a simple yet effective tool for analysts to understand the accuracy of the statistics at their disposal. However, it is not so easy to understand the actual impact of MRE, and what is the threshold differentiating between a "good enough" and a "bad" MRE. In the next section, we will experiment with the PDD platform on a real-life use-case, and study the actual impact of the privacy "layer" on the accuracy of the results obtained by analysts.

5 BUILDING A SYNDROMIC SURVEILLANCE MODEL FOR INFLUENZA-LIKE ILLNESS

In this section, we experiment with a health-related use-case, showing how data collected through PDD can be used to monitor the prevalence of influenza-like illness (ILI). By using an established model for this task that provides a significant level of accuracy [21, 22], we are particularly interested in quantifying the impact that introducing PDD may have on its performance.

Flu season	True query frequencies			Estimated query frequencies		
	MAE	RMSE	r	MAE	RMSE	r
2014/15	2.5211	3.7022	0.8631	3.0163 (0.6112)	4.0382 (0.6251)	0.8574 (0.0211)
2015/16	2.1023	2.8766	0.9439	2.4415 (0.1949)	3.1805 (0.2586)	0.9202 (0.0140)
2016/17	2.1907	3.3163	0.9165	2.0212 (0.2980)	2.6704 (0.3501)	0.9020 (0.0313)
Avg.	2.2714	3.2984	0.9078	2.4930	3.2964	0.8932

Table 2: Performance of the ILI rate estimation task

5.1 Methodology

Starting from the simulator described in Section 4.1, we modified the users' activity module to sample the searches from a set of actual flu-related queries. More specifically, we use data from Google Health Trends to accurately model the behavior of users when interacting with the Google search engine. We retrieve the daily frequencies of 1k flu-related queries from January 1, 2008 to December 31, 2017 (10 years). We follow the approach presented in [23] to extract and filter queries based on their semantic relationship with the topic of flu. Note that we only have access to frequencies (and not absolute counts), i.e., the number of times a query was issued over the total number of queries issued that day. For every query, we fit a frequency distribution using a maximum likelihood estimation. We split the queries in two classes: sparse queries, which are fitted to a beta distribution, and denser queries, fitted to a generalized extreme value distribution. During the simulation, we use those distributions to sample, for each query and every day, a frequency.

In total, the added frequencies of the 1k queries of interest account on average for about 0.34% of the daily number of searches. This means that, as opposed to the previous behavior, the large majority of the searches that are generated are not of interest for influenza modeling. Consequently, we run a much larger-scale simulation in order to collect enough search samples, even for sparse queries; to this end, we simulate 1 million users over 20 years, which yields 825k samples for the 1k queries of interest. We use a delay of 2 days and a group size of 100 clients.

We then use the outputs of the simulation to compute daily query frequency estimates, which are then compared with their corresponding true values. We use a relative error metric, i.e., $(f_t - f_e)/f_t$, where f_t, f_e, denote the true and the estimated query frequency, respectively. Note that, on the frequency space, errors may be positive as well as negative. Given that positive and negative errors have different properties, we model them separately using two Weibull distributions per query (different distribution parameters for each query). Moreover, we capture the overall tendency for positive versus negative errors during daily data extracts, modeled by a Gaussian distribution. We filter out queries with less than a 100 nonzero true frequency estimates from this process, as their error samples are very sparse (466 from 1k queries were kept).

Finally, we use the fitted error distributions to introduce errors to true query frequencies from Google Health Trends. We rely on a two-step sampling process, where first the error signs are drawn for all queries for particular day, and then for each query, based on its allocated error sign, a relative error is drawn from its positive or negative error distribution. We deploy 50 sign draws per day, and for each one 50 error distribution draws per query, which generates 2,500 query frequency data sets where errors have been propagated.

5.2 Evaluating the Impact of PDD

Next, we set to assess the effect of the errors discussed above in the context of a practical task. To this end, we used the estimated query frequency datasets as inputs for modeling ILI rates in England – a well-studied task in the literature [18, 21, 23, 41].

Model structure. Disease rate estimation from online search data is commonly formulated as a regression task [18, 21]. The aim is to learn a function g: $\mathbf{X} \rightarrow \mathbf{y}$ that maps the input space of search query frequencies, $\mathbf{X} \in \mathbb{R}^{n \times m}$, to the target variable, $\mathbf{y} \in \mathbb{R}^{n}$, representing disease rates; n denotes the number of samples and m is the number of unique search queries we are considering. The time interval for each sample is set to a week to match the frequency of syndromic surveillance reports. Here, we use elastic net [47] as our regression function, similarly to previous work on the topic [21, 22]. Elastic net combines ℓ_1-norm and ℓ_2-norm regularization to obtain sparse solutions and to address model consistency problems that arise when collinear predictors exist in the input space [45]. It is formulated by the following optimization problem:

$$\underset{\mathbf{w},\beta}{\operatorname{argmin}} \left(\|\mathbf{y} - \mathbf{X}\mathbf{w} - \beta\|_2^2 + \lambda_1 \|\mathbf{w}\|_2^2 + \lambda_2 \|\mathbf{w}\|_1 \right), \tag{6}$$

where $\lambda_1 > 0$, $\lambda_2 > 0$ are respectively the ℓ_1-norm and ℓ_2-norm regularization parameters, and β denotes the intercept term.

Metrics. We assess the performance of elastic net models in estimating ILI rates in England during three flu seasons (2014–2017). Test periods are 1-year long (52 weeks) and training sets include all data prior to the corresponding test period. Prior to applying elastic net, we filter out queries with a Pearson correlation < 0.3 with the ground truth (per training set). We measure performance using mean absolute error (MAE), root mean squared error (RMSE), and Pearson correlation (r).

Results. We report performance figures in Table 2. Overall, we see that the average performance (based on the 2,500 trials) obtained by the estimated query frequency data does not differ much to the one obtained by the error-free data. There is a 9.7% increase in MAE, a 1.6% decrease in correlation, while RMSE remains unaffected. Figure 7 depicts ILI rate estimates across all the test periods in comparison to ground truth data. We plot the mean ILI rate across the 2,500 trials and use two standard deviations as a confidence interval. There are minor differences in the estimates of the privacy-preserving and true frequency models, although overall the time series appear as visually similar.

Overall, our analysis shows that both provide good estimates of the actual ILI rates, which serves as a practical indication that the error introduced by the privacy-preserving scheme does not severely affect the utility of the search data.

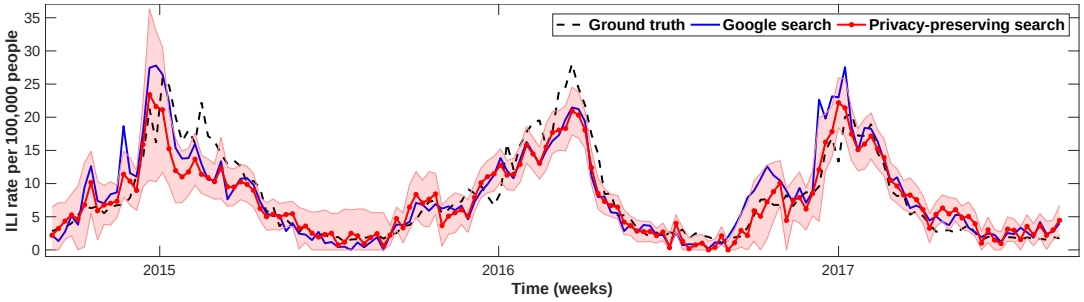

Figure 7: ILI rate estimates based on true and estimated (privacy-preserving) query frequency values compared to the ground truth. Confidence intervals depict two standard deviations from the mean for the 2,500 drawn query frequency estimates.

6 REAL-WORLD DEPLOYMENT

As mentioned earlier, we have implemented PDD as a fully-functional platform, which is freely available to health researchers. In this section, we detail our prototype, presenting its architecture as well as a real-world experiment with it.

6.1 System Architecture

PDD follows a classical client-server architecture, as depicted in Figure 8. The client-side is deployed to each user as a browser extension for Google Chrome/Chromium. The server is hosted by the research institution in charge of running the data collection campaign. A Web dashboard is also available to administrators and data analysts, allowing them to tune the data collection parameters and to export the results once they are available.

Server. The PDD server is the central component of our architecture, implementing three core services. First, it provides the concept of a *campaign*, which corresponds to a set of queries being monitored over some period of time. Several campaigns can be running independently in parallel, allowing different research teams to rely on a common crowd-sourcing infrastructure for their research. Second, the server is in charge of regularly initializing empty count vectors. Once a day, it scans the active campaigns and clients and organizes the latter into groups according to the algorithms described in Section 4. One or several empty count vectors are then initialized for each client that is expected to contribute some data to one or more campaigns. Each time a client pings the server, the latter will look for all those yet-to-be-filled vectors, and asks the client for the missing data. Third, the server is responsible for the aggregation of count vectors. Once a day, this service collects the encrypted vectors sent by the clients, decrypts them whenever possible, and updates the global count vector for the target day.

Each campaign has its own system parameters (i.e., delay and group size) as well as a distinct list of queries of interest. Note that, while Section 3 only describes the ability of monitoring queries, our implementation can monitor both keywords as well as queries. That is, by splitting every search around whitespaces, we can extract tokens and monitor the searches that contain them or combinations of them. For instance, instead of monitoring the query "symptoms of flu," an analyst might choose to track the keywords "symptoms" and "flu," allowing to match different variations such as "flu symptoms."

Communication between the clients and the server is through a REST API, secured by TLS. The REST API itself is divided in

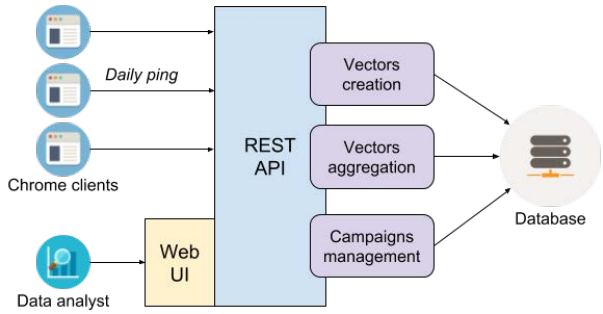

Figure 8: Architecture of the PDD system.

two parts: a public and a private APIs. The former is accessible to the clients and essentially contains three endpoints: (i) client registration, used when a Chrome extension is installed, (ii) ping, used by clients to get their instructions, and (iii) vector submission, used to update the vectors back as instructed by the server. The latter is only accessible to the analysts and is used for administrative operations. The server is written in Scala (a language running on the Java Virtual Machine), while the dashboard in Javascript. The data is stored in a MySQL database, although the persistence layer is designed to be pluggable to accommodate other storage systems.

Client. The client-side is implemented as a Google Chrome extension, although it can be ported to other browsers, such as Firefox, with minimal effort. The extension includes 733 source lines of code written in Javascript. The main goal of the extension is to contact the server on a daily basis (whenever possible) via a ping. The response of a ping is a set of instructions about some information to compute in order to fill empty count vectors. Each instruction contains a set of monitored queries, the period of interest (typically a day), the round number and the public keys of the members of the group. The client is then in charge of computing the count vectors, thanks to the API provided by Chrome, by locating the Google searches from their URL, extracting the query, tokenizing it into keywords and aggregating them with respect to the set of monitored keywords. This vector is then encrypted, using the public keys provided and round number, and sent back to the server.

The browser extension also has a lightweight interface for the user, providing transparency about the collection process. Notably, it allows the user to see which searches are going to be sent to the PDD server at the beginning of the next day. If the user does not want some of this data to be contributed (even though it is aggregated and encrypted), he has the option of creating a blacklist.

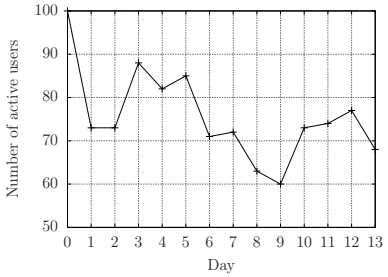

Figure 9: Daily activity during the real-life experiment.

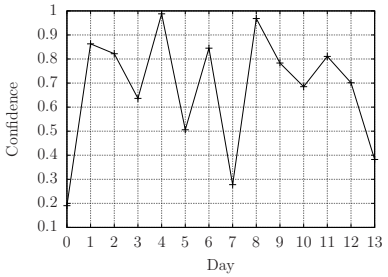

Figure 10: Daily confidence during the real-life experiment.

The latter contains a list of keywords that the user does not want to be sent to the server, permanently.

Source Code. The PDD platform is available in open source, under the GNU General Public License v3, on GitHub.[1] The Chrome extension is also available on the Chrome Web Store.[2]

6.2 Real-World Experiment

In order to experiment with our prototype and real-life users, we used the Prolific.ac [29] website to recruit a pool of (paid) volunteers. Our study received ethics approval from University College London. In total, we ran two studies. The first one aimed to validate that the system was actually working and reliably collecting data, and involved 10 participants for a week. A couple of months later, we launched a larger-scale study involving 100 participants over two weeks. In the following, we report on the latter.

Participants were asked to install our Chrome extension and leave it active, but were not otherwise asked to alter their behavior in any way. We only required them to be active for at least 10 days (out of 14 in total), in order to prevent dishonest participants claiming a reward without actually contributing any data. Because the season was not favorable to experiment with flu-related searches (it was done during summer 2018), we instead monitored the usage of the 10k most common English words.[3]

User behavior. To analyze the activity of the participants, in Figure 9, we show the number of daily active users throughout our experiment. The plot highlights that there are indeed variations in the number of daily active users, varying between 60% and 90%. This also confirms that we cannot realistically expect, even with as little as 100 paid users, that all users will be active on a single day. In fact, on average, users were active 10 days out of 14. Overall, we detected a total of 3000 to 5000 keywords per day. This rather high number is due to the fact that we are monitoring the 10k most common English words, meaning that each search will likely generate several keywords, one for each of the common words in it.

Error. Because we had a small number of users, we used a group size of only 10, fixing the delay to 2 days. Figure 10 plots the confidence throughout the 14 days of our experiment. The average confidence is 71.3%, even though there are significant variations. Note that the results for the first day exhibit very low confidence, because of the participants who left the experiment and were never active again. The confidence for day 7 is also low at 28%; it corresponds to a turning point between both a peak of active users at day 5 and the lowest number of active users at day 9 (cf. Figure 9), meaning the users' future activity was overestimated when creating groups for day 7.

Performance. The PDD server is packaged as a Docker image and deployed on a single virtual machine equipped with 4×2.1 GHz and 16 GB of RAM. Over the 2 weeks, the user CPU usage was on average 0.2%, while the memory consumption was on average 2.1GB. We did not experience any crash, and the resource usage leaves plenty of room to grow to more users.

7 CONCLUSION

This paper introduced PDD, a platform enabling researchers to access crowd-sourced Web searches, collected in a privacy-friendly way. We built on an existing cryptographic protocol for privacy-preserving data aggregation [26], adapted it to our settings, and evaluated our solution through extensive simulations. In particular, we highlighted the importance of two parameters, delay (i.e., the number of days to wait for the results) and group size (i.e., the anonymity of users). We then validated the suitability of our approach on a real-life use case, building a model monitoring the prevalence of influenza from Web searches. We compared the quality of the model produced when using PDD to both ground truth and the model obtained from *raw* Google searches, and observed very similar performance. Finally, we deployed our PDD prototype in the wild and ran a small pilot deployment involving 100 paid participants, achieving a reasonable confidence (more than 70%) while keeping resource requirements low.

Although we focus on health-related use cases, we believe that PDD can accommodate other contexts. Overall, we envision the opportunity to build a fully-fledged privacy-preserving analytics platform on top of this work, paving the way to more use cases while enforcing strict privacy guarantees. Our experimental evaluation showed opportunities to improve even more the way we select and organize users into groups; we believe that leveraging machine learning, in addition to our heuristics, could greatly increase the confidence while lowering error. In future work, we also plan to study the feasibility of possible inference attacks against aggregate statistics (e.g., membership [34]), and mitigate them using differentially private mechanisms.

Acknowledgments. This work has been supported by the EPSRC grants EP/K031953/1 and EP/R00529X/1. We also wish to thank Google for providing access to the Health Trends API and Lukasz Olejnik for early work on the PDD prototype.

ABSTRACT

Community detection is one of the most important problems in network analysis. Among many algorithms proposed for this task, methods based on statistical inference are of particular interest: they are mathematically sound and were shown to provide partitions of good quality. Statistical inference methods are based on fitting some random graph model (a.k.a. *null model*) to the observed network by maximizing the likelihood. The choice of this model is extremely important and is the main focus of the current study. We provide an extensive theoretical and empirical analysis to compare several models: the widely used planted partition model, recently proposed degree-corrected modification of this model, and a new null model having some desirable statistical properties. We also develop and compare two likelihood optimization algorithms suitable for the models under consideration. An extensive empirical analysis on a variety of datasets shows, in particular, that the new model is the best one for describing most of the considered real-world complex networks according to the likelihood of observed graph structures.

1 INTRODUCTION

Among various properties shared by many real-world complex networks, community structure is extremely important. It is characterized by the presence of highly interconnected groups of vertices (*communities* or *clusters*) relatively well separated from the rest of the network. In social networks communities are formed by users with similar interests, in citation networks they represent papers on related topics, etc. The presence of communities highly affects, e.g., the promotion of products via viral marketing, the spreading of infectious diseases, computer viruses and information, and so on. Being able to identify communities in a network could help us to exploit this network more effectively: find similar scientific papers, discover users with similar interests for targeted advertisement, compress or visualize the network, etc.

Among other algorithms proposed for community detection, the notable ones are methods based on statistical inference. In such methods, some underlying random graph model is assumed, the evidence is represented by the observed graph, and hidden variables to be inferred are the parameters of the model together with community assignments. Such methods are appealing since they are theoretically sound and consistent: e.g., it has been proved that when the maximum-likelihood method is applied to networks generated from the same stochastic block model, it returns correct cluster assignments in the limit of large degrees [7]. Also, likelihood can be used to formalize the notion of a community [15].

The choice of the proper null model is essential for statistical inference algorithms as it highly affects their performance. There are two types of models: with fixed or non-fixed number of parameters. Direct likelihood optimization for models with non-fixed number of parameters leads to trivial partitions, as discussed in Section 4.1, and additional heuristics are needed to define the number of clusters. Hence, in this paper we focus on models with fixed number of parameters. We analyze strengths and weaknesses of two most popular models — planted partition model and its degree-corrected variant (they are discussed in Section 3). We also propose a new model, which has only one parameter, satisfies a desired statistical property of preserving the expected degree sequence, and shows the best fit for a variety of real-worlds networks according to the likelihood of observed structures. To the best of our knowledge, we are the first to perform a thorough theoretical and empirical evaluation of the null models used for community detection.

To sum up, the contributions of this paper are the following:

- We theoretically analyze two well-known null models used for community detection. Based on this analysis, we propose a new one-parameter model which has a desirable statistical property of preserving the expected degree sequence.
- We empirically demonstrate that the new model gives the best fit to a variety of real-world complex networks.
- We show that the likelihood based on the proposed model can be used as a new, more reliable, alternative to the well-known modularity measure.

- We develop several likelihood optimization algorithms suitable for all discussed models. We perform an extensive empirical comparison of all the algorithms on various synthetic and real-world datasets.
- The implementation of the proposed algorithms is available as an open-source library.[1]

The rest of the paper is organized as follows. In the next section we overview related papers and introduce the required background. Then, in Section 3, we formally define and analyze all null models used in the current research. In Section 4, we discuss the method of statistical inference and present the likelihoods for all models. The proposed likelihood optimization algorithms are discussed in Section 5. Section 6 provides an extensive empirical analysis of all models and algorithms and Section 7 concludes the paper.

2 BACKGROUND AND RELATED WORK

2.1 Community Detection Methods

In this section, we briefly overview algorithms used for community detection. However, most of the related work will be discussed in the corresponding background sections: Section 2.2 discusses modularity measure; Section 2.3 defines the LFR bechmark; Sections 3.1 and 3.2 describe standard null models; Section 4.2 discusses papers on statistical inference; Section 5.1 deals with some optimization techniques. For a deeper overview of community detection area, we refer the reader to several survey papers, e.g., [10, 16, 19, 21, 33].

The problem of community detection has recently attracted a lot of attention and many algorithms were proposed to solve this problem. The proposed methods include: spectral algorithms [55]; methods based on statistical inference (see Section 4); methods based on optimization (see Section 5); methods based on dynamical processes on networks, like diffusion, spin dynamics, synchronization, and so on. Also, existing approaches differ by a particular task at hand: detecting overlapping communities [57], clustering in dynamic [51], directed [48], or weighted [3] networks, community detection in annotated [39] or layered [44] networks, and so on.

In this paper, we focus on the basic problem of detecting non-overlapping communities in undirected and unweighted graphs. However, ideas discussed in this paper can be applied to more general cases, since there exist the corresponding generalizations of the null models. We leave this analysis for the future research, since there is a lot to be understood even for the basic case.

2.2 Modularity

Throughout this paper we assume that we are given a simple undirected graph $G = (V(G), E(G))$ and the task is to find a partition $C = \{C_1, \dots, C_k\}$ of its vertex set $V(G)$ such that $\bigcup C_i = V(G)$ and $C_i \bigcap C_j = \emptyset$ for $i \neq j$. The notation used in the paper is summarized in Table 1.

Let us introduce the notion of *modularity*, which is the most well-known measure of a goodness of a partition C for a graph G. It was first introduced in [40] and is widely used in community detection literature: modularity is directly optimized by some algorithms, used as a stopping criteria in iterative methods, or used as a metric to compare different algorithms when no ground truth

[1] https://github.com/altsoph/community_loglike

Table 1: Notation

Variable	Description
G	observed graph, simple and undirected
$V(G)$	set of vertices
$E(G)$	set of edges
$n = \|V(G)\|$	number of vertices in G
$m = \|E(G)\|$	number of edges in G
$C = \{C_1, \dots, C_k\}$	partition of $V(G)$
$k = \|C\|$	number of communities
$Q_0(C, G, \gamma)$	simple modularity defined in (1)
$Q_1(C, G, \gamma)$	standard modularity defined in (2)
$c(i)$	cluster assignment of vertex i
$m_{in} = m_{in}(C, G)$	number of intra-community edges
$m_{out} = m_{out}(C, G)$	number of inter-community edges
$P = \binom{n}{2}$	number of pairs of vertices
$P_{in} = \sum_{C \in C} \binom{\|C\|}{2}$	number of intra-community pairs of vertices
$P_{out} = P - P_{in}$	number of inter-community pairs of vertices
$d(i)$	degree of vertex i in G
$d_{in}(i)$	number edges going from i to vertices in $C_{c(i)}$
$d_{out}(i) = d - d_{in}(i)$	number of edges going from i to outside $C_{c(i)}$
$D(C) = \sum_{i \in C} d(i)$	degree of cluster C
$D_{in}(C) = \sum_{i \in C} d_{in}(i)$	twice the number of edges induced by C
$m(C_q, C_r)$	number of edges between C_q and C_r or twice the number of intra-cluster edges if $q = r$

partition is available. The basic idea is to consider the fraction of intra-community edges among all edges of G and penalize it in order to avoid trivial partitions like $C = \{V(G)\}$. In its general form, modularity is

$$Q(C, G, \gamma) = \frac{1}{m} \left(m_{in} - \gamma \mathbb{E}(m'_{in}) \right),$$

where $m = m(G) = |E(G)|$ is the number of edges in G; $m_{in} = m_{in}(C, G)$ is the number of intra-community edges; $m'_{in} = m'_{in}(C)$ is a (random) number of intra-community edges in a graph constructed according to some underlying random graph model; γ is the *resolution parameter* [47], which is usually added to get the possibility of varying the number of communities obtained after maximizing $Q(C, G, \gamma)$.

The simplest underlying model is the Erdős–Rényi random graph, i.e., we assume that G is sampled uniformly at random from the set of all graphs with n vertices and m edges. For this model, $\mathbb{E}(m'_{in}) = P_{in} \cdot \frac{m}{P}$, where $P = \binom{n}{2}$ is the number of pairs of vertices and $P_{in} = \sum_{C \in C} \binom{|C|}{2}$ is the number of intra-community pairs. So, the formula for *simple modularity* is

$$Q_0(C, G, \gamma) = \frac{1}{m} \left(m_{in} - \gamma \frac{P_{in} m}{P} \right). \quad (1)$$

However, the Erdős–Rényi random graph model is known to be not a good descriptor of real-world networks since its Poisson degree distribution significantly differs from heavy-tailed degree distributions observed in real-world networks. A standard solution is to consider a random graph with a given expected degree sequence [12] as a null model, and to take the degree sequence

from the observed graph.[2] For this model, the probability that vertices i and j are connected equals $\frac{d(i)d(j)}{2m}$, where $d(i)$ is the degree of a vertex i.[3] In this case we have $\mathbb{E}(m'_{in}) = \frac{1}{4m}\sum_{C\in C} D(C)^2$, where $D(C) = \sum_{i\in C} d(i)$ is the degree of cluster C. So, the standard expression for *modularity* is

$$Q_1(C, G, \gamma) = \frac{m_{in}}{m} - \frac{\gamma}{4m^2}\sum_{C\in C} D(C)^2 . \tag{2}$$

Originally, modularity was introduced with $\gamma = 1$, but is was proven to have a resolution limit [20], i.e., it fails to detect communities smaller than a certain size; varying the resolution parameter helps to overcome this problem, but tuning γ is challenging.

Despite some known shortcomings [19], modularity remains the most popular way to measure the quality of a partition and many algorithms are based on direct modularity optimization (see Section 5). Also, under certain assumptions, modularity maximization is equivalent to likelihood optimization [36].

2.3 LFR Model

Let us now describe the LFR (Lancichinetti-Fortunato-Radicchi) model [29], which is the most widely used synthetic benchmark for comparison of community detection algorithms.

LFR generates a graph G on n vertices. The main parameters of the model are: the exponent of the power-law degree distribution γ, the exponent of the power-law community size distribution β, the average degree $\bar{d}$, and mixing parameter $\hat{\mu}$. First, we generate the degrees of vertices by sampling them independently from the power-law distribution with exponent γ and mean $\bar{d}$. Each vertex shares a fraction $1-\hat{\mu}$ of its edges with the vertices of its community and a fraction $\hat{\mu}$ with the other vertices of the network. The sizes of the communities are sampled from the power-law distribution with exponent β, such that the sum of all sizes equals n. Then, vertices are assigned to communities such that the internal degree of any vertex is less than the size of its community. Finally, the configuration model [35] with rewiring steps is used to construct a graph with the given degree sequence and with the required fraction of internal edges. See [29] for the detailed description of this procedure.

3 NULL MODELS

In this section, we analyze several random graph models having community structure and suitable for using as null models for likelihood optimization.

3.1 Stochastic Block Model

The most well-known random graph model with community structure is the *stochastic block model* (SBM) [26]. In this model, the vertices are divided in k clusters and for each pair of vertices i, j we draw an edge between them with probability $p_{c(i),c(j)}$ independently of all other edges. Here $c(i)$ is a community assignment for a vertex i. The values $p_{q,r}$, $1 \le q, r \le k$ are parameters of the model, $0 \le p_{q,r} \le 1$ and $p_{q,r} = p_{r,q}$. In many community detection algorithms a simplified version of SBM called *planted partition model* (PPM) is used [14]. PPM is a special case of SBM, where $p_{q,q} = p_{in}$ for $1 \le q \le k$ and $p_{q,r} = p_{out}$ for $1 \le q, r \le k, q \ne r$.

3.2 Degree-Corrected Stochastic Block Model

Similarly to the Erdős–Rényi random graph, SBM is unable to model heavy-tailed degree distributions, so community detection algorithms based on this model may have a poor quality. To overcome this issue, Karrer and Newman proposed the *degree-corrected stochastic block model* (DCSBM) [28]. In this model the vertices are again assigned to k clusters and edges are placed independently at random. The number of edges between vertices i and j follows a Poisson distribution with the mean $\frac{d(i)d(j)}{2m}p_{c(i),c(j)}$ or a half that number for self-loops. Let us show that DCSBM is able to generate graphs with desired expected degrees.

Proposition 1. *There exist such $p_{q,r}$ that in DCPPM we have $\mathbb{E}(d'(i)) = d(i)$ for all i.*

Proof. Let us set $p_{q,r} = \frac{2\,m\,m(C_q, C_r)}{D(C_q)\,D(C_r)}$, where $m(C_q, C_r)$ is the number of edges between clusters C_q and C_r or twice the number of intra-cluster edges if $q = r$. Note that these parameters maximize the likelihood for DCSBM [28]. For such parameters we get the desired condition:

$$\begin{aligned}\mathbb{E}(d'(i)) &= \sum_{j=1}^{n}\frac{d(i)d(j)}{2m}p_{c(i),c(j)} \\ &= \frac{d(i)}{D\big(C_{c(i)}\big)}\sum_{C\in C}\frac{m\big(C, C_{c(i)}\big)}{D(C)}\sum_{j\in C} d(j) = d(i) .\end{aligned}$$

So, we proved that in its general form DCSBM is able to preserve the desired degree sequence. □

The *degree-corrected planted partition model* (DCPPM) [36] is a simplified version of DCSBM, where $p_{q,q} = p_{in}$ for $1 \le q \le k$ and $p_{q,r} = p_{out}$ for $1 \le q, r \le k, q \ne r$. Let us prove the following "negative" proposition.

Proposition 2. *If $p_{in} \ne p_{out}$ and for some q, r we have $D(C_q) \ne D(C_r)$, then $\mathbb{E}(d'(i)) \ne d(i)$ for some i.*

Proof. Let us compute the expected degree of i:

$$\begin{aligned}\mathbb{E}(d'(i)) &= \frac{d(i)}{2m}p_{in}\sum_{j\in C_{c(i)}} d(j) + \frac{d(i)}{2m}p_{out}\sum_{C\ne C_{c(i)}}\sum_{j\in C} d(j) \\ &= \frac{d(i)}{2m}\left(D\big(C_{c(i)}\big)(p_{in} - p_{out}) + 2m\,p_{out}\right) .\end{aligned}$$

To get $\mathbb{E}(d'(i)) = d(i)$ for all i, we need to have, for *any* cluster C, $D(C)(p_{in} - p_{out}) + 2m\,p_{out} = 2m$. As we have at least two clusters with different values $D(C)$, we have to take $p_{in} = p_{out} = 1$, which leads to the standard configuration model without any community structure and contradicts the statement of the proposition. □

As a result, we obtain that the standard method of limiting the number of parameters in DCSBM leads to inability of the obtained model to preserve the expected degree sequence.

[2] At large scale, this model is essentially equivalent to the configuration model [35]: a random graph sampled uniformly from the set of graphs with a given degree sequence.

[3] For technical purposes, it is more convenient (and conventional) to allow the underlying model to have loops and multiple edges and to assume that the number of edges between i and j follows a Poisson distribution with the mean $\frac{d(i)d(j)}{2m}$ if $i \ne i$ and the expected number of loops for a vertex i is $\frac{d(i)^2}{4m}$. Note that usually $d(i)d(j) \ll 2m$, so multiple edges rarely appear.

3.3 Independent LFR Model

Motivated by Proposition 2, we developed a one-parameter model which preserves the expected degree sequence. It is a special case of DCSBM and we call it *independent LFR model* (ILFR) due to its analogy to the LFR benchmark.

The core problem of DCPPM is the assumption that the probability of an internal edge is independent of the size of its community, so the fraction of internal edges for a vertex *depends on the community size*. On the contrary, we propose using the mixing parameter μ to control this fraction. Namely, we consider DCSBM with the following expected number of edges between two vertices i and j: $\frac{\mu d(i)d(j)}{2m}$ if $c(i) \neq c(j)$ or $\frac{(1-\mu)d(i)d(j)}{D(C_{c(i)})} + \frac{\mu d(i)d(j)}{2m}$ if $c(i) = c(j)$ (or half this number for the self loops). Note that making the probability of an internal edge dependent on the size of the community is very natural: e.g., if a community of people is very small, one would expect that its members are much closer related to each other than members of large communities. The following proposition holds for the proposed model.

Proposition 3. *In ILFR we have* $\mathbb{E}(d'(i)) = d(i)$ *for all* i.

Proof. Indeed, let us compute the expected degree of i:

$$\mathbb{E}(d'(i)) = d(i)\left((1-\mu)\sum_{j\in C_{c(i)}}\frac{d(j)}{D(C_{c(i)})} + \mu\sum_{j\in V(G)}\frac{d(j)}{2m}\right) = d(i)\,.$$

□

So, this model solves the problem with expected degrees. Another advantage of ILFR is that it has only one parameter μ instead of p_{in} and p_{out} in planted partition models.

4 STATISTICAL INFERENCE

4.1 Method

Having discussed possible options for the null models, we are ready to describe the statistical inference method. For community detection problem, this method consists of two ingredients: the evidence, expressed by a graph G, and a random graph null model with parameters $\boldsymbol{\theta}$ ($\boldsymbol{\theta}$ include community assignments and μ or p_{in} and p_{out} for the models under consideration). The goal is to find such parameters $\boldsymbol{\theta}$ that maximize the posterior distribution

$$\mathrm{P}(\boldsymbol{\theta}|G) = \frac{\mathrm{P}(G|\boldsymbol{\theta})\mathrm{P}(\boldsymbol{\theta})}{\mathrm{P}(G)}\,,$$

where $\mathrm{P}(\boldsymbol{\theta})$ is the prior distribution of parameters and $\mathrm{P}(G) = \int \mathrm{P}(G|\bar{\boldsymbol{\theta}})\mathrm{P}(\bar{\boldsymbol{\theta}})\,d\bar{\boldsymbol{\theta}}$ is independent of $\boldsymbol{\theta}$, therefore $\arg\max_{\boldsymbol{\theta}} \mathrm{P}(\boldsymbol{\theta}|G) = \arg\max_{\boldsymbol{\theta}} \mathrm{P}(G|\boldsymbol{\theta})\mathrm{P}(\boldsymbol{\theta})$. The choice of the prior distribution $\mathrm{P}(\boldsymbol{\theta})$ is usually not obvious. Therefore, in the community detection literature, the likelihood $P(G|\boldsymbol{\theta})$ that the model is consistent with the observed graph structure is often maximized.

Let us also stress that in Section 3 we discussed two types of models: SBM/DCSBM having non-fixed number of parameters and PPM/DCPPM/ILFR with a fixed number of parameters. If the number of parameters is fixed, then the likelihood optimization can be applied directly. Otherwise, one needs another tool to find the optimal number of clusters, since direct likelihood maximization would lead to a trivial partition with all vertices forming their own clusters and the probability of an edge between two vertices equals 1 if they are connected and 0 otherwise. To avoid this problem, we further focus only on the models with fixed number of parameters.

4.2 Related Work on Statistical Inference

Let us briefly describe previous literature on statistical inference in community detection. Hastings [24] considers PPM, as defined in Section 3.1. He shows a connection between the obtained likelihood and the Hamiltonian of a Potts model with short- and long-range interactions. For $p_{in} > p_{out}$, the model is a spin glass with ferromagnetic nearest-neighbor interactions and antiferromagnetic long-range interactions. Belief propagation is used to find the ground state of the spin model. Another method based on the directed SBM is presented by Newman and Leicht [41], they use the expectation-maximization technique to optimize the parameters. These ideas are close to the a posteriori blockmodel proposed in [42]. A variational approach to parameter estimation is adopted in [17]. Some improvements and modifications of these approaches are introduced in, e.g., [11, 25, 45, 59]. A generalization to the overlapping SBM is proposed by McDaid and Hurley [34]. As we discussed, DCSBM is defined in [28] and communities are detected based on the likelihood in this model. Copic et al. [15] define an axiomatization for the problem of community detection based on PPM. Likelihood is used as a quality function to define rankings between graph partitions and it is shown that such rankings satisfy a number of desired properties. The authors also propose an algorithm to find (approximately) the maximum likelihood partition.

Finally, if the number of parameters in the model is not fixed, some additional tools are required to figure out the optimal number of clusters. Here the average entropy of the classification [45] or the Integrated Classification Likelihood [17, 59] can be used.

4.3 Likelihood for PPM and Simple Modularity

The log-likelihood for PPM can be easily written:

$$\log L'_{PPM}(C, G, p_{in}, p_{out}) = m_{in}\log p_{in} + m_{out}\log p_{out} + (P_{in} - m_{in})\log(1-p_{in}) + (P_{out} - m_{out})\log(1-p_{out})\,.$$

Although it can be optimized directly using the algorithms discussed further in the paper, in order to demonstrate a connection of the log-likelihood to simple modularity defined in (1) and to deal with all models in a unified way, we use the conventional trick and say that the number of edges between i and j follows a Poisson distribution with parameter p_{in} or p_{out}. Then we get:

$$\log L_{PPM}(C, G, p_{in}, p_{out}) = m_{in}\log p_{in} + m_{out}\log p_{out} - P_{in}p_{in} - P_{out}p_{out}\,. \quad (3)$$

Note that the values p_{in} and p_{out} maximizing (3) are

$$p_{in} = \frac{m_{in}}{P_{in}},\quad p_{out} = \frac{m_{out}}{P_{out}}\,. \quad (4)$$

In a resent paper by Newman [36] it was shown that if we assume p_{in} and p_{out} to be fixed, then maximizing (3) is equivalent to maximizing simple modularity (1) with

$$\gamma = \frac{P(p_{in} - p_{out})}{m(\log p_{in} - \log p_{out})}\,. \quad (5)$$

4.4 Likelihood for DCPPM and Modularity

The log-likelihood for DCPPM is [36]:

$$\log L_{DCPPM}(C,G,p_{in},p_{out}) = m_{in}(\log p_{in} - \log p_{out}) - \frac{p_{in}-p_{out}}{4m}\sum_{C\in C} D(C)^2 + \sum_i d(i)\log d(i) + m\log p_{out} - mp_{out} - m\log(2m)\,. \quad (6)$$

The values of parameters maximizing this likelihood are:

$$p_{in} = \frac{4\,m\,m_{in}}{\sum_C D(C)^2}\,,\quad p_{out} = \frac{4\,m\,m_{out}}{4m^2 - \sum_C D(C)^2}\,. \quad (7)$$

As shown in [36], if p_{in} and p_{out} are fixed, then maximizing $\log L_{DCPPM}(C,G,p_{in},p_{out})$ is exactly equivalent to maximizing modularity (2) with

$$\gamma = \frac{p_{in}-p_{out}}{\log p_{in} - \log p_{out}}\,. \quad (8)$$

4.5 Likelihood for ILFR

Let us compute the likelihood for the proposed ILFR model:

$$\log L_{ILFR}(C,G,\mu) = -\frac{1}{2}\sum_{i,j:c(i)=c(j)} d(i)d(j)\left(\frac{(1-\mu)}{D(C_{c(i)})} + \frac{\mu}{2m}\right) - \sum_{\substack{i,j:i<j,\\ c(i)\neq c(j)}} \frac{\mu d(i)d(j)}{2m} + \sum_{\substack{(i,j)\in E(G),\\ i<j,c(i)=c(j)}} \log\left(d(i)d(j)\left(\frac{(1-\mu)}{D(C_{c(i)})} + \frac{\mu}{2m}\right)\right) + \sum_{\substack{(i,j)\in E(G),\\ i<j,c(i)\neq c(j)}} \log\frac{\mu d(i)d(j)}{2m} = \sum_{C\in C}\frac{D_{in}(C)}{2}\log\left(\frac{(1-\mu)}{D(C)} + \frac{\mu}{2m}\right) + m_{out}\log\mu + \sum_i d(i)\log d(i) - m_{out}\log 2m - m\,, \quad (9)$$

where $D_{in}(C) = \sum_{i\in C} d_{in}(i)$ is twice the number of edges induced by C. Note that the optimal value of μ is hard to find analytically, but it can be approximated numerically by optimizing (9).

The following approximation helps to speed up the optimization algorithms and to make formulas more concise:

$$\log\left(\frac{(1-\mu)}{D(C)} + \frac{\mu}{2m}\right) = \log\frac{(1-\mu)}{D(C)} + \log\left(1 + \frac{\mu\,D(C)}{(1-\mu)\,2\,m}\right) \approx \log\frac{(1-\mu)}{D(C)} + \frac{\mu D(C)}{(1-\mu)\,2\,m} \approx \log\frac{(1-\mu)}{D(C)}\,,$$

since $\left|\log\frac{1-\mu}{D(C)}\right| \gg \frac{\mu D(C)}{(1-\mu)\,2\,m}$. This leads to another quality function, which we further refer to as ILFRS (S stands for "simplified"):

$$\log L_{ILFRS}(C,G,\mu) = m_{in}\log(1-\mu) + m_{out}\log\mu - m_{out}\log 2m - \sum_C \frac{D_{in}(C)}{2}\log D(C) + \sum_i d(i)\log d(i) - m\,. \quad (10)$$

The optimal μ according to (10) can now be computed analytically:

$$\mu = \frac{m_{out}}{m}\,. \quad (11)$$

Note that now we can substitute μ in (10) by the optimal value (11) and obtain a non-parametric quality function:

$$\log L_{ILFRS}(C,G) = m_{in}\log\frac{m_{in}}{m} + m_{out}\log\frac{m_{out}}{m} - m - m_{out}\log 2m - \sum_C \frac{D_{in}(C)}{2}\log D(C) + \sum_i d(i)\log d(i)\,. \quad (12)$$

The obtained function is fairly simple and, as we show by further experiments, it can successfully replace the standard modularity function in many applications.

Let us also note that in contrast to ILFR, the likelihood for the standard LFR model cannot be computed. First, LFR is based on the configuration model, which introduces complex dependences between all edges, making the likelihood intractable. Second, and most importantly, the number of iter-community edges for each vertex is deterministic (the fraction of such edges is μ); as a result, for most of graphs and partitions the likelihood is equal to zero.

5 OPTIMIZATION

5.1 Related Work on Modularity Optimization

First, let us discuss some optimization approaches used in community detection. The most widely used measure to be optimized is modularity (2). The following types of approaches are known.

Greedy optimization. Newman and Girvan [40] proposed a greedy algorithm for modularity optimization, where the clusters are iteratively merged by choosing the pair which leads to a greater modularity increase (while it is positive). A speedup of the greedy algorithm was proposed by Clauset et al. [13]. Some other modifications were also suggested in, e.g., [49, 56]. Probably the most well-known and widely used greedy algorithm is called Louvain [8]. At the beginning each vertex forms its own cluster. Then we create the first level of the partition by iterating through all vertices: for each vertex i we compute the gain in modularity coming from putting i to the community of its neighbor and pick the community with the largest gain, as long as it is positive. After that the first level is formed and we replace the obtained communities by supervertices, and two supervertices are connected by a (weighted) edge if there is at least one edge between vertices of the corresponding communities. Then the process is repeated with the supervertices, and so on, as long as modularity increases. This algorithm was shown to be fast and provide partitions of good quality. We choose Louvain algorithm as the basis for our experiments, the detailed description of its application to our problem is given in Section 5.2.

Simulated annealing. Simulated annealing was first applied to modularity optimization in [23]. This method combines two types of moves: local moves, where a single vertex is shifted from one cluster to another; global moves, consisting of merges and splits of communities. Methods based on simulated annealing are relatively slow and cannot be applied to large datasets.

Spectral optimization. Spectral methods are quite popular in modularity optimization. Such methods use the eigenvalues and eigenvectors of a so-called modularity matrix. Some examples can be found in [37, 53].

Many other algorithms exist, among them are methods based on extremal optimization [18], mathematical programming [2], mean field annealing [30], genetic algorithms [54], etc.

5.2 Proposed Likelihood Optimization Methods

In Section 4, we presented four quality functions based on the likelihood: PPM (3), DCPPM (6), ILFR (9), and ILFRS (10). All functions are parametric: PPM and DCPPM have parameters p_{in} and p_{out}, ILFR and ILFRS have one parameter μ. In this section, we discuss the possible ways to maximize these likelihoods. Below we assume that we are given an arbitrary algorithm $FindPartition(\bar{Q}, G)$ which is able to find a partition by maximizing some quality function $\bar{Q}(C, G)$.

Although the optimization strategies proposed below are able to work with any algorithm *FindPartition*, let us first discuss our particular choice. As we already mentioned, we choose Louvain algorithm [8], which is arguably the most widely used method for community detection. Louvain is fast and allows to process large datasets. Importantly, it can be adapted to all quality functions discussed in this paper. Initially the method is designed to optimize modularity, so it can be directly applied to the likelihood of DCPPM due to their equivalence. To adapt Louvain to other likelihoods, we have to change one part of the original algorithm: when we try to remove a vertex (or supervertex) from one community an add to another, we need to efficiently compute the difference in likelihood. This can be done for any of the considered quality functions: for ILFR and ILFRS the differences can be computed using (9) and (10); for PPM we have to additionally store the sizes of supervertices in order to compute the difference for P_{in} in (1). The rest of the Louvain algorithm remains the same.[4] Therefore, the asymptotic time complexity of our Louvain-based *FindPartition* and of the original Louvain are the same, up to a constant multiplier (the complexity of Louvain is empirically evaluated to be $O(n \log n)$).

Note that both the original Louvain and our modifications can be applied to the likelihoods with fixed values of parameters p_{in}, p_{out} or μ. Therefore, the key question is how to find the optimal values of these parameters.

Iterative strategy. The simplified version of this strategy was initially proposed in [36] for PPM and DCPPM models. Detailed description of our method is presented in Algorithm 1. Initially, we fix $\gamma = 1$ or $\mu = 0.5$ depending on the null model. Then, we apply *FindPartition* to the corresponding log-likelihood function. Using the obtained partition we can re-estimate the parameters and continue this procedure until convergence or until some maximum allowed number of steps is reached. In our experiments we noticed that for any null model the parameters may end up cyclically varying near some value. Therefore, at each iteration we additionally check if we obtain an already seen parameter and stop in this case. This additional trick allows to significantly reduce the overall number of iterations. In our experiments we observed that we never need more than 50 iterations and the mean value is much smaller, see Section 6 for more details.

Maximization strategy. An alternative strategy is to directly search for parameters which maximize likelihood of the obtained partition. Here we can use any black-box optimization method. At each iteration of optimization, for some value of γ or μ, we run *FindPartition* to obtain a partition C, then, using C, we find the optimal parameters according to (4), (7), (11) or by optimizing (9). Finally, we compute the likelihood to be maximized using (3), (6), (9), or (10). In our experiments, for simplicity and reproducibility, we use grid search in this strategy. However, any other method of black-box parameter optimization can be used instead, e.g., random search [5], Bayesian optimization [50], Gaussian processes [22], sequential model-based optimization [6, 27], and so on.

Algorithm 1: Iterative strategy

input : graph G, *Model*, algorithm *FindPartition*, N, ε

Initialize $param = 1$ (γ for PPM, DCPPM) or $param = 0.5$ (μ for ILFR, ILFRS), $Params = \emptyset$;
for $i \leftarrow 1$ **to** N **do**
  Define $\bar{Q}$ according to (1) for PPM, (2) for DCPPM, (9) for ILFR, (10) for ILFRS with parameter $param$;
  $C = FindPartition(\bar{Q}, G)$;
  if *Model is PPM or DCPPM* **then**
    Compute p_{in} and p_{out} according to (4) or (7);
    Compute $param_{new}$ according to (5) or (8);
  if *Model is ILFRS* **then**
    Compute $param_{new}$ according to (11);
  if *Model is ILFR* **then**
    Compute $param_{new}$ by optimizing (9);
  if $|param - param_{new}| < \varepsilon$ *or* $param_{new} \in Params$ **then**
    break;
  Add $param_{new}$ to $Params$;
  $param \leftarrow param_{new}$;
return C

To summarize, the maximization strategy directly maximizes the obtained likelihood, while the iterative one searches for a "stable" parameter, i.e., the one which does not change after applying *FindPartition*. Note that the convergence of the iterative strategy is not guaranteed for real-world networks. Therefore, initially we expected the maximization strategy to be more stable. However, our experiments show that these two strategies demonstrate similar performance, but the iterative one is faster.

Let us mention another possible optimization strategy, which we do not use in our experiments. Given a partition C, for each likelihood function except ILFR, we can compute the optimal values of parameters according to (4), (7), and (11). Therefore, for the corresponding models we can substitute these parameters and obtain non-parametric likelihoods, as we did in (12) for ILFRS. All obtained non-parametric quality functions can potentially be optimized directly since they do not have free parameters. However, we do not consider such strategy since: 1) it cannot be applied to ILFR as there is no analytical formula for optimal μ, 2) this strategy cannot be easily combined with the Louvain algorithm. The reason is that Louvain has several partition levels and partitions obtained on earlier levels cannot be changed later. At the beginning of the algorithm our estimates of μ, p_{in}, and p_{out} are far from optimal:

[4] To make our results reproducible, we made the source code publicly available at https://github.com/altsoph/community_loglike.

all vertices form their own communities, so $\mu = 1$, $p_{out} = 1$, and $p_{in} = 0$. As a result, the first level of the partition, which has a big impact on the final quality, is constructed based on non-optimal parameters. In fact, in most cases the algorithm does not even start optimization due to the huge overestimate of μ or p_{out}.

6 EXPERIMENTS

In this section, we conduct an extensive experimental study to compare the discussed models. We start with some preliminaries and discuss evaluation metrics and datasets. In Section 6.3, we measure how well the models describe various real-world networks. Next, we compare all proposed community detection algorithms. Finally, Section 6.5 presents some negative results on the limits of statistical inference algorithms when applied to real-world networks.

6.1 Evaluation Metrics

In order to evaluate the performance of any algorithm, we have to compare the partition C obtained by this algorithm with the ground truth partition C_{GT}. The problem of choosing a good similarity measure for this comparison does not have any standard solution in community detection literature. Different similarity measures can possibly give preferences to different algorithms. Usually, a suitable measure is chosen according to a practical problem at hand. That is why in this work we compute and compare several standard similarity measures. In particular, we consider Normalized Mutual Information (NMI) of two partitions C and C_{GT}, which is often used for the comparison of community detection algorithms [4, 19]. The idea behind NMI is that if two partitions are similar, one needs very little information to infer C_{GT} given C. We also use two well-known similarity measures based on counting correctly and incorrectly classified pairs of vertices: Rand and Jaccard indices [19, 46].

6.2 Datasets

6.2.1 Synthetic networks. We use the LFR model described in Section 2.3 to generate synthetic networks. The parameters of the generated graphs are the following: the number of vertices $n = 10^4$; the parameter of the power-law degree distribution $\gamma = 2.5$; the average degree $\bar{d} = 30$; the parameter of the community size distribution $\beta = 1.5$, with the minimum cluster size 50 and the maximum 600; the mixing parameter $\hat{\mu}$ is varied in range $[0, 1]$.[5] Note that there are other benchmark models proposed in the literature. However, community detection in synthetic networks is not the main focus in this paper, therefore we do not consider such models.

6.2.2 Real-world networks. We collected several networks with different structural properties (see Table 2). In addition to widely used networks, such as Zachary's karate club, dolphin social network, and American college football, we also used annotated books about politics[6] and political blogs [1]. The dataset email-Eu-core is obtained from SNAP,[7] here the ground truth communities correspond to the departments of a research institute. In Cora citation dataset communities correspond to subjects of research papers, while in AS [9] the vertices are annotated with their countries. These are all publicly available datasets we found for non-overlapping community detection.[8]

[5]We additionally experimented with synthetic graphs of different edge densities obtained by varying the average degree. The results are omitted since the only difference observed is that the qualities of all algorithms are usually larger for denser graphs.

6.3 Comparison of Likelihoods

Since the main aim of this paper is to analyze and compare several null models having community structure, we start with the following research question: *Which model gives the best fit for real-world complex networks*? To answer this question, we compare the probabilities that real-world networks were generated by each of the null models. Namely, we compared the log-likelihoods (3) for PPM, (6) for DCPPM and (9) for ILFR.[9] Note that (10) is a simplified expression for (9), so we consider it only as a quality function but not as log-likelihood.

In the first experiment, we took the datasets described in Section 6.2.2 and assumed that the partitions are defined by the ground truth cluster assignments provided for these datasets. Then, we computed the optimal parameters p_{in}, p_{out} or μ and used them to compute the corresponding log-likelihood (see Table 3). One can see that PPM is the best model describing the Football dataset, DCPPM is the best for Pol-books, while for all other datasets ILFR has the largest likelihood. Note that ILFR has only one parameter to be tuned while DCPPM has two. Therefore, we initially expected that for many datasets DCPPM may have a larger likelihood. In this case, to decide which model better describes the data, we would have to adapt some information criterion (e.g., the Bayesian information

[8]It is easier to find datasets with ground truth overlapping communities, see, e.g., http://snap.stanford.edu/data/index.html#communities
[9]We intentionally do not consider synthetic networks in this experiment: likelihoods are expected to be heavily affected by the particular synthetic model used. For example, LFR benchmark could give a preference to ILFR null model.

criterion) to our problem, which is a nontrivial task for the models under consideration. Surprisingly, for most of the datasets ILFR has a larger likelihood, which clearly indicates that this model is more suitable for describing real-world networks.[10]

However, as we further discuss in Section 6.4.2, even though for each dataset under consideration we have a ground truth partition (a.k.a. attributes or metadata), this partition can be not an ideal division of vertices into communities and also can be not the only ground truth partition possible. Fortunately, likelihoods can be compared even for datasets without any knowledge about community structure, which allows to compare null models on a much larger variety of datasets. In order to measure the likelihood for any graph, we first have to find a partition that maximizes this value (among all possible partitions), which is feasible only for very small datasets. However, the optimal partition (and the corresponding likelihood) can be approximately found by applying the corresponding maximization algorithm: PPM-max, DCPPM-max or ILFR-max. We performed such comparison on the datasets introduced in Section 6.2.2 as well as on 8 new datasets of various nature downloaded from http://snap.stanford.edu/data/index.html (see Table 4). According to this experiment, for almost all datasets the largest likelihood is again obtained for ILFR model, despite it has fewer free parameters, which means that this model is the best one for describing real-world datasets, which is the main empirical result supporting the introduction of ILFR and the corresponding log-likelihood quality function.

Let us note that the log-likelihoods presented in Table 4 can be underestimated, since we cannot guarantee that our optimization algorithms find exactly the maximum likelihood partition. However, we believe that this does not introduce any bias into this experiment (i.e., does not change the conclusions) since the same optimization procedure is applied for all models. Also, note that in all cases the log-likelihoods in Table 3 are smaller than the corresponding ones in Table 4, which means that our optimization algorithms found

[10]Note that using these results we cannot compare ILFR and DCPPM with PPM since ILFR and DCPPM are based on the observed degree sequences, while PPM only uses the cluster assignments.

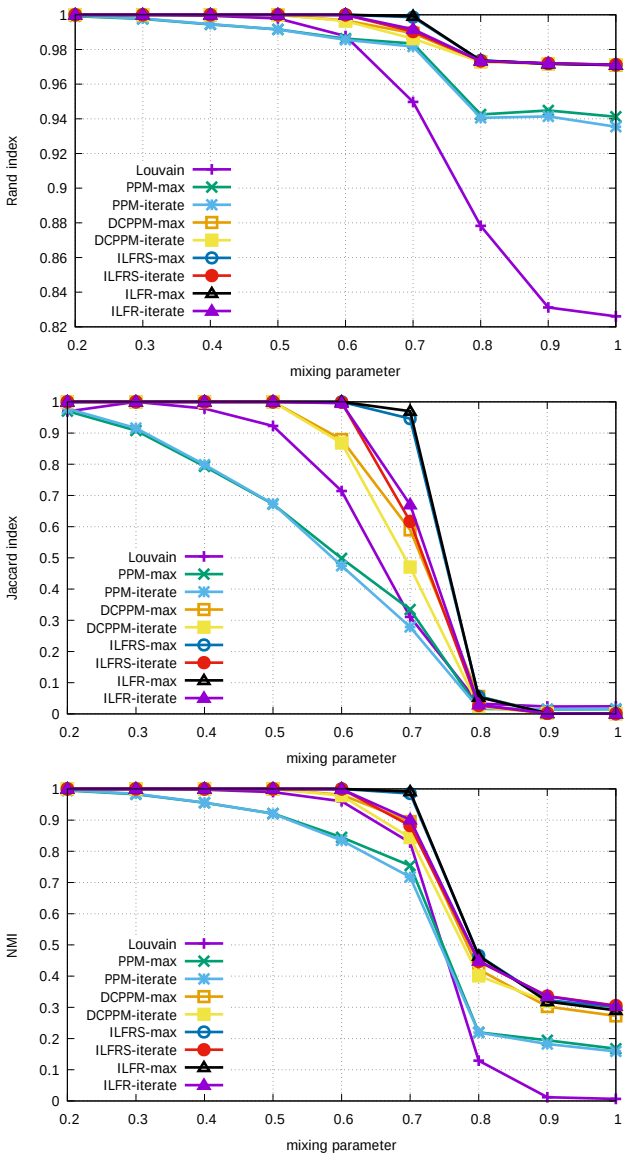

Figure 1: Comparison on synthetic networks

partitions providing better likelihoods for the corresponding models than the ground truth ones, which is expected (since partitions were tuned).

6.4 Community Detection Algorithms

In this section, we compare all algorithms proposed in Section 5.2. Note that we intentionally use only methods based on the likelihood optimization since this paper focuses on the analysis and comparison of null models.

6.4.1 Synthetic networks. First, we compared all algorithms on synthetic networks described in Section 6.2.1. For each $\hat{\mu}$ we generated 5 random samples of LFR and averaged the results. Figure 1 shows the results obtained for all similarity measures under consideration

(Rand, Jaccard and NMI). Note that in most cases these similarity measures are consistent, i.e., for a given mixing parameter they rank the algorithms similarly. However, Jaccard index is less descriptive for large mixing parameters.

Based on the obtained results, several important observations can be made. For all values of $\hat{\mu}$, the best (or very close to the best) quality is obtained by ILFRS-max and ILFR-max strategies. For both ILFR and ILFRS it turns out that maximizing the likelihood is better than iteratively estimating the parameters, which supports our intuition that better partitions are expected to have higher likelihoods. For small values of $\hat{\mu}$ the worst results are obtained by PPM (both strategies), while for large values Louvain algorithm is the worst.

We also measured statistical significance of the obtained improvements: for each $\hat{\mu}$, we applied the algorithms to 5 random samples of LFR and used the paired t-test. For instance, it turns out that according to NMI ILFRS-max never looses significantly and it is significantly better (p-value < 0.05) than: DCPPM-max for $\hat{\mu} \in \{0.7, 0.9, 1\}$; DCPPM-iterate for $\hat{\mu} \in \{0.7, 0.8\}$; PPM-max and PPM-iterate for all $\hat{\mu} \in [0.2, 1]$; ILFR-iterate and ILFRS-iterate for $\hat{\mu} = 0.7$; and Louvain for $\hat{\mu} \in [0.4, 1]$. These results additionally support the choice of the quality function L_{ILFRS} (12) for community detection instead of the standard modularity function.

6.4.2 Real-world complex networks. It is argued in several papers that ground truth community labels (a.k.a. metadata) available for some real-world networks should not be used to analyze and compare community detection algorithms [43]. Indeed, such labels are usually obtained using some discrete-valued vertex attributes which are not guaranteed to be reasonable community assignments. For example, users in a social network can be split by gender, city, or interests, and each of these partitions could be treated as ground truth cluster assignments. An algorithm performing better for "city" labels can be worse for "interests" ones. As a result, no meaningful conclusion can be made based on such comparison. However, for the sake of completeness, we compare all algorithms on real-world networks, since it is still a standard practice in community detection literature.

Tables 5 and 6 present the results for the iterative and maximization strategies, respectively (in both cases we add Louvain for comparison).[11] Note that we cannot properly measure statistical significance since we cannot sample several copies for each dataset. However, we can account for the randomness included in the algorithms: they all order vertices at each iteration randomly. To do this, for each dataset we run all algorithms 5 times and then apply the unpaired t-test to compare them. We put numbers in bold in Tables 5 or 6 if there is a group of algorithms without significant differences (p-value > 0.05) inside the group and with significant differences with the rest of the algorithms.

The results in general are not consistent: although DCPPM is often the best, the winning model may depend on a graph under consideration and on a target metric. For example, Louvain wins on Cora and AS according to Jaccard index, but it is the worst on the same datasets according to Rand index. This supports the claim that ground truth community assignments can be noisy or irrelevant.

We also noticed that iterative and maximization strategies usually have similar performance and the choice between them is not straightforward. For example, for ILFRS it is often better to apply maximization strategy, while for PPM iterative one should be

[11] Recall that Louvain optimizes modularity, so it is similar to DCPPM but with fixed values of p_{in} and p_{out}.

Table 7: Quality functions: ground truth vs optimization

	Modularity		$\log L_{PPM}$		$\log L_{DCPPM}$		$\log L_{ILFRS}$		$\log L_{ILFR}$

preferred. Based on this observation, we propose using the iterative strategy, which is faster (it converges after a small number of iteration, as discussed below).

The performance of ILFRS is in general slightly better than of ILFR. Taking into account our results on synthetic networks, we propose using the faster ILFRS instead of ILFR in all practical applications.

Finally, we analyzed the speed of convergence for iterative strategies on real-world datasets. Namely, we measured the number of iterations made by Algorithm 1 before some stopping criteria is reached. Note that the algorithm never stopped because of reaching the maximum allowed number of iterations $N = 50$, so we either observed a convergence or applied the cycling criteria (i.e., encountered an already seed parameter). The average number of iterations obtained for PPM is 12.6 (in all cases the algorithm converged). For DCPPM we got 6.2 (converged in all cases except AS, where we applied cycling stopping criteria after 18 iterations). For ILFRS we have 5.4 iterations (cycling criteria is applied to 3 datasets). For ILFR we got 4.4 (again, with 3 applications of cycling criteria).

6.5 Statistical Inference, Negative Result

Having noticed unstable results for real-world datasets, we tried to answer the following research question: *Is any of the null models suitable for community detection in real-world graphs?*

In order to answer this question, for each quality function we compare its value for the ground truth partition with its value for the partition obtained by the corresponding maximization algorithm (see Table 7). For all quality functions, including the widely used modularity, and for all datasets the ground truth partition has a lower value of the quality function. This means that further optimization of *any* quality function would not lead us towards the ground truth partition, which is a negative observation. In particular, there is no hope in improving the results obtained by our algorithms by replacing Louvain-based $FindPartition$ with some more effective maximization algorithm.

Note that in the literature it is often assumed that a partition with larger modularity is better and, as a result, an algorithm which leads to a partition with larger modularity is better. However, our observation above demonstrates that on the considered real-world datasets it is not the case. We also performed additional experiments and noticed that in almost all cases the value of a quality function for the ground truth partition is lower than for the partition obtained by *any* discussed optimization algorithm (not necessary optimizing the same quality function), which is an even stronger negative observation.

The following conclusion can be made: either the ground truth metadata contained in the considered real-world networks is not a good descriptor for a community structure or statistical inference algorithms based on all null models discussed in this paper are unable to detect real-world communities.

7 CONCLUSION

In this paper, we focused on the comparison of null models which can be used by likelihood optimization algorithms for community detection. We compared two well-known models, PPM and DCPPM, and a new model, ILFR, which has only one parameter and is proved to preserve the desired expected degree sequence. For the new model we have written the log-likelihood, both in parametric and self-contained forms. To maximize the parametric log-likelihood functions, we proposed and compared two optimization strategies: maximization and iterative.

The most important conclusion is that the proposed model, ILFR, is the best one for describing most of the considered real-world complex networks according to the likelihood of the observed graph structures, despite the fact that it has only one free parameter. We argue that the likelihood can be considered as the main argument in evaluating the null models instead of the direct comparison of community detection algorithms. The reason is that one cannot fully rely on ground truth cluster labels available for real-world networks. Also, we demonstrated that ILFR-based algorithms have the best performance on synthetic networks. Based on the obtained results, we believe that the proposed ILFR-based quality function (12) can be successfully used as a target for optimization algorithms, instead of the widely adopted modularity.

A natural direction for the future research is to analyze null models for overlapping community detection. This would be useful since many observed networks have overlapping communities. However, fundamental analysis of this problem is complicated by the fact that null models with overlapping communities are less developed and more complex for mathematical analysis.

ABSTRACT

We study the problem of large-scale network embedding, which aims to learn latent representations for network mining applications. Previous research shows that 1) popular network embedding benchmarks, such as DeepWalk, are in essence implicitly factorizing a matrix with a closed form, and 2) the explicit factorization of such matrix generates more powerful embeddings than existing methods. However, directly constructing and factorizing this matrix—which is dense—is prohibitively expensive in terms of both time and space, making it not scalable for large networks.

In this work, we present the algorithm of large-scale network embedding as sparse matrix factorization (NetSMF). NetSMF leverages theories from spectral sparsification to efficiently sparsify the aforementioned dense matrix, enabling significantly improved efficiency in embedding learning. The sparsified matrix is spectrally close to the original dense one with a theoretically bounded approximation error, which helps maintain the representation power of the learned embeddings. We conduct experiments on networks of various scales and types. Results show that among both popular benchmarks and factorization based methods, NetSMF is the only method that achieves both high efficiency and effectiveness. We show that NetSMF requires only 24 hours to generate effective embeddings for a large-scale academic collaboration network with tens of millions of nodes, while it would cost DeepWalk months and is computationally infeasible for the dense matrix factorization solution. The source code of NetSMF is publicly available[1].

1 INTRODUCTION

Recent years have witnessed the emergence of network embedding, which offers a revolutionary paradigm for modeling graphs and networks [16]. The goal of network embedding is to automatically learn latent representations for objects in networks, such as vertices and edges. Significant lines of research have shown that the latent representations are capable of capturing the structural properties of networks, facilitating various downstream network applications, such as vertex classification and link prediction [12, 14, 27, 33].

Over the course of its development, the DeepWalk [27], LINE [33], and node2vec [14] models have been commonly considered as powerful benchmark solutions for evaluating network embedding research. The advantage of LINE lies in its scalability for large-scale networks as it only models the first- and second-order proximities. That is to say, its embeddings lose the multi-hop dependencies in

Efficiency	√				√
Global context		√	√	√	√
Theoretical guarantee				√	√
High-order proximity			√		

networks. DeepWalk and node2vec, on the other hand, leverage random walks on graphs and skip-gram [24] with large context sizes to model nodes further away (i.e., global structures). Consequently, it is computationally more expensive for DeepWalk and node2vec to handle large-scale networks. For example, with the default parameter settings [27], DeepWalk requires months to embed an academic collaboration network of 67 million vertices and 895 million edges[2]. The node2vec model, which performs high-order random walks, takes more time than DeepWalk to learn embeddings.

More recently, a study shows that both the DeepWalk and LINE methods can be viewed as implicit factorization of a closed-form matrix [28]. Building upon this theoretical foundation, the NetMF method was instead proposed to explicitly factorize this matrix, achieving more effective embeddings than DeepWalk and LINE. Unfortunately, it turns out that the matrix to be factorized is an $n \times n$ dense one with n being the number of vertices in the network, making it prohibitively expensive to directly construct and factorize for large-scale networks.

In light of these limitations of existing methods (See the summary in Table 1), we propose to study representation learning for large-scale networks with the goal of achieving efficiency, capturing global structural contexts, and having theoretical guarantees. Our idea is to find a sparse matrix that is spectrally close to the dense NetMF matrix implicitly factorized by DeepWalk. The sparsified matrix requires a lower cost for both construction and factorization. Meanwhile, making it spectrally close to the original NetMF matrix can guarantee that the spectral information of the network is maintained, and the embeddings learned from the sparse matrix is as powerful as those learned from the dense NetMF matrix.

In this work, we present the solution to network embedding learning as sparse matrix factorization (NetSMF). NetSMF comprises three steps. First, it leverages the spectral graph sparsification technique [7, 8] to find a sparsifier for a network's random-walk matrix-polynomial. Second, it uses this sparsifier to construct a matrix with significantly fewer non-zeros than, but spectrally close to, the original NetMF matrix. Finally, it performs randomized singular value decomposition to efficiently factorize the sparsified NetSMF matrix, yielding the embeddings for the network.

With this design, NetSMF offers both efficiency and effectiveness with guarantees, as the approximation error of the sparsified matrix is theoretically bounded. We conduct experiments in five networks, which are representative of different scales and types.

[2]With the default DeepWalk parameters (walk length: 40 and #walk per node: 80), 214+ billion nodes (67M×40×80) with a vocabulary size of 67 million are fed into skip-gram. As a reference, Mikolov et al. reported that training on Google News of 6 billion words and a vocabulary size of only 1 million cost 2.5 days with 125 CPU cores [24].

Table 2: Notations.

Notation	Description
G	input network
V	vertex set of G with $\|V\|$=n
E	edge set of G with $\|E\| = m$
$\boldsymbol{A}$	adjacency matrix of G
$\boldsymbol{D}$	degree matrix of G
$\mathrm{vol}\,(G)$	volume of G
b	number of negative samples
T	context window size
d	embedding dimension
$\boldsymbol{L}$	random-walk molynomial of G (Eq. (4))
$\widetilde{\boldsymbol{L}}$	$\boldsymbol{L}$'s sparsifier
$\boldsymbol{M}$	$\frac{1}{T}\sum_{r=1}^{T}(\boldsymbol{D}^{-1}\boldsymbol{A})^r\boldsymbol{D}^{-1}$
$\widetilde{\boldsymbol{M}}$	$\boldsymbol{M}$'s sparsifier
$\mathrm{trunc_log}^{\circ}\left(\frac{\mathrm{vol}(G)}{b}\boldsymbol{M}\right)$	NetMF matrix
$\mathrm{trunc_log}^{\circ}\left(\frac{\mathrm{vol}(G)}{b}\widetilde{\boldsymbol{M}}\right)$	NetMF matrix sparisifier
M	number of non-zeros in $\widetilde{\boldsymbol{L}}$
ϵ	approximation factor
$[x]$	set $\{1, 2, \cdots, x\}$ for positive integer x

Experimental results show that for million-scale or larger networks, NetSMF achieves orders of magnitude speedup over NetMF, while maintaining competitive performance for the vertex classification task. In other words, both NetSMF and NetMF outperform well-recognized network embedding benchmarks (i.e., DeepWalk, LINE, and node2vec), but NetSMF addresses the computation challenge faced by NetMF.

To summarize, we introduce the idea of network embedding as sparse matrix factorization and present the NetSMF algorithm, which makes the following contributions to network embedding:

Efficiency. NetSMF reaches significantly lower time and space complexity than NetMF. Remarkably, NetSMF is able to generate embeddings for a large-scale academic network of 67 million vertices and 895 million edges on a single server in 24 hours, while it would cost months for DeepWalk and node2vec, and is computationally infeasible for NetMF on the same hardware.

Effectiveness. NetSMF is capable of learning embeddings that maintain the same representation power as the dense matrix factorization solution, making it consistently outperform DeepWalk and node2vec by up to 34% and LINE by up to 100% for the multi-label vertex classification task in networks.

Theoretical Guarantee. NetSMF's efficiency and effectiveness are theoretically backed up. The sparse NetSMF matrix is spectrally close to the exact NetMF matrix, and the approximation error can be bounded, maintaining the representation power of its sparsely learned embeddings.

2 PRELIMINARIES

Commonly, the problem of network embedding is formalized as follows: Given an undirected and weighted network $G = (V, E, \boldsymbol{A})$ with V as the vertex set of n vertices, E as the edge set of m edges, and $\boldsymbol{A}$ as the adjacency matrix, the goal is to learn a function $V \rightarrow$

$\mathbb{R}^d$ that maps each vertex to a d-dimensional ($d \ll n$) vector that captures its structural properties, e.g., community structures. The vector representation of each vertex can be fed into downstream applications such as link prediction and vertex classification.

One of the pioneering work on network embedding is the DeepWalk model [27], which has been consistently considered as a powerful benchmark over the past years [16]. In brief, DeepWalk is coupled with two steps. First, it generates several vertex sequences by random walks over a network; Second, it applies the skip-gram model [25] on the generated vertex sequences to learn the latent representations for each vertex. Commonly, skip-gram is parameterized with the context window size T and the number of negative samples b. Recently, a theoretical study [28] reveals that DeepWalk essentially factorizes a matrix derived from the random walk process. More formally, it proves that when the length of random walks goes to infinity, DeepWalk implicitly and asymptotically factorizes the following matrix:

$$\log^\circ\left(\frac{\mathrm{vol}(G)}{b}\boldsymbol{M}\right), \tag{1}$$

where $\mathrm{vol}\,(G) = \sum_i \sum_j \boldsymbol{A}_{ij}$ denotes the volume of the graph, and

$$\boldsymbol{M} = \frac{1}{T}\sum_{r=1}^{T}(\boldsymbol{D}^{-1}\boldsymbol{A})^r\boldsymbol{D}^{-1}, \tag{2}$$

where $\boldsymbol{D} = \mathrm{diag}\,(d_1, \cdots, d_n)$ is the degree matrix with $d_i = \sum_j \boldsymbol{A}_{ij}$ as the generalized degree of the i-th vertex. Note that $\log^\circ(\cdot)$ represents the element-wise matrix logarithm [18], which is different from the matrix logarithm. In other words, the matrix in Eq. (1) can be characterized as the result of applying element-wise matrix logarithm (i.e., $\log^\circ$) to matrix $\frac{\mathrm{vol}\,(G)}{b}\boldsymbol{M}$.

The matrix in Eq. (1) offers an alternative view of the skip-gram based network embedding methods. Further, Qiu et al. provide an explicit matrix factorization approach named NetMF to learn the embeddings [28]. It shows that the accuracy for vertex classification based on the embeddings from NetMF outperforms that based on DeepWalk and LINE. Note that the matrix in Eq. (1) would be ill-defined if there exist a pair of vertices unreachable in T hops, because $\log(0) = -\infty$. So following Levy and Goldberg [22], NetMF uses the logarithm truncated at point one, that is, $\mathrm{trunc_log}(x) = \max(0, \log(x))$. Thus, NetMF targets to factorize the matrix

$$\mathrm{trunc_log}^\circ\left(\frac{\mathrm{vol}(G)}{b}\boldsymbol{M}\right). \tag{3}$$

In the rest of this work, we refer to the matrix in Eq. (3) as *the NetMF matrix*.

However, there exist a couple of challenges when leveraging the NetMF matrix in practice. First, almost every pair of vertices within distance $r \le T$ correspond to a non-zero entry in the NetMF matrix. Recall that many social and information networks exhibit the small-world property where most vertices can be reached from each other in a small number of steps. For example, as of the year 2012, 92% of the reachable pairs in Facebook are at distance five or less [2]. As a consequence, even if setting a moderate context window size (e.g., the default setting $T = 10$ in DeepWalk), the NetMF matrix in Eq. (3) would be a dense matrix with $O(n^2)$ number of non-zeros. The exact construction and factorization of such a matrix is impractical for large-scale networks. More concretely, computing the matrix power in Eq. (2) involves dense matrix multiplication which costs $O(n^3)$ time; factorizing a $n \times n$ dense matrix is also time consuming. To reduce the construction cost, NetMF approximates $\boldsymbol{M}$ with its top eigen pairs. However, the approximated matrix is still dense, making this strategy unable to handle large networks.

In this work, we aim to address the efficiency and scalability limitation of NetMF, while maintaining its superiority in effectiveness. We list necessary notations and their descriptions in Table 2.

3 NETWORK EMBEDDING AS SPARSE MATRIX FACTORIZATION (NetSMF)

In this section, we develop network embedding as sparse matrix factorization (NetSMF). We present the NetSMF method to construct and factorize a sparse matrix that approximates the dense NetMF matrix. The main technique we leverage is random-walk matrix-polynomial (molynomial) sparsification.

3.1 Random-Walk Molynomial Sparsification

We first introduce the definition of spectral similarity and the theorem of random-walk molynomial sparsification.

Definition 1. *(Spectral Similarity of Networks) Suppose* $G = (V, E, \boldsymbol{A})$ *and* $\widetilde{G} = (V, \widetilde{E}, \widetilde{\boldsymbol{A}})$ *are two weighted undirected networks. Let* $\boldsymbol{L} = \boldsymbol{D}_G - \boldsymbol{A}$ *and* $\widetilde{\boldsymbol{L}} = \boldsymbol{D}_{\widetilde{G}} - \widetilde{\boldsymbol{A}}$ *be their Laplacian matrices, respectively. We define* G *and* $\widetilde{G}$ *are* $(1+\epsilon)$*-spectrally similar if*

$$\forall \boldsymbol{x} \in \mathbb{R}^n, (1-\epsilon)\cdot \boldsymbol{x}^\top\widetilde{\boldsymbol{L}}\boldsymbol{x} \le \boldsymbol{x}^\top\boldsymbol{L}\boldsymbol{x} \le (1+\epsilon)\cdot\boldsymbol{x}^\top\widetilde{\boldsymbol{L}}\boldsymbol{x}.$$

Theorem 1. *(Spectral Sparsifiers of Random-Walk Molynomials [7, 8]) For random-walk molynomial*

$$\boldsymbol{L} = \boldsymbol{D} - \sum_{r=1}^{T}\alpha_r\boldsymbol{D}\left(\boldsymbol{D}^{-1}\boldsymbol{A}\right)^r, \tag{4}$$

where $\sum_{r=1}^{T}\alpha_r = 1$ *and* α_r *non-negative, one can construct, in time* $O(T^2m\epsilon^{-2}\log^2 n)$*, a* $(1+\epsilon)$*-spectral sparsifier,* $\widetilde{\boldsymbol{L}}$*, with* $O(n\log n\epsilon^{-2})$ *non-zeros. For unweighted graphs, the time complexity can be reduced to* $O(T^2m\epsilon^{-2}\log n)$*.*

To achieve a sparsifier $\widetilde{\boldsymbol{L}}$ with $O(\epsilon^{-2}n\log n)$ non-zeros, the sparsification algorithm consists of two steps: The first step obtains an initial sparsifier for $\boldsymbol{L}$ with $O(Tm\epsilon^{-2}\log n)$ non-zeros. The second step then applies the standard spectral sparsification algorithm [30] to further reduce the number of non-zeros to $O(\epsilon^{-2}n\log n)$. In this work, we only adopt the first step because a sparsifier with $O(Tm\epsilon^{-2}\log n)$ non-zeros is sparse enough for our task. Thus we skip the second step that involves additional computations. From now on, when referring to the random-walk molynomial sparsification algorithm in this work, we mean its first step only.

One can immediately observe that, if we set $\alpha_r = \frac{1}{T}, r \in [T]$, the matrix $\boldsymbol{L}$ in Eq. (4) has a strong connection with the desired matrix $\boldsymbol{M}$ in Eq. (2). Formally, we have the following equation

$$\boldsymbol{M} = \boldsymbol{D}^{-1}\left(\boldsymbol{D} - \boldsymbol{L}\right)\boldsymbol{D}^{-1}. \tag{5}$$

Thm. 1 can help us construct a sparsifier $\widetilde{\boldsymbol{L}}$ for matrix $\boldsymbol{L}$. Then we define $\widetilde{\boldsymbol{M}} \triangleq \boldsymbol{D}^{-1}(\boldsymbol{D} - \widetilde{\boldsymbol{L}})\boldsymbol{D}^{-1}$ by replacing $\boldsymbol{L}$ in Eq. (5) with its sparsifier $\widetilde{\boldsymbol{L}}$. One can observe that matrix $\widetilde{\boldsymbol{M}}$ is still a sparse one with the same order of magnitude of non-zeros as $\widetilde{\boldsymbol{L}}$. Consequently, instead of factorizing the dense NetMF matrix in Eq. (3), we can factorize its sparse alternative, i.e.,

$$\mathrm{trunc_log}^\circ\left(\frac{\mathrm{vol}(G)}{b}\widetilde{\boldsymbol{M}}\right). \tag{6}$$

In the rest of this work, the matrix in Eq. (6) is referred to as *the NetMF matrix sparsifier*.

3.2 The NetSMF Algorithm

In this section, we formally describe the NetSMF algorithm, which consists of three steps: random-walk molynomial sparsification, NetMF sparsifier construction, and truncated singular value decomposition.

Algorithm 1: NetSMF

Input : A social network $G = (V, E, \boldsymbol{A})$ which we want to learn network embedding; The number of non-zeros M in the sparsifier; The dimension of embedding d.

Output: An embedding matrix of size $n \times d$, each row corresponding to a vertex.

1 $\widetilde{G} \leftarrow (V, \emptyset, \widetilde{\boldsymbol{A}} = \boldsymbol{0})$

/* Create an empty network with $E = \emptyset$ and $\widetilde{\boldsymbol{A}} = 0$. */

2 **for** $i \leftarrow 1$ **to** M **do**

3 Uniformly pick an edge $e = (u, v) \in E$

4 Uniformly pick an integer $r \in [T]$

5 $u', v', Z \leftarrow$ PathSampling(e, r)

6 Add an edge $\left(u', v', \frac{2rm}{MZ}\right)$ to $\widetilde{G}$

/* Parallel edges will be merged into one edge, with their weights summed up together. */

7 **end**

8 Compute $\widetilde{\boldsymbol{L}}$ to be the unnormalized graph Laplacian of $\widetilde{G}$

9 Compute $\widetilde{\boldsymbol{M}} = \boldsymbol{D}^{-1}\left(\boldsymbol{D} - \widetilde{\boldsymbol{L}}\right)\boldsymbol{D}^{-1}$

10 $\boldsymbol{U}_d, \Sigma_d, \boldsymbol{V}_d \leftarrow$ RandomizedSVD(trunc_log$^\circ\left(\frac{\mathrm{vol}(G)}{b}\widetilde{\boldsymbol{M}}\right), d$)

11 **return** $\boldsymbol{U}_d\sqrt{\Sigma_d}$ as network embeddings

Algorithm 2: PathSampling algorithm as described in [8].

1 **Procedure** PathSampling($e = (u, v)$, r)

2 Uniformly pick an integer $k \in [r]$

3 Perform $(k-1)$-step random walk from u to u_0

4 Perform $(r-k)$-step random walk from v to u_r

5 Keep track of $Z(\boldsymbol{p})$ along the length-r path $\boldsymbol{p}$ between u_0 and u_r according to Eq. (7)

6 **return** $u_0, u_r, Z(\boldsymbol{p})$

Step 1: Random-Walk Molynomial Sparsification. To achieve the sparsifier $\widetilde{\boldsymbol{L}}$, we adopt the algorithm in Cheng et al. [8]. The algorithm starts from creating a network $\widetilde{G}$ that has the same vertex set as G and an empty edge set (Alg. 1, Line 1). Next, the algorithm constructs a sparsifier with $O(M)$ non-zeros by repeating the PathSampling algorithm for M times. In each iteration, it picks an edge $e \in E$ and an integer $r \in [T]$ uniformly (Alg. 1, Line 3-4). Then, the algorithm uniformly draws an integer $k \in [r]$ and performs $(k-1)$-step and $(r-k)$-step random walks starting from the two endpoints of edge e respectively (Alg. 2, Line 3-4). The above process samples a length-r path $\boldsymbol{p} = (u_0, u_1, \cdots, u_r)$. At the same time, the algorithm keeps track of $Z(\boldsymbol{p})$, which is defined by

$$Z(\boldsymbol{p}) = \sum_{i=1}^{r} \frac{2}{\boldsymbol{A}_{u_{i-1}, u_i}}, \tag{7}$$

and then adds a new edge (u_0, u_r) with weight $\frac{2rm}{MZ(\boldsymbol{p})}$ to $\widetilde{G}$ (Alg. 1, Line 6).[3] Parallel edges in $\widetilde{G}$ will be merged into one single edge, with their weights summed up together. Finally, the algorithm computes the Laplacian of $\widetilde{G}$, which is the sparsifier $\widetilde{\boldsymbol{L}}$ as we desired (Alg. 1, Line 8). This step gives us a sparsifier with $O(M)$ non-zeros.

Step 2: Construct a NetMF Matrix Sparsifier. As we have discussed at the end of Section 3.1, after constructing a sparsifier $\widetilde{\boldsymbol{L}}$, we can plug it into Eq. (5) to obtain a NetMF matrix sparsifier as shown in Eq. (6) (Alg. 1, Line 9-10). This step does not change the order of magnitude of non-zeros in the sparsifier.

Algorithm 3: Randomized SVD on NetMF Matrix Sparsifier

/* In this work, the matrix to be factorized (Eq. (6)) is an $n \times n$ symmetric sparse matrix. We store this sparse matrix in a row-major way and make use of its symmetry to simplify the computation. */

1 **Procedure** RandomizedSVD($\boldsymbol{A}$, d)

2 Sampling Gaussian random matrix $\boldsymbol{O}$ // $\boldsymbol{O} \in \mathbb{R}^{n \times d}$

3 Compute sample matrix $\boldsymbol{Y} = \boldsymbol{A}^\top \boldsymbol{O} = \boldsymbol{A}\boldsymbol{O}$ // $\boldsymbol{Y} \in \mathbb{R}^{n \times d}$

4 Orthonormalize $\boldsymbol{Y}$

5 Compute $\boldsymbol{B} = \boldsymbol{A}\boldsymbol{Y}$ // $\boldsymbol{B} \in \mathbb{R}^{n \times d}$

6 Sample another Gaussian random matrix $\boldsymbol{P}$ // $\boldsymbol{P} \in \mathbb{R}^{d \times d}$

7 Compute sample matrix of $\boldsymbol{Z} = \boldsymbol{B}\boldsymbol{P}$ // $\boldsymbol{Z} \in \mathbb{R}^{n \times d}$

8 Orthonormalize $\boldsymbol{Z}$

9 Compute $\boldsymbol{C} = \boldsymbol{Z}^\top \boldsymbol{B}$ // $\boldsymbol{C} \in \mathbb{R}^{d \times d}$

10 Run Jacobi SVD on $\boldsymbol{C} = \boldsymbol{U}\Sigma\boldsymbol{V}^\top$

11 **return** $\boldsymbol{Z}\boldsymbol{U}$, Σ, $\boldsymbol{Y}\boldsymbol{V}$

/* Result matrices are of shape $n \times d, d \times d, n \times d$ resp. */

Step 3: Truncated Singular Value Decomposition. The final step is to perform truncated singular value decomposition (SVD) on the constructed NetMF matrix sparsifier (Eq. (6)). However, even the sparsifier only has $O(M)$ number of non-zeros, performing exact SVD is still time consuming. In this work, we leverage a modern randomized matrix approximation technique—Randomized SVD—developed by Halko et al. [15]. Due to space constraint, we cannot include many details. Briefly speaking, the algorithm projects the original matrix to a low-dimensional space through a Gaussian random matrix. One only needs to perform traditional SVD (e.g. Jacobi SVD) on a $d \times d$ small matrix. We list the pseudocode algorithm in Alg. 3. Another advantage of SVD is that we can determine the dimensionality of embeddings by using, for example, Cattell's Scree test [5]. In the test, we plot the singular values and select a rank

[3] Details about how the edge weight is derived can be found in Thm. 4 in Appendix.

Table 3: Time and Space Complexity of NetSMF.

	Time	Space
Step 1	$O(MT \log n)$ for weighted networks $O(MT)$ for unweighted networks	$O(M + n + m)$
Step 2	$O(M)$	$O(M + n)$
Step 3	$O(Md + nd^2 + d^3)$	$O(M + nd)$

d such that there is a clear drop in the magnitudes or the singular values start to even out. More details will be discussed in Section 4.

Complexity Analysis. Now we analyze the time and space complexity of NetSMF, as summarized in Table 3. As for step 1, we call the PathSampling algorithm for M times, during each of which it performs $O(T)$ steps of random walks over the network. For unweighted networks, sampling a neighbor requires $O(1)$ time, while for weighted networks, one can use roulette wheel selection to choose a neighbor in $O(\log n)$. It taks $O(M)$ space to store $\widetilde{G}$, while the additional $O(n + m)$ space comes from the storage of the input network. As for step 2, it takes $O(M)$ time to perform the transformation in Eq. (5) and the element-wise truncated logarithm in Eq. (6). The additional $O(n)$ space is spent in storing the degree matrix. As for step 3, $O(Md)$ time is required to compute the product of a row-major sparse matrix and a dense matrix (Alg. 3, Lines 3 and 5); $O(nd^2)$ time is spent in Gram-Schmidt orthogonalization (Alg. 3, Lines 4 and 8); $O(d^3)$ time is spent in Jacobi SVD (Alg. 3, Line 10).

Connection to NetMF. The major difference between NetMF and NetSMF lies in the approximation strategy of the NetMF matrix in Eq. (3). As we mentioned in Section 2, NetMF approximates it with a dense matrix, which brings new space and computation challenges. In this work, NetSMF aims to find a sparse approximator to the NetMF matrix by leveraging theories and techniques from spectral graph sparsification.

Example. We provide a running example to help understand the NetSMF algorithm. Suppose we want to learn embeddings for a network with $n = 10^6$ vertices, $m = 10^7$ edges, context window size $T = 10$, and approximation factor $\epsilon = 0.1$. The NetSMF method calls the PathSampling algorithm for $M = Tm\epsilon^{-2} \log n \approx 1.4 \times 10^{11}$ times and provides us with a NetMF matrix sparsifier with at most 1.4×10^{11} non-zeros (Notice that the reducer in Step 1 and trunc_log$^\circ$ in Step 2 will further sparsify the matrix, making 1.4×10^{11} an upper bound). The density of the sparsifier is at most $\frac{M}{n^2} \approx 14\%$. Then, when computing the sparse-dense matrix product in randomized SVD (Alg. 3, Lines 3 and 5), the sparseness of the factorized matrix can greatly accelerate the calculation. In comparison, NetMF must construct a dense matrix with $n^2 = 10^{12}$ non-zeros, which is an order of magnitude larger in terms of density. Also, the density of the sparsifier in NetSMF can be further reduced by using a larger ϵ, while NetMF does not have this flexibility.

3.3 Approximation Error Analysis

In this section, we analyze the approximation error of the sparsification. We assume that we choose an approximation factor $\epsilon < 0.5$. We first see how the constructed $\widetilde{\boldsymbol{M}}$ approximates $\boldsymbol{M}$ and then compare the NetMF matrix (Eq. (3)) against the NetMF matrix sparsifier (Eq. (6)). We use σ_i to denote the i-th descending-order singular value of a matrix. We also assume the vertices' degrees are sorted in ascending order, that is, $d_{\min} = d_1 \le d_2 \cdots \le d_n$.

Theorem 2. *The singular value of $\widetilde{\boldsymbol{M}} - \boldsymbol{M}$ satisfies $\sigma_i(\widetilde{\boldsymbol{M}} - \boldsymbol{M}) \le \frac{4\epsilon}{\sqrt{d_i d_{\min}}}, \forall i \in [n]$.*

Proof. See Appendix. □

Theorem 3. *Let $\|\cdot\|_F$ be the matrix Frobenius norm. Then*

$$\left\| \text{trunc_log}^\circ\left(\frac{\text{vol}(G)}{b}\widetilde{\boldsymbol{M}}\right) - \text{trunc_log}^\circ\left(\frac{\text{vol}(G)}{b}\boldsymbol{M}\right) \right\|_F \le \frac{4\epsilon\,\text{vol}(G)}{b\sqrt{d_{\min}}} \sqrt{\sum_{i=1}^{n} \frac{1}{d_i}}.$$

Proof. See Appendix. □

Discussion on the Approximation Error. The above bound is achieved without making assumptions about the input network. If we introduce some assumptions, say a bounded lowest degree $d_{\min}$ or a specific random graph model (e.g., Planted Partition Model or Extended Planted Partition Model), it is promising to explore tighter bounds by leveraging theorems in literature [6, 11].

3.4 Parallelization

Each step of NetSMF can be parallelized, enabling it to scale to very large networks. The parallelization design of NetSMF is introduced in Figure 1. Below we discuss the parallelization of each step in detail.

At the first step, the paths in the PathSampling algorithm are sampled independently with each other. Thus we can launch multiple PathSampling workers simultaneously. Each worker handles a subset of the samples. Herein, we require that each worker is able to access the network data $G = (V, E, \boldsymbol{A})$ efficiently. There are many options to meet this requirement. The easiest one is to load a copy of the network data to each worker's memory. When the network is extremely large (e.g., trillion scale) or workers have memory constraints, the graph engine should be designed to expose efficient graph query APIs to support graph operations such as random walks. At the end of this step, a reducer is designed to merge parallel edges and sum up their weights. If this step is implemented in a big data system such as Spark [45], the reduction step can be simply achieved by running a reduceByKey(_+_)[4] function. After the reduction, the sparsifier $\widetilde{\boldsymbol{L}}$ is organized as a collection of triplets, a.k.a, COOrdinate format, with each indicating an entry of the sparsifier.

The second step is the most straightforward step to scale up. When processing a triplet (u, v, w), we can simply query the degree of vertices u and v and perform the transformation defined in Eq. (5) as well as the truncated logarithm in Eq. (6), which can be well parallelized.

For the last step, we organize the sparsifier into row-major format. This format allows efficient multiplication between a sparse and a dense matrix (Alg. 3, Line 3 and 5). Other dense matrix operators (e.g., Gaussian random matrix generation, Gram-Schmidt

[4] https://spark.apache.org/docs/latest/rdd-programming-guide.html

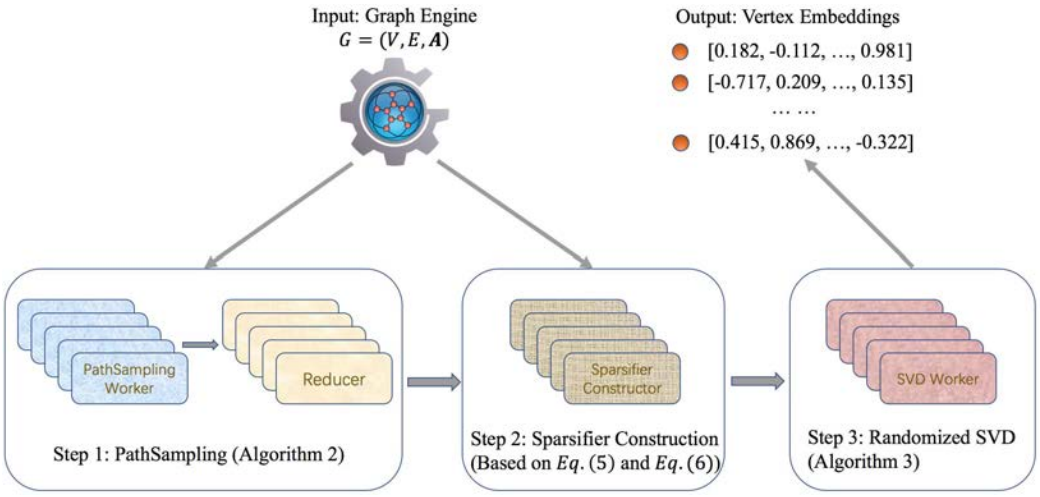

Figure 1: The System Design of NetSMF. The input comes from a graph engine which stores the network data and provides efficient APIs to graph queries. In Step 1, the system launches several PathSampling workers. Each worker handles a subset of samples. Then, a reducer is designed to aggregate the output of the PathSampling algorithm. In Step 2, the system distributes data to several sparsifier constructors to perform the transformation defined in Eq. (5) and the truncated element-wise matrix logarithm in Eq. (6). In the final step, the system applies truncated randomized SVD on the constructed sparsifier and dumps the resulted embeddings to storage.

Table 4: Statistics of Datasets.

Dataset	BlogCatalog	PPI	Flickr	YouTube	OAG
$\|V\|$	10,312	3,890	80,513	1,138,499	67,768,244
$\|E\|$	333,983	76,584	5,899,882	2,990,443	895,368,962
#labels	39	50	195	47	19

orthogonalization and Jacobi SVD) can be easily accelerated by using multi-threading or common linear algebra libraries.

In this work, we adopt a single-machine shared-memory implementation. We use OpenMP [10] to parallelize NetSMF in our implementation[5].

4 EXPERIMENTS

In this section, we evaluate the proposed NetSMF method on the multi-label vertex classification task, which has been commonly used to evaluate previous network embedding techniques [14, 27, 28, 33]. We introduce our datasets and baselines in Section 4.1 and Section 4.2. We report experimental results and parameter analysis in Section 4.3 and Section 4.4, respectively.

4.1 Datasets

We employ five datasets for the prediction task, four of which are in relatively small scale but have been widely used in network embedding literature, including BlogCatalog, PPI, Flickr, and YouTube. The remaining one is a large-scale academic co-authorship network, which is at least two orders of magnitude larger than the largest one (YouTube) used in most network embedding studies. The statistics of these datasets are listed in Table 4.

BlogCatalog [1, 35] is a network of social relationships of online bloggers. The vertex labels represent the interests of the bloggers.

Protein-Protein Interactions (PPI) [31] is a subgraph of the PPI network for Homo Sapiens. The vertex labels are obtained from the hallmark gene sets and represent biological states.

Flickr [35] is the user contact network in Flickr. The labels represent the interest groups of the users.

YouTube [36] is a video-sharing website that allows users to upload, view, rate, share, add to their favorites, report, comment on videos. The users are labeled by the video genres they liked.

Open Academic Graph (OAG) [6] is a publicly available academic graph indexed by Microsoft Academic [29] and AMiner.org [34]. We construct an undirected co-authorship network from OAG. This network contains 67,768,244 authors and 895,368,962 collaboration edges. The vertex labels are defined to be the top-level fields of study of each author, such as computer science, physics, psychology, and so on. In total, there are 19 distinct fields (labels) and authors may publish in more than one field, making the associated vertices have multiple labels.

4.2 Baseline Methods

We compare NetSMF with NetMF [28], LINE [33], DeepWalk [27], and node2vec [14]. For NetSMF, NetMF, DeepWalk, and node2vec that allow multi-hop structural dependencies, the context window size T is set to be 10, which is also the default setting used in both DeepWalk and node2vec. Across all datasets, we set the embedding

[5] Code is publicly available at https://github.com/xptree/NetSMF

[6] www.openacademic.ai/oag/

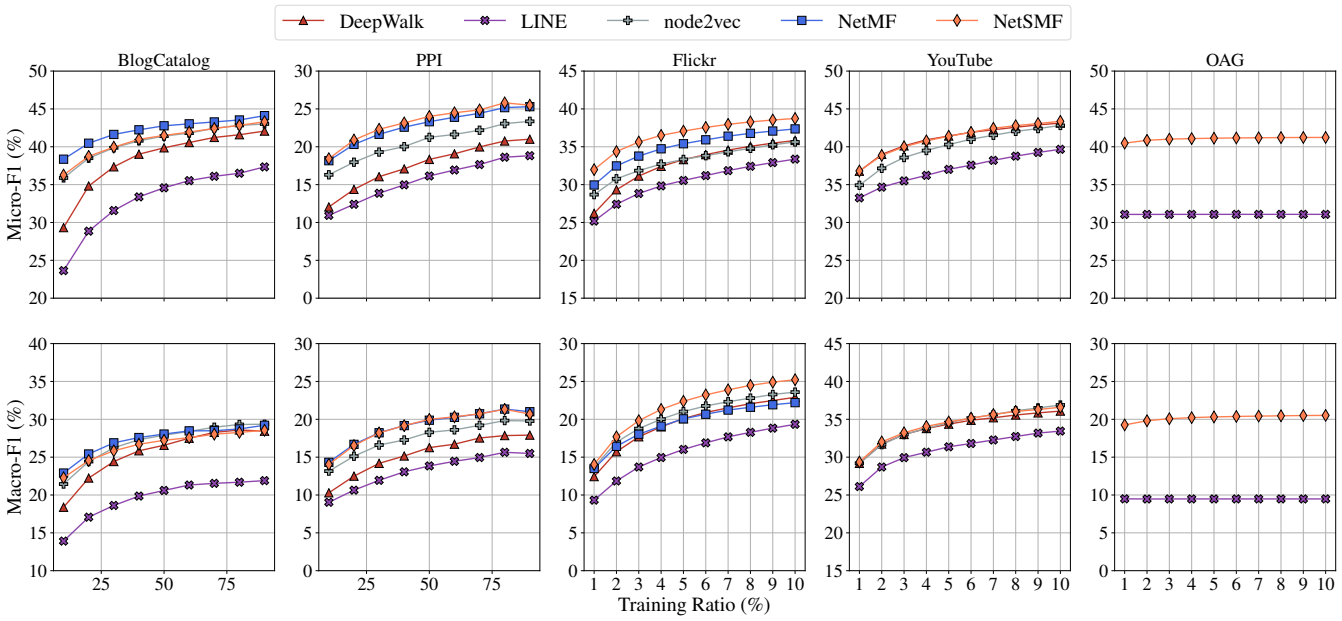

Figure 2: Predictive performance w.r.t. the ratio of training data. The x-axis represents the ratio of labeled data (%), and the y-axis in the top and bottom rows denote the Micro-F1 and Macro-F1 scores (%) respectively. For methods which fail to finish computation in one week or cannot handle the computation, their results are not available and thus not plotted in this figure.

dimension d to be 128. We follow the common practice for the other hyper-parameter settings, which are introduced below.

LINE. We use LINE with the second order proximity (i.e., LINE (2nd) [33]). We use the default setting of LINE's hyper-parameters: the number of edge samples to be 10 billion and the negative sample size to be 5.

DeepWalk. We present DeepWalk's results with the authors' preferred parameters, that is, walk length to be 40, the number of walks from each vertex to be 80, and the number of negative samples in skip-gram to be 5.

node2vec. For the return parameter p and in-out parameter q in node2vec, we adopt the default setting that was used by its authors if available. Otherwise, we grid search $p, q \in \{0.25, 0.5, 1, 2, 4\}$. For a fair comparison, we use the same walk length and the number of walks per vertex as DeepWalk.

NetMF. In NetMF, the hyper-parameter h indicates the number of eigen pairs used to approximate the NetMF matrix. Following the authors' preferred setting [28], we choose $h = 256$ for the BlogCatalog and PPI datasets, and $h = 16384$ for Flickr. For both NetMF and NetSMF, we have $b = 1$.

NetSMF. In NetSMF, we set the number of samples $M = 10^3 \times T \times m$ for the PPI, Flickr, and YouTube datasets, $M = 10^4 \times T \times m$ for BlogCatalog, and $M = 10 \times T \times m$ for OAG in order to achieve desired performance.

Prediction Setting. We follow exactly the same experiment and evaluation procedures that were performed in DeepWalk [27]. First, we randomly sample a portion of labeled vertices for training and use the remaining for testing. For the BlogCatalog and PPI datasets, the training ratio varies from 10% to 90%. For Flickr, YouTube and OAG, the training ratio varies from 1% to 10%. We use the one-vs-rest logistic regression model implemented by LIBLINEAR [13] for the multi-label vertex classification task. In the test phase, the one-vs-rest model yields a ranking of labels rather than an exact label assignment. To avoid the thresholding effect, we take the assumption that was made in DeepWalk, LINE, and node2vec, that is, the number of labels for vertices in the test data is given [14, 27, 37]. We repeat the prediction procedure ten times and evaluate the average performance in terms of both Micro-F1 and Macro-F1 scores [41]. All the experiments are performed on a server with Intel Xeon E7-8890 CPU (64 cores), 1.7TB memory, and 2TB SSD hard drive.

4.3 Experimental Results

We summarize the prediction performance in Figure 2. To compare the efficiency of different algorithms, we also list the running time of each algorithm across all datasets, if available, in Table 5.

NetSMF vs. NetMF. We first focus on the comparison between NetSMF and NetMF, since the goal of NetSMF is to address the efficiency and scalability issues of NetMF while maintaining its superiority in effectiveness. From Table 5, we observe that for YouTube and OAG, both of which contain more than one million vertices, NetMF fails to complete because of the excessive space and memory consumption, while NetSMF is able to finish in four hours and one day, respectively. For the moderate-size network Flickr, both methods are able to complete within one week, though NetSMF

Table 5: Efficiency comparison. The running time includes filesystem IO and computation time. "–" indicates that the corresponding algorithm fails to complete within one week. "×" indicates that the corresponding algorithm is unable to handle the computation due to excessive space and memory consumption.

	LINE	DeepWalk	node2vec	NetMF	NetSMF
BlogCatalog	40 mins	12 mins	56 mins	19 mins	13 mins
PPI	41 mins	4 mins	4 mins	1 min	10 secs
Flickr	42 mins	2.2 hours	21 hours	5 days	48 mins
YouTube	46 mins	4.3 hours	4 days	×	4.1 hours
OAG	2.6 hours	–	–	×	24 hours

is 150× faster (i.e., 48 mins vs. five days). For the two small-scale networks—BlogCatalog and PPI, NetSMF beats NetMF by a relatively narrow margin. This is because when the input networks contain only thousands of vertices, the advantage of sparse matrix construction and factorization over its dense alternative could be marginalized by the other components of the workflow, such as filesystem IO.

In terms of prediction performance, Figure 2 suggests NetSMF and NetMF yield consistently the best results among all compared methods, empirically demonstrating the power of the matrix factorization framework for network embedding. In BlogCatalog, NetSMF has slightly worse performance than NetMF (on average less than 3% worse regarding both Micro- and Macro-F1). In PPI, the two leading methods' performance are relatively indistinguishable in terms of both metrics. In Flickr, NetSMF achieves significantly better Macro-F1 than NetMF (by 11% on average), and also higher Micro-F1 (by 4.8% on average). Recall that NetMF uses a dense approximation of the matrix to factorize. These results show that the sparse spectral approximation used by NetSMF does not necessarily yield worse performance than the dense approximation used by NetMF.

Overall, not only NetSMF improves the scalability, and the running time of NetMF by orders of magnitude for large-scale networks, it also has competitive, and sometimes better, performance. This demonstrates the effectiveness of our spectral sparsification based approximation algorithm.

NetSMF vs. DeepWalk, LINE & node2vec. We also compare NetSMF against common graph embedding benchmarks—DeepWalk, LINE, and node2vec. For the OAG dataset, DeepWalk and node2vec fail to finish the computation within one week, while NetSMF requires only 24 hours. Based on the publicly reported running time of skip-gram [24], we estimate that DeepWalk and node2vec may require months to generate embeddings for the OAG dataset. In BlogCatalog and YouTube, DeepWalk and NetSMF require similar computing time, while in Flickr and PPI, NetSMF is 3× and 24× faster than DeepWalk, respectively. In all the datasets, NetSMF achieves 4–25× speedup over node2vec.

Moreover, the performance of NetSMF is significantly better than DeepWalk in BlogCatalog, PPI, and Flickr, by 7–34% in terms of Micro-F1 and 5–25% in terms of Macro-F1. In YouTube, NetSMF achieves slightly better results than DeepWalk. Compared with node2vec, NetSMF achieves comparable performance in BlogCatalog and YouTube, and significantly better performance in PPI and Flickr. In sum, NetSMF consistently outperforms DeepWalk and node2vec in terms of both efficiency and effectiveness.

LINE has the best efficiency among all the five methods and together with NetSMF, they are the only methods that can generate embeddings for OAG within one week (and both finish in one day). However, it also has the worst prediction performance and consistently loses to others by a large margin across all datasets. For example, NetSMF beats LINE by 21% and 39% in Flickr, and by 30% and 100% in OAG in terms of Micro-F1 and Macro-F1, respectively.

In summary, LINE achieves efficiency at the cost of ignoring multi-hop dependencies in networks, which are supported by all the other four methods—DeepWalk, node2vec, NetMF, and NetSMF, demonstrating the importance of multi-hop dependencies for learning network representations.

More importantly, among these four methods, DeepWalk achieves neither efficiency nor effectiveness superiority; node2vec achieves relatively good performance at the cost of efficiency; NetMF achieves effectiveness at the expense of significantly increased time and space costs; NetSMF is the only method that achieves both high efficiency and effectiveness, empowering it to learn effective embeddings for billion-scale networks (e.g., the OAG network with 0.9 billion edges) in one day on one modern server.

4.4 Parameter Analysis

In this section, we discuss how the hyper-parameters influence the performance and efficiency of NetSMF. We report all the parameter analyses on the Flickr dataset with training ratio set to be 10%.

How to Set the Embedding Dimension d. As mentioned in Section 3.1, SVD allows us to determine a "good" embedding dimension without additional supervised information. There are many methods available such as captured energy and Cattell's Scree test [5]. Here we propose to use Cattell's Scree test. Cattell's Scree test plots the singular values and selects a rank d such that there is a clear drop in the magnitudes or the singular values start to even out. In Flickr, if we sort the singular values in decreasing order, we can observe that the singular values approach 0 when the rank increases to around 100, as shown in Figure 3(b). In our experiments, by varying d form 2^4 to 2^8, we reach the best performance at $d = 128$, as shown in Figure 3(a), demonstrating the ability of our matrix factorization based NetSMF for automatically determining the embedding dimension.

The Number of Non-Zeros M. In theory, $M = O(Tm\epsilon^{-2} \log n)$ is required to guarantee the approximation error (See Section 3.1). Without loss of generality, we empirically set M to be $k \times T \times m$ where k is chosen from 1, 10, 100, 200, 500, 1000, 2000 and investigate how the number of non-zeros influence the quality of learned embeddings. As shown in Figure 3(c), when increasing the number of non-zeros, NetSMF tends to have better prediction performance because the original matrix is being approximated more accurately. On the other hand, although increasing M has a positive effect on the prediction performance, its marginal benefit diminishes gradually. One can observe that setting $M = 1000 \times T \times m$ (the

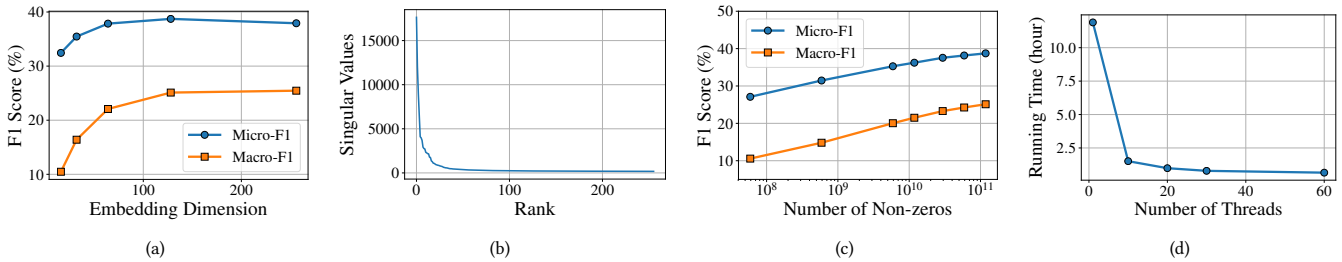

Figure 3: Parameter analysis: (a) Prediction performance v.s. embedding dimension d; (b) Cattel's Scree Test on singular values. We plot the top 256 singular values to find a clear drop in the magnitudes or the singular values start to even out. (c) Prediction performance v.s. the number of non-zeros M; (d) Running time v.s. the number of threads.

second-to-the-right data point on each line in Figure 3(c)) is a good choice that balances NetSMF's efficiency and effectiveness.

The Number of Threads. In this work, we use a single-machine shared memory implementation with multi-threading acceleration. We report the running time of NetSMF when setting the number of threads to be 1, 10, 20, 30, 60, respectively. As shown in Figure 3(d), NetSMF takes 12 hours to embed the Flickr network with one thread and 48 minutes to run with 30 threads, achieving a 15× speedup ratio (with ideal being 30×). This relatively good sub-linear speedup supports NetSMF to scale up to very large-scale networks.

5 RELATED WORK

In this section, we briefly review the related work of network embedding, large-scale embedding algorithms, and spectral graph sparsification.

5.1 Network Embedding

Network embedding has been extensively studied over the past years [16]. The success of network embedding has driven a lot of downstream network applications, such as recommendation systems [44]. Briefly, recent work about network embedding can be categorized into three genres: (1) Skip-gram based methods that are inspired by word2vec [24], such as LINE [33], DeepWalk [27], node2vec [14], metapath2vec [12], and VERSE [40]; (2) Deep learning based methods such as [21, 44]; (3) Matrix factorization based methods such as GraRep [4] and NetMF [28]. Among them, NetMF bridges the first and the third categories by unifying a collection of skip-gram based network embedding methods into a matrix factorization framework. In this work, we leverage the merit of NetMF and address its limitation in efficiency.

Among literature, PinSage is notably a network embedding framework for billion-scale networks [44]. The difference between NetSMF and PinSage lies in the following aspect. The goal of NetSMF is to pre-train general network embeddings in an unsupervised manner, while PinSage is a supervised graph convolutional method with both the objective of recommender systems and existing node features incorporated. That being said, the embeddings learned by NetSMF can be consumed by PinSage for downstream network applications.

5.2 Large-Scale Embedding Learning

Studies have attempted to optimize embedding algorithms for large datasets from different perspectives. Some of them focus on improving the skip-gram model, while others consider it as a matrix factorization problem.

Distributed Skip-Gram Model. Inspired by word2vec [25], most of the modern embedding learning algorithms are based on the skip-gram model. There is a sequence of work trying to accelerate the skip-gram model in a distributed system. For example, Ji et al. [19] replicate the embedding matrix on multiple workers and synchronize them periodically; Ordentlich et al. [26] distribute the columns (dimensions) of the embedding matrix to multiple executors and synchronize them with a parameter server [23]. Negative sampling is a key step in skip-gram, which requires to draw samples from a noisy distribution. Stergiou et al. [32] focus on the optimization of negative sampling by replacing the roulette wheel selection with a hierarchical sampling algorithm based on the alias method. More recently, Wang et al. [43] propose a billion-scale network embedding framework by heuristically partitioning the input graph to small subgraphs, and processing them separately in parallel. However, the performance of their framework highly relies on the quality of graph partition. The drawback for partition-based embedding learning is that the embeddings learned in different subgraphs do not share the same latent space, making it impossible to compare nodes across subgraphs.

Efficient Matrix Factorization. Factorizing the NetMF matrix, either implicitly (e.g., LINE [33] and DeepWalk [27]) or explicitly (e.g., NetMF [28]), encounters the following two issues. First, the denseness of this matrix makes computation expensive even for a moderate context window size (e.g., $T = 10$). Second, the non-linear transformation, i.e., element-wise matrix logarithm, is hard to approximate. LINE [33] solves this problem by setting $T = 1$. With such simplification, it achieves good scalability at the cost of prediction performance. NetSMF addresses these issues by efficiently sparsifying the dense NetMF matrix with a theoretically-bounded approximation error.

5.3 Spectral Graph Sparsification

Spectral graph sparsification has been studied for decades in graph theory [38]. The task of graph sparsification is to approximate a

"dense" graph by a "sparse" one that can be effectively used in place of the dense one [38], which arises in many applications such as scientific computing [17], machine learning [3, 7] and data mining [46]. Our NetSMF model is the first work that incorporates spectral sparsification algorithms [7, 8] into network embedding, which offers a powerful and efficient way to approximate and analyze the random-walk matrix-polynomial in the NetMF matrix.

6 CONCLUSION

In this work, we study network embedding with the goal of achieving both good efficiency and effectiveness. To address the efficiency and scalability challenges faced by the NetMF model, we propose to study large-scale network embedding as sparse matrix factorization. We present the NetSMF algorithm, which achieves a sparsification of the (dense) NetMF matrix. Both the construction and factorization of the sparsified matrix are fast enough to support very large-scale network embedding learning. For example, it empowers NetSMF to efficiently embed the Open Academic Graph in 24 hours, whose size is computationally intractable for the dense matrix factorization solution (NetMF).

Theoretically, the sparsified matrix is spectrally close to the original NetMF matrix with an approximation bound. Empirically, our extensive experimental results show that the sparsely learned embeddings by NetSMF are as effective as those from the factorization of the NetMF matrix, leaving it outperform the common network embedding benchmarks—DeepWalk, LINE, and node2vec. In other words, among both matrix factorization based methods (NetMF and NetSMF) and common skip-gram based benchmarks (DeepWalk, LINE, and node2vec), NetSMF is the only model that achieves both efficiency and performance superiority.

Future Work. NetSMF brings an efficient, effective, and guaranteed solution to network embedding learning. There are multiple tangible research fronts we can pursue. First, our current single-machine implementation limits the number of samples we can take for large networks. We plan to develop a multi-machine solution in the future to further scale NetSMF. Second, building upon NetSMF, we would like to efficiently and accurately learn embeddings for large-scale directed [9], dynamic [20], and/or heterogeneous networks. Third, as the advantage of matrix factorization methods demonstrated, we are also interested in exploring the other matrix definitions that may be effective in capturing different structural properties in networks. Last, it would be also interesting to bridge matrix factorization based network embedding methods with graph convolutional networks.

APPENDIX

We first prove Thm. 2 and Thm. 3 in Section 3.3. The following lemmas will be useful in our proof.

Lemma 1. *([39]) Singular values of a real symmetric matrix are the absolute values of its eigenvalues.*

Lemma 2. *(Courant-Fisher Theorem) Let $\boldsymbol{A} \in \mathbb{R}^{n\times n}$ be a symmetric matrix with eigenvalues $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n$, then for $i \in [n]$,*

$$\lambda_i = \min_{\dim(U)=i} \max_{\boldsymbol{x}\in U, \|x\|_2=1} \boldsymbol{x}^\top \boldsymbol{A}\boldsymbol{x}.$$

Lemma 3. *([18]) Let $\boldsymbol{B}, \boldsymbol{C}$ be two $n \times n$ symmetric matrices. Then for the decreasingly-ordered singular values σ of $\boldsymbol{B}, \boldsymbol{C}$ and $\boldsymbol{BC}$,*

$$\sigma_{i+j-1}(\boldsymbol{BC}) \leq \sigma_i(\boldsymbol{B}) \times \sigma_j(\boldsymbol{C})$$

holds for any $1 \leq i, j \leq n$ and $i + j \leq n + 1$.

Lemma 4. *Let $\boldsymbol{\mathcal{L}} = \boldsymbol{D}^{-1/2}\boldsymbol{L}\boldsymbol{D}^{-1/2}$ and similarly $\widetilde{\boldsymbol{\mathcal{L}}} = \boldsymbol{D}^{-1/2}\widetilde{\boldsymbol{L}}\boldsymbol{D}^{-1/2}$. Then all the singular values of $\widetilde{\boldsymbol{\mathcal{L}}} - \boldsymbol{\mathcal{L}}$ are smaller than 2ϵ, i.e., $\forall i \in [n]$, $\sigma_i(\widetilde{\boldsymbol{\mathcal{L}}} - \boldsymbol{\mathcal{L}}) < 4\epsilon$.*

Proof. Notice that

$$\boldsymbol{\mathcal{L}} = \boldsymbol{D}^{-1/2}\boldsymbol{L}\boldsymbol{D}^{-1/2} = \boldsymbol{I} - \sum_{r=1}^{T} \alpha_r \left(\boldsymbol{D}^{-1/2}\boldsymbol{A}\boldsymbol{D}^{-1/2}\right)^r$$

which is a normalized graph Laplacian whose eigenvalues lie in the interval $[0, 2)$, i.e., for $i \in [n]$, $\lambda_i(\boldsymbol{\mathcal{L}}) \in [0, 2)$ [42]. Since $\widetilde{\boldsymbol{L}}$ is a $(1 + \epsilon)$-spectral sparsifier of $\boldsymbol{L}$, we know that for $\forall \boldsymbol{x} \in \mathbb{R}^n$,

$$\frac{1}{1+\epsilon}\boldsymbol{x}^\top \boldsymbol{L}\boldsymbol{x} \leq \boldsymbol{x}^\top \widetilde{\boldsymbol{L}}\boldsymbol{x} \leq \frac{1}{1-\epsilon}\boldsymbol{x}^\top \boldsymbol{L}\boldsymbol{x}.$$

Let $\boldsymbol{x} = \boldsymbol{D}^{-1/2}\boldsymbol{y}$ which is bijective, we have

$$\frac{1}{1+\epsilon}\boldsymbol{y}^\top \boldsymbol{\mathcal{L}}\boldsymbol{y} \leq \boldsymbol{y}^\top \widetilde{\boldsymbol{\mathcal{L}}}\boldsymbol{y} \leq \frac{1}{1-\epsilon}\boldsymbol{y}^\top \boldsymbol{\mathcal{L}}\boldsymbol{y}$$
$$\Longrightarrow \left|\boldsymbol{y}^\top(\widetilde{\boldsymbol{\mathcal{L}}} - \boldsymbol{\mathcal{L}})\boldsymbol{y}\right| \leq \frac{\epsilon}{1-\epsilon}\boldsymbol{y}^\top \boldsymbol{\mathcal{L}}\boldsymbol{y} < 2\epsilon \boldsymbol{y}^\top \boldsymbol{\mathcal{L}}\boldsymbol{y}.$$

The last inequality is because we assume $\epsilon < 0.5$. Then, by Courant-Fisher Theorem (Lemma 2), we can immediately get, $\forall i \in [n]$,

$$\left|\lambda_i(\widetilde{\boldsymbol{\mathcal{L}}} - \boldsymbol{\mathcal{L}})\right| \leq 2\epsilon\lambda_i(\boldsymbol{\mathcal{L}}) < 4\epsilon.$$

Then, by Lemma 1, $\sigma_i(\widetilde{\boldsymbol{\mathcal{L}}} - \boldsymbol{\mathcal{L}}) < 4\epsilon, \forall i \in [n]$. □

Given the above lemmas, we can see how the constructed $\widetilde{\boldsymbol{M}}$ approximates $\boldsymbol{M}$ and how the constructed NetMF matrix sparsifier (Eq. (6)) approximates the NetMF matrix (Eq. (3)).

Theorem 2. *The singular value of $\widetilde{\boldsymbol{M}} - \boldsymbol{M}$ satisfies $\sigma_i(\widetilde{\boldsymbol{M}} - \boldsymbol{M}) \leq \frac{4\epsilon}{\sqrt{d_i d_{\min}}}, \forall i \in [n]$.*

Proof. First notice that $\widetilde{\boldsymbol{M}} - \boldsymbol{M} = \boldsymbol{D}^{-1}\left(\widetilde{\boldsymbol{L}} - \boldsymbol{L}\right)\boldsymbol{D}^{-1} = \boldsymbol{D}^{-1/2}(\widetilde{\boldsymbol{\mathcal{L}}} - \boldsymbol{\mathcal{L}})\boldsymbol{D}^{-1/2}$. Apply Lemma 3 twice and use the result from Lemma 4, we have

$$\sigma_i\left(\widetilde{\boldsymbol{M}} - \boldsymbol{M}\right) \leq \sigma_i\left(\boldsymbol{D}^{-1/2}\right) \times \sigma_1\left(\widetilde{\boldsymbol{\mathcal{L}}} - \boldsymbol{\mathcal{L}}\right) \times \sigma_1\left(\boldsymbol{D}^{-1/2}\right)$$
$$\leq \frac{1}{\sqrt{d_i}} \times 4\epsilon \times \frac{1}{\sqrt{d_{\min}}} = \frac{4\epsilon}{\sqrt{d_i d_{\min}}}.$$

□

Theorem 3. *Let $\|\cdot\|_F$ be the matrix Frobenius norm. Then*

$$\left\|\text{trunc_log}^\circ\left(\frac{\text{vol}(G)}{b}\widetilde{\boldsymbol{M}}\right) - \text{trunc_log}^\circ\left(\frac{\text{vol}(G)}{b}\boldsymbol{M}\right)\right\|_F \leq \frac{4\epsilon\,\text{vol}(G)}{b\sqrt{d_{\min}}}\sqrt{\sum_{i=1}^{n}\frac{1}{d_i}}.$$

Proof. It is easy to observe that trunc_log$^\circ$ is 1-Lipchitz w.r.t. Frobenius norm. So we have

$$\begin{aligned}
&\left\|\text{trunc_log}^\circ\left(\frac{\text{vol}(G)}{b}\widetilde{\boldsymbol{M}}\right)-\text{trunc_log}^\circ\left(\frac{\text{vol}(G)}{b}\boldsymbol{M}\right)\right\|_F\\
\le&\left\|\frac{\text{vol}(G)}{b}\widetilde{\boldsymbol{M}}-\frac{\text{vol}(G)}{b}\boldsymbol{M}\right\|_F=\frac{\text{vol}(G)}{b}\left\|\widetilde{\boldsymbol{M}}-\boldsymbol{M}\right\|_F\\
=&\frac{\text{vol}(G)}{b}\sqrt{\sum_{i\in[n]}\sigma_i^2(\widetilde{\boldsymbol{M}}-\boldsymbol{M})}\le\frac{4\epsilon\,\text{vol}(G)}{b\sqrt{d_{\min}}}\sqrt{\sum_{i=1}^{n}\frac{1}{d_i}}.
\end{aligned}$$

□

We finally explain the remaining question in Step 1 of NetSMF: After sampling a length-r path $\boldsymbol{p}=(u_0,\cdots,u_r)$, why does the algorithm add a new edge to the sparsifier with weight $\frac{rm}{MZ(\boldsymbol{p})}$? Our proof relies on two lemmas from [8].

Lemma 5. *(Lemma 3.3 in [8]) Given the path length r, the probability for the PathSampling algorithm to sample a path $\boldsymbol{p}$ is $\tau(\boldsymbol{p})=\frac{w(\boldsymbol{p})Z(\boldsymbol{p})}{2rm}$, where $Z(\boldsymbol{p})$ is defined in Eq. (7) and*

$$w(\boldsymbol{p})=\frac{\prod_{i=1}^{r}\boldsymbol{A}_{u_{i-1},u_i}}{\prod_{i=1}^{r-1}\boldsymbol{D}_{u_i}}.$$

Lemma 6. *(Theorem 2.2 in [8]) After sampling a length-r path $\boldsymbol{p}=(u_0,u_1,\cdots,u_r)$, the weight corresponding to the new edge (u_0,u_r) added to the sparsifier should be $\frac{w(\boldsymbol{p})}{\tau(\boldsymbol{p})M}$.*

Theorem 4. *After sampling a length-r path $\boldsymbol{p}=(u_0,u_1,\cdots,u_r)$ using the PathSampling algorithm (Alg. 2). The weight of the new edge added to the sparsifier $\widetilde{\boldsymbol{L}}$ is $\frac{2rm}{MZ(\boldsymbol{p})}$.*

Proof. The proof is to plug the definition of $Z(\boldsymbol{p})$, $w(\boldsymbol{p})$, and $\tau(\boldsymbol{p})$ from Lemma 5 into Lemma 6, that is,

$$\frac{w(\boldsymbol{p})}{\tau(\boldsymbol{p})M}=\frac{w(\boldsymbol{p})}{\frac{w(\boldsymbol{p})Z(\boldsymbol{p})}{2rm}\times M}=\frac{2rm}{MZ(\boldsymbol{p})}.$$

For unweighted networks, this weight can be simplified to $\frac{m}{M}$, since $Z(\boldsymbol{p})=2r$ for unweighted networks. □

ABSTRACT

Knowledge about the organization of the main physical elements (e.g. streets) and objects (e.g. trees) that structure cities is important in the maintenance of city infrastructure and the planning of future urban interventions. In this paper, a novel approach to crowd-mapping urban objects is proposed. Our method capitalizes on strategies for generating crowdsourced object annotations from street-level imagery, in combination with object density and geo-location estimation techniques to enable the enumeration and geo-tagging of urban objects. To address both the coverage and precision of the mapped objects within budget constraints, we design a scheduling strategy for micro-task prioritization, aggregation, and assignment to crowd workers. We experimentally demonstrate the feasibility of our approach through a use case pertaining to the mapping of street trees in New York City and Amsterdam. We show that anonymous crowds can achieve high recall (up to 80%) and precision (up to 68%), with geo-location precision of approximately 3m. We also show that similar performance could be achieved at city scale, possibly with stringent budget constraints.

1 INTRODUCTION

Streets, squares, plots, and buildings constitute the most important elements that shape the physical form of cities [27]. Integral to these elements are city objects such as trees, lamp posts, and other artifacts of urban infrastructure (e.g. benches, fire hydrants etc.). The combination and configuration of physical elements and their constituent objects contribute to the "character" of a city [17] and lead to different formations of the urban fabric [6, 15]. An up-to-date knowledge of the amount and distribution of physical elements and objects across the urban fabric is of vital importance in planning future urban interventions.

At present, the process of constructing such body of knowledge is based on two main approaches. The first, and more traditional one, relies on commissioned authoritative work, by means of on-site documentation conducted by municipal workers [2, 4]. This method usually entails high costs, in addition to being laborious and time consuming. The second approach involves the voluntary contribution of geographic information, which is enabled by collaborative mapping platforms, e.g. OpenStreetMap [5, 12]. On one hand, its participatory and voluntary nature makes it a less costly approach to mapping the urban environment. On the other, it makes it prone to limited participation and, subsequently, to variable spatial coverage and precision [24]. Moreover, it assumes a degree of familiarity of the contributors with the places mapped [5]. Although it has been shown that actual knowledge of a place contributes to the amount and quality of the provided content [13, 24], it could also be seen as a limiting factor, in terms of the number of individuals who can actively create and assemble data about a place.

One way to make contributors familiar with an area of interest, without requiring knowledge at the local level, is by means of street-level imagery. The recent availability of this type of image data through online platforms, such as Google Street View and Mapillary, could enable the documentation of physical elements of the urban environment from a wider pool of potential contributors. Street-level imagery provides panoramic digital representations of – mostly – open public spaces along the street network. Contrary to the widely-used satellite imagery, it simulates the process of a person walking along the streets, thereby providing a detailed three-dimensional overview of visible spatial elements (e.g. building frontages, trees, lamp posts, trash bins, and other objects of the built environment). Given its high penetration rate, currently covering all major cities in the world, it could open up new avenues in perceiving, documenting, and understanding urban systems.

The coupling of street-level imagery with state-of-the-art computer vision and machine learning techniques enables the automatic discovery of highly recognizable recurring objects (e.g. traffic lights, street lamps) [18, 35]. However, with object types characterized by high visual variability (e.g. trees), automatic approaches suffer from severe identification and geo-location accuracy issues.

Recent studies [8–11, 31] have shown that the combination of street-level imagery with micro-task crowdsourcing can successfully engage a larger number of contributors – possibly unfamiliar with the targeted urban area – through object annotation tasks. While demonstrating the feasibility of a micro-task crowdsourcing approach, these works do not fully address the important quality and scalability issues that generally characterize large scale object annotation campaigns. Two issues are of importance: 1) the precision of object detection and geo-location within an area of interest, and 2) the ability to cover large areas within budget constraints.

Original Contributions. In this paper, we introduce a novel approach to crowd-mapping physical objects of the urban environment. Our method enables the annotation and geo-tagging of urban objects along the street network, through the combination of (a) cost- and worker quality-aware strategies for micro-task scheduling and assignment, and (b) inference methods for object density and geo-location estimation. We develop a dedicated Web user interface that facilitates urban object annotation by crowd workers, using Google Street View imagery as a proxy for real-world places. Annotation, geo-location estimation, and aggregation techniques allow us to map the objects in space, and to estimate their location. A specifically designed scheduling strategy estimates the density of objects in street segments in an iterative fashion, and uses it to prioritize mapping tasks with the aim to maximize the coverage of the mapped objects within budget constraints. Task assignment strategies allocate workers in accordance to their measured annotation quality, so as to improve the geo-location estimation quality.

To evaluate our method, we conducted two experiments. Specifically, we use areas of New York City and Amsterdam as case studies, and focus on the estimation of the number and location of trees along their street networks. Results show that through the proposed Crowd Mapping interface and geo-location estimation techniques, it is possible to engage anonymous crowd workers and achieve high recall (up to 80%) and precision (up to 68%), with geo-location precision of approximately 3m. Using a discrete event simulation technique, we show that it is possible to obtain high object density estimation precision (up to 80%) and promising geo-location precision (up to 85%) at city scale, also with limited budget availability.

The remainder of the paper is organized as follows: Section 2 discusses related work. In Section 3, we present the logical organization of the proposed crowd-mapping method. Section 4 introduces the Web interface for urban object annotation, and describes in detail the methods used to geo-locate and aggregate the labeled annotations. Section 5 describes the developed scheduling, task aggregation, and task assignment strategies. In Section 6, we present the configuration and metrics of the conducted experiments regarding the evaluation of our proposed method. In Section 7, we present and discuss the results of the experiments. Finally, Section 8 summarizes the conclusions and discusses future lines of research.

2 RELATED WORK

We address previous work on crowdsourcing with street-level imagery, and then discuss the relevant work about using street-level imagery to mapping urban objects. We acknowledge the existence of abundant literature related to task assignment and scheduling strategies (e.g. [14, 34]) for crowdsensing. However, as this paper specifically focuses on crowd-mapping with street-level imagery, we consider the analysis of such literature outside of our scope.

2.1 Crowdsourcing using Street-level Imagery

Previous work has addressed the problem of integrating crowdsourcing and street-level imagery, to enable task execution by workers through Web-based platforms. In an early feasibility study [9] manually created a database consisting of 100 images from Google Street View. Researches from the same group afterwards studied the combination of crowdsourcing and Google Street View to identify street-level accessibility problems [10] and developed an online curb ramp data collection system *Tohme* [11]. The system enables workers to remotely label curb ramps through Google Street View with the assistance of computer vision and machine learning techniques. The combination of crowdsourcing techniques and street-level imagery has further applications in risk assessment studies and, particularly, the vulnerability of structures against earthquakes [28]. Relevant techniques have also been applied in medical- and health-related research [3, 33]. Street-level imagery, informed by data from parents of school children, has been used as an efficient alternative to on-site observations for the assessment of the environmental characteristics of cycling-to-school routes [33].

These studies show the feasibility of a crowdsourcing approach to urban scenes and object labeling through street-level imagery. However, issues of accurate object detection and geo-tagging, scalability, and cost received limited attention. To the best of our knowledge, our work is the first to fill this gap.

2.2 Mapping Urban Objects using Street-level Imagery

Street-level imagery is increasingly used in studies concerned with the mapping of urban objects. *Mapillary* [1] is a dataset consisting of 400M street-level images covering 6M kilometers worldwide, in which images are processed with computer vision, and identified objects are connected to open-source and commercial mapping platforms (such as OpenStreetMap, and Here) [26]. Street-level imagery has already been an important data source for mapping urban trees. *Treepedia* is a project estimating the vegetation index of cities. Researchers proposed a method that can automatically detect urban greenery with computer vision by assessing street-level imagery from Google Street View [20, 21]. The urban canopy cover was mapped in Singapore using the hemispherical photographs from Google Street View [29]. Similar works are also conducted in Chinese cities with alternative street-level imagery sources, such as Tencent Street View [23]. It is also used in the detection and mapping of other types of physical objects. Balali et al. used images from Google Street View to detect, classify, and map traffic signs of two interstate highways in the United States [1].

[1] https://www.mapillary.com/

Street-level imagery has also been used in the classification of POI types [25]. Previous work used deep learning techniques to geo-locate and match a street-level image to an aerial one [22].

Work on the automatic analysis of street-level imagery still suffers from geo-localization issues. Moreover, the lack of training datasets results in limited applicability to object types that present high visual variability (e.g. trees). Our work is complementary to these effort, and can simplify the collection of street-level imagery training data for computer vision.

3 METHOD

The Crowd Mapping method proposed in this paper is organized in three sequential steps, elaborated in Algorithm 1: (1) initialisation, (2) Crowd Mapping, and (3) geo-location prediction. The algorithm takes as *input* a set of n streets $ST = \{st_1, st_2, \cdots, st_n\}$ pertaining to an urban area of interest. Streets are partitioned into segments, where $S(st) = \{s_1, s_2, \cdots, s_l\}$ is the set of segments of a given street $st \in ST$, and $U_S = \{S_1, S_2, \cdots, S_n\}$ is the set of all street segments. The set $E = \{e_1, e_2, \cdots, e_m\}$ defines all the physical objects of a given type that are present in the targeted area; in the scope of our work, each object $e = (lat, lng)$ is described by the World Geodetic System (WGS) coordinates of its lat and lng. We define x_s the *density*[2] of urban objects contained in a street segment $s \in U_S$; $X(st) = \{x_1, x_2, \cdots, x_l\}$ is the corresponding set of segment densities in a street st; and $U_X = \{X_1, X_2, \cdots, X_n\}$ is the universe of all sets densities.

Algorithm 1: The proposed Crowd Mapping method

Input: all the streets ST, workers W, and *budget*.
Output: estimated physical elements of a given type $\hat{E}$

```
// Step 1: Initialization
U_S ← Segmentation(ST) ;
T ← InitTaskGeneration(U_S) ;
// Step 2: Crowd Mapping with Street Level Imagery
while budget > TaskMaximumCost() ∨ T = ∅ do
    w ← GetNewWorker(W);
    t ← TaskAssignment(T, w);
    A ← A ∪ AnnotationUI(w, t);
    budget ← budget − TaskCost() ;
    T ← T − t ;
    Ê, U_X̂ ← Aggregation(A);
    H_PS ← SegmentScheduling(U_S, U_X̂);
    T ← T ∪ TaskGeneration(H_PS) ;
end
// Step 3: Geolocation Prediction
Ê ← Ê ∪ GeoLocationPrediction(Ê, H_PS, ST);
```

Given ST, a set $W = \{w_1, w_2, \cdots, w_i\}$ of available crowd workers, and a *budget*, the goal of our method is to calculate: (1) the set $\hat{E} = \{\hat{e}_1, \hat{e}_2, \cdots \hat{e}_m\}$ of estimated physical objects; and (2) the set $U_{\hat{X}} = \{\hat{X}_1, \hat{X}_2, \cdots, \hat{X}_n\}$ of estimated segments density. Indeed, $|\hat{E} \cup E| \neq |E|$, as the crowd mapping activity could miss existing objects, or produce non existing ones, due to crowd mapping issues. Conversely, all $\hat{X}_n$ are estimated.

The first step, `Initialisation`, segments each street within ST according to a defined *segmentation* policy (e.g. streets are split in segments of at least 50 meters), to create the set $U_S = \{S_1, S_2, \cdots, S_n\}$ of street segments. Here each $s \in S_n$ is a unit of work. The initial set of crowd tasks $T = \{t_1, t_2, \cdots, t_j\}$ is then created, where each task t contains one or more segments from U_S that are selected and aggregated according to an *initial task generation* strategy (e.g. include one random segment from each street).

The `Crowd Mapping` step, executed until either *budget* is available or $T = \emptyset$, involves the creation of the object *annotations* set $A = \{a_1, a_2, \cdots, a_j\}$ through a Web interface. An annotation $a \in A$ is a *bounding box* drawn on a street-level image by a worker w. Annotations are aggregated by means of an *aggregation function* that progressively populates the set $\hat{E}$, and the set $U_{\hat{X}}$ for the considered segments. The details of the annotation user interface and aggregation strategies are described in Section 4. As segments get annotated, new tasks are created by a *Segment Scheduling* strategy, which establishes the priority of all pending segments into a priority queue H_{PS} that is then used to generate new tasks. A *Task Assignment* strategy distribute tasks to available workers. Section 5 describes the segment scheduling and Task Assignment strategies.

The final `Geo-location Prediction` step enriches the set $\hat{E}$ by predicting the location of urban objects in segments that are not annotated by crowd workers. This could be done by using the density information acquired from the second step, including measured or estimated segment densities, and the location of objects in nearby segments. The adopted geo-location prediction method heavily depends on the targeted urban object, as the regularity of spatial distribution varies significantly among different objects (e.g. street trees and lamp posts are usually more regularly distributed than trash bins). We describe a prediction method in Section 6, where we elaborate on the use case addressed in the experiments.

4 CROWD MAPPING OF URBAN OBJECTS WITH STREET-LEVEL IMAGERY

This section describes the Crowd Mapping step (i.e. Step 2). Section 4.1 describes the Web user interface supporting the *annotation* of urban objects using Street-Level Imagery. Section 4.2 and Section 4.3 respectively elaborate on the methods used to geo-locate and aggregate annotations for urban object mapping.

4.1 User Interface

Figure 1 presents the Web user interface for object annotation. The top-left panel renders the Street-Level Imagery (SLI) exploration widget; the worker can virtually visit an urban area of interest by navigating between *bubbles* [16], i.e. 360° panoramas that provide a photorealistic impression of an area as seen from a given viewpoint. The user can pan and zoom inside the bubble, and move towards contiguous bubbles. The **ANNOTATE** button activates the object annotation interface, described below. The bottom-left panel contains a map of the area under analysis, with the segments pertaining to the current annotation tasks masked. Visual clues provide the workers with an indication of the explored bubbles

[2]With a slight abuse of terminology, we refer to *density* as to the normalized number of objects in a given street segment.

Figure 1: Urban Object Annotation Web interface. In the example, workers are asked to annotate *street trees*.

Figure 2: Object Annotation Procedure.

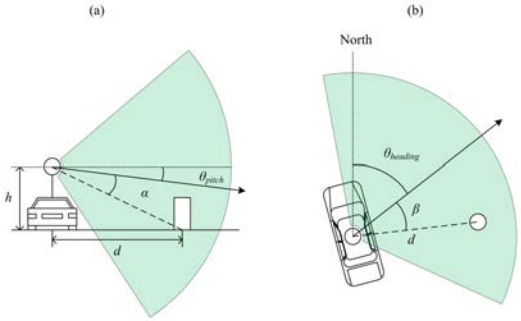

Figure 3: Estimation of the distance between the observation viewpoint and the object's center (a) and geo-location (b).

(red *footprint* dots), and of the location of the provided annotations (green *annotation* dots). The bottom panel contains a task description, a task progress bar, and commands to teleport to the previous or next segments to analyze. The right panel lists all the objects annotated in the current task, and allows the workers to teleport back in the same bubble where the annotation has been made. Finally, the SUBMIT button finalizes the task. The interface supports different SLI and map services, including Google Street View.

The annotation interface is central to the mapping task, as it allows for the estimation of an object's geo-location. We assume an object's coordinates to indicate the centroid of its bottom surface. As we show later, this is a precondition for geo-location estimation. Workers are asked to draw the bounding box as described in Figure 2, according to the following steps: (1) Position the mouse pointer at the center point of the object's bottom surface. If this point is not obvious or occluded by other objects, workers should estimate the position of the point. (2) Click and drag the mouse upwards to draw a symmetrical box that bounds the object.

4.2 Linking Individual Crowd Annotations to Geo-Locations

Street-Level Imagery is typically acquired by vehicles (e.g. cars and bicycles) equipped with 360° image acquisition devices. The geo-location of a bubble (i.e. the virtual observation viewpoint) corresponds to the geo-location of the vehicle at the image acquisition time, as acquired by a GPS device. As shown in Figure 3(a), the distance d between the bubble geo-location and the geo-location of the annotated object can be calculated using $h/\tan(90° - \theta_{pitch} - \alpha)$, where h is the height of the camera installed on the acquisition vehicle. The pitch angle θ_{pitch} (i.e. the up or down angle of the camera) is one of the essential parameters of a street-level panorama image. The angle α and β (in Figure 3(b)) are the angles between the central ray of camera and the ray casting to the bottom of the object in vertical and horizontal plane respectively, which could be estimated from the relative position of the bounding box on the Street View panel.

Figure 3(b) shows how the geo-location of an object could be estimated, using the calculated distance, and the $\theta_{heading}$ could be acquired from parameters of the panorama image. Then, assuming the current latitude and longitude of the observation viewpoint are (lat_{cam}, lng_{cam}), the relative Cartesian coordinate (rx_a, ry_a) (if the coordinate origin is the location of camera) of an annotation a can be calculated as:

$$\begin{cases} rx_a = C_a^x h, \\ ry_a = C_a^y h, \end{cases} \quad \begin{cases} C_a^x = \frac{\cos(90^\circ - \theta_{heading} - \beta)}{tan(90^\circ - \theta_{pitch} - \alpha)}, \\ C_a^y = \frac{\sin(90^\circ - \theta_{heading} - \beta)}{tan(90^\circ - \theta_{pitch} - \alpha)}. \end{cases} \tag{1}$$

where C_a^x and C_a^y are coefficients of the parameters (such as heading, pitch, etc.) of the annotation a, and the arc length of each degree of latitude is approximately $L = 111300$ meters. The WGS coordinate of the annotation a can then be calculated as:

$$\begin{cases} lat_a = lat_{cam} + ry_a / L, \\ lng_a = lng_{cam} + rx_a / [L \cos(lat_{cam})]. \end{cases} \tag{2}$$

Camera Height Correction. The height h of the camera is the only parameter that could not be measured nor estimated from the user interface. In the case of Google Street View, online documentation suggests that the height of the camera is around 8.2 feet[3]. We however account for different acquisition configurations, and for differences in altitude between the street and the object's bottom surface. The camera height might also be inconsistent due to different vehicles and different acquisition time. Therefore, we estimate an optimal camera height to minimize the measurement error. High accuracy annotations can be acquired for the set of objects $SE \in E$, and the relative Cartesian coordinate (rx_e, ry_e) of the exact location of the urban object $e \in E$ can be expressed as:

$$\begin{cases} rx_e = L(lng_e - lng_{cam}) \cos(lat_{cam}), \\ ry_e = L(lat_e - lat_{cam}). \end{cases} \tag{3}$$

Having the Cartesian coordinates of all the real objects in the sample set SE and the corresponding high-quality annotations, the camera height correction minimizes the distances between these pairs (e, a_e). Specifically, the following cost function indicating the mean square error should be minimized:

$$J(h) = \sum_{e \in SE} \{[rx_e - rx_{a_e}(h)]^2 + [ry_e - ry_{a_e}(h)]^2\}. \tag{4}$$

After differentiation, the corrected camera height is:

$$\hat{h} = \frac{\sum_{e \in T}(rx_e C_{a_e}^x + ry_e C_{a_e}^y)}{\sum_{e \in T}({C_{a_e}^x}^2 + {C_{a_e}^y}^2)}. \tag{5}$$

4.3 Aggregation of Crowd Annotations for the Location Estimation of Urban Objects

To improve the quality of the estimation, the same object is annotated multiple times, possibly by different crowd workers. While each single annotation might be imperfect – as well as its geo-location estimation – it is reasonable to assume that different labels for the same object will be distributed around its centroid, and that the location of the object should correspond to the highest density of annotations. Traditional density-based clustering algorithms such as DBSCAN are sensitive to a density threshold parameter. We use the clustering algorithm proposed in [30] and extend it to account for the quality $quality_w$ of the worker that performed the aggregation. In Algorithm 2, the density ρ of objects is first calculated (Lines **1–3**). The function $dis(a, a')$ calculates the distance between the estimated geo-locations of a and a', and it is used to estimate the minimum distance δ_a between the annotation a and any other annotation with higher density (Lines **4–6**). Finally, the location of all objects $\hat{E}$ is calculated by selecting annotations whose δ_a is larger than the minimum threshold δ_{min} (Lines **8–14**).

Algorithm 2: Geo-location aggregation algorithm

Input: all annotations A, the minimum distance threshold between trees δ_{min}, radius $r = \delta_{min}/2$ for calculating density

Output: estimated geo-locations $\hat{E}$

```
1  for each annotation a ∈ A do
2  |  ρ_a ← Σ_{a'∈A:dis(a,a')<r} quality_{w_a'} ;
3  end
4  for each annotation a ∈ A do
5  |  δ_a ← min_{a'∈A:ρ_a>ρ_a'} {dis(a, a')} ;
6  end
7  Ê = ∅;
8  for each annotation a ∈ A do
9  |  if δ_a > δ_min then
10 |  |  lat ← Σ_{a'∈A:dis(a,a')<r} quality_{w_a'} lat_a'/ρ_a' ;
11 |  |  lng ← Σ_{a'∈A:dis(a,a')<r} quality_{w_a'} lng_a'/ρ_a' ;
12 |  |  Ê ← Ê ∪ (lat, lng);
13 |  end
14 end
```

5 SEGMENT SCHEDULING AND TASK GENERATION

To maximize the coverage and quality of estimation within budget constraints, street segments must be scheduled, aggregated in tasks, and assigned to crowd workers.

5.1 Segment Scheduling

The *Segment Scheduling* (Algorithm 1, **Line 10**) operation is responsible for the prioritization of segments to be allocated to crowd masking tasks. Scheduling is logically organized around a priority queue (heap) data structure, which orders segments to be analyzed according to their priority. Segments with the highest priority are at the head of the heap and are, therefore, selected first. Prioritization is generally related to the likelihood of the successful prediction of object densities $U_{\hat{X}}$, while simultaneously optimizing budget consumption. Such likelihood is assumed to be unknown in advance and must, therefore, be calculated dynamically from the annotations produced by crowd workers on processed segments.

We define $AS = \{as_1, as_2, \cdots, as_{l_a}\}, AS \in S$ as the set of segments that have been already annotated by crowd workers; $PS = \{ps_1, ps_2, \cdots, ps_{l_p}\}, PS \in S$ is the set of segments yet to be annotated. Clearly, $AS \cap PS = \emptyset$, $AS \cup PS = S$. Considering spatial

[3] A Glimpse of Google's Fleet of Camera-Equipped Street View Cars. https://petapixel.com/2012/10/15/a-glimpse-of-googles-fleet-of-camera-equipped-street-view-cars/

dependence, deriving from Tobler's first law of geography [32], we assume that it is more likely for adjacent street segments to feature a similar amount and configuration of urban objects. It is therefore possible, with some degree of uncertainty, to walk a street in a given direction and build a density model for that street. In other words, we can assume that the probability of the object density of a street segment depends on the object density of its previous segment. We can easily calculate the density of the segment $as \in AS$ using the estimated objects $\hat{E}$. The question is how to predict the missing density of the segment $ps \in PS$.

Our solution, called **Maximum Likelihood** (ML) of density prediction is inspired by the *Greedy-based Minimization Entropy* algorithm [14]. We model the object density of street segments as a Markov model. $\hat{X} = \{\hat{x}_1, \hat{x}_2, \cdots, \hat{x}_l\}$ is the set of object densities of all segments in S. The probability of object density $\hat{x}$ of a segment s is a function of the object density $\hat{x}'$ of the previous segment s', which is denoted as $p(\hat{x}', \hat{x})$. When the densities $\hat{x}_\sigma$ and $\hat{x}_\tau$ of two segments (s_σ and s_τ) from the same street are calculated, it is therefore possible to estimate the density of the other segments located between them. Thus, the problem is to find the most likely density sequence $\hat{X}_{\sigma\to\tau} = \{\hat{x}_{\sigma+1}, \hat{x}_{\sigma+2}, \cdots, \hat{x}_{\tau-1}\}$. The estimated density is $\hat{x} = k/length, \hat{x} \in \hat{X}_{\sigma\to\tau}$, where $k \in K = \{0, 1, 2, \cdots, k_{max}\}$ is the possible amount of objects and $length$ is the length of the street segment $s \in S$. k_{max} is the maximum possible amount of object, which is used for limiting the estimation range.

The optimal density sequence is efficiently calculated with dynamic programming. Let $D_{s,k}$ record the maximum likelihood of the sequence (the product of all the transition probabilities) from the crowd-annotated density $\hat{x}_\sigma = k_\sigma/length$ to a possible density $\hat{x}_s = k/length, \sigma < s < \tau$. The final goal is to maximize D_{τ,k_t} and estimate the most likely sequence $\hat{X}_{\sigma\to\tau} = \{\hat{x}_{\sigma+1}, \hat{x}_{\sigma+2}, \cdots, \hat{x}_{\tau-1}\}$. $D_{s,k}$ can be calculated using the following equations (here s' means the previous segment of s):

$$\begin{cases} D_{\sigma,k_\sigma} = 1, \\ D_{s,k} = \max_{k' \in K}\{p(k',k) D_{s',k'}\} \end{cases} \tag{6}$$

Algorithm 3 describes how the most likely sequence is finally calculated. During the process of predicting the density of pending segments, the likelihood π of optimal prediction of the street can be calculated by the following equation:

$$\pi = \prod_{s \in AS : s' \in PS} D_{s', \hat{x}'_s length} \tag{7}$$

For each street, the scheduling strategy calculates the priority of segments by first calculating the product of likelihood of the optimal prediction of all streets, which is denoted as $\prod_\pi$. Then, we use the predicted density $\hat{x}$ of the pending segment as "true" analyzed data, and take it together with the density values of analyzed segments AS to re-calculate the product of likelihood of the optimal prediction of all streets, which is denoted as $\prod'_\pi$. The final segment priority is then determined as $priority = \prod'_\pi - \prod_\pi$.

5.2 Task Generation

Task generation is performed 1) at task initialization time (Algorithm 1, **Line 2**), when no prior information about the distribution of urban objects is available; and 2) at run time (Algorithm 1, **Line 11**), after segment scheduling. We employ a *street-based initialization strategy* where, for each street, the first and the last segments of streets are first selected. At run-time, tasks are selected by drawing street segments from the heap, as shown in Figure 4.

Algorithm 3: Dynamic programming. Find the most likely state sequence

Input: Initial density $x_\sigma = k_\sigma/length$ and $x_\tau = k_\tau/length$, the set of possible number of objects $K = \{0, 1, 2, \cdots, k_{max}\}$, transition probability function p

Output: the most likely density sequence $\hat{X}_{\sigma\to\tau} = \{\hat{x}_{\sigma+1}, \hat{x}_{\sigma+2}, \cdots, \hat{x}_{\tau-1}\}$

```
1  D_{σ,k_σ} ← 1 ;
2  for each s ∈ {σ + 1, σ + 2, ··· , τ} do
3      for each k ∈ K do
           // s' means the previous segment of s.
4          D_{s,k} ← max_{k'∈K}{p(k', k) D_{s',k'}} ;
           // Variable pre records the sequence.
5          pre_{s,k} ← arg max_{k'∈K}{p(k', k) D_{s',k'}} ;
6      end
7  end
   // Get the most like sequence using pre.
8  k = pre_{τ,k_τ} ;
9  for each s ∈ {τ − 1, τ − 2, ··· , σ + 1} do
10     x̂_s ← k/length ;
11     k ← pre_{s,k} ;
12 end
```

As tasks are typically published in batches having the same monetary compensation for workers, it is important to balance the total amount of time needed to complete a task. Segments might have variations in length; their *exploration* might, therefore, require different amounts of time. Similarly, segments contain a varying amount of objects to be annotated. We, therefore, introduce the notion of segment *workload*, which is defined as follows:

$$workload = length + w \cdot \hat{x} \cdot length, \tag{8}$$

where w is used to balance the effort needed for *exploration* (that is proportional to the segment length), and the effort needed for *annotation*, which is proportional to both the segment length and the estimated amount of objects in it. In a set of preliminary experiments conducted with crowd workers of the FigureEight[4] platform, we found that the average time needed for object annotation (8.05 seconds) is 2.5 times longer than the time needed for exploration (3.20 seconds per meter). We therefore set $w = 2.5$. At task initialization, when no prior information is available about the density of objects, the *workload* is calculated only using segment length information.

Segments are, therefore, included in tasks in a greedy fashion, until the sum of their workload reaches a predefined minimum value that is proportional to the targeted total task execution time and compensation.

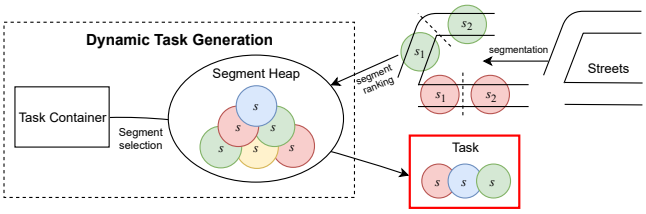

Figure 4: Heap-based Task Generation.

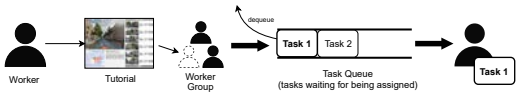

Figure 5: Single-queue Assignment Strategy.

5.3 Worker Quality-Aware Task Assignment

A task includes several street segments. To acquire annotations for the same street segments and objects, tasks are assigned to multiple workers. The quality of incoming workers is assessed through an initial evaluation task.

Worker Quality Evaluation. After reading the task instructions, the worker is offered an assessment task to perform on segments and objects with known geo-location. The quality of the worker is assessed according to three properties: the annotation recall (R), precision (P), and root mean square error ($RSME$):

$$R = \frac{\#\text{ of annotated objects}}{\#\text{ of objects in assessment}} \qquad P = \frac{\#\text{ of correct annotations}}{\#\text{ of annotations of the worker}}$$

$$RMSE = \sqrt{\frac{\sum (\text{distance from groundtruth annotations})^2}{\#\text{ of correct annotations}}}$$

We consider an annotation to be correct if its distance from the targeted objects is lower than a given *threshold*. The worker *quality score* is evaluated by synthesizing these three properties as:

$$\text{quality score} = (1 - RMSE/threshold) + recall + precision \quad (9)$$

Task Assignment Strategies. We consider two strategies.

Single-queue Assignment Strategy. This task assignment strategy is commonly used in microtask crowdsourcing. Tasks are pushed in an execution queue, and then served to workers according to their order of arrival (Figure 5). Tasks are de-queued when the number of required workers is reached.

Multi-queue Assignment Strategy. The final annotation quality can be significantly affected by the performance of their workers. Previous work [36] suggests that the overall quality can be increased by assigning workers with different quality levels, while keeping the average worker quality of each task as high as possible. Inspired by the finding in skill-and-stress-aware assignment [19], the Multi-queue Assignment Strategy divides workers into three groups (*low*, *medium* and *high*) by ranking them according to their quality score, and equally splitting the rank in three groups.

The multiple-queue strategy builds three tasks queue corresponding to three quality levels. After evaluating the quality level of the worker, the task at the head of queue of the same quality level will

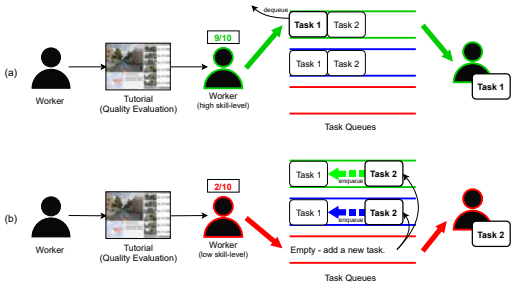

Figure 6: Multi-queue Task Assignment Strategy.

be de-queued and assigned to the worker (Figure. 6 (a)). If there is no task in the queue of the same quality level as worker's, a new task will be generated and assigned to the worker. Meanwhile, this task will be queued into the other two queues, waiting for being assigned to workers with different quality levels (Figure. 6 (b)).

6 EXPERIMENTAL SETUP

We conducted a number of experiments to investigate: (RQ 1) to what extent can the designed interface, geo-location annotation, and aggregation algorithms lead to correct and complete maps of urban objects when operated by crowd workers from micro-task crowdsourcing platform; and (RQ 2) to what extent the proposed segment scheduling and task assignment strategies can provide correct and complete maps within budget constraints. In this section, we provide details on the case study, the adopted datasets, experimental configuration, and evaluation metrics.

6.1 Case Study: Mapping Street Trees

Urban green infrastructure (e.g. street trees, parks etc.) is an integral set of physical objects and elements comprising the urban fabric [15] [6]. Trees have obvious ecological benefits in terms of air quality and heat regulation, and further contribute to defining the "character" of an urban area. It is therefore important to regularly record information about their location, properties (e.g. tree type), and status for maintenance and planning purposes. American cities such as New York[5] and San Francisco[6] have tree census projects that are run in collaboration, between the municipalities and volunteer organizations. The municipality of Amsterdam, began to record the information about trees since 1875.[7] Although of significant value for cities and communities, tree mapping is still a tedious and expensive task to perform.

6.2 Cities and Datasets

The experiments focus on two regions of two world cities [7], respectively New York City's Manhattan borough, and the area of Amsterdam that is defined by the ring of the A10 highway. We retrieve information about the street networks from OpenStreetMap[8], excluding pedestrian ways, bicycle ways, and other similar types

[5] https://tree-map.nycgovparks.org
[6] https://urbanforestmap.org
[7] www.amsterdam.nl/bomen
[8] https://www.openstreetmap.org/. We selected streets whose tag is *motorway*, *trunk*, *primary*, *secondary*, *tertiary*, *residential* or *unclassified*.

of streets for which associated street-level imagery might not be available. Ground truth data about the location of trees have been collected from the *New York City Street Tree Map* project[9] and the official trees dataset from the municipality of Amsterdam.[10]

We removed from the ground truth datasets trees that are at a distance larger than 30 meters from the street's mid-line, to heuristically exclude trees that could belong to parks or other public spaces (e.g. squares). Table 1 provides basic statistics on the number of streets and the total number of urban trees in the considered datasets. While these datasets are extensive, they are difficult to maintain and can contain errors. The Google Street View panel has been configured to display the latest available version of SLI. We acknowledge the likely presence of temporal mismatches between SLI acquisition time and the dataset update. We address the issue when manually refining the set of street segments used in RQ1 (Section 7.1). However, we ignore such inconsistencies in the experiments addressing RQ2, considering the emerging differences negligible in the context of the experimental goal.

Table 1: Dataset Statistics on the Two Areas of Interest.

# Urban elements and objects	**Manhattan**	**Amsterdam**
# Streets	4081	9084
# Trees	57499	88512
# Segments	18676	23974
Segment Length (m)	44.60 ± 6.45	39.46 ± 10.81
Segment Tree density (#/100m)	3.15 ± 7.34	5.77 ± 11.75

6.3 Configurations

Our crowd-mapping method has a number of parameters that can be configured.

Street Segmentation. We set the maximum length of each segment to 50 meters, to allow for short micro-tasks and reduce annotation fatigue. All segments belonging to the same street have equal length, which is calculated as $length_{st}/(\lceil length_{st}/50 \rceil + 1)$. The resulting number of segments is reported in Table 1.

Camera Height Correction. For each city, we manually select 10 segments with abundant vegetation, and accurately annotate the trees they contain. The locations of these trees are used to estimate the corrected camera heights, which are set to 1.979 and 1.730 meters in Manhattan and Amsterdam, respectively.

Geo-location Prediction. The last step of the crowd-mapping method must be customized for the urban object at hand. For the targeted use case, we designed a simple interpolation method that predicts the location of trees in non-annotated segments from the estimated location of objects in contiguous street segments. To achieve this, we calculate (1) the distance between the centroid of the tree (on both sides of the street) and the mid-line of the street, and (2) the distance between the centroids of adjacent trees in the annotated segments. Based on the corresponding measured distances of the last trees in the annotated segments, we perform the interpolation to estimate the number and location of trees in the non-annotated parts.

Annotation Task Configuration. The urban object annotation Web interface has been deployed on the Figure-Eight platform. For each segment, we collected three judgments. To maximize diversity in the pool of recruited workers while providing sufficient incentives for participation, we allowed workers to perform a maximum of three annotation tasks per city. As a quality control mechanism, workers were allowed to submit the task (and receive compensation) only if the whole area covered by the task segments was explored, and if the exploration of each segment lasted at least 60 seconds. The minimum *workload* for each task has been set to 500 (see Section 5.2), with an average hourly compensation greater than the current US minimal wage. In Figure Eight preliminary experiments, each task contains one segment.

For each city, 50 segments were selected (for RQ1) as follows. We retrieved the vegetation index for each segment in the street networks of New York City and Amsterdam from Google satellite imagery using the vegetation index equation from previous work [21]. We then performed importance sampling on the segments, where the frequencies of samples were sorted according to the vegetation index (importance weight) on the segments. Given that the vegetation index is measured from satellite imagery, it cannot fully reflect the amount of trees at the street level. Therefore, we excluded some street segment that were selected by the sampling method, but were not compatible with our experimental setup. These street segments are usually at the outskirts of the areas in question and contain a large amount of trees that are not included in the ground truth data set. Eight segments from Manhattan and nine segments from Amsterdam were, respectively, excluded, resulting in 42 remaining sampled segments for Manhattan (i.e. 2.2‰of the total number of street segments, 5.4‰of the total number of urban trees) and 41 for Amsterdam (i.e. 1.7‰of the total number of street segments, 3.8‰of the total number of urban trees).

6.4 Evaluation Metrics

We evaluate the performance of crowd workers, annotation aggregation, density prediction, and geo-location prediction against the ground truth in the selected datasets. We consider an annotation *correct* if its distance from the corresponding tree in the ground truth dataset is equal to or lower than 5 meters.

In terms of density estimation, we measure *Density Prediction* (*DP*) and *Density Mean Square Error* (*DE*) as follows:

$$\mathrm{DP} = \frac{|\{s|\text{Density Error} = 0,\ s \in S\}|}{|U_S|} \quad \mathrm{DE} = \hat{x}_s - \frac{|E_s|}{length_s} \tag{10}$$

where E_s is the set of physical objects (i.e. street trees in this case) of the segment s. In terms of object geo-location, we measure *Recall* (R), *Precision* (P), and *Root Mean Square Error* as follows:

$$\mathrm{R} = \frac{\#\text{ annotated objects}}{|E|} \quad \mathrm{P} = \frac{\#\text{ of correct annotations}}{\#\text{ of all aggregated annotations}}$$

$$\mathrm{RMSE} = \sqrt{\frac{\sum_{\text{correct annotations}} (\text{annotation error})^2}{\#\text{ of correct annotations}}}$$

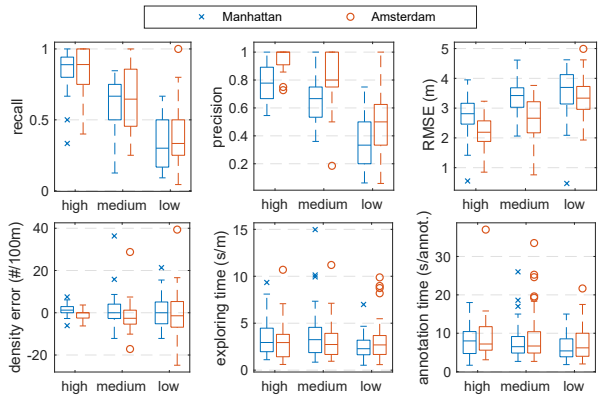

Figure 7: Performance distribution of FigureEight workers.

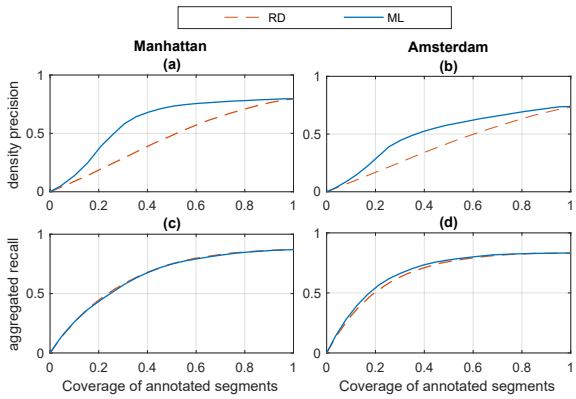

Figure 8: Density precision and Aggregated Annotations Recall for increasing segment coverage with SQ task assignment strategy.

7 RESULTS AND DISCUSSION

7.1 RQ1: Crowd Mapping with Street-Level Imagery

A total of 71 and 63 unique workers (Level 3) from Figure-Eight selected the annotation tasks for Manhattan and Amsterdam, respectively. On average, $N = 44$ workers were *Somewhat Satisfied* by the task (3.9/5); they were *neutral* with regard to task difficulty (2.9/5); they found the instructions and the interface *Somewhat Clear* (3.8/5), the quality control *Somewhat Fair* (3.9/5), and the compensation *Somewhat better* than similar tasks (3.8/5).

We manually processed the results. From the Manhattan experiment, we excluded 26 task executions where workers provided no annotations, or the annotation was of bad quality. In Amsterdam, 9 task executions were excluded for the same reasons. With the remaining judgments, we split workers into three quality classes (High, Medium, and Low) of equal size.

Table 2 and Figure 7 show the performance of crowd workers. The precision, recall, and RSME of high-quality individual workers are remarkably high. As expected, worker annotation recall and precision decrease with the worker quality level (high to low) in both Manhattan and Amsterdam, while RMSE increases. The resulting density error is good in general, with larger standard deviation at lower quality levels. Interestingly, workers in Manhattan have (on average) a positive density error, whereas the Amsterdam ones have a negative error. A manual inspection of the worker annotations shows no significant difference between workers of similar quality. We, therefore, account the issue to the mismatch between the tree datasets (the latest updated Manhattan dataset is from 2015) and Google Street View imagery. The aggregation method generally mitigates the impact of low-quality annotations, although the precision is negatively affected. Workers of lower quality tend to speed through tasks, but only the difference in exploration time between the low-quality level and the other two levels in Manhattan is of statistical significance (Wilcoxon rank-sum test, $p < 0.1$). Furthermore, the differences in recall, precision, and RMSE across quality levels are also of statistical significance. Other metrics are of no statistical significance across all quality levels ($p > 0.1$).

7.2 RQ2: Segment Scheduling and Task Assignment

To test the performance of the segment scheduling and task assignment strategies, we simulated the behavior of workers by drawing their annotation performance (in terms of precision, recall, and RSME) from the distribution of the workers that participated in the previous experiment. We fed these distributions to a Discrete Event Simulation (DEVS) system that mimics the exploration and annotation behavior of workers of different quality.

When a simulated worker annotates an object, the *Precision* similation parameter decides whether the annotation is correct or not; the error (distance) between simulated annotations and the object following normal distribution $N(0, RMSE)$, while the direction of annotation follows a uniform distribution $U(0, \pi)$. The *Recall* parameter controls the number of correctly annotated objects in a segment. For each experimental configuration, the simulation has been run five times.

Segment scheduling strategy. We first test the performance of the Maximum Likelihood (ML) scheduling strategy (Section 5.1). We employ the single-queue (SQ) task assignment strategy, and compare ML against a random segment scheduling baseline, where segments from U_S are picked randomly. Figure 8 (a) and (b) illustrates how the density precision increases, with regard to increased annotated segments – i.e. allocated *budget*: 100% of segment coverage can be achieved with infinite funds. Note that density precision measures density estimation with *zero* estimation error. ML can achieve greater density precision at lower coverage levels. The maximum performance gain of ML against RD is respectively obtained in at 35% segment coverage, with 35% increase in Manhattan and 22.23% increase in Amsterdam. Table 3 ($\mu \pm \sigma$ of five simulation executions) shows that the average density prediction error also decreases.

Figure 8 (c) and (d), and Table 3 show that ML can provide small improvements in terms of predicted tree locations. This is an expected result, as the Geo-location step implemented in this experiment does not make use of the predicted segment density.

Table 2: $\mu \pm \sigma$ (average and standard deviation) of recall, precision, RMSE (meter), density error (# of objects per 100 meters), normalized exploration time (second/meter), and normalized annotation time (second/annotation) of Figure Eight workers.

Parameters	Manhattan				Amsterdam			
	High	Medium	Low	Aggregation	High	Medium	Low	Aggregation
Recall	0.85 ± 0.15	0.61 ± 0.19	0.33 ± 0.18	0.75 ± 0.33	0.85 ± 0.17	0.64 ± 0.22	0.38 ± 0.21	0.80 ± 0.23
Precision	0.79 ± 0.14	0.66 ± 0.16	0.35 ± 0.18	0.54 ± 0.20	0.96 ± 0.07	0.81 ± 0.17	0.48 ± 0.25	0.68 ± 0.26
RMSE	2.75 ± 0.62	3.41 ± 0.60	3.35 ± 0.80	3.19 ± 0.73	2.26 ± 0.50	2.59 ± 0.74	3.36 ± 0.70	2.74 ± 0.73
Density error	1.28 ± 2.65	1.56 ± 8.32	0.20 ± 8.20	2.16 ± 4.19	−0.97 ± 2.19	−1.71 ± 7.13	−0.53 ± 10.08	−0.39 ± 5.37
Exploration Time	3.55 ± 1.99	3.88 ± 3.05	2.54 ± 1.27	/	2.97 ± 2.03	3.10 ± 2.07	3.21 ± 2.33	/
Annotation Time	8.06 ± 3.66	7.98 ± 5.00	6.48 ± 3.53	/	8.69 ± 5.71	9.25 ± 7.06	7.82 ± 4.70	/

Table 3: $\mu \pm \sigma$ density error (# objects / 100m), annotation precision and RMSE (meter) of predicted annotations, with SQ task assignment, unlimited $budget$

City	*Strategy*	Density Prediction	Predicted Annotations	
		Error	Precision	RMSE
Manhattan	*RD*	1.22 ± 0.05	0.04 ± 0.00	3.51 ± 0.07
	ML	1.11 ± 0.02	0.04 ± 0.00	3.51 ± 0.02
Amsterdam	*RD*	0.64 ± 0.03	0.05 ± 0.00	3.50 ± 0.01
	ML	0.55 ± 0.03	0.05 ± 0.01	3.51 ± 0.01

Task assignment strategy. We compare the performance of the multiple-queue (MQ) task assignment strategies against the single-queue (SQ) baseline. In both cases, we employ the ML scheduling strategy, and we simulate an unlimited *budget*. As the MQ task assignment is designed to mitigate the impact of low-quality workers, we progressively skew the distribution of workers towards the low-quality end: in MQ2, half of the workers are of low quality, a third of medium quality, and a sixth of high quality. In MQ3 only low quality workers are simulated. Results ($\mu \pm \sigma$ of five simulation executions) are summarized in Table 4. While recall remains similar to SQ, the precision of the aggregated annotations substantially increases, and the RSME also lowers. Density estimation error and precision also improve. Table 4 reports the performance variations brought by lower quality workers. As the proportion of low-quality workers increases, recall, precision, and RSME progressively worsen. When half of the worker population is of low quality, the recall (-0.03 and -0.01) and RMSE (+0.05 and +0.03) variations in Manhattan and Amsterdam respectively are still acceptable, but the precision is still significantly higher than for the SQ strategy. MQ3 brings more extreme performance decay, especially for recall. In terms of density estimation, precision remains generally similar; density error substantially increases only in the MQ3 configuration.

Table 4: Estimation performance with multiple-queues (MQ) scheduling strategy, and unlimited $budget$.

City	*Strategy*	Aggregated Annotations			Object Density	
		Recall	Precision	RMSE	Error	Precision
Manhattan	*SQ*	0.87 ± 0.00	0.44 ± 0.00	3.04 ± 0.01	1.71 ± 0.02	0.80 ± 0.00
	MQ	0.87 ± 0.00	0.67 ± 0.01	2.89 ± 0.01	0.13 ± 0.01	0.84 ± 0.00
	MQ2	0.84 ± 0.00	0.62 ± 0.00	3.09 ± 0.01	0.11 ± 0.03	0.83 ± 0.00
	MQ3	0.60 ± 0.01	0.46 ± 0.00	3.46 ± 0.00	−0.54 ± 0.05	0.82 ± 0.00
Amsterdam	*SQ*	0.83 ± 0.00	0.55 ± 0.00	2.36 ± 0.01	1.10 ± 0.04	0.73 ± 0.00
	MQ	0.83 ± 0.00	0.87 ± 0.00	2.18 ± 0.01	−0.72 ± 0.02	0.80 ± 0.00
	MQ2	0.82 ± 0.00	0.79 ± 0.00	2.39 ± 0.01	−0.69 ± 0.01	0.78 ± 0.00
	MQ3	0.71 ± 0.01	0.58 ± 0.01	3.32 ± 0.00	−1.37 ± 0.09	0.74 ± 0.00

7.3 Discussion

RQ1. Results show that the designed user interface and overall annotation experience have been positively received by workers. The task has been perceived as moderately difficult, yet the overall judgment has been positive. The annotation, geo-location estimation, and aggregation methods also proved reasonably accurate: despite the approximations introduced by the different technologies (e.g. the α and β angles estimated through the position of the bounding box, Figure 3), our interface achieved geo-location accuracy comparable to GPS-enabled smartphones[11]. A main simplification in the proposed approach concerns the estimation of the camera height h (Section 4.2). The difference of the height of the camera with regard to the terrain level of the targeted object could vary greatly, thus leading to inaccurate annotation geo-location estimation. Workers of high quality achieved remarkable precision, recall, and RSME performance. The impact of low quality workers on the aggregated annotations suggest the introduction of better in-task quality control mechanisms. Considering the average exploration and annotation time, the annotation of Manhattan and Amsterdam would take a total of **4.11** and **5.85** man months, and would cost 33K$ and 46K$ respectively.

RQ2. The Maximum Likelihood (ML) scheduling strategy allows for good density prediction and errors, also at low segment coverage levels. While the performance increase as regards the random scheduling strategy is not overwhelming, it is important to notice that the method is not informed by any prior knowledge about the distribution of physical objects in the city. We believe that the integration of third-party data sources in the density prediction could result in better coverage/recall ratio. On the other hand, we observed that the prediction performance of the geo-location estimation step is relatively low. This is neither surprising nor discomforting, as the developed method is rather simple. The multi-queue task assignment strategy brought clear benefits in terms of aggregated annotation precision, and proved reasonably robust to workers with lower annotation quality.

8 CONCLUSION

In this paper, we have presented an approach to crowd-mapping urban objects from street-level imagery. The proposed method is novel with regard to the combination of an object annotation Web interface for micro-task crowdsourcing with object density and geo-location inference methods. Task scheduling and assignment strategies provide increased performance in terms of cost/quality

[11] https://www.gps.gov/systems/gps/performance/accuracy/

ratio. Through a use case pertaining to the mapping of urban greenery along streets, we have demonstrated the feasibility of the approach, showing very good annotation, geo-location estimation, and aggregation figures, and promising object density prediction performance. This work is only the first step towards a better understanding of how crowd-mapping with street-level imagery can provide accurate and economic object annotation data. In future work, we plan to improve the density and object geo-location estimation methods by incorporating third-party sources (e.g. greenery indexes) and machine learning techniques for object identification. We believe that active learning techniques and hybrid workflows could lead to more accurate and cheaper annotations. Finally, we aim to extend our experiments to other cities and classes of objects.

ABSTRACT

Measuring and characterizing web page performance is a challenging task. When it comes to the mobile world, the highly varying technology characteristics coupled with the opaque network configuration make it even more difficult. Aiming at reproducibility, we present a large scale empirical study of web page performance collected in eleven commercial mobile networks spanning four countries. By digging into measurement from nearly two million web browsing sessions, we shed light on the impact of different web protocols, browsers, and mobile technologies on the web performance. We find that the impact of mobile broadband access is sizeable. For example, the median page load time using mobile broadband increases by a third compared to wired access. Mobility clearly stresses the system, with handover causing the most evident performance penalties. Contrariwise, our measurements show that the adoption of HTTP/2 and QUIC has practically negligible impact. To understand the intertwining of all parameters, we adopt state-of-the-art statistical methods to identify the significance of different factors on the web performance. Our analysis confirms the importance of access technology and mobility context as well as webpage composition and browser. Our work highlights the importance of large-scale measurements. Even with our controlled setup, the complexity of the mobile web ecosystem is challenging to untangle. For this, we are releasing the dataset as open data for validation and further research.

1 INTRODUCTION

We are witnessing two major changes in the Internet. On the one hand, smartphones and mobile broadband (MBB) networks have revolutionized the way people consume web content. On the other hand, web protocols are undergoing a deep rethinking, with the advent of SPDY [33], HTTP/2 [18] and now QUIC [39], that are designed to improve performance and overcome HTTP(S) [27, 48] and TCP bottlenecks.

In this dynamic scenario, the ultimate goal is improving the end-user quality of experience (QoE) for companies that aim at offering better services to their customers. Natural questions arise: Which are the major factors that affect web performance in MBB networks? What are the benefits of HTTP/2 and QUIC? How do mobility or browser choice impact the user experience? Are MBB networks at the point where they are able to offer QoE on par with wired networks?

Measurements are vital to answer such questions and to gauge the impact of the changes in the Internet. Not surprisingly, the research community has put a lot of effort towards empirical quantification of the benefits of new technologies. However, to the best of our knowledge, previous work mainly focused on specific measurement setups, and on specific angles of this otherwise complex ecosystem. The intertwining of technologies, protocols, setups and website design makes it very complicated to answer the above questions, to design and run scientifically sound and robust measurement campaigns.

In this paper, we present a large scale measurement campaign that we carefully designed following the scientific principles of

repeatability and reproducibility. To this end, we leverage the open access MONROE [14] platform that allows us to run measurements with full control of devices scattered in more than 100 locations across four different countries and connected via 11 commercial MBB providers. We instrument the measurement campaign over a period of two months and collect nearly two million page visits of popular websites, which we further augment with metadata about the MBB channel and network status. We dig into this large amount of data to quantify the penalties when accessing the web using 3G or 4G access technology, under mobility, and the benefits of adopting HTTP/2 or QUIC rather than HTTPS. We quantify differences using state of the art statistics tools that allow us not only to obtain the significance of the measurements, but also to study which parameters affect results the most.

The contributions we make in this paper are four-fold. First, we present our methodology to design large-scale and scientifically sound measurements (Section 3). We offer all collected data to the community in the effort of allowing researchers to verify and to extend our findings. Second, we quantify the impact of MBB access technology in both stationary and mobile scenarios. We use two web browsers (Firefox and Chrome), and three objective QoS metrics (First Paint, Page Load Time, and RUMSpeedIndex). With respect to wired access, results consistently show significant penalties in MBB networks, with mobile nodes suffering further penalties due to changing channel conditions, and inter-technology handovers (Section 5). Third, we investigate deeper the benefits of HTTP/2 and QUIC versus HTTPS (Sec 6). In some specific cases (in benchmarking pages), we do see HTTP/2 improvements. In the wild, however, results show marginal benefits and controversial figures. Even when comparing impact on wired networks, we record no significant benefits in 55% of back-to-back visits, with the rest of measurements equally split among HTTP/2 performs better than HTTPS, and conversely. When moving to MBB scenarios, the additional randomness of the setup makes it even harder to observe any significant benefits. QUIC does not change the picture either. Fourth, data analytics unveils the impact of single features that characterize the context in which browsing occurs (Section 7). Our results show that there is a large number of features that significantly impact web performance, and, ultimately, QoE. Among these, the MBB access technology and mobility context, along with webpage composition and the browser used are among the most important.

Before moving into the details of our contributions (Sections 3-6), we present background and related work in Section 2 and we follow up our analysis with concluding remarks in Section 8.

2 BACKGROUND AND RELATED WORK

There are mainly three approaches for measuring the performance and reliability of MBB networks: (i) crowd-sourced measurements [44, 49, 54], (ii) operator's measurements [31, 32, 51, 52], and (iii) measurements collected using dedicated infrastructure [16, 38, 50]. In this paper, we collect data from the MONROE dedicated infrastructure to gain full control over the measurements and systematically collect a rich quality dataset over more than two months.

With respect to the web, HTTP/1.1 [27] has been the de-facto standard for loading webpages since 1999. With the increasing complexity in webpages, HTTP/1.1 (also HTTP over TLS or HTTPS -hereinafter H1s- [48]) has been shown to limit the performance of web access [56] due to problems such as inefficient use of concurrent TCP connections [47] and header overhead. To improve web performance, Google proposed SPDY [33], which soon led to HTTP/2.0 -hereinafter H2- [18]. The latter uses a single multiplexed TCP connection per domain, allowing request prioritization. Efficiency is further optimized through header compression. However, TCP is still a bottleneck because of handshaking latency and head-of-line blocking. To address these shortcomings, Google proposed QUIC [34, 39] that uses UDP instead of TCP.

The relative performance difference between HTTP versions has received much attention [13, 20, 25, 26, 30, 40, 45, 58–61, 63]. The results are mixed, hence it is hard to make a clear conclusion on which version is better and under which circumstances. Moreover, there is no systematic attempt to characterize HTTP performance for MBB users. Similarly among [19, 23, 34, 39, 42] we found only few experimental works on QUIC performance in operational networks [39] with real webpages, while rest of them considered synthetic webpages with testbed settings. We aim to present a large-scale web measurements campaign using operational MBB networks across different countries. We not only measure the protocol difference from different vantage points, but also set the operators performance in a common scale. We run measurements using two popular browsers (Chrome and Firefox) to present how the protocols behave in different browsers.

Previous works also differ in the metric they chose to evaluate performance. Work in [19, 25, 26, 39, 40, 42, 57, 60, 64] used the page load time (PLT), a metric primarily based on OnLoad event fired by the browser. Unfortunately, PLT does not tell much of the user experience [2, 21, 35, 55]. An alternative metric is First Paint, which tells how long it takes to see something on the screen [21, 28]. SpeedIndex captures the user perceived experience [8, 10, 11]. However, it requires to *film* the page loading process. The RUMSpeedIndex method was proposed to estimate the SpeedIndex using "resource timing" data [4, 6, 9]. ObjectIndex and ByteIndex are similar in goal [21]. Additionally, [29] proposed the "3rd Party Trailing Ratio" metric, which measures the fraction of download time for the 3rd party assets on the webpage critical path. In our measurements, we consider Page Load Time, First Paint and RUMSpeedIndex.

We tackle the need for understanding the relationship between web performance and network characteristics. For example, while generating a model to determine a webpage's QoE, Balachandran et al. [15] found evidence of the impact of the number of users and radio access technology (RAT) handovers on the webpage performance. They discovered that the performance is greatly affected by a website's own complexity (e.g., number of objects, domains visited) with some influence of the time-of-day feature. They show that understanding non-binary QoE metrics (e.g., latency, download progress, etc.) requires regression modeling. Here, we use regression to dig into our measurements and bring to light the correlations between various aspects of the browsing process and the experience of the users.

3 MEASUREMENTS DESIGN

For our extensive measurements campaign, we engineer a flexible setup that on the one hand allows us to investigate as many different scenarios as possible, and on the other hand follows the best practice of scientific approach by letting us control as much as possible the experimental setup, with reproducibility in mind. In the following, we describe the experiment design and the collected dataset.

3.1 Experimental Setup

For our experiments, we rely on the MONROE platform, the first European open access platform for independent, multi-homed, and large-scale mobile measurements on commercial providers. Overall, the geographical extent of our measurement campaign covers four countries in Europe (Italy, Norway, Spain and Sweden). The platform comprises a set of 100 nodes equipped with Ethernet, WiFi and 3G/4G interfaces with commercial MBB subscriptions. Nodes operate either under mobility (e.g., on-board of trains or buses) or in stationary scenarios (e.g., in laboratories, or hosted by volunteers in homes).

We leverage a customizable Docker container called MONROE-browsertime [5] (based on [7]) that we specifically engineered and deployed on MONROE nodes. We configured MONROE-browsertime to mimic a mobile device browser (by setting both the screen resolution and the user-agent accordingly) to retrieve the mobile versions of the visited pages. With it, we direct the browser to load a page and, at the end of page rendering, execute a custom JavaScript script to collect a large number of metrics. We use the X virtual framebuffer (Xvfb) [12] for display emulation to let the browsers actually render the webpages. MONROE-browsertime provides a configurable experiment template to enable web measurements. We configure each measurement by controlling (i) the network to test (Ethernet, or the desired MBB interfaces), (ii) the browser (Firefox 56.0.1 or Chrome 64.0.3282.186), and (iii) the web protocol (H1s , H2, or QUIC).[1] A combination of these parameters builds an *experiment setup*.

We select a list of target pages to visit. Considering the time constraints of the MONROE platform, we select 20 target pages on popular websites with H2 support from the most viewed sites in the Alexa [3] top ranking, see Table 1. We avoid the landing page in case it is too trivial (e.g., visiting `https://instagram.com/leomessi/` instead of `https://instagram.com/`). This ensures that our selection covers a wide range of user interests in terms of topics, including social networks, video, career, education, search engine, travel help, news, wiki and shopping. All websites expect TLS connections by default. This allows us to run fair comparison between H1s and H2.

Given a network to test, we shuffle the order of pages to visit. Next, we visit each page with every browser and protocol combination, in a random order. The visit of all pages with one network setup constitutes a *run*. Browser caches and cookies are active during each run, and cleaned when the last page has been tested. Note that we use separate profiles for the same browser, one for each protocol, so that caches are separated (i.e., visits with H1s do not interfere with next visits to the same pages with H2 and vice-versa). We execute four rounds of measurements per day.

[1]The nodes use the mobile carrier DNS resolver consistently with the operator currently in use.

3.2 Web QoE Metrics

In this paper, we track three main metrics for our analysis: Page Load Time (PLT), FirstPaint (FP) and RUMSpeedIndex (SI), which we detail next. The tool derives these metrics from browser timing metrics [1], [41] that record the timing of different rendering phases of a page, from the initial DNS resolution to each HTTP request, from JavaScript processing to objects rendering.

First Paint (FP): It corresponds to the time when the browser starts rendering the first element of the page. This happens as soon as the first element of the page has been fetched and processed, and after the downloading of all needed elements (e.g., stylesheets).

Page Load Time (PLT): This is the time the last object in the page has been downloaded. It occurs when all the HTML files and any sub-resources (images, fonts, css, videos, etc.) are loaded. Note that not all these elements are needed to complete the rendering of the visible portion of the page.

RUMSpeedIndex (SI): It monitors the rendering process of the page by tracking the evolution of visible rectangles with elements that loaded external resources in a page. The original SpeedIndex requires to film the rendering process, and to postprocess the video to observe changes. Given the limited resources of the MONROE nodes (in terms of CPU, storage and communication bandwidth), we opt for the RUMSpeedIndex approximation, which uses the sequence of events as reported by the browser to estimate the time in which the visible portion of the screen would be modified [9]. Intuitively, it calculates the likely time that a paint event happens, given the processing and downloading of the various elements by the browser. This is considered a QoE approximation, since it considers the evolution of the rendering process as seen by the user.

Given the interplay of objects, rendering, and visible portion of the page on the screen, there is no clear ordering on the metrics. For instance, the rendering of a page can start after one, or some, or all objects have been downloaded. Similarly, the rendering process may involve a portion of the area which is not currently on the visible part on the browser window. In addition, analytics objects are typically downloaded as last elements, after the rendering is completed, thus inflating the PLT. For this, it is consistent to compare results considering the same metric, but it is not appropriate to compare across different metrics.

3.3 Metadata Metrics

Context information is crucial. MONROE gives access to the information about network, time and location, as well as metadata from the mobile modems, including cell ID, signal strength, and connection mode. We log all this information, and associate it to each experiment for later post-processing, to understand the impact of the different operator configurations, the radio coverage, and all the time varying parameters that may impact the page rendering process.

More specifically, we collect the following parameters: i) **Experimental context**: This includes the type of browser, the protocol, the node type (stationary/mobile) and the distance the node travelled during an experiment. ii) **Access Network context**: This

Table 1: List of the target webpages and their corresponding number of domains and objects. The table details the % of H2 resources in each page obtained using Chrome.

includes parameters from the the Radio Access Technology (RAT) (more specifically for 3G and 4G technology) such as radio status before the start of the experiment (Initial RAT, Initial Reference Signal Received Quality (RSRQ), Initial Reference Signal Received Power (RSRP), Initial Received Signal Strength Indicator (RSSI)) and the radio changes throughout the experiment (median values for RSRQ, RSRP, RSSI parameters, the number of RAT handovers), and average RTT against the target webpage server (measured via Ping). iii) **Web context:** This includes metrics that characterize the single web page visit, such as the number of objects or the total amount of data being downloaded.

3.4 Dataset Description

For experiments in this paper, we deploy MONROE-browsertime on 100 MONROE nodes, measuring 11 mobile operators in 4 countries. We ran our measurement campaign for more than 2 months, from 1st of April 2018 to 4th of June 2018. This dataset focuses on measurements considering H1s and H2 protocols. In total, we collected performance for about 1.8 million page visits, as detailed in Table 2, of which 550,000 under mobility in trains, buses or trucks. In addition to MBB tests, we run experiments using wired connectivity for those nodes operating in campus networks and connected via regular 100Mb/s or faster Ethernet interfaces. These experiments constitute our baseline.

As a first step, we performed data cleaning by identifying anomalies in the data. Indeed, we observed inconsistencies in the results from `Google search` - Chrome and Firefox were showing different results for the same search url - and `Linkedin` - this site was blocking visits from our nodes, detecting the repeated page visit as illegitimate crawlers, or attacks. We have discarded these sites from any further processing. We also removed those experiments in which either the browser could not complete the page download or some metadata were missing.

We run a separate measurement campaign for measuring the performance of the QUIC protocol as compared to H2. This batch of experiments ran during a week, from the 5th to the 10th of June 2018. We focused here on websites that supports QUIC (version 39): `Google search`, `Youtube`, `Lightspeedtech`, `Keycdn`, `Meetup`, `Justwatch`, and `Free-power-point-templates`. We used only Chrome browser (the only one supporting QUIC). After performing data cleaning operations, we collected approximately 80 000 samples.

To summarize, our full dataset includes nearly two million page visits, a deluge of data that – to the best of our knowledge – constitutes the largest experiment of mobile web performance tests on commercial operators. We open the data for further processing and to enable reproducibility.[2]

Table 2: Statistics on the dataset; the country shows where the subscription is active.

Operator Name	# Tot. Measurements	# Mobile
Telia (SE)	246 839	41 936
Telenor (SE)	249 459	45 580
Tre (SE)	223 050	43 469

Yoigo (ES)	142 502	0
Orange (ES)	44 528	0
Total	1.8M	550K

Dataset limitations. Despite all the care we took in designing our experiment to ensure that they are extensive, repeatable, and with limited biases, we discuss some limitations that we could not avoid.

We measure using MONROE hardware, which integrates three 3G/4G MC7455 miniPCI express mobile broadband modems supporting LTE CAT6 on top of PC Engines APU2D4 boards [53]. The end-user experience is strongly correlated with the device of the end-user [24, 43], especially for web browsing. Our design aims to remove device bias and capture a wide geographical footprint with one single type of device.

We use commercial-grade mobile subscriptions for our measurements. While this represents what end customer can get, we do not know which specific configuration each MBB operator is using for each of these (e.g., in terms of QoS, or presence of proxies commonly found in MBB networks [36]). As such, our results do not generalize all possible subscriptions, nor in different locations.

The differences in commercial offers reflect in the different data quota which in turn affects the dataset we can collect. We explicitly opted to limit the number of pages in our tests and prefer several repetitions of the same test to obtain a large dataset where we can obtain statistically significant results for each page. Completing a single experimentation takes about 2 hours, making it impossible to cover more pages.

The disparities in the number of samples we could collect from each node stem from the way the MONROE scheduler assigns experiments to the nodes based on their available monthly data

[2] https://zenodo.org/record/2574157

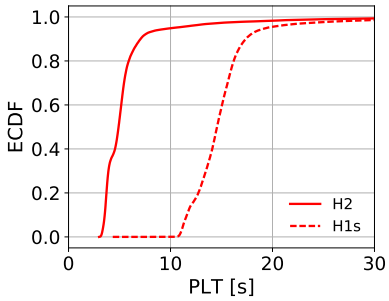

Figure 1: ECDF of PLT when accessing httpvshttps.com using H2 and H1s.

quota. For example, we observe in Table 2 that the number of samples for Orange (ES) (limited data plan, 10GB) is much smaller than the number of samples we collected for Telia (SE) (very large data plan, 200GB). Moreover, because of the MONROE deployment strategy, we do not have any mobility measurements in Spain.

The RUMSpeedIndex represents a client-side approach for measuring the Speed Index metric using Real User Monitoring (RUM). Though this metric is appropriate for our experimental setup and goes along the idea of the original Speed Index metric of measuring how much of the "above-the-fold" content is visually complete until the web page has finished loading, it also has a series of limitations. Specifically, it only works for browsers that support Resource Timings, it does not handle content within iframes and does better for Chrome which supports reporting a "first paint" event.

4 VALIDATION OF THE EXPERIMENTAL SETUP

Before digging into measurements, we validate out setup by using a specifically crafted page that allows one to gauge the benefites of H2 vs. H1s, the www.httpvshttps.com page. Hosted by cloudflare, it contains 360 not-cacheable identical images (each 20×20 pixels, 1.7 kB each) with a total of 604 kB. All images are hosted from a single domain. This scenario is particularly beneficial for H2 which can multiplex all the HTTP requests over a single TCP connection and benefit of header compression. Conversely, H1s would open a large number of TCP connections each suffering from TCP and TLS handshaking overhead and TCP's slowstart. H2 is therefore expected to provide much faster web performance than H1s.

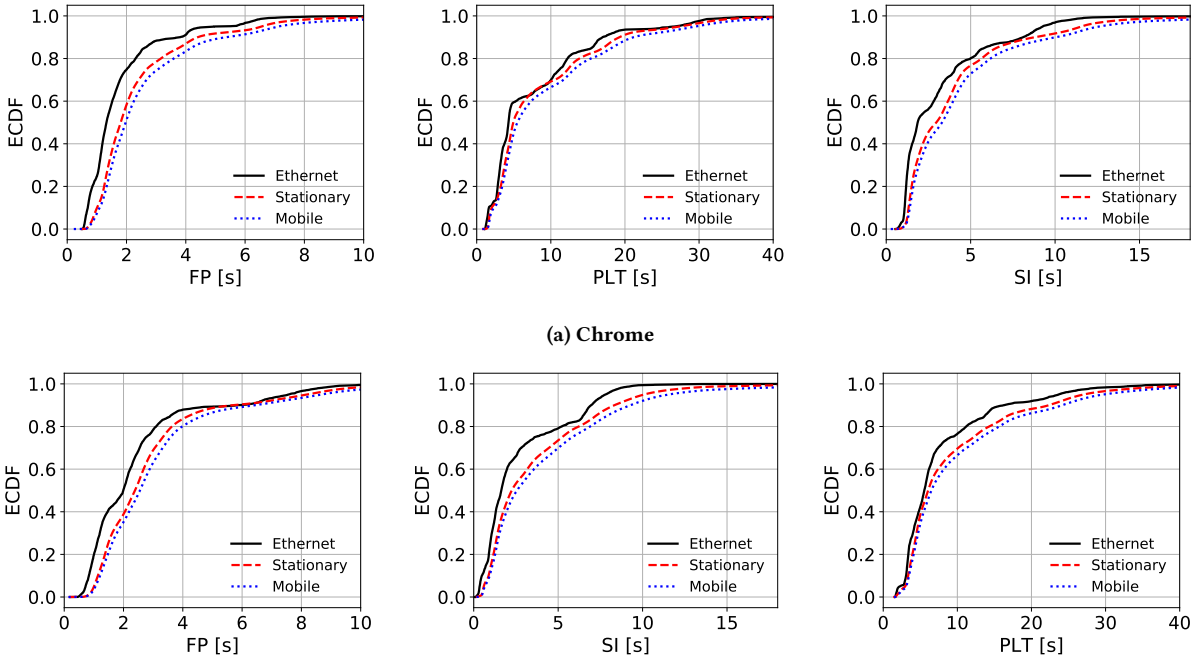
We run a preliminary validation test on all MONROE nodes for every hour continuously for five days producing a total of 130 000 page visits. Figure 1 shows the Empirical Cumulative Distribution Function (ECDF) for PLT for both browsers. H2 provides much better performance than H1s as expected. In nearly 90% visits, H2 manages to load the whole page under 5s whereas using H1s, the PLT rises well over 15s for 80% visits. The behaviour stays similar when we separate the browsers (Firefox and Chrome). This simple test shows that our testbed is giving consistent and realistic results.

5 BROWSING CONTEXT IMPACT

In this section, we explore our measurement results and highlight the impact of major parameters, such as MBB access and mobility. We then dig into more details to quantify the impact of radio access status leaving the discussion on web protocol impact to Section 6.

5.1 Mobile Access and Browser Impact

We aim to assess the impact of MBB access and mobility compared to wired access. Figure 2 shows results separately for Chrome (on the top) and Firefox (on the bottom). For each metric (notice the different scales), we calculate the ECDF for i) stationary nodes with wired connection (black solid line), ii) stationary nodes with MBB connections (red dashed line), and iii) mobile nodes with MBB connections (blue dotted line). Smaller values correspond to better performance.

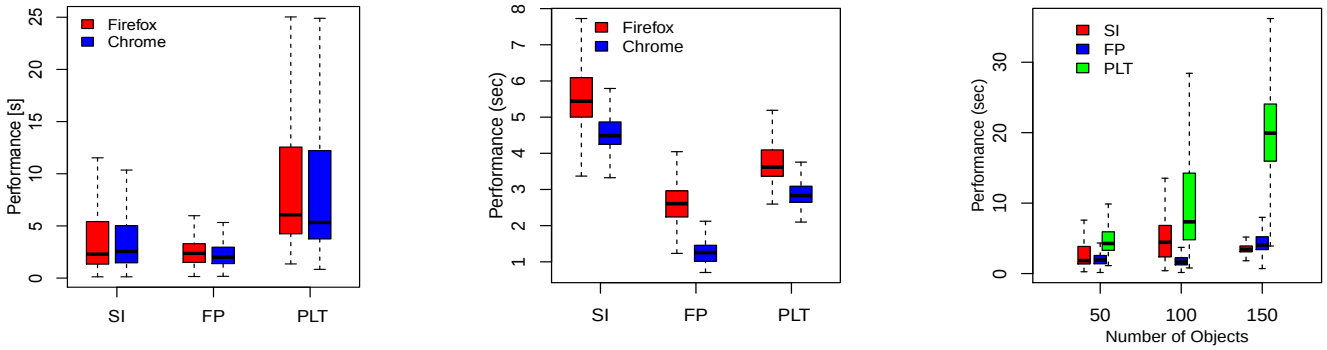


Few considerations hold: First, wired connections have better performance than 3G/4G stationary nodes, which in turn perform better than 3G/4G mobile nodes (consistent across all metrics). Interestingly, the performance degradation with respect to wired high-speed access is much more visible than the impact of mobility. For instance, the FP in Chrome (top-left figure) shows that the median worsens by 36.5% when comparing Wired and MBB access, and only by 9.6% when comparing stationary and mobile nodes. We verified this to be consistent in single pages, and found more complex pages to be more impacted (as expected).

Second, all ECDFs exhibit a heavy tail in measurements, with the mass of the distribution concentrated on low values and a non-negligible number of samples that reach much higher indexes. This is more evident for MBB tests. For example, in the case of FP for Chrome, we note 60-80% of pages start the rendering process in 2-3 seconds. But more than 20% of pages have to wait for more than 4-6 s (i.e., a 2x factor). This heavy tailed distribution is consistent on all pages, hinting at variability among single experiments.

Third, and less intuitive, results on Firefox and Chrome are hardly comparable. For example, for the FP metric (top plots, Figure 2), Firefox clearly has worse performance than Chrome. However, when checking the PLT (bottom plots, Figure 2), the difference is much less evident. To analyze this in more detail, we focus on the measurements we collect from stationary nodes in Sweden, and compare the impact of the browser. Figure 3a shows much less evident results, with Chrome performing slightly better than Firefox. However, when restricting to a single website, results can change dramatically, depending on the target website. For example, for the case of ebay in Figure 3b, we note that Chrome is faster and less variable than Firefox.

Fourth, the impact of the number of objects of the target website (Figure 3c) differs depending on the metric. Page rendering may start only after some specific object has been downloaded (e.g., fonts, CSS, and background images) which may be loaded later, as captured by FP, but is not directly related to the total number of objects on the page. The PLT metric, on the other hand, tends to be affected by pages that include analytics services that are loaded as the last object – and often after executing complex scripts. Thus, we observe that PLT may increase considerably with number of objects.



Takeaway: MBB access and mobility are factors that impact performance in a consistent way. However, even in controlled environments we observe a lot of variations for all performance metrics and there are different factors that impact the page rendering process in a not trivial way. We investigate this in detail in Section 7.

(a) Chrome

(b) Firefox

Figure 2: Browsing performance on commercial MBB networks in two different scenarios (moving and stationary mobile devices) considering all three metrics for two browsers. We use the browsing performance on fixed Internet provider connectivity (Ethernet) as a baseline.

(a) Browser impact (all). **(b) Browser impact (*ebay*).** **(c) Websites structure impact.**

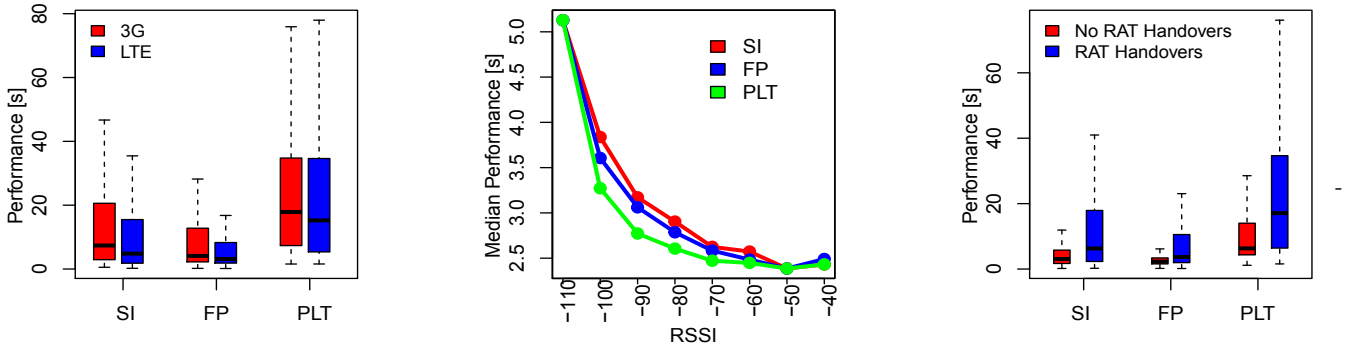


Figure 3: Impact of experimental context (browser type and target website) on PLT, FP, and SI, aggregated over all webpages in Sweden.

5.2 Network Context Impact

As the capacity of the mobile networks continues to increase, users expect better performance. As we saw in the previous section, MBB access and mobility significantly impact the user experience and it correlates with highly varying network conditions. With MBB technologies that are much more complex than wired access, we need to delve into more details to understand what is the impact of particular setup.

We first observe the impact of the Radio Access Technology (3G and 4G/LTE). Using the experiments from nodes within Sweden under mobility scenarios, Figure 4a captures the impact of RAT on web performance. The better performance offered by 4G/LTE technology benefits the FP and SI albeit not as dramatically as one would expected [46]. Instead, the PLT seems to be marginally affected. Again, this is due to the PLT definition which needs to wait for the last object to be downloaded. In most cases, this is inflated by analytics objects (notice the median in the 20 s, a time that would translate in poor QoE for users).

Coverage of MBB networks is also expected to clearly affect performance. This is captured in Figure 4b, where the median performance clearly degrades under poor signal strength conditions. The figure shows results from *Reddit* web experiments performed in Sweden. Interestingly, the RSSI has a non-linear effect, with

(a) RAT impact (all). **(b) Signal Strength Impact (*Reddit*).** **(c) Inter-RAT Handovers Impact.**

Figure 4: Impact of network context on PLT, FP, and SI, aggregated over all webpages in Sweden.

sudden degradation for RSSI smaller than -80dBm. Above -60dBm, we observe no further improvement, an important observation for network operator's looking for optimal network configuration.

As a last parameter, we showcase the impact of the number of handovers under mobility, reported in Figure 4c. Here we compare experiments with no inter-RAT handover against experiments where at least one inter-RAT (3G to 4G or vice-versa) handover has been observed. Results clearly show the penalty introduced by inter-RAT handovers, with a worsening factor of 2x on the average, and worst case up to 5x slower (when several inter-RAT handovers are suffered).

Takeaway: Coverage and inter-RAT handovers [17], are among the most prominent causes of web performance degradation. However, their impact is not linear. Faster technologies bring some, but limited benefits. As known for wired networks [46], for MBB we observe that the performance gets increasingly latency-bound when network speed increases.

6 WEB PROTOCOL IMPACT

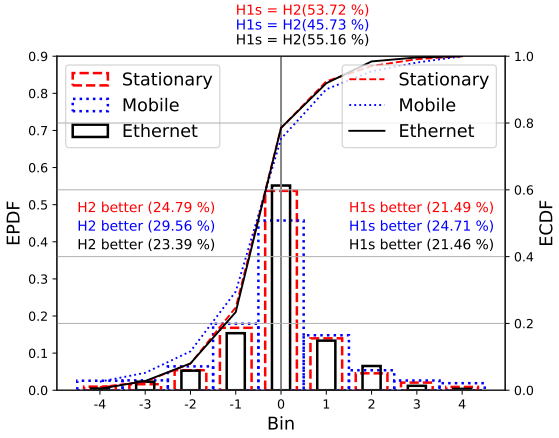
This section provides an in depth quantification of the benefits of using new protocols such as H2 and QUIC compared to the original H1s standard.

6.1 H1s vs H2 Impact

We first compare performance when using H1s and H2. We consider back-to-back visits to the same page. The first visit uses one protocol and the second visit uses the other one. Node, operator, browser and location are same for both visit. Based on the PLT reported in Figure 2, these two visits can happen in a limited time window (20 urls * 2 protocols * 20 seconds = 800 s ∼ 13.3 minutes) in more than 90% of the experiments. Thus, we pick any two visits that happened within 15 minutes between each other, and directly compare page visit performance. The aim is to provide a sound comparison between the two protocols under as much similar conditions as possible.

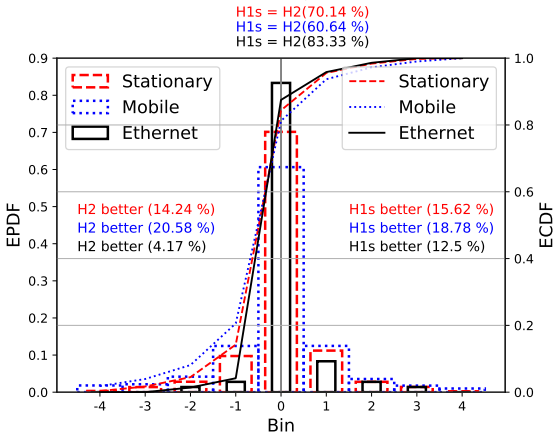
Let $M(i)$ be the i-th visit of metric $M \in \{FP, SI, PLT\}$. We compute the *protocol gain* $\Delta M(i)$ as :

$$\Delta M(i) = \frac{M_{H2}(i) - M_{H1s}(i)}{\max\{M_{H2}(i), M_{H1s}(i)\}}$$



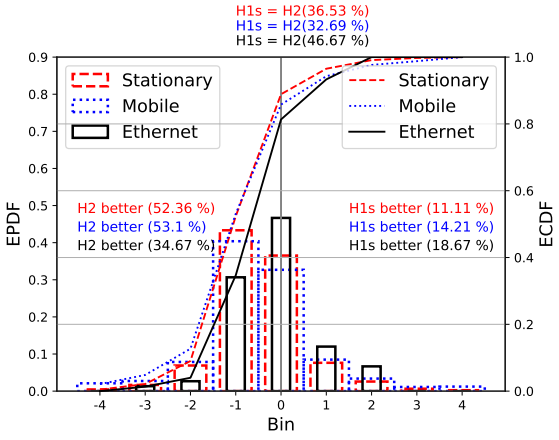
$\Delta M \in [-1, 1]$ – with negative (positive) values when H2 performs better (worse) than H1s on the i-th visit. Next, we compute the distribution of the $\Delta M(i)$ over all experiments, and quantize results into 9 bins centred around zero.[3] The rationale is to identify ranges for which performance is equivalent (center bin), slightly better/worse (the first bin on the left or right), moderately better, much better, extremely better. We opted for 5 bins to mimic the Mean Opinion Score.

Figure 5a shows the distribution of the protocol gain for SI for Chrome. Left y-axis, right y-axis, and x-axis illustrate the Empirical Probability Density Function (EPDF) of samples in each bin, the ECDF, and bins, respectively. We distinguish between three different cases: mobile nodes with MBB connections (blue curve), stationary nodes with MBB connections (red curve) and stationary nodes with wired connection (black curve). Bars show the EPDF; lines the ECDF. Ideally, when H2 is better than H1s, the probability of having $\Delta M(i) < 0$ would be larger than the probability of having $\Delta M(i) > 0$. We observe that the distributions are (i) having similar modes with zero mean – independently from the scenario, (ii) similar distribution, but (iii) slightly more skewed for MBB networks than for wired access. Specifically, in about 50% of cases, ΔM falls in the central bin (i.e., the relative performance gain of H2 and H1s are within 10%). Moreover, cases where either H2 or H1s have better performance are approximately balanced, although there is a moderate bias towards negative values (H2 has better performance than H1s). Finally, mobility tends to add more variability in the experiment, so that ΔM becomes larger, but equally favoring H1s or H2.



We next drill down our analysis to look separately at each website, to verify if some pages do see some improvement in using H2. Figure 5b is a notable example which reports the protocol gain for *Wikipedia* using Chrome. We observe that the differences are perfectly balanced. This is a generic result, which holds true for SI, PLT and FP as well as for Chrome and Firefox. The only case we observe H2 having a sizeable protocol gain is the case of *R*eddit, detailed in Figure 5c while using Chrome. In this case, we observe that H2 outperforms H1s in 52% of tests. To illustrate the actual absolute improvement as previously done in Figure 1, Figure 6 details the ECDF of all experiments involving these 2 websites for the SI metric. Figures confirm the results shown by the protocol gain: *Reddit* does benefit of H2, while *Wikipedia* obtains no gain.

All measurements presented so far offer a qualitative measure of the impact of protocols. Next, we apply statistical analysis techniques to compare measurements referring to different datasets to precisely quantify the



[3]We assign samples to bin in $[-4, -3, -2, -1, 0, 1, 2, 3, 4]$ if $\Delta M(i)$ falls in $[(-1, -0.7), (-0.7, -0.5), (-0.5, -0.3), (-0.3, -0.1), (-0.1, 0.1), (0.1, 0.3), (0.3, 0.5), (0.5, 0.7), (0.7, 1)]$.

performance difference between the two protocols. Our goal is to answer how (dis)similar are the distributions of the H1s and H2 datasets.

In the literature, there are different well-known Statistical Distance Metrics (SDM), each with its own properties and limitations. In this work,

(a) SI *Reddit*

(b) SI *Wikipedia*

Figure 6: Some example ECDFs for SI using H1s and H2 with Chrome.

we chose the Jensen-Shannon divergence (JS_{div}), which is defined as:

$$JS_{div} = \sum_i \left\{ \frac{1}{2} p_i \ln\left(\frac{p_i}{\frac{1}{2}p_i + \frac{1}{2}q_i} \right) + \frac{1}{2} q_i \ln\left(\frac{q_i}{\frac{1}{2}q_i + \frac{1}{2}p_i} \right) \right\}$$

where p_i and q_i (relating respectively to H1s and H2) are the EPDF values generated by samples falling in the i-th bin. JS_{div} is a statistical measure based on the Kullback-Leibler divergence. JS_{div} adds symmetry (i.e., $JS_{div}(p, q) = JS_{div}(q, p)$), and bounded image to the Kullback-Leibler divergence. In fact, the reason we chose the JS_{div} is to obtain a symmetric bounded value for our comparisons. JS_{div} is equal to 0 if $p = q$, while it reaches ln(2) for two completely disjoint distributions.

Intuitively, when $JS_{div} > Th^+$, the difference between the two EPDFs is significant. Conversely, differences are negligible if $JS_{div} < Th^-$ and when $JS_{div} \in [Th^-, Th^+)$ the difference is observable. We select the threshold values $Th^- = 0.02$ and $Th^+ = 0.1$ as common in statistics. For a more in depth discussion of which SDM to use, and the proper usage of thresholds we refer the reader to [22]. To estimate the EPDF for H1s (p) and H2 (q) separately, we consider stationary nodes only. We use a bin size of 100 milliseconds, and we compute the frequency p_i, q_i of samples falling in each bin. Then, we compute the JS_{div}. Table 3 reports the results for three websites for all browsers and metrics.[4] We observe that *Reddit* for the Chrome browser is the only case where $JS_{div} = 0.124 > Th^+$ for FP, hence falling in the range of a significant difference (red color). The difference for PLT and SI are less evident, but still sizeable. *Wikipedia* for the Chrome browser shows instead no statistically significant changes (green color) – as discussed before.

We further carried out analysis to statistically compare performance of H2 and H1s by conditioning on operators, independent from the website and other conditioning variables. In all cases, we did not observe any statistically significant difference in the performance observed when using H1s or H2. These results are not presented here due to space considerations.

[4]We explored all websites. Results are omitted for the sake of brevity.

Table 3: Jensen-Shannon divergence of FP, PLT and SI comparing H1s vs H2 for three websites.

Website	FP Chrome/FFox	PLT Chrome/FFox	SI Chrome/FFox
ebay	0.006/0.004	0.009/0.006	0.009/0.005
reddit	0.124/0.002	0.025/0.007	0.079/0.002
wikipedia	0.008/0.003	0.006/0.005	0.009/0.003

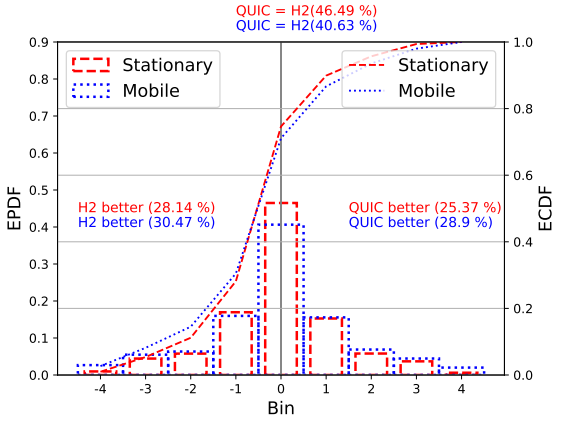

Figure 7: QUIC vs. H2: Distribution of ΔM for SI.

Takeaway: The benefit for H2 is very limited or absent in our tests. One reason that has been identified could be that some of the key H2 features are still not in use at large in the server side [64]. Similarly, results from the work in [62] show that the current prioritization in off-the-shelf browsers is not yet optimized for H2. Also, we have observed that domain wise resource placement is quite similar for both the H1s and H2 cases. This sharding influences the potential gain from multiplexing in H2. Similar observation is mentioned in [37]. Furthermore, for a majority of the webpages in our tests, we have noticed that a considerable number of resources were downloaded using H1s even when the browser used H2 (see Table 1). This clearly limits benefit of H2. At last, MBB access and mobility scenarios exhibit a very high variability in performance – due to the more random nature and complexity of MBB scenarios. This randomness dominates over the benefit of H2.

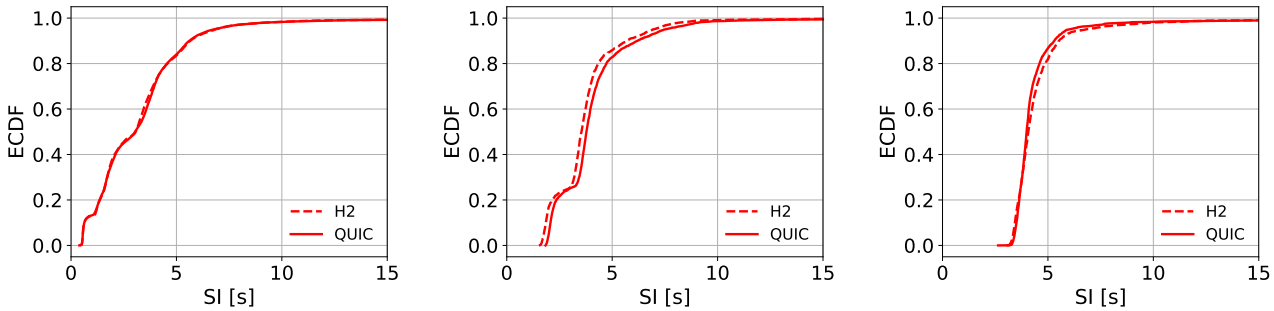
6.2 QUIC vs H2 Performance

Here, we report the performance comparison between QUIC and H2. We follow the same process as in the previous section to compute the protocol gain. Here we use the set of websites that support QUIC (Section 3.1). Accordingly, we examine H2 and QUIC back-to-back measurements towards the same website and compute the protocol gain similar to Section 6.1. As before, $\Delta M(i) < 0$, indicate H2 is better than QUIC.

Figure 7 presents the performance of QUIC and H2 we capture with SI using Chrome over all websites. Here we show two scenarios, stationary nodes with MBB connections (red curve) and mobile nodes with MBB connections (blue curve). From the distribution, it is clear that QUIC and H2 performance are very similar. Again we see an increase in the variability of results for mobile nodes, but still with similar relative performance gains for the two protocols. Although not displayed, we observe the same trends for FP and PLT. When the performances differ, we see H2 being better more often than QUIC for both stationary and mobile nodes. We observe that most QUIC websites include external resources where the browser needs to fall back to H1s/H2. This may introduce extra delays and limits the protocol gain QUIC can deliver. Such scenarios were never considered in previous works that used synthetic pages and controlled servers [19, 23, 34, 42]. These show more prominent (but artificial) gain using QUIC.

Next, we offer a closer look. In Figure 8a, we illustrate the performance comparison between QUIC and H2 using an ECDF of all experiments for SI. Again, we do not observe any significant difference. This observation holds true for FP and PLT as well. We only observe some notable differences for two websites: *Free-power-point-template* where H2 performs slightly better (Figure 8b) and *Youtube* where QUIC shows slightly better performance (Figure 8c). In the former case, we observe some heavy resources which hurt QUIC performance due to the use of pacing [42].

Takeway: We observe even less benefits for using QUIC instead of H2. Our detailed analysis of QUIC traces show that some objects from the QUIC compatible sites are still not transported using the QUIC protocol, which we believe a hurdle to put QUIC and H2/H1s in a common performance scale. Again, many factors also influence and bring variability into mobile Web browsing performance, overshadowing the impact of the protocols and leading to mixed performance results.



7 MODELLING WEB PERFORMANCE

In our analysis so far, we explored a large dataset of mobile web measurements and investigated the different factors that impact the mobile web performance by considering three main QoE metrics. Our statistical analysis, however, partially captures how the collection of features characterizing the web browsing process actually impacts the quality of the user session. Even when using a platform specifically meant to enable comparison and eliminate biases, we show that the complexity of the experiments is high and multiple factors can influence the results and the experience of the end-user. In this section, we aim to use data analytics, more specifically regression models, to formally capture the correlation between the set of features that characterize the browsing context of the user (e.g., radio signal quality, radio access technology, mobility etc.) with the quality of experience for that same user (PLT, SI or FP).

We first use *multiple-linear regression (LM)* to investigate how the web QoE metrics (e.g., PLT, FP and SI) vary with respect to different features that characterize the context in which the user surfs the web. We include the following features in our analysis: the node type mobile/stationary (Node Type), number of vertical handovers occurring throughout the duration of one website visit (RAT Handovers), the number of objects downloaded for a specific website under a given experimental configuration (# of Objects), the distance travelled by the node during one website visit (Distance), values of radio strength parameters at the beginning of the experiment to one website (RSRP, RSRQ, RSSI), average value of round-trip-time we measured against the target website during one visit (Avg. RTT), the radio access technology type (RAT), the browser type (Browser), the web protocol version (Protocol). To identify the most prominent features, in the linear regression model we use standard step-wise sub-scheme (as a Wrapper method) and subsequently apply the filter method to retain only the most significant attributes by looking at their P values (i.e., P values ≤ 0.05). The P values indicate how confident we can be that a feature has some correlation with the web QoE metrics.

Figure 9 demonstrates the significance of these context features on web performance, by focusing on SI as our web QoE metric. We capture the significance of each variable in the final model by the color gradient of each cell. We first produce a model using only the samples we collect under mobility scenarios ("Mobility" model, label on the x axis) and another using the samples that we collect from stationary nodes which are always connected to the same network and do not experience any inter-RAT handovers ("Stationary" model, label on the x axis).

For the Mobility model, we note the strong significance of the initial RAT, inter-RAT handovers and the distance traveled, confirming our observations in Section 5. This confirms the previous work that highlights the strong impact of mobility on the end-user QoE [15]. Furthermore, the

(a) Over all sites (b) SI *Free-power-point-template* (c) SI *Youtube*

Figure 8: Some example ECDFs for SI using QUIC and H2 with Chrome.

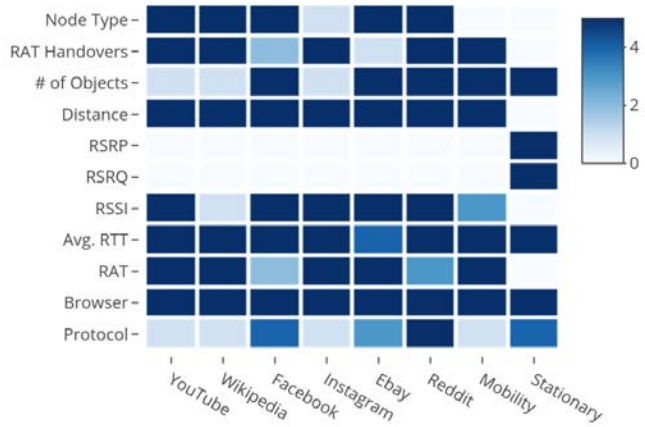


Figure 9: Significance of features for SI captured by a linear modelling approach.

number of objects, RTT and browser type also have a strong significance. At the same time, the signal strength value (RSSI) is not as significant as the mobility context, and the protocols is the least significant from the set of features we consider. In the Stationary model, we note that the features we consider including the number of objects for the target webpage, RSRP, RSRQ, browser type and even the protocol are significantly correlated with the end-user experience. These results are consistent with our findings in Section 5, except for the protocols. Regarding the protocols, although in Section 6 we concluded that there are no significant differences among protocols (they do not provide gains more than 10%), our model still considers protocol version as a significant feature indicating that the model tries to capture even marginal gains.

Next, we generate separate models for six of the target websites in Sweden (namely, *Youtube*, *Wikipedia*, *Facebook*, *Instagram*, *Ebay*, *Reddit*), by merging all the data from mobility/stationary conditions, operators, protocols or browser type. We break down our analysis per target webpage and note in Figure 9 the significance each feature has on the SI. Overall, we observe that the browser type and the mobility context (more specifically, the distance travelled during browsing) are consistently influencing the end-user experience, regardless the target webpage. For a given webpage, the number of downloaded objects is not significant, except for webpages that are potentially more dynamic over time (such as *Facebook* or *Ebay*). In all cases the signal strength value is highly correlated with the end-user experience, except for *Wikipedia*, which is potentially due to the smaller size of the page (which contains mostly text).

Takeaway: We observe that web performance under mobility is heavily impacted by RAT and inter-RAT handovers. For the stationary case, on the other hand, parameters such as browser, number of objects downloaded in a webpage and also signal strength values play an important role for the web performance. Overall, we observe that the browser type and the mobility context are consistently influencing the end-user experience, regardless the target webpage. The number of objects downloaded is not as significant for individual webpages, except for webpages that are potentially more dynamic over time.

8 CONCLUSION

This paper presented a cross-European study of web performance on commercial mobile carriers using the MONROE open measurement infrastructure. The novelty of the study stands in the sheer volume of data we were able to collect, nearly two million page visits from 11 different operational MBB networks in 4 countries, and in the rich context information captured along with the measurements that allowed us to analyze the complex interactions that influence mobile web user experience. Our results show a performance penalty of over 30% for mobile broadband access as compared to our wired baseline, with further performance drops for mobile users due to inter-technology handovers and varying channel conditions. Regrettably, except for few individual webpages, our measurements show that the performance improvements promised by newly emerging web protocols H2 and QUIC still remain to be experienced. Majority of back-to-back visits with H1s and H2 web protocols show similar performance with equal split of gains by H1s or H2 for the rest. Our results were confirmed by data analytics capturing the impact of single features that characterize the context in which browsing occurs. The presented measurements were designed to be scientifically sound and with reproducibility in mind and we offer the captured dataset to the community for other researchers to verify and build upon.

ABSTRACT

Information about world events is disseminated through a wide variety of news channels, each with specific considerations in the choice of their reporting. Although the multiplicity of these outlets should ensure a variety of viewpoints, recent reports suggest that the rising concentration of media ownership may void this assumption. This observation motivates the study of the impact of ownership on the global media landscape and its influence on the coverage the actual viewer receives. To this end, the selection of reported events has been shown to be informative about the high-level structure of the news ecosystem. However, existing methods only provide a static view into an inherently dynamic system, providing underperforming statistical models and hindering our understanding of the media landscape as a whole.

In this work, we present a dynamic embedding method that learns to capture the decision process of individual news sources in their selection of reported events while also enabling the systematic detection of large-scale transformations in the media landscape over prolonged periods of time. In an experiment covering over 580M real-world event mentions, we show our approach to outperform static embedding methods in predictive terms. We demonstrate the potential of the method for news monitoring applications and investigative journalism by shedding light on important changes in programming induced by mergers and acquisitions, policy changes, or network-wide content diffusion. These findings offer evidence of strong content convergence trends inside large broadcasting groups, influencing the news ecosystem in a time of increasing media ownership concentration.

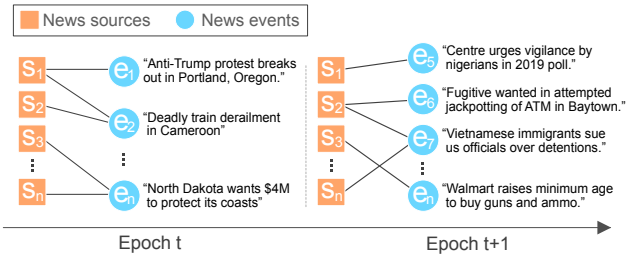

Figure 1: Illustration of the setting: we observe the coverage of news events from a fixed set of sources over several time epochs. Example events are extracted from the GDELT database.

1 INTRODUCTION

Information about world events is reported as a continuous stream, processed then broadcast to an audience through a large number of channels and across various mediums. As no coverage could claim to be exhaustive, sources must first filter the stories that will be disseminated. The selection made by each channel is partial by nature. However, the variety of outlets, each with a wide array of considerations in the choice of its reporting, is assumed to ensure the diversity of news to which the reader is exposed to. This principle is often referred to as the *external pluralism* assumption. It should ensure heterogeneity in the media space, encapsulating anything from the diversity of ownership to the independence of the editorial board. [1] *External pluralism* is also known as the "supplier" pluralism, since it should exclude the possibility of large broadcast groups exerting influence on downstream reporting. Yet in practice, this assumption does not always hold. News channels are often owned or operated by commercial, private entities, implying that the ecosystem as a whole is influenced by economically motivated forces, such as mergers, acquisitions, or regulatory actions. The increase in concentration of ownership has been observed to be the dominating force in the media landscape, as reported by the Pew Research Institute in a 2017 study on the acquisition of local television stations. [2]

While the literature, discussed in more detail in Section 2, still debates the causal effects of market ownership structures on the diversity of offerings, the Federal Communications Commission (FCC) [3] has defended the idea that "there is a positive correlation between viewpoints expressed and ownership of an outlet". [4] This

[1] As opposed to *internal pluralism*, where sources are assumed to present a wide variety of ideological viewpoints, communicated through different mediums. [8]
[2] http://www.pewresearch.org/fact-tank/2017/05/11/buying-spree-brings-more-local-tv-stations-to-fewer-big-companies/
[3] The FCC is the regulating body for multimedia communications in the United States.
[4] FCC, Biennial Media Ownership Order (2003)

uncertainty strongly motivates the development of novel and interpretable methods, which would allow the observation of large-scale movements in the media landscape and allow correlating the observations with real-world factors.

Recent studies have tackled the problem of evaluating similarities across news sources [5, 38] and have found that the analysis of coverage patterns can highlight non-obvious relationships between sources, such as the aforementioned corporate ownership structures. However, they have only captured a static snapshot of the media landscape. This hinders the ability to observe changes in content diffusion, and limits attempts to correlate the observations with potential factors in the news space. These models' predictive power is also limited by their inability to incorporate temporal dependencies. In other words, it restricts them to an informative but partial and static view of the news ecosystem. Indeed, the model of any dynamic system requires a time-dependent formulation, necessary to detect variations and measure trends. Existing approaches are blind to such transient effects.

Studying the effect of real-world factors on content diffusion is a challenging task. It requires the detection of subtle variations in the coverage patterns of individual channels, which can occur over long time spans. Any attempt to characterize these effects would suffer from the absence of a ground truth, prompting the need for a comparison across news channels. While similarities between channels are straightforward to compute for short, consistent periods of time, the continuous occurrence of new and unpredictable events breaks the ability to reason across successive snapshots of the news. A successful estimate of similarity over time should hence maintain temporal consistency of pairwise distances across news channels. At any given point in time, it should ideally do so without compromising its predictive accuracy compared to static methods. These challenges and constraints motivate the use of the models presented here.

In this work, we propose a dynamic embedding model of the media landscape. By predicting news sources' coverage, the model captures their similarities throughout the observed period. The embedding space is maintained consistent over time by augmenting the model with a knowledge of previous time steps, and by adding a temporal regularization on the model's parameters. This improves the model's predictive capabilities and provides a temporally coherent source-wise similarity metric, allowing the visualization and analysis of long-ranging fluctuations in the news ecosystem. We also propose a systematic method to detect abrupt transition patterns in this similarity space. This enables the analysis of the news ecosystem beyond domain-specific knowledge and hand-crafted analysis.

In the context of news reporting, temporally-aware models provide a powerful tool for correlating content programming changes and real-world factors, from individual news outlet's behaviors to large-scale dynamics. Shining a light on these movements would naturally guide the search for source-level context, helping to characterize and identify the observation's driving forces. This information could then provide context to journalists investigating the coverage of a particular story or feed watchdog-like processes that monitor the health and evolution of the media landscape. To illustrate, we provide some prototypical questions which could arise in a journalistic probe, and that could be elucidated by information derived from the proposed model:

- What effect does the ownership of a news channel have on its content diffusion?
- Which sources are most similar (resp. dissimilar) to a sample source, and how has this similarity evolved over time?
- Which are the most consistent (or varying) news channels in terms of broadcast content?
- Which broadcast groups exert a large influence on the content of their respective channels?

The rest of this paper is organized as follows. In Section 2, we present relevant work from the literature. In Section 3, we describe the dataset used in our study. In Section 4, we introduce our model. In Section 5, we discuss the predictive performance of the model. In Section 6, we illustrate the use of our model in the identification of abrupt changes the media landscape, attempting to interpret these changes in coverage in Section 7. In Section 8, we conclude and propose future research directions.

2 RELATED WORK

The study of the evolution of the media landscape has led to prolific research lines spanning various fields. Early work had a tendency to examine the media ecosystem in isolation. For example Steiner's seminal work [43] studies the interplay of consumer preferences and in-market competition on the diversity of radio broadcasting. This study omitted the role of external driving forces, which were only later modeled by Anderson & Coate. [3] They predicted that media consolidation, while economically beneficial for the market, would reduce competition and hence diversity for the viewer. This insight was later formulated in terms of ideological bias by Gentzkow & Shapiro [10] in the case of newspapers.

The tendency to integrate external driving factors has picked up steam in recent years, most notably with a theory of convergence in the media ecosystem. This convergence expresses itself through two seemingly contradictory features. On one hand, information is being delivered through an ever-increasing number of channels and means of diffusion. On the other hand, media ownership concentration has seen an upwards trend, with a large proportion of channels being owned by only a handful of media conglomerates. [31] This dichotomy has been studied by, among others, Jenkins. [20] The author proposed a sketch of the phenomenon that looks further than the sole technological influence, reaching for larger cultural factors. Vizcarrondo et al. [45] have more specifically investigated the concentration of media ownership. They reported on changes in the diversity of ownership within the media industry covering the 1976 through 2009 time period.

A large body of work has also been introduced to study the effect of an ideologically slanted press. For instance in a large-scale observational study, DellaVigna et al. [6] measured the effect of the introduction of a conservative-oriented channel (Fox News) led to gains of 0.4 to 0.6 percentage points in Republican voting in the towns where the channel was being broadcast. While specific to a particular orientation, this work is in line with studies showing the profound influence of the media in voters' political awareness [27] and their participation in the electoral process. [11, 12, 28]

Notation	Description
R	Interaction matrix $\in \mathbb{R}^{\lvert S \rvert \times \lvert E \rvert}$
S / E	News source / Event set
$E^+_{s_i}$	Set of events covered by source s_i
s_i	Source $s_i \in S$
e_k	Event $e_k \in E$
K	Number of latent factors
$\hat{x}_{s_i,e_k}$	Predicted preference of source s_i for event e_k
D / D_s	Training / Testing set
γ	STD of the Gaussian random walk
α	Learning rate
λ_Θ	ℓ_2-regularization weight
λ_T	Temporal regularization weight
Θ	Set of model parameters

Table 1: Notation

The Federal Communications Commission (FCC) regularly issues studies regarding the state of the news ecosystem. Specifically, some of these studies focus on the effect of ownership on local news stations' content programming behaviors. However, by the authors' own admission [5], these works often lack the breadth required by a large-scale empirical study. For example, Pritchard [32] conducted a study of the diversity of coverage for cross-owned media outlets during the 2000 presidential campaign but on a sample of only 10 newspapers. Groseclose & Milyo [16] proposed a measure of media bias which was evaluated on a set of 8 newspapers. Djankov et al. [7] did survey the news ecosystem on large scale, building a map of media ownership in 97 countries around the world, but this work dates back to 2003.

Dimensionality reduction methods have been extensively used to model different perspectives or opinions. For example, Lahoti et al. [24] rely on Non-Negative Matrix Factorization methods to learn a liberal-conservative ideology space on Twitter. In particular, the authors propose to approximate the users' ideology based on their online news consumption.

The study performed by Saez-Trumper et al. [39] relies on a Principal Component Analysis (PCA) to detect similarities across news channels. In particular, they performed their analysis by covering three different types of biases in the press: *gatekeeping bias*, *coverage bias* and *statement bias*. The authors' bias-capturing method does present similarities to our approach, but is formulated as an unsupervised approach and does not tackle temporal variability. Recently, Bourgeois et al. [5] proposed a supervised, embedding-based method to capture similarities across news sources based on their respective coverage. This model was also designed statically and is hence unable to accurately model temporal variations in news coverage.

Learning to produce a personalized ranking from positive interactions only is a well-studied problem that has been investigated in the context of recommendations from implicit feedback [30] and as One-Class feedback [19] in the context of recommender systems.

[5] "[a] larger number of independent owners will tend to generate a wider array of viewpoints in the media than would a comparatively smaller number of owners. We believe this proposition, even without the benefit of conclusive empirical evidence." FCC, Biennial Media Ownership Order (2003)

Temporally-aware methods have received increasing attention and many previous models have now been adapted to the temporal setting. The *dynamic embedding*, proposed by Rudolph et al. [36] as a variation of traditional embedding methods, is generally aimed toward temporal consistency. The method is introduced in the context of word embeddings, which are used to characterize the evolution of English language. The model is built upon the initial *exponential family embeddings* model. [37]

The field of personalization has many examples of temporally-aware models since human preferences tend to evolve over time. For example, influential work from Koren et al. [22] models the changing nature of preference through a linear drifting term. Another approach relies on the use of Tensor Factorization (TF), [1, 9, 46] in which the extra dimension models temporal patterns in the data. We do not consider TF-based methods as valid candidate approaches since we focus on the problem of grounding representations over time by penalizing unnecessary differences between successive solutions of the model. The temporal modelling capabilities of TF-based methods would predict the evolution of sources and introduce additional temporal variations, consequently degrading interpretability.

He et al. [18] introduced a temporally-aware model of a recommender system in order to capture the evolution of fashion trends. Similar to Koren et al. [22], the authors also proposed the addition a drifting term to the model. The authors later proposed the use of a higher-order Markov chain that captures both short- and long-term dynamics [17]. Note that both models make use of Bayesian Personalized Ranking (BPR [35]) for their respective optimization procedure. In the context of networks, Yu et al. [48] proposed a temporal factorization for analyzing the evolution of network structures.

The media response to global events has been studied, with many using the same data-source as our work. However, these approaches have focused mainly on content-level analysis, leveraging the multimodal capabilities of the GDELT dataset (please refer to Section 3 for more detailed information about the dataset). These works have monitored the media response to events such as protests, [33] natural disasters [23] or conflicts. [14, 21, 47] This data-source was also used to get a world-wide view on coverage of global issues like climate change. [29]

Research Questions: Given the work above, several research questions are of our interest and have remained unanswered:

RQ1: How can we model the global media landscape over time?
RQ2: Is media consolidation highlighted by the resulting latent representation?
RQ3: How to systematically detect abrupt deviations in content diffusion at a source-level?

3 DATA

In this section, we present the selected data source and explicit our data collection process, providing general statistics about the resulting dataset.

	GDelt Dataset
# sources	7 278
# unique events	174M
# interactions	588M
time span	Feb 2015 - May 2018

Table 2: Meta-data about the dataset (after preprocessing)

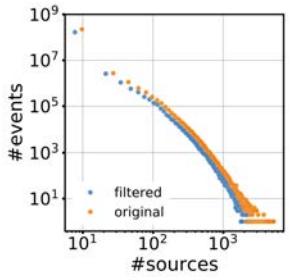

Figure 2: Number of sources covering an event.

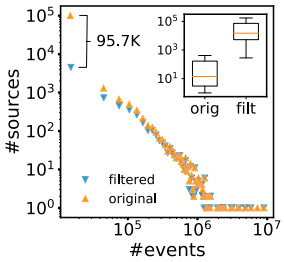

Figure 3: Number of events covered per source.

3.1 Data Source

Recently, several event collection databases have emerged on the Web, making accessible to the general public a global view of the daily world events. In this work, we rely on the *Global Database of Events, Language, and Tone* (GDELT [26]), a large database of annotated news events. GDELT [6] was selected since it is publicly available and covers a reasonably large timespan and geography, offering a larger set of sources [2] to study compared to alternatives such as EventRegistry. [7]

For decades, event coding was performed manually. In the 1990s, the first automated systems started to gain traction in the academic community, with initiatives such as the KEDS system. [40] Its successor was proposed in the form of *Text Analysis By Augmented Replacement Instructions* (TABARI), which is the engine that runs event coding for GDELT. This framework is designed to process large amounts of text to extract the presence of pairs of *actors* and *verbs*. To do so it matches elements from user-provided dictionaries, which contain a massive collection of event protagonists (i.e. actors) ranging from recognizable named entities (e.g. *Barack Obama*) to functional placeholders (e.g. *a local woman*). These actors are able to interact with the world through *verbs* (i.e. actions), which can be self-contained (e.g. *announces their intent to*) or involve a second actor (e.g. *criticizes their opponent*). Several standards exist for these dictionaries. GDELT uses the *Conflict and Mediation Event Observations* (CAMEO [13]). [8] Note that, as a remnant of previous hand-curated event annotation frameworks [25], TABARI also provides an interface for manual hand-off to domain experts if the sentences become too complex. This reinforces GDELT's ability to uniquely annotate even the most fine-grained events.

GDELT also augments every news event it tags by extracting meta-information about the article including, but not limited to, its location, its tone, its Goldstein Scale [15] and refences the URL the event was scanned at. It scours a wide array of sources, from television stations to blogs, news wires and papers. Thanks to the information provided by this augmented event coding framework, GDELT assigns, for each news event, a global identifier, which makes it possible to link the same event's coverage across different news sources. Beyond the rich annotations provided by GDELT, this tracking is central to our study given that we only work at the coverage level, without considering the content itself.

[8] An exhaustive list of the considered categories can be found at http://data.gdeltproject.org/documentation/CAMEO.Manual.1.1b3.pdf

3.2 Data Preprocessing

From the massive resource maintained by GDELT we can gather a dataset of interactions between sources and events, recording which sources covered which uniquely identifiable events. We focus our data collection campaign on the publicly available dumps of GDELT 2.0, released every 15 minutes since February 2015. General statistics about the dataset are presented in Table 2 as well as Fig. 2 and Fig. 3.

When considering the full time-span, GDELT references more than 105K different news sources. This represents a considerable increase compared to the 63K sources reported by Kwak et al. [2] in 2016. However, as is shown in Fig. 3, most of the sources have only published a few articles over the relevant stretch. To maintain a consistent number of channels over time, we discard all channels inactive in any one of the time slices from our dataset. This retains around 7 278 news sources in our dataset. The filtering step does remove a large fraction of available channels, but it mostly affects sources with a very low publishing rate: despite preserving only 7% of the total channels, the selection still accounts for more than 76% of interactions in the dataset (see Fig. 3).

The dataset is split into slices with a duration of one month. This allows for a decent trade-off between having a significant amount of events covered in the training set, while also providing enough samples to observe time-dependent changes over the considered period. In principle, this scale could be modified to study the media landscape at different granularity levels. For example, a more fine-grained split might allow the observation of changes correlated with specific events. However, we choose to leave this analysis as future work given the significant amount of computation that the model requires.

4 MODEL

In this section, we first motivate our approach. Then, we briefly introduce the use of Matrix Factorization methods in a ranking setting by formally describing the task and its objectives. Finally, we propose two strategies to extend the model to a temporal setting.

4.1 Motivation

The main focus of our work is to establish a dynamic model of coverage similarities across news channels in order (i) to uncover congruent coverage patterns in the pool of available channels, (ii) to establish a dynamic, predictive model of coverage and (iii) to

provide a systematic methodology to identify and interpret structural changes in the media landscape. Recent political and societal focus on media accountability and transparency provide strong motivators in the development of such tools (see Section 1).

We model the interrelationships between sources and events by relying on a Matrix Factorization (MF) method. MF methods represent a natural way of projecting two disjoint sets of items in a common latent space of K dimensions in order to model their interactions. Such personalized methods are commonly use by recommender systems, which routinely aim to model retail purchasing decisions. Used in our context, they model coverage decisions instead. We cast the problem to a One-Class learning setting [30] since we observe positive interactions only. The One-class formulation avoids making assumptions about negative examples: we do not distinguish between real negatives (i.e. the source purposely didn't cover an event) and unobserved interactions (i.e. the source wasn't aware of the event).

4.2 Problem Statement

Let us consider a set of news sources S and a set of events E. Interactions between the two are represented by an interaction matrix $R \in \mathbb{R}^{|S|\times|E|}$. Observations take the form of dyadic interactions $(s_i, e_j), s_i \in S, e_j \in E$ which express source s_i's coverage of event e_j. Equivalently, we define in matrix form that $R_{i,j} = 1$ if source s_i has covered event e_j and $R_{i,j} = 0$ otherwise.

Predicting the unobserved entries of matrix R is achieved by taking the dot-product of two low rank matrices, such that $R \approx P^T \cdot Q$, where $P \in \mathbb{R}^{K\times|S|}$ and $Q \in \mathbb{R}^{K\times|E|}$ with $K << |S|, |E|$. Every source s_i (resp. every event e_j) is represented by a column in P (resp. Q). We will refer to these columns as an embedding vector throughout the remainder of this work. We will refer to Θ as the set of parameters for our MF predictor, such that $\Theta = \{P, Q\}$.

Objectives: The model is trained with the objective of predicting the likelihood of a source covering a particular event. The predicted likelihood $\hat{x}_{s_i,e_j}$ of source s_i covering event e_j is computed as the dot-product between the two respective embedding vectors,

$$\hat{x}_{s_i,e_j} = p_{s_i}^T \cdot q_{e_j} \,. \tag{1}$$

Instead of best approximating the reconstruction of matrix R, this objective is stated as a ranking problem in which positive examples should obtain a higher rank than negative ones, i.e. to predict a higher score for an event that has been covered than for random negative samples. Optimizing a MF model with a ranking criterion is equivalent to maximizing the following probability,

$$\begin{aligned} \Pr(e_j >_{s_i} e_k|\Theta) &:= H(\hat{x}_{s_i,e_j} - \hat{x}_{s_i,e_k}) \\ &\approx \sigma(\hat{x}_{s_i,e_j} - \hat{x}_{s_i,e_k}) \end{aligned} \tag{2}$$

where e_j is an event covered by source s_i and e_k is a randomly sampled negative event; formally, $e_j \in E_{s_i}^+$ and $e_k \in E \setminus E_{s_i}^+$. We adopt the notation $>_{s_i}$ to denote a source s_i preferring to cover e_j over e_k and model the observation of this preference using $H(\cdot)$, the Heaviside step function: $H(\cdot)$ is equal to $\mathbf{1.0}$ for positive inputs and to $\mathbf{0.0}$ otherwise. Therefore, $H(\hat{x}_{s_i,e_j} - \hat{x}_{s_i,e_k})$ would always be equal to $\mathbf{1.0}$ for an ideal predictor. In practice, $H(\cdot)$ is approximated by the differentiable logistic sigmoid $\sigma(\cdot)$.

Finally, we maximize BPR, our log-likelihood criterion

$$\text{BPR} := \sum_{(s_i,e_j,e_k)\in D} \ln \sigma(\hat{x}_{s_i,e_j} - \hat{x}_{s_i,e_k}) - \lambda_\Theta \, ||\Theta||^2 \,. \tag{3}$$

Note the inclusion of an ℓ_2-regularization term over the set of parameters Θ. We please refer the reader to the work of Rendle et al. [35] for more details about this optimization scheme.

4.3 Temporal Setting

In this section, we describe the adoption of the dynamic embedding scheme proposed by Rudolph et al. [36] in the context of news coverage modeling. In particular, we adopt two strategies to maintain temporal consistency across time slices, respectively based (i) on a Gaussian random walk (*RW*) and (ii) on the addition of a temporal regularization term (*RG*). We adopt the notation $p_{s_i}^{(t)}$ to denote the embedding vector of news source s_i at the t-th time step.

Prior on the embedding vectors: Without information about former time slices, existing methods typically initialize embedding vectors to small, randomly distributed values. However, such approaches do not take advantage of any prior knowledge acquired during anterior training steps. The addition of a prior on embedding vectors represents a simple, yet powerful strategy to leverage previously acquired knowledge about sources. In particular, embedding vectors at the t-th time step are initialized using a Gaussian random walk around their final values at time step $(t-1)$. The Gaussian random walk is expressed as follows:

$$p_{s_i}^{(t)} \sim \begin{cases} \mathcal{N}(0, \gamma^{-1} I), & \text{if t=0} \,. \\ \mathcal{N}(p_{s_i}^{(t-1)}, \gamma^{-1} I), & \text{otherwise} \,. \end{cases} \tag{4}$$

This initialization scheme ensures a smooth transition of the parameter set learned in two consecutive time slices. This yields a more stable embedding space, offering a coherent expression of divergence across time-steps. Since events are inherently much more volatile than sources, we initialized their embedding vectors at random at each new time slice.

Optimization using temporal regularization: The second part of the dynamic scheme takes the form of a temporal regularization term. The newly introduced term penalizes large variations across time steps by minimizing the distance of an embedding vector at the t-th step to its final value at step $(t-1)$.

The final log-likelihood criterion, BPR-T, can then be formulated as follows for the t-th time split

$$\begin{aligned} \text{BPR-T}^{(t)} := \sum_{(s_i,e_j,e_k)\in D} & \ln \sigma(\hat{x}_{s_i,e_j} - \hat{x}_{s_i,e_k}) \\ & - \lambda_\Theta \, ||\Theta||^2 \\ & - \underbrace{\lambda_T \|p_{s_i}^{(t)} - p_{s_i}^{(t-1)}\|^2}_{\text{temporal regularization}} \end{aligned} \tag{5}$$

The model is optimized using stochastic gradient ascent and is fitted once for every time split. Update steps are defined as follows:

$$
\begin{aligned}
q_{e_j}^{(t)} &\leftarrow q_{e_j}^{(t)} + \alpha(\sigma(-\hat{x}_{s_i,e_j,e_k}) \cdot \quad p_{s_i}^{(t)} \quad - \lambda_\Theta \, q_{e_j}^{(t)}) \\
q_{e_k}^{(t)} &\leftarrow q_{e_k}^{(t)} + \alpha(\sigma(-\hat{x}_{s_i,e_j,e_k}) \cdot (-p_{s_i}^{(t)}) - \lambda_\Theta \, q_{e_k}^{(t)}) \\
p_{s_i}^{(t)} &\leftarrow p_{s_i}^{(t)} + \alpha(\sigma(-\hat{x}_{s_i,e_j,e_k}) \cdot (q_{e_j}^{(t)} - q_{e_k}^{(t)}) \\
&\quad - \lambda_\Theta \, p_{s_i}^{(t)} \\
&\quad - \lambda_T (p_{s_i}^{(t)} - p_{s_i}^{(t-1)}))
\end{aligned}
\tag{6}
$$

where α is our learning rate. We use the notation $\hat{x}_{s_i,e_j,e_k}$ to denote the quantity $(\hat{x}_{s_i,e_j} - \hat{x}_{s_i,e_k})$. Note that triplets $(s_i, e_j, e_k), e_j \in E_{s_i}^+$ and $e_k \in E \setminus E_{s_i}^+$ forming the training dataset D are randomly sampled during the optimization. [9]

4.4 Evaluation

To assess the performance of the different methods, we adopt a *leave-one-out* methodology, in which a single event per source is withheld at random from the training set D to constitute the test set D_s. This approach ensures that all sources have similar weights in the evaluation. We adopt the widely used *Area Under the Curve* (AUC) as a measure of performance. In the context of this work, the evaluation procedure is formally defined as follows

$$
\text{AUC} = \frac{1}{|D_s|} \sum_{(s_i,e_j,e_k) \in D_s} H(\hat{x}_{s_i,e_j} - \hat{x}_{s_i,e_k}) \, . \tag{7}
$$

where e_j is an event covered by s_i and e_k is an event that s_i hasn't covered, randomly sampled at testing time. Negative samples are drawn uniformly at random across all unique event of the current time slice (we omitted the time indices for the sake of brevity).

4.5 Experimental Setting

The code for experiment and analysis will be made available at publication time under an open-source license. All experiment-related code was run on a 6-core machine, equipped with an `Intel(R) Xeon(R) CPU E5-2630 @ 2.30GHz`, for a total training time of approximately 3 days. [10] We restricted the tuning of hyper-parameter λ_T to a subset of values $\in \{0.001, 0.01, 0.1, 1.0\}$. All scores and figures are reported using $\lambda_T = 0.1$, which we found to provide the highest cross-validated accuracy. For computational reasons, the other parameters were coarse-tuned on a static snapshot and were set to $K = 20$ and $\lambda_\Theta = 0.1$, $\gamma = 0.01$ and $\alpha = 0.1$.

5 RESULTS

In this section, we compare the existing static embedding model with the dynamic method presented in Section 4. The effect of both the prior on the embedding vectors and the temporal regularization are then measured in isolation.

Table 3 summarizes the performances of the various approaches by taking the mean AUC scores obtained, for each month, over the considered period. *BPR* denotes the core of the algorithm without any temporal component. *RG* denotes the use of temporal regularization and *RW* denotes the use of a Gaussian random walk for embedding initialization. To compare with a non-parametrized approach, we also include *POP*, a popularity-based baseline: the score for a given event is a function of its frequency in the training set.

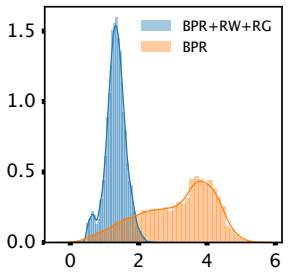

Figure 4: Average displacement of embeddings

	AUC
POP	0.6509
BPR	0.8959
BPR + RG	0.9089
BPR + RW	0.9318
BPR + RW + RG	**0.9337**

Table 3: Method contribution to performance

Several observations can be made in light of these results. Firstly, the combination of the two strategies *RG* and *RW* is shown to provide the best observed predictive performances. Secondly, the individual strategies do not provide the same performance improvements. Results suggest that a proper initialization contributes much more to an accurate prediction than strong temporal regularization. In parallel experiments, we even observed that an increase of λ_T decreases performances. We hypothesize that this is due to the model's inability to handle abrupt changes in source behavior, since a strong regularizer would penalize a large difference with respect to the previous time step.

The use of the proposed dynamic strategies (*RG* and *RW*) provides better overall consistency of the latent space across time slices. This is visible by measuring the average displacement of sources in embedding space. As shown in Fig. 4, sources are much more stable in the dynamic setting compared to the static embedding procedure. The added stability of the embedding space provides a usable expression of divergence across time-steps. This means source similarity can be coherently compared across the entire observed period, while also providing an overall improvement of the AUC scores (see Fig. 5).

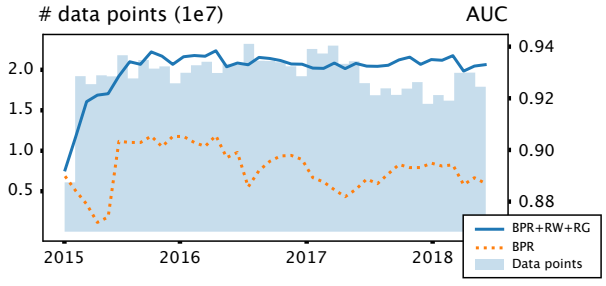

Figure 5: Performances (AUC) and dataset size per month

[9] We sampled both positive and negative examples uniformly. More complex sampling approaches exist [34] but are outside of the scope of this work.

[10] The training time is reported for the full 3-year period; a production-ready application would typically be optimized and use incremental updates instead.

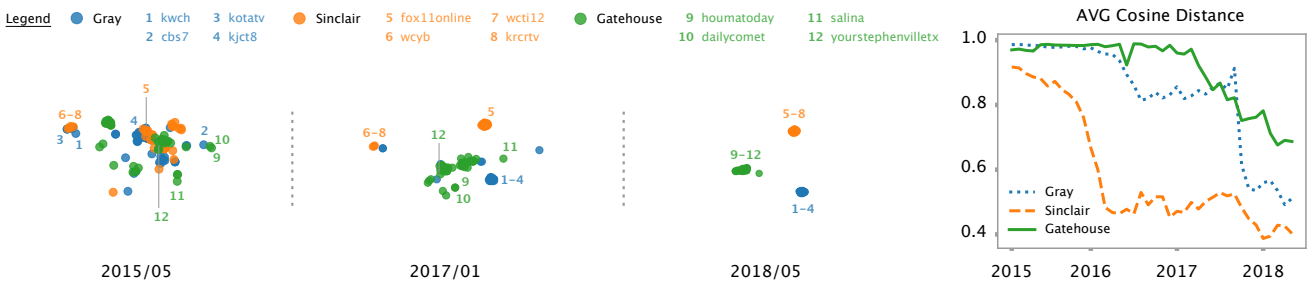

Figure 6: Case-study of the influence of ownership on the selection of covered events (best seen in color)
Left: Sample of the temporal evolution of the media landscape, learned with dynamic embeddings, illustrated with t-SNE. [44] To test the effect of ownership on diversity of coverage, we monitor the evolution of a set of sources all owned by the same broadcast group in 2018, backtracking their evolution in embedding space. Starting with an initial seed source known to be operated by - or affiliated to - one of three large American media conglomerates (Gray Television Inc., Sinclair Broadcasting Group and GateHouse Media), we build a set of 50 sources per group so as to have a comparably sized sample for each. These sources are also all verified to be owned - or operated by - one of these groups at the last observed time-frame of our dataset (May 2018) by cross-checking publicly available information. We project their positions from the embedding space onto a display-friendly plane, showcasing snapshots of their movement over time, as they collapse into highly similar and cohesive clusters in the similarity space.
Right: Average inter-source cosine distance between sources of each group in the dynamic embedding space, over time.

6 ANALYSIS

In the following section, we discuss the interpretation of the model introduced in Section 4. We first describe an approach to visualize the evolution of the news ecosystem. Then, we propose a systematic, unsupervised way to detect abrupt deviations in this space.

6.1 Visualizing the Media Landscape

We start by introducing an example case-study, which should illustrate the usefulness of the presented model in facilitating the understanding of the news ecosystem. The study is centered on three representative media conglomerates that we track throughout the 40-month period covered by our dataset: *Gray Television Inc.* (over 100 television stations), *Sinclair Broadcasting Group* (over 190 television stations) and *GateHouse Media* (over 140 newspapers). [11]

As a starting point, the model described in Section 4 is optimized in its most successful setting (*RW+RG*). Dimensionality reduction is performed in order to have a more interpretable view into the embedding vectors. In Fig. 6 - (*left*) we use a t-distributed Stochastic Neighbor Embedding (t-SNE [44]), a popular method for the visualization of high-dimensional data. In order to maintain consistency across time steps in the projection, we initialize the parameters of the t-SNE optimization procedure at time slice t with the final parameters of time step $t-1$. This seeds the projected points' positions instead of assigning them to a random initial position, allowing for easier tracking between time steps.

Additionally, in order to avoid interpreting from model parameters only, which might be misleading due to optimization artifacts, we correlate sources' trajectories with the average pairwise cosine distance between sources of each group. These distances are computed using sources' respective sets of covered events for each month. Overall, this procedure allows us to coherently visualize the evolution of the media landscape over time, uncovering non-obvious dynamics at several scales, from the ecosystem as whole (e.g. convergence phenomenons) down to individual sources (e.g. shift toward a group).

The designed visualization of the media landscape is presented in Fig. 6. Please refer to Section 7 for a more detailed discussion.

6.2 Detecting Fluctuations in the Media Landscape

Even with extensive domain knowledge, tracking the evolution of a group of sources belonging to specific entities remains a tedious task, since it requires the manual identification of sources of interest and the validation of their common factors. Therefore, in the following section, we propose an unsupervised method which leverages the models' a priori knowledge to identify abrupt changes in sources' content diffusion patterns. In particular, the proposed framework aims to identify attractors, e.g. sources that tend of attract others in latent space, suggesting an alignment of coverage.

Attractors: News channels involved in a consolidation of resources typically tend to have increasingly similar coverage patterns. As seen in Fig. 6 - (*right*), the phenomenon manifests itself as the convergence of a subset of sources toward a common position in embedding space. Systematically detecting such gatherings around a common location, that we will loosely refer to as attractors, would allow to interpret each of these patterns in isolation. We propose a method in two steps. Firstly, we identify sources whose distances to other channels are abruptly reduced at any point in time. Secondly, we identify the absolute position towards which those sources tend to converge.

[11] as of August 2018.

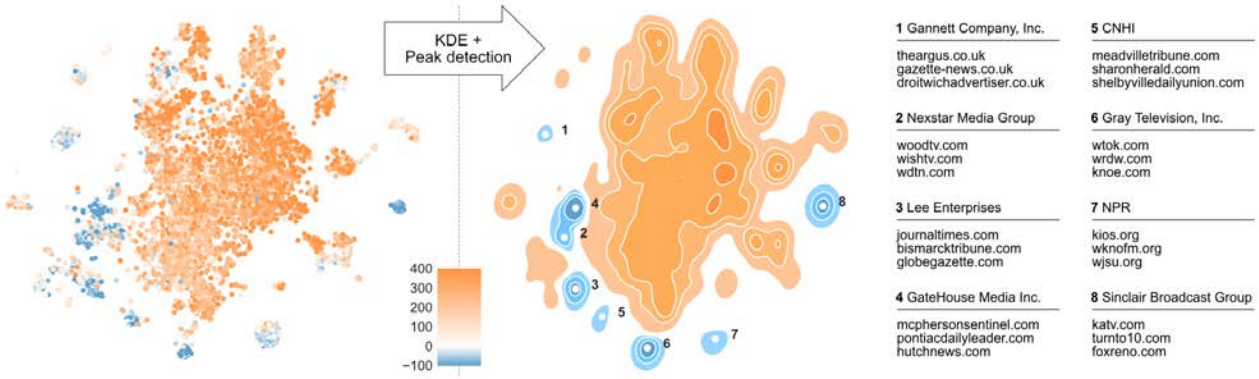

Figure 7: Left: t-SNE [44] projection of the embedding space for May 2018, colors represent the weight w_{s_i} of each source s_i. **Center:** Identified attractor map built from the attraction potential map ($\sigma = 1.9$, $k = 500$). **Right:** Detail and affiliation of attractors identified in (*center*), with the set of 3 sources closest to the uncovered poles. Best seen in color.

We first define the matrix $Z \in \mathbb{R}^{|S|\times|S|}$ that represents the cumulative difference of distances between any two news sources over time. We compute such distances in relative terms in order to avoid any drift component from the evolving latent space. More formally, we define Z as follows.

$$Z_{i,j} = \sum_t \; \|p_{s_i}^{(t)} - p_{s_j}^{(t)}\| - \|p_{s_i}^{(t-1)} - p_{s_j}^{(t-1)}\|\,, \tag{8}$$

where $\|\cdot\|$ is the Euclidean norm. In this setting, two sources whose distances are consistently reduced would produce a negative value of large magnitude in their corresponding entries of Z. Therefore, we rely on the matrix Z to identify channels having undergone large reductions of distance with other sources. In more details, we retrieve from Z the k-sources having the largest negative cumulative difference with any other source, i.e. the minimal value of each row in $Z_{i,j}$. By taking into consideration only the top-k, we can capture large shifts only and avoid considering small movements due to random factors. Once identified, the relative displacement of these k sources can be visualized in latent space. In particular, each source s_i in our dataset will be qualified by a single weight w_{s_i}, computed as the sum of the cumulative difference in Z with respect to the k considered sources. As shown in Fig. 7 - (*left*), negative values reveal sources that tend to exhibit agglomerative behaviors.

Until now, we observed strong fluctuations in terms of inter-source distances. The next step is to define a systematic way of identifying the centers around which these shifts occur, in absolute terms and at any given point in time. On a 2D projection of sources, we apply a weighted Kernel Density Estimator (KDE), a non-parametric method for estimating the Probability Density Function from a set of samples, under weak smoothness assumptions. The objective is to detect areas containing a high density of sources with negative weights and locate their density peaks. We use the weights w_{s_i} as input of the estimator. The bandwidth selection is a function of the data's covariance, multiplied by a constant factor σ. [42] An example of the resulting density is presented in Fig. 7 - (*center*). Finally, local extrema are collected using a local minimum filter, a simple method routinely used in computer vision. The set of identified poles and the top-3 closest sources surrounding them is shown in Fig. 7 - (*right*).

Attractees: Having identified a set of attractors in latent space, the dual observation can be made: the identification of sources that experienced large movements in latent space toward any of the previously identified attraction poles. These are sources that have been strongly influenced by external forces, for example in the content consolidation phase after an acquisition. The detection of these phenomenon is done relative to a specific pole of attraction. In order to track the distance to a pole over time, we start with a set of seed sources. An obvious choice is to study the top-3 closest sources from the poles, detailed in Fig. 7 - (*right*). The ranking of sources having undergone a large shift can once again be made systematic. In particular, we rank sources according to the largest difference in distance to the pole between two consecutive time steps. The distance to the centroid of these sources yields the distance maps shown in Fig. 8 for the top-4 sources with the largest shifts.

7 DISCUSSION

The structure of the news landscape is in a constant state of flux. It is often difficult to follow the evolution of its organizational structure and even more so to determine what influenced these changes. In this section, we discuss how the fluctuations of broadcast patterns can be informative about channels' organizational structure. We report that important changes in this structure are identifiable through abrupt shifts in content diffusion, and showcase the models' ability to systematically highlight this variability in the coverage space.

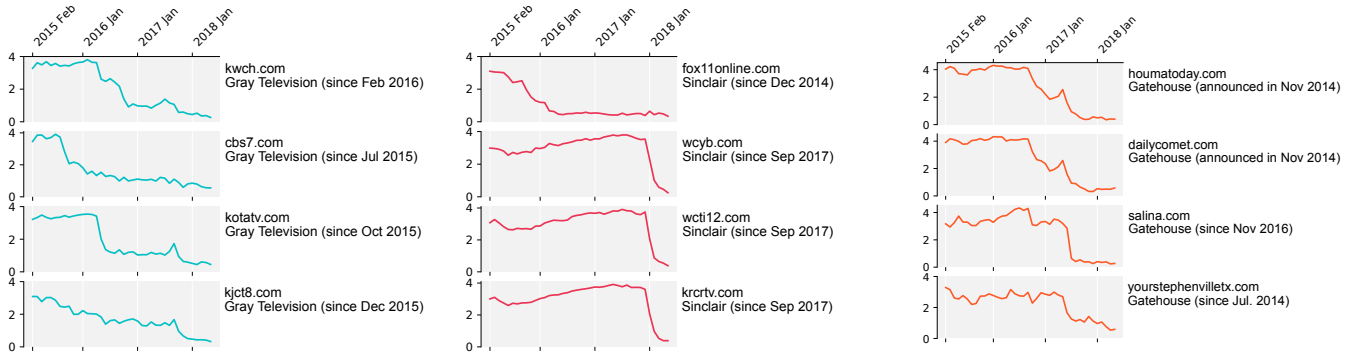

Figure 8: Euclidean distance from channels to their respective affiliations, in latent space, over time. Affiliation positions are computed as the centroid of 3 seed sources (taken from Figure 7 - (*right*)). Those patterns are extracted without any supervision: retrieved channels are the ones having undertaken the largest shift of content over the considered period (2015-2018). Channels acquisition dates are given for reference.

7.1 Observing the effects of ownership on the media landscape

The selection and diffusion of events by individual news channels could be influenced by a large number of factors, from obfuscated economic drivers to convoluted distribution schemes. Theoretically, the external pluralism assumption would prevent large-scale organizational changes in news outlets from inducing significant shifts in coverage. Our findings question the validity of this assumption.

We provide evidence that ownership can indeed exert its influence on the content being distributed downstream. The most distinct and recurring pattern pointing to this conclusion is the subsequent alignment of coverage patterns after an outlet's acquisition. Some examples are clearly observable in Fig. 6, such as the acquisition of 14 stations from the Bonten Media Group by Sinclair Broadcasting Group (SBG) in a deal completed on September 1st, 2017. [12] Visible through the lens of a decrease in the average inter-source distance of the Sinclair stations, this consolidation of coverage can also be tracked in the embedding spaces' visualization in Fig. 6 - (*left*). This can be observed in Fig. 8 as well, albeit with a slight delay with a sharp decrease in the distance from channels like `wcyb.com`, `wcti12.com` or `krcrtv.com` to the center of the Sinclair attraction pole (#8 in Fig. 7).

We observe similar behaviors during others large-scale acquisitions, for example in the purchase of a group of assets from the Morris Publishing Group by GateHouse in August 2017. [13] Other observations of this phenomenon include the sudden increase in coverage similarity of Gatehouse-owned stations around April 2017 (see Fig. 8 - *right*). While not directly correlated to a specific merger or acquisition, these movements could hint at a company-wide content alignment campaign.

Such observations also support the convergence hypothesis. The visualization in Fig. 6 exemplifies this effect: many of the sources that are present in one of these group's media portfolios start out from vastly different regions in embedding space. This is visible in their high initial average cosine distance in Fig. 6 - (*right*) and their dispersed placement in Fig. 6 - (*left*). In the last frame however, these same sources form highly coherent, tight groups in embedding space - and in the visualization. Despite the fact that this case-study back-tracks the evolution of sources across time, explaining the density of the last frame, their convergence points to a unification of coverage patterns over time.

7.2 Detecting highly influential broadcast groups

News outlets present complex content distribution schemes, as is particularly visible in television broadcasting: the on-air content is produced by a wide range of affiliates, from well-known household names to in-house teams, [14] being distributed through channels with another, often different set of owners. While the consolidation of broadcast material for economies of scale or investigative resources for economies of scope can be economically beneficial for the broadcaster, it is also potentially deceitful for a news consumer, as the exact origin of the broadcast content is not always known. By extension, the unique slant it carries in its selection of news is not clearly obvious. Not only does it carry is unique biases in terms of the way in which it covers the content, a topic not discussed in this work, but it also has the ability to over-emphasize or under-report certain events with little accountability.

This influence on coverage can be observed when interpreting the agglomeration dynamics highlighted by Fig. 7. Information sinks can be highlighted through the discovery of attraction poles in the embedding space.

[12] https://tvnewscheck.com/article/103465/sinclair-buying-bonten-stations-for-240m/

[13] https://www.poynter.org/news/gatehouse-acquires-morris-publishings-11-daily-newspapers

[14] A study conducted by Pew Research in 2014 already demonstrated a steady decline in locally produced content, with 1 in 4 local news stations not producing any of their own content [31].

Such sets of highly accretive sources, i.e. sources that draw other sources to align with their coverage, cluster neatly into large broadcast entities, some of which have been mentioned before. Fig. 7-(right) presents these groupings more exhaustively. The three large media groups chosen for analysis in Fig. 6 are present (*Gray Television Inc.*, *Sinclair Broadcasting Group* and *GateHouse Media Inc.*), along with several other large players in the American media landscape.

Previous studies [41] and [4] have studied differences in terms of the types of content covered in television and newspapers outlets, finding that TV stations cover proportionally more "global" news than newspapers. Television is traditionally thought to be more impacted by media consolidation for this reason: content is costly to produce, hence it makes sense for large entities to share their footage at scale. In our model, this should intuitively lead to the flagging of television conglomerates as the strongest attractors, with high content similarities. However, we observe in Fig. 7 that all mediums are represented and impacted by the convergence phenomenon. This could hint to the effect a convergence of mediums can have on the media landscape, with the efficacy co-ownership regulations being jeopardized by the all-encompassing nature of online content delivery.

7.3 Interpretation of the temporal consistency

None of this qualitative analysis would be possible without a temporal consistency constraint on the embedding space. Without such stability, the model could take advantage of an unnecessarily large number of degrees of freedom to align sources. In consequence, it would converge to very different solutions from one epoch to another. Due to the stochastic nature of the procedure, coverage changes would be rendered indistinguishable from optimization artifacts (see Fig. 3). By penalizing sources that deviate from their previous positions, only significant coverage changes can force a source to migrate to a different region in space. In other words, in order to provoke a displacement, the channels' coverage should differ enough from the previous time step to outweigh the temporal constraint. If this condition is met, the source will converge towards a different neighborhood that better fits its coverage patterns, typically getting closer to similar channels.

This variability in time can be tuned through the regularization parameter λ_T, as detailed in Section 4, providing a way to highlight more global dynamics - in the case of strong regularization - or more individual variations - with weak regularization. We also observe that the constraint provides predictive gains. This can be explained by the accumulation of knowledge about sources over time. This last hypothesis is corroborated by the pattern observed in Fig. 5, in which the accuracy reaches its maximum after the first few epochs before stabilizing until the end of the considered period.

8 CONCLUSION

This work tackles the problem of dynamically modeling the filtering decisions of individual actors of the news ecosystem. Beyond the predictive capabilities of the approach, the knowledge gathered by the model is leveraged to characterize the evolution of the media landscape over time. Firstly, we report performance benefits of adding a temporal component to a coverage prediction model. In particular, we show that a dynamic embedding model is able to outperform existing approaches thanks to its ability to propagate knowledge obtained from former time slices to the current prediction step. Secondly, we demonstrate the application of this model as a framework in which to reason about the latent structure of media landscape, modeling the temporal evolution of news outlets' decision processes. Maintaining a consistent latent representation of sources' preferences enables powerful interpretation and visualization methods, highly effective in investigating shifts in the media ecosystem, at a large scale but also at the individual source level.

We demonstrate the potential of the method on several channel acquisition campaigns. We show drastic post-acquisition content alignment in channels belonging to large, well-known broadcast conglomerates. This corroborates the hypothesis of deep consolidation of broadcast material inside news networks. Our work highlights the fragility of the external plurality assumption, which is supposed to guarantee a diversity of ownership and hence viewpoints. Finally, we automate this investigative process and explore several strategies to systemically identify abrupt variations in the news ecosystem, fingerprints of sharp changes in media programming.

Future work: The main focus of this work was to provide a clear and insightful representation of the news landscape, and we foresee several directions to pursue this research effort. Firstly, the method is ripe for the addition of content-based refinements. Our approach focuses on the information's propagation patterns but it is still blind to the content itself and the way it is handled by news outlets. We could for example mention in this vein a semantic analysis of the covered articles. The fact that the model is content-agnostic can however be of great use for its application to other domains. Such methods could be applied to other dynamic systems in which information propagates and evolves, such as online social-networks, knowledge bases or citation networks. Lastly, as has been highlighted throughout this work, particularly in the context of the case-study, we believe that our work would strongly benefit from an interdisciplinary approach, providing tools to journalists, policy-makers or economists, whose expertise would also add great insight to our analysis.

ABSTRACT

While keyphrase extraction has received considerable attention in recent years, relatively few studies exist on extracting keyphrases from social media platforms such as Twitter, and even fewer for extracting disaster-related keyphrases from such sources. During a disaster, keyphrases can be extremely useful for filtering relevant tweets that can enhance situational awareness. Previously, joint training of two different layers of a stacked Recurrent Neural Network for keyword discovery and keyphrase extraction had been shown to be effective in extracting keyphrases from general Twitter data. We improve the model's performance on both general Twitter data and disaster-related Twitter data by incorporating contextual word embeddings, POS-tags, phonetics, and phonological features. Moreover, we discuss the shortcomings of the often used F1-measure for evaluating the quality of predicted keyphrases with respect to the ground truth annotations. Instead of the F1-measure, we propose the use of embedding-based metrics to better capture the correctness of the predicted keyphrases. In addition, we also present a novel extension of an embedding-based metric. The extension allows one to better control the penalty for the difference in the number of ground-truth and predicted keyphrases.

1 INTRODUCTION

Keyphrase extraction is the task of automatically extracting words or phrases from a text, which concisely represent the essence of the text. Keyphrases can be used for multiple tasks including text summarization, classification, and opinion mining. They can also be highly valuable for retrieving relevant documents when searching for specific information. In particular, keyphrases can be used to organize and retrieve useful information from Twitter.

Twitter is an online social media platform, where people communicate via short, terse messages ("tweets"). Due to the ease of posting a tweet, and the popularity of the platform, Twitter can provide up-to-date news around the world, faster than standard media outlets. Thus, in recent years, Twitter has become an important source of real-time information [55, 61]. Specifically, during crisis situations, Twitter has revolutionized the way in which affected populations communicate with response organizations [6, 8]. On one hand, the affected populations can follow and spread the latest updates from government and response organizations on Twitter. On the other hand, affected individuals can post information that can be used to enhance situational awareness and, in some cases, save lives. Emergency hotlines, such as 911, could be overwhelmed by the large number of calls received during major disasters, and as a consequence, individuals often turn to social media, including Twitter, to request assistance [14, 23, 29, 45]. For example, a North Carolina family was rescued during Hurricane Florence after posting the following message on Twitter: *'If anybody could help… our car is under water and so is our house. Stuck in the attic. Phone is about to die. Please send help'* [23].

While social media can help enhance situational awareness, facilitate rescue operations, and ultimately save lives, its value is highly unexploited by response teams, in part due to the lack of tools that can help filter relevant, informative, and actionable information posted during disasters [60]. To address this limitation, the annotation of tweets with informative keyprhases can enable filtering of actionable information by the disaster management and response teams, in real time. In fact, in Twitter, hashtags assigned directly by the users posting the tweets are sometimes used to annotate tweets and can be seen as keyprases useful for filtering. However, a vast majority of tweets do not have any hashtags associated with them, as illustrated by a dataset we crawled during several crisis events that happened in the fall of 2017. Thus, to speed up the search and retrieval of potentially actionable disaster tweets posted by affected individuals, there is an urgent need for methods that can automatically extract keyphrases from tweets without primarily relying on hashtags. The extracted keyphrases can potentially be recommended to users as they are typing their messages, and thus a smaller number of relevant tweets would be retrieved by systems that facilitate filtering of information for the response teams.

Keyphrase extraction from tweets, however, is a non-trivial task due to the tweets' informal nature, noisiness and short length (currently, tweets have a limit of 280 characters). These factors limit the utility of many of the existing unsupervised keyword extraction techniques, which are designed to work on longer text using term-frequencies, word co-occurrences, and clustering methods. Recently, researchers started to explore keyphrase extraction from single tweets using deep-learning models. For example, Zhang et al.

[63] proposed a model based on joint-layer Recurrent Neural Networks (RNNs) and achieved an F1-score of 80.97% when used to extract keyphrases from the general Twitter. However, this RNN-based model has not been extended to extract keyphrases from tweets posted in a specific context, e.g., during a disaster. In fact, there is a distinctive lack of works for extracting keyphrases from disaster tweets. This task is especially challenging as the vocabulary used during a disaster is focused and limited, as compared to the vocabulary in a general collection of tweets. Furthermore, the keyphrases extracted should reflect information related to the event, people involved and their locations, the type of assistance needed, the type of situational awareness provided, etc. Thus, our research agenda is designed to answer the following questions:

(1) *Can we enhance the existing model to improve its performance on both disaster tweets and general tweets?*
(2) *How do the joint-layer-Recurrent Neural Network based models trained on general tweets perform on disaster tweets?*
(3) *How well do the joint-layer-Recurrent Neural Network models perform when trained and tested on disaster tweet data?*

Regarding question (1), we discovered that adding contextual word information, phonetics and phonological features, along with part of speech (POS) tag information, tends to increase the performance of the model on both the general domain and the disaster domain, when training the model on data from the relevant domain. Regarding question (2), it is expected that the model will not perform very well if trained on a general-domain Twitter data and tested on a specific-domain data (e.g., disaster data). However, considering that the general training data and the specific disaster test data are both collected from Twitter, it is still interesting to empirically find the degree to which the RNN-based model trained on general Twitter data can or cannot generalize to disaster data. Finally, regarding question (3), while it is expected that the model will have better performance when trained and tested on specific disaster tweet data, it is interesting to understand how significant the improvement is and what additional information helps the most.

While investigating the above research questions, we found that the exact match F1-based evaluation is not ideal for determining the quality of the extracted keyphrases. As an alternative to the exact match F1 metric, we explored embedding-based similarity metrics [11, 12, 35, 48], and proposed a novel extension to symmetric greedy embedding based similarity scoring. The extension allows for more fine-grained control over the penalty for the difference in the number of ground-truth and predicted keyphrases.

We describe our extensions to the original RNN-based model for keyphrase extraction [63] in Section 3. In Section 4, we present the details of our datasets. We describe the experimental setting in Section 5.1, and the details of our embedding-based evaluation metric in Section 5.2. Finally, we present and discuss our results in Section 5.3 and conclude the paper in Section 6.

2 RELATED WORK

Keyphrase extraction can be supervised or unsupervised. Supervised approaches treat keyphrase extraction as a classification problem. In supervised approaches, a model is trained to learn to classify keyphrases from training data that is annotated with keyphrases [7, 13, 18, 28, 56, 57, 62]. Many unsupervised keyphrase extraction techniques had also been previously proposed [10, 15, 24, 27, 33, 47, 49, 53]. They usually extract candidate keyphrases and rank them based on term frequencies, word co-occurrences, and other similar features. However, the length of tweets is usually too short for most of these techniques to be applicable. Currently, tweets are limited to a length of 280 characters, with the average length of the tweets in a collection being even smaller. Furthermore, keyphrases will rarely occur more than once in a single tweet. These issues along with the noisiness of tweets can make keyphrase extraction from social media platforms such as Twitter a difficult task.

Some of the previous works on keyphrase extraction from Twitter [5, 66] take the approach of inferring keyphrases from multiple tweets. Thus, they can only extract some topical information and trends that are common to multiple tweets. At the level of multiple tweets, some of the word-count based approaches for keyphrase extraction can be still applicable. However, our target is to extract keyphrases from single tweets. Along this line, the approaches proposed by Marujo et al. [30] and Zhang et al. [63] work for single tweets. Marujo et al. [30] showed that word embeddings in a system such as MAUI [31] performs better than the TF-IDF baseline [53]. Furthermore, the Joint-Layer-RNN model proposed by Zhang et al. [63] was shown to be even better than the model proposed by Marujo et al. [30]. The joint-layer RNN model can predict keyphrases of any arbitrary length, based on single tweets, without any significant pre-processing or hand-engineered features. Thus, we chose to focus on this model in our study.

Regarding retrieval and filtering of tweets during disasters, there are many previous works related to processing social media during emergency situations [19], extracting information from Twitter to enhance situational awareness [21, 58, 59], and classifying or clustering disaster-relevant tweets [3, 54, 64], among others. However, to the best of our knowledge, no existing works have focused specifically on the extraction of keyphrases from disaster tweets, a task that we focus on in this study.

Finally, in terms of evaluation, there are previous works related to embedding-based similarity metrics [11, 12, 35, 48], which we also investigate. These metrics have been used for paraphrase detection, assessment of student input [48], and other similar tasks including assessment of the quality of generated dialogues [25, 51] by conversational models. We show that embedding-based similarity metrics can also be used to compare the quality of predicted keyphrases with respect to the ground truth keyphrases. Our specific evaluation method is based on the symmetric greedy matching embedding-based metric, which was introduced in [48].

3 APPROACH

Recurrent Neural Networks (RNN): All models investigated in this work are based on RNN, and are inspired by the model proposed by Zhang et al. [63]. Given an input sequence, $(x_1, x_2, x_3, ..., x_n)$, an RNN processes each token x_t at every time-step t by producing a hidden state, h_t, using the previous hidden state, h_{t-1}, from the previous time-step $t-1$. Formally, this can be expressed as:

$$h_t = f(x_t, h_{t-1}) \tag{1}$$

where f is a non-linear activation function. The final output of an RNN can be a sequence of hidden states, $(h_1, h_2, h_3, ..., h_n)$. We used a specific type of RNN, called Long-Short Term Memory (LSTM)

network [17]. An LSTM is equipped with three gates (an input gate, i, an output gate, o, and a forget gate, f), along with a cell-state, c, and a hidden state, h. The function of an LSTM at each time-step, t, given the input, x_t, can be described with the following equations:

$$f_t = \sigma(x_t W_f + h_{t-1} U_f + b_f) \quad (2)$$

$$i_t = \sigma(x_t W_i + h_{t-1} U_i + b_i) \quad (3)$$

$$o_t = \sigma(x_t W_o + h_{t-1} U_o + b_o) \quad (4)$$

$$g_t = \tanh(x_t W_c + h_{t-1} U_c + b_c) \quad (5)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot g_t \quad (6)$$

$$h_t = o_t \odot \tanh(c_t) \quad (7)$$

where $x_t \in \mathbb{R}^d, h_t, c_t \in \mathbb{R}^h, W_f, W_i, W_o, W_c \in \mathbb{R}^{dxh}, U_f, U_i, U_o, U_c \in \mathbb{R}^{hxh}$, $b_f, b_i, b_o, b_c \in \mathbb{R}^h$ (h represents the number of hidden units, and d represents the dimension of the input), σ is usually the sigmoid activation function, and $\odot$ is the Hadamard product.

The LSTM that we used is bidirectional [16], in that it has two encoders: one forward and one backward. The forward encoder starts processing the input sequence $(x_1, x_2, x_3, ..., x_n)$ from left to right, thus, creating a forward hidden state representation $(\overrightarrow{h_1}, \overrightarrow{h_2}, \overrightarrow{h_3}, .., \overrightarrow{h_n})$ of the input sequence. The backward encoder starts processing the input sequence from right to left, thus, creating a backward hidden state representation $(\overleftarrow{h_1}, \overleftarrow{h_2}, \overleftarrow{h_3}, .., \overleftarrow{h_n})$ of the input sequence. The final hidden state representation $(h_1, h_2, h_3, ..., h_n)$ is created by combining the forward and backward representations (often using the concatenation operator). Formally, we have:

$$\overrightarrow{h_t} = LSTM(x_t, \overrightarrow{h}_{t-1}) \quad (8)$$

$$\overleftarrow{h_t} = LSTM(x_t, \overleftarrow{h}_{t-1}) \quad (9)$$

$$h_t = [\overrightarrow{h_t}; \overleftarrow{h_t}] \quad (10)$$

To make predictions, linear transformations of the hidden states are then passed to a softmax layer.

Similar to the model proposed by Zhang et al. [63], our models use a stack of two Bi-LSTMs. The first Bi-LSTM layer takes the original sequence, $(x_1, x_2, x_3, ..., x_n)$, as input, and produces a hidden state sequence, $h^{(1)}_{1:n} = (h^{(1)}_1, h^{(1)}_2, h^{(1)}_3, ..., h^{(1)}_n)$. The second Bi-LSTM takes the hidden sequence produced by the first Bi-LSTM layer as input, and produces a sequence of deeper hidden state representations $h^{(2)}_{1:n} = (h^{(2)}_1, h^{(2)}_2, h^{(2)}_3, ..., h^{(2)}_n)$. Formally:

$$h^{(1)}_t = BiLSTM_1(x_t, h^{(1)}_{t-1}) \quad (11)$$

$$h^{(2)}_t = BiLSTM_2(h^{(1)}_t, h^{(2)}_{t-1}) \quad (12)$$

Following Zhang et al. [63], we jointly trained the two stacked Bi-LSTMs on two different but related tasks, in a supervised fashion. The first Bi-LSTM was trained to simply find keywords in a text. This can be viewed as a binary classification task, where detected keywords are classified as '1', and other words are classified as '0'. Let the loss function $J_1(\theta)$ represent the classification error of a non-linear transformation of the first hidden layer units, $h^{(1)}_{1:n}$. The hidden layer of the second Bi-LSTM was trained for a relatively more complex task that builds upon the task of the hidden layer of the first Bi-LSTM. Specifically, the second Bi-LSTM was trained to detect keyphrases by using its hidden units $h^{(2)}_{1:n}$ to tag the sequence using the BIOES scheme. In BIOES, 'B' refers to the beginning word of a keyphrase, 'E' refers to the last word of the keyphrase, 'I' refers to the word being inside the keyphrase (in-between 'B' and 'E'), 'S' refers to any single word keyphrase, and 'O' is any word that is not a part of a keyphrase. Let the loss function $J_2(\theta)$ represent the tagging error of a non-linear transformation of the second RNN hidden layer units, $h^{(2)}_{2:n}$. The final loss $J(\theta)$ can then be expressed as the combination of the two losses, $J_1(\theta)$ and $J_2(\theta)$, specifically:

$$J(\theta) = \gamma \cdot J_1(\theta) + (1 - \gamma) \cdot J_2(\theta) \quad (13)$$

where γ is a hyperparameter in the interval [0,1]. The model updates its trainable parameters to minimize the loss function, $J(\theta)$, through backpropagation during training. The loss from a low-level task (keyword discovery) can also serve as additional regularization for the main task (keyphrase extraction). Intuitively, the two stacked networks correspond to two different, but related tasks - essentially, it is an instance of multi-task learning [26, 52].

Contextual Word Embeddings: Word embeddings are high dimensional vector representations of words. Often, embedding algorithms encode contextual information into the vector representations, such that when clustering word-vectors using the Euclidean distance or Cosine-similarity, vectors corresponding to words that appear in similar contexts tend to cluster together. However, classic word embedding models [34, 42] have certain limitations. They can only accommodate one particular vector representation for each word. This restricts the models from being able to capture polysemy (the same word can have completely different meanings in different contexts). The models can also be restricted to a specific vocabulary, which the model has been trained on. Moreover, they can also be blind to morphological information.

Peters et al. [43] proposed the use of a pre-trained language model to create contextualized word embeddings (called ELMo embeddings), which can tackle some of these issues. They used a character level Convolutional Neural Network (CNN) [65] followed by a language model based on Bi-LSTM (however, other architectures can be used [44]). The word embeddings were constructed by a weighted summation of the hidden state representations of the words at various layers of the language model. As a result, there are some interesting benefits. As the initial word-embedding can be done by a CNN at the character level, there is no word-level vocabulary restriction. Also, as the embedding is done by a language model, the embedding of a word is conditioned on the context of all the surrounding words. Therefore, the same word can be represented using different word-vectors if it appears in different contexts.

As an enhancement to the main RNN-based model, which uses Glove embeddings[1] [42] to represent the input words, we concatenated the ELMo embeddings with GloVe embeddings pre-trained on a Twitter corpus. We used Flair[2][2] to load the Twitter GloVe embeddings and TensorFlow hub[3] to load the ELMo embeddings.

Modeling Tweet Noisiness: In Twitter, people often use shorthands, slang, arbitrary capitalizations, and varied lexical representations for a word, all of which contribute to a high overall noisiness

in tweets. For this reason, many Natural Language Processing tools are found to perform noticeably worse when used on Twitter or similar social media domains, even when they perform very well on cleaner data (like news articles) [1, 46]. Aguilar et al. [1] proposed various ways to combat the inherent noisiness in social media platforms. They noted how Twitter users often tend to spell words based on their pronunciations. Thus, while spellings of a word may differ in their lexical format, they tend to have similar phonetics. Therefore, we can create more normalized representations of the words by using their phonetics or corresponding IPA (International Phonetic Alphabet) letters, alongside with their phonological features. Following the work of Aguilar et al. [1], we used Epitran[4] [36] to convert graphemes to phonemes (represented using IPA), and Panphon[5] [37] to convert each IPA phoneme into a vector representing various phonological (articulatory) features associated with it. In addition, we noticed that words that are nouns or adjectives are generally better candidates for keywords. For example, disaster names (nouns) can often be used as keyphrases. Therefore, similar to [1], we also added part-of-speech (POS) information to our model. We used the Twitter optimized POS-tagger[6] as provided by Owoputi et al. [41] for POS-tagging.

We used randomly initialized trainable embeddings for each POS-tag and IPA symbol. We directly used the phonological vector representations created with Panphon as embeddings for phonological features. We concatenated the embeddings of IPA symbols with their corresponding phonological feature vectors. The result of the concatenation, a character level representation of the phonetics and phonological features for each word, was fed to a character-level CNN [65], followed by a global max-pooling layer, to create word level representations. Note that the character-level processing may also allow the network to capture some morphological information. Unlike Aguilar et al., we chose to use a CNN as opposed to a Bi-LSTM for creating the word level representations, because using a Bi-LSTM at character level can be much more computationally expensive and time-consuming than using a CNN. The output of the CNN was concatenated with the POS embeddings, ELMo embeddings, and GloVe embeddings. The resultant representation was then fed to the stacked Bi-LSTM. Figure 1 illustrates this setup.

4 DATASETS

We performed our experiments on both general and disaster-related Twitter datasets. For the general Twitter dataset, we used the dataset[7] published in [63], which is annotated with keyprases. The training and test data were provided as separate files. We used 80% of the training data for actual training and 20% for validation.

We constructed the disaster training and validation datasets by combining disaster-related tweets that have hashtags, from several disasters, specifically, Boston Bombing, Hurricane Harvey, and Hurricane Sandy. We used 80% of the data for training and 20% for validation. We used the combination of disaster-related tweets, with hashtags, from Mexico Earthquake, Hurricane Maria, and Hurricane Irma as test data. To annotate the training, validation and test tweets with keyphrases, we first made use of hashtags. The hashtagged units (marked with '#') in the tweets used are often multi-word phrases without any spaces in-between. We used WordSegment[8] to split the hashtagged multi-word phrases into individual words. These segmented words were used as ground truth for keyphrase extraction. This is similar to how Zhang et al. [63] prepared their annotations. Since hashtags are often used to mark topical phrases or phrases related to some trends, they represent good candidates for keyphrases. In addition, we also used a crisis-lexicon [38] to find disaster-related words (at both unigram and bigram level) in the dataset, and marked them as ground-truth keyphrases. We also added some of our own phrases such as "Boston Bombing", "Hurricane Sandy", "Mexico Earthquake" to the crisis-lexicon.

For both the general and disaster datasets, we filtered out tweets that were longer than 200 tokens or shorter than 5 tokens after tokenization. Table 1 shows the exact number of tweets we used for training, validation, and testing in each dataset. In addition, Table 1 shows the total number of keyphrases and the average number of keyphrases per tweet in each dataset. As can be seen, the average number of keyphrases/hashtags per tweet in the disaster dataset is approximately twice the average number of keyphrases/hashtags per tweet.

There are other differences in terms of keyphrase usage between the general and the disaster datasets. First, the types of keyphrases used in the two datasets are quite different, as the disaster dataset contains a more limited vocabulary related to disasters, while the general dataset has a more diverse vocabulary. This can be seen by comparing the two wordclouds shown in Figure 2. Furthermore, from Figure 2, we can also see that there are many frequently

Table 1: Dataset summary.

occurring keyphrases in the disaster data, whereas there are a lot fewer keyphrases that appear as frequently in the general data. At last, we point out that the disaster test data is quite different from the disaster training (and validation) data, given that the test data contains tweets related to different disasters as compared to the disasters in the training and validation data. In particular, a significant fraction of the disaster test data is made of disaster tweets posted during the Mexico Earthquake, while the training and validation data do not contain tweets related to earthquakes. However, both training/validation and test data contain tweets collected during hurricanes, although the hurricanes used in the training/validation are different from those used in the test. The differences in the disaster training and test data can be observed in Figure 3. We intentionally created a challenging test dataset that allows us to evaluate the model's performance on data from a disaster that does not appear in the training, to understand the usability of the model in a realistic scenario.

5 EXPERIMENTS AND RESULTS

5.1 Experimental Setting

One of our goals was to enhance the original model proposed in [63] with contextual information (in the form of contextual word embeddings), and also with information that can alleviate the noisiness of the Twitter data (specifically, phonology and POS tag information). Thus, our set of experiments was designed to compare the baseline model [63] with the proposed variants. The implementation details of the models are described below. Hyperparameters were selected based on common values used in similar prior architectures, and/or (limited) tuning on the validation set.

Joint-layer Bi-LSTM (J-Bi-LSTM): This model serves as our baseline. We parsed each sequence using a window of size 3, that is, each token in the sequence was represented by three consecutive words. As an example, if the sequence is (s_1, s_2, s_3), after parsing it with a window of size 3, the sequence gets converted into $([SOS, s_1, s_2], [s_1, s_2, s_3], [s_2, s_3, EOS])$ (where SOS is a special tag denoting the start of the sequence, and EOS is a similar tag denoting the end of the sequence). The 3-word representation of a token was used to encode more contextual information into each token, before feeding the tokens into the LSTM. Zhang et al. [63] empirically found 3 to be a good choice for the window size. Each word/token in the sequence was embedded with a 100-dimensional GloVe vector pre-trained on a general Twitter corpus. The embeddings were further fine-tuned during training. Each LSTM network had 300 hidden units. We used a dropout of 0.5 [4] on the input to the first and second LSTMs. We also used a dropout with the same rate on the output from the second LSTM. For training, we used the nadam optimizer [9] with a learning rate of 0.0015. Finally, we used an γ value of 0.5 for joining the two loss functions $J_1(\theta)$ and $J_2(\theta)$. Tuning this hyperparameter may lead to better results.

J-Bi-LSTM with ELMo Embeddings (J-Bi-LSTM+ELMo): This variant is similar to the baseline model, except that it uses 1024 dimensional ELMo embeddings, along with the GloVe embeddings. The two types of embeddings, GloVe and ELMo, are concatenated together. As the ELMo embeddings have much higher dimensionality, and are designed to encode contextual information, we did not use the window approach for this model. Other implementation details and hyperparameters are similar to those in the baseline.

J-Bi-LSTM with IPA & POS (J-Bi-LSTM+IPA+POS): This variant is also similar to the baseline, except that it uses IPA-embeddings, phonological feature vectors and POS-tag embeddings along with the GloVe embeddings (with a window of size 3). We used 64-dimensional embeddings for POS-tags and 22-dimensional embeddings for IPA symbols. The phonological feature vectors have 22 dimensions as well. For the character-level CNN, we used 128 filters and a kernel of size 3. As before, other implementation details and hyperparameters are similar to those in the baseline.

J-Bi-LSTM with ELMo, IPA & POS (J-Bi-LSTM+ELMo+IPA+POS): To evaluate the combined effect of the contextual word embeddings and IPA/POS-tags, this variant makes use of IPA-embeddings, phonological feature vectors and POS-tag embeddings, along with the concatenation of GloVe and ELMo embeddings. Other implementation details and hyperparameters are the same as before.

We compare the above models in three different settings: (1) we train all models on general tweet data and test them also on general tweet data. The goal of this comparison was to see if the additional information used can improve the performance of the baseline; (2) we train all models on the general tweet data and test them on the disaster tweet data, with the goal of understanding how much information can be transferred from the general tweet data to the disaster-specific tweet data; (3) we train all models on disaster tweet data and test them also on disaster tweet data. The goal of this experiment was to see how much the models improve by being trained on specific disaster data, and also what type of information leads to the largest performance improvements.

5.2 Evaluation Metrics

The J-Bi-LSTM based models take a sequence-labeling approach towards keyphrase extraction. Thus, the precision, recall, and F1-measure can be used to evaluate the results. A keyphrase predicted by the model is considered to be correct if there exists an exact matching keyphrase in the same position in the ground-truth annotation; otherwise, the prediction is considered incorrect.

Despite being frequently used, the F1-measure may not be ideal for evaluating the quality of predicted keyphrases. For example, if the

ground-truth keyphrase is "harvey", and the extracted keyphrase is "harvey hurricane", the exact-F1 measure will be zero. Therefore, the model can produce appropriate predictions, or sometimes even better predictions than the ground-truth annotations, but still, receives a zero score. Similarly, a model may detect some keyphrases that are semantically similar to the ground-truth, but not exact matches. For example, the model may detect 'tremor' instead of 'earthquake'. In these cases too, the model will receive a zero score, whereas presumably some points should be awarded to the model for predicting something close to the ground truth.

The above reasons led us to explore embedding-based measures. It has been shown that the cosine-similarity between certain vector representations (such as GloVe or word2vec embeddings) of semantically similar words tend to be high. Intuitively, we can use cosine-similarity of such word embeddings to measure the degree of similarity between them, as an alternative to simply checking for an exact match. Embedding-based metrics have been used in evaluating the quality of generated dialogues, detecting paraphrases, assessing student responses, and other similar tasks. Here, we are interested in comparing the ground-truth keyphrases with the predicted keyphrases. However, taking the order and positional information into account, while comparing them can be complicated. For example, consider a case where there are two gold keyphrases 'K_1' and 'K_2' at consecutive locations P_1 and P_2, respectively, whereas the predicted keyphrase is '$K_1\ K_2$' (covering both P_1 and P_2 locations). Such cases make it complicated to use positional information for comparison. Thus, we moved our focus from the standard sequence-labeling evaluation approach to an approach that seems more natural to the task of keyphrase extraction.

Specifically, we first extracted the gold and predicted keyphrases from a labeled sequence and converted them into sets of keyphrases. By doing this, the order information was ignored, and duplicates were removed. As a result, we obtained two sets - a set of gold keyphrases and a set of predicted keyphrases. Our goal was to use the embedding based metrics to measure the overlap between these sets. However, each keyphrase in the gold and predicted sets, respectively, can have an arbitrary number of words, each with its own word embedding. This further complicates the keyphrase-to-keyphrase comparison. To simplify the task, we took the average of the word-embeddings in each phrase to create phrase-level embeddings. Given the phrase-level embeddings, the embedding-based metrics can be used in several ways to score the overall quality of the predicted keyphrases using the gold keyphrases as the standard. Some of these methods are described below.

Average Embeddings: One approach is to take the average [11, 22, 35] of all phrase-level embeddings in the set of gold keyphrases. (Alternatively, we can also use the most extreme value [12] along each dimension, across all the phrase-level-embeddings in the set.) Then, we can either compute the average of cosine-similarity scores between the phrase-level embedding of each predicted keyphrase and the average-gold-embedding, or we can compute the cosine-similarity score between the average embedding of the predicted keyphrases and the average embedding of the gold keyphrases.

Greedy Matching: Another approach is to make word to word (or in our case, keyphrase to keyphrase) comparisons without creating single representations for all keyphrases in the sets. In this approach, we can score each keyphrase from the set of predicted keyphrases in two steps. In the first step, we compute the cosine-similarity scores between the predicted keyphrase under consideration and each keyphrase in the set of gold keyphrases. In the second step, we take the maximum of all the computed cosine-similarity scores for each predicted keyphrase. The maximum cosine-similarity score should correspond to the best matching keyphrase in the gold set for a particular predicted keyphrase. Thus, each predicted keyphrase can be scored. Finally, we can take the average of the scores to get the final score for the model's prediction [48]:

$$GM(\ pred, gold\ ) = \frac{\sum_{i=1}^{p} score(pred_i, gold)}{p} \tag{14}$$

where p is the number of predicted keyphrases, *pred* is the set of predicted keyphrases, *gold* is the set of gold keyphrases, and $pred_i$, with $i \in \overline{1,p}$, are the elements of *pred*. *GM* is the greedy match scoring function, and $score(pred_i, gold)$ is the maximum cosine-similarity achieved between $pred_i$ and any keyphrase from *gold*.

However, this scoring is not symmetric. $GM(\ pred, gold\ )$ will not necessarily be the same as $GM(\ gold, pred\ )$. Inspired from [48], we can use the following formula to calculate a symmetric score:

$$T = GM(\ pred, gold\ ) + GM(\ gold, pred\ ) \tag{15}$$

$$SymmGM(\ pred, gold\ ) = \frac{T}{2} \tag{16}$$

There is another benefit of the symmetric scoring. If $GM(pred, gold)$ is used alone, the model can be scored highly even if there is only one prediction in the set which happens to match very well with just one gold keyphrase, among multiple other gold keyphrases that were not predicted. Similarly, $GM(\ gold, pred\ )$ can produce a high score, even if there is only one keyprhase in the gold set that matches very well with just one predicted keyphrase, among multiple other predicted keyphrases that do not match with the gold. Using $SymmGM(\ pred, gold\ )$ mitigates these issues.

Optimal matching: This approach, proposed by Rus and Lintean [48], can be used to first create an optimal group of exclusive phrase-to-phrase pairs using the Kuhn-Munkres method [20] for optimal assignment. Then, each predicted keyphrase can be scored simply by computing its cosine-similarity with the gold-keyphrase that it is paired with. The later steps are similar to those of greedy matching.

Proposed embedding-based metric: We chose greedy matching as the backbone of our proposed embedding-based metric. As we are dealing with small sets of discrete keyphrases, we found it more appropriate to choose a phrase-to-phrase comparison approach such as greedy matching or optimal matching. A predicted keyphrase can be considered appropriate if it is similar to any of the gold keyphrases. Therefore, to score the correctness of the predictions, we chose to allow multiple predicted keyphrases to be matched to the same gold keyphrase if needed. However, optimal matching can only allow exclusive one-to-one pairs. This is why we did not choose the optimal matching.

We should note that if we simply use the average score when calculating $GM(\ pred, gold\ )$ and $GM(\ gold, pred\ )$, the variation in the

	Gold and prediction	F1	No alpha-beta No threshold General Embd	No alpha-beta No threshold Crisis Embd	General Embd	Crisis Embd
1	**Gold:** teen choice **Prediction:** teen choice awards	0%	95.6%	88.4%	95.6%	88.4%
2	**Gold:** earthquake, volunteers, working together **Prediction:** earthquake, volunteers working together	40%	93.1%	92.1%	80.5%	79.8%
3	**Gold:** storm, cloud, calamity **Prediction:** tornado, cloudy sky, disaster	0%	61.1%	30.9%	52.3%	13.4%
4	**Gold:** harvey **Prediction:** hurricane	0%	25.2%	63.20%	0%	63.20%

Table 2: General and crisis embedding-based scores versus F1 scores on seven sets of gold/predicted keyphrases.

number of keyphrases in *gold* and *pred* may not be completely taken into account by greedy matching. More specifically, $GM(pred, gold)$ can be high as long as all the predicted keyphrases achieve high cosine-similarity scores with any one of the gold keyphrases. But it may not take into account how many more or less keyphrases there may be in the *gold* set as compared to those in the *pred* set. Similarly, $GM(gold, pred)$ can be high, as long as all the gold keyphrases achieve high cosine-similarity scores with any of the predicted keyphrases, without taking into account how many more or less keyphrases there may be in the *pred* set as compared to those in the *gold* set. Both $GM(pred, gold)$ and $GM(gold, pred)$ may be high at the same time despite wide variation in the number of predicted keyphrases and gold keyphrases, when most of the keyphrases in *gold* and *pred* are very similar to each other. To account for this, we may want to penalize the model for extracting too little or too many keyphrases compared to the gold. This can be done with a simple modification to the *GM* definition:

$$GM'(pred, gold) = \frac{\sum_{i=1}^{p} score(pred_i, gold)}{max(p, g)} \tag{17}$$

$$GM'(gold, pred) = \frac{\sum_{i=1}^{g} score(gold_i, pred)}{max(p, g)} \tag{18}$$

$$T' = GM'(pred, gold) + GM'(gold, pred) \tag{19}$$

$$SymmGM'(pred, gold) = \frac{T'}{2} \tag{20}$$

where g is the number of gold keyphrases, and p is the number of predicted keyphrases as defined before. $SymmGM'(pred, gold)$ is the overall score. If g is higher than p, the $GM'(pred, gold)$ score will be lower as compared to the $GM(pred, gold)$ score, and if p is higher than g, then $GM'(gold, pred)$ will be lower as compared to $GM(gold, pred)$. Intuitively, we can think of $GM'(pred, gold)$ as penalizing the overall score, when g is higher than p, and we can think of $GM'(gold, pred)$ as penalizing the overall score when p is higher than g.

However, we may also want to have more fine-grained control over the degree of penalty. Typically, $SymmGM(pred, gold)$ will be high even when there is wide variation in the lengths of *pred* and *gold* sets if most of the predicted and gold kephrases are similar to each other. But if that is the case, the predictions are still likely to be appropriate. Moreover, in general, variation in the number of keyphrases can be implicitly penalized by plain averages (with $GM(gold, pred)$ and $GM(pred, gold)$) because with wide variation, there will be higher chances for there to be phrases unique to only one set, which are dissimilar with any of the phrases in the other set. For these reasons, we may want to constrain the penalty for the variation of length, which can be achieved as another extension of the *GM* scoring. First note that:

$$max(p, g) = p + max(0, g - p) = g + max(0, p - g) \tag{21}$$

To gain more fine-grained control over the penalty for the length variation, we use two new parameters α and β, as follows:

$$GM_{ext}(pred, gold) = \frac{\sum_{i=1}^{p} score(pred_i, gold)}{p + \alpha \cdot max(0, g - p)} \tag{22}$$

$$GM_{ext}(gold, pred) = \frac{\sum_{i=1}^{g} score(gold_i, pred)}{g + \beta \cdot max(0, p - g)} \tag{23}$$

$$T_{ext} = GM_{ext}(pred, gold) + GM_{ext}(gold, pred) \tag{24}$$

$$G(pred, gold) = \frac{T_{ext}}{2} \tag{25}$$

Intuitively, α and β can be used to modulate the penalty for p being smaller than g, and for p being greater than g, respectively. This leads to a more general formulation. For example, when α is 0, $GM_{ext}(pred, gold)$ is just $GM(pred, gold)$, and when α is 1, $GM_{ext}(pred, gold)$ is just $GM'(pred, gold)$. $G(pred, gold)$ is symmetric when α and β have the same value.

We used $G(pred, gold)$ to compare a predicted keyphrase set with a gold keyphrase set, with α and β both being set to 0.7. In addition, we also used a threshold θ of 0.4 on each cosine-similarity scores to limit the contribution of lower-scoring matches, and implicitly, to limit the range of $G(pred, gold)$ to values between 0 and 1. That is, if the cosine similarity score is lower than a specified

threshold, we assigned it a score of 0, otherwise, the actual score is used. The values of α, β, and θ were selected intuitively. There is room for empirical studies in the future to determine how people judge the evaluation quality for different values of α, β, and θ.

Embedding-based versus F1-measure evaluation: In Table 2, we used several sets of predicted keyphrases and gold keyphrases to compare the exact-match F1-measure with greedy matching (no alpha-beta and no threshold), and our proposed embedding-based metric. The last five examples are fabricated pairs of gold keyphrases and predictions to serve as case studies for comparison. For the embedding-based metric, we used both GloVe embeddings pre-trained on general Twitter (General Embd), and GloVe embeddings that we trained on a crisis-related Twitter corpus (Crisis Embd). The crisis-related embeddings were trained on three previously published crisis datasets, specifically, CrisisLexT6 [39], CrisisLexT26 [40] and 2CTweets [50], together with tweets collected using the Twitter Streaming API during Hurricanes Harvey, Irma, and Maria, and Mexico Earthquake. The total corpus contains approximately 5.8 million tweets. As can be seen in Table 2, the embedding-based scores appear to be more appropriate than the F1 scores, based on a human understanding of the keyphrases. We can also notice (see example 3) that the general Twitter GloVe embeddings can be better for scoring the semantic similarity between general words than the crisis embeddings. This may be because the general Twitter embeddings were trained on a much larger corpus, which is more diverse and general. However, crisis embeddings appear to be better for scoring the similarity between disaster-related words, especially if disaster-related named-entities are involved (see example 4). This is probably because the crisis embeddings were trained on more recent Twitter data and, specifically, on disaster-related data. Not so surprisingly, we also find that crisis embedding-based scores are higher on the disaster data, and general Twitter embedding-based scores are higher on the general data in Table 4. Alpha-beta modulated embedding scores are generally more stringent than embedding scores without the modulation. Without alpha-beta modulation and thresholding, the embedding metrics work as standard greedy matching. The difference made by alpha-beta modulation is most sharply noticeable in examples 6 and 7 where there is a significant difference in the number of gold keyphrases and predicted keyphrases. As can be seen, without alpha-beta modulation, the embedding scores are very high despite the difference in length between the two sets of keyphrases.

5.3 Results

The results of our experiments for the three settings discussed in Section 5.1 are presented in Tables 3 and 4. Table 3 shows precision, recall, and F1 scores, based on exact keyphrase matches (where the order of the keyphrases and the position are both taken into account). Table 4 shows F1 scores versus GM_{ext} embedding-based scores, computed by comparing a set of predicted keyphrases with a set of gold keyphrases (where the order of the keyphrases and the position are both ignored, and duplicate keyphrases are removed). Thus, while the F1 scores in Tables 3 and 4 may appear to be inconsistent, we would like to point out that the differences are due to the way the scores are calculated in each table, as explained above.

Table 4: General and crisis embedding-based scores versus F1 scores, when comparing predicted with gold keyphrases.

We calculated the F1-scores in Table 4 by comparing sets, in order to make them more comparable to the embedding-based scores. We will next analyze the performance of each model individually.

Baseline (J-Bi-LSTM): The baseline achieved scores in the low-to-mid 80% range when trained and tested on general data, and scores in the low-to-mid 60% range when trained and tested on disaster data. Surprisingly, its performance is close to the performance of other models, which use richer information. Furthermore, the J-Bi-LSTM model produced higher recall than models with ELMo on disaster test data. Also, interestingly, the baseline model achieved the best F1 score in Table 3, when trained on general data and tested

on disaster data. However, it was not the best scorer if we consider its embedding-based scores in Table 4 instead.

J-Bi-LSTM+ELMo: The model enhanced with contextual word embeddings achieved a slightly higher score than the baseline when trained and tested on general Twitter data. An even better score may have been possible if the ELMo embeddings were pre-trained on a Twitter corpus. However, the F1 performance of this model on disaster data after being trained on general data is lower than the performance of the baseline, but its embedding-based scores are higher. There is no significant difference between the overall F1 score of the baseline and the F1 score of this model when trained and tested on disaster data. Although the model seems to get slightly better precision, it struggles on recall more than the baseline.

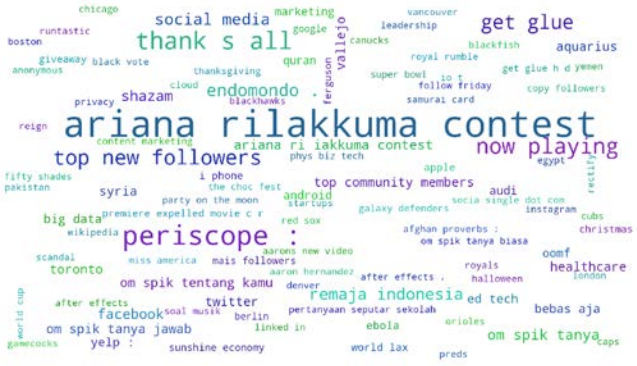
J-Bi-LSTM+IPA+POS: The addition of POS, IPA and phonological feature information generally improves the performance of the J-Bi-LSTM+IPA+POS model over the baseline. The model even gets a better score than the J-Bi-LSTM+ELMo model, and it achieves similar performance to J-Bi-LSTM+ELMo+IPA+POS on the general test data. So, simply adding POS, IPA and phonological information may eliminate the need for ELMo embeddings. This could be because both ELMo and IPA (with phonological features) can model some similar character-level information (like morphology). Furthermore, as mentioned above, ELMo may not be expressing its full potential in the Twitter domain because it was not pre-trained on a noisy social media corpus. Interestingly, the J-Bi-LSTM+IPA+POS appears to have the worst F1 score when trained on general data and tested on disaster data, but it performs the best in terms of the crisis embedding-based metric. When trained and tested on disaster data, this model is also one of the better performers.

J-Bi-LSTM+ELMo+IPA+POS: Finally, the model enhanced with ELMo embeddings, and also POS, IPA and phonological feature information, achieved the best overall F1 score when trained and tested on general data, but not in the other two scenarios. It seems that the ELMo embeddings and the POS/phonetics may contain somewhat overlapping information. ELMo can capture some character level information, which may be why adding further character level information from IPA and phonological features do not give a significant boost in performance. Overall the performance of this model is similar to the performance of the JRNN+ELMo model on the disaster data. We also considered training models using crisis embeddings but they did not help.

In the remaining of this section, we will use the results in Tables 3 and 4 to answer our original questions. First, regarding question (1), we can say that the models enhanced with contextual and/or POS/phenomes information generally perform better than the baseline model, although the baseline is not much worse.

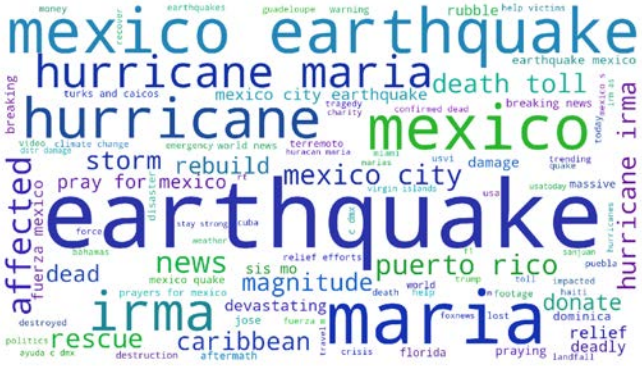
Regarding our original question (2), we noted that the models achieved much lower F1 scores when trained on general data and tested on disaster data. It should be expected that the domain differences contribute to the low score. However, there is another important reason. As we mentioned before in Section 4, the average number of keyphrases per disaster tweet is approximately twice the average number of keyphrases per general tweet. Thus, it is likely that the models, when trained on the general tweet data, learn to predict one keyphrase per sample on average. This results in a substantial hit to their recall when tested on the disaster data, which presents more variety in the number of keyphrases per tweet. Nevertheless, as can be seen from figure 4(a), a model trained on general data, can still predict keyphrases similar to the gold (Figure 3(b)). Furthermore, their embedding-based scores are also much higher than their overall F1 scores. Due to the fundamental differences in the two datasets (as discussed in more details in Section 4), a model may learn some parameters which are useful for general tweets, but the same parameters may be counter-productive in the case of tweets from the disaster test data. This may be why the models that performed better on general data struggled more to generalize on disaster data. But the results are not too straightforward, because some of those models did generalize better on disaster data when considering their embedding-based scores. Overall, it may be better to be cautious about judging the models' capabilities based on their performance on a domain they were not even trained on.

Finally, to answer question (3), we can claim that the models trained and tested on the disaster data can perform significantly better than the models trained on general data and tested on disaster data. However, the performance scores on the disaster test data are overall lower than those on the general test data. This is because we used a rather challenging test set for the disaster data, as discussed earlier. Furthermore, the low diversity of keyphrases in the disaster training data can encourage the models to memorize more (and thus overfit) instead of learning more general abstract features. Nevertheless, they can still predict keyphrases that are fairly similar to the gold (see Figures 3(b) and 4(b)), and their embedding-based scores are better than the F1 scores.



6 CONCLUSIONS AND FUTURE WORK

We showed that the Joint-layer Bi-LSTM model can be a promising approach for extracting disaster-related keyphrases from Tweets. We also showed that ELMo embeddings and/or phonetics and phonological features, along with POS-tags, can generally improve the performance of the model. We discussed how the exact match F1 can be an unsuitable metric for evaluating the quality of the predicted keyphrases, and we showed that embedding-based metrics are more appropriate for this task. We further introduced novel extensions to the embedding-based metrics, to account for differences in terms of the number of predicted and gold keyphrases.



In future work, we would like to focus on abstractive keyphrase generation [32]. Taking a generative approach as opposed to an extractive one would allow us to generate keyphrases that are absent from the source text but still appropriate given the semantics of the text. This can further enhance keyphrase-based search of tweets related to a particular context (including disaster context).

ABSTRACT

Wikipedia is playing an increasingly central role on the web, and the policies its contributors follow when sourcing and fact-checking content affect million of readers. Among these core guiding principles, *verifiability* policies have a particularly important role. Verifiability requires that information included in a Wikipedia article be corroborated against *reliable secondary sources*. Because of the manual labor needed to curate Wikipedia at scale, however, its contents do not always evenly comply with these policies. Citations (i.e. reference to external sources) may not conform to verifiability requirements or may be missing altogether, potentially weakening the reliability of specific topic areas of the free encyclopedia. In this paper, we aim to provide an empirical characterization of the reasons *why* and *how* Wikipedia cites external sources to comply with its own verifiability guidelines. First, we construct a *taxonomy of reasons* why inline citations are required, by collecting labeled data from editors of multiple Wikipedia language editions. We then crowdsource a large-scale dataset of Wikipedia sentences annotated with categories derived from this taxonomy. Finally, we design algorithmic models to determine if a statement *requires a citation*, and to predict the *citation reason*. We evaluate the accuracy of such models across different classes of Wikipedia articles of varying quality, and on external datasets of claims annotated for fact-checking purposes.

CCS CONCEPTS

• **Computing methodologies** → *Neural networks*; *Natural language processing*; • **Information systems** → *Crowdsourcing*; • **Human-centered computing** → *Wikis*.

1 INTRODUCTION

Wikipedia is playing an increasingly important role as a "neutral" arbiter of the factual accuracy of information published in the web. Search engines like Google systematically pull content from Wikipedia and display it alongside search results [38], while large social platforms have started experimenting with links to Wikipedia articles, in an effort to tackle the spread of disinformation [37].

Research on the accuracy of information available on Wikipedia suggests that despite its radical openness—anyone can edit most articles, often without having an account —the confidence that other platforms place in the factual accuracy of Wikipedia is largely justified. Multiple studies have shown that Wikipedia's content across topics is of a generally high quality[21, 34], that the vast majority of vandalism contributions are quickly corrected [20, 33, 42], and that Wikipedia's decentralizedprocess for vetting information works effectively even under conditions where reliable information is hard to come by,such as in breaking news events [27].

Wikipedia's editor communities govern themselves through a set of collaboratively-created policies and guidelines [6, 19]. Among those, the Verifiability policy[1] is a key mechanism that allows Wikipedia to maintain its quality. Verifiability mandates that, in principle, "all material in Wikipedia... articles must be verifiable" and attributed to reliable secondary sources, ideally through inline citations, and that unsourced material should be removed or challenged with a *{citation needed}* flag.

While the role citations serve to meet this requirement is straightforward, the process by which editors determine which claims require citations, and why those claims need citations, are less well understood. In reality, almost all Wikipedia articles contain at least some unverified claims, and while high quality articles may cite hundreds of sources, recent estimates suggest that the proportion of articles with few or no references can be substantial [35]. While as of February 2019 there exists more than 350,000 articles with one or more *{citation needed}* flag, we might be missing many more.

Furthermore, previous research suggests that editor citation practices are not systematic, but often contextual and ad hoc. Forte et al. [17] demonstrated that Wikipedia editors add citations primarily for the purposes of "information fortification": adding citations to protect information that they believe may be removed by other editors. Chen et al. [10] found evidence that editors often add citations to existing statements relatively late in an article's lifecycle. We submit that by understanding the reasons why editors prioritize

[1] https://en.wikipedia.org/wiki/Wikipedia:Verifiability

adding citations to some statements over others we can support the development of systems to scale volunteer-driven verification and fact-checking, potentially increasing Wikipedia's long-term reliability and making it more robust against information quality degradation and coordinated disinformation campaigns.

Through a combination of qualitative and quantitative methods, we conduct a systematic assessment of the application of Wikipedia's verifiability policies at scale. We explore this problem throughout this paper by focusing on two tasks:

(1) Citation Need: identifying *which* statements need a citation.
(2) Citation Reason: identifying *why* a citation is needed.

By characterizing qualitatively and algorithmically these two tasks, this paper makes the following contributions:

- We develop a Citation Reason Taxonomy[2] describing reasons why individual sentences in Wikipedia articles require citations, based on verifiability policies as well as labels collected from editors of the English, French, and Italian Wikipedia (See Sec. 3).
- We assess the validity of this taxonomy and the corresponding labels through a crowdsourcing experiment, as shown in Sec. 4. We find that sentences needing citations in Wikipedia are more likely to be historical facts, statistics or direct/reported speech. We publicly release this data as a Citation Reason corpus.
- We train a deep learning model to perform the two tasks, as shown in Secc. 5 and 6. We demonstrate the high accuracy (F1=0.9) and generalizability of the Citation Need model, explaining its predictions by inspecting the network's attention weights.

These contributions open a number of further directions, both theoretical and practical, that go beyond Wikipedia and that we discuss in Section 7.

2 RELATED WORK

The contributions described in this paper build on three distinct bodies of work: crowdsourcing studies comparing the judgments of domain experts and non-experts, machine-assisted citation recommendations on Wikipedia, and automated detection and verification of factual claims in political debates.

Crowdsourcing Judgments from Non-Experts. Training machine learning models to perform the citation need and citation reason tasks requires large-scale data annotations. While generating data for the first task necessarily requires expert knowledge (based on understanding of policies), we posit that defining the *reasons* why a citation that has already been deemed appropriate is needed can be effectively performed by people without domain expertise, such as crowdworkers.

Obtaining consistent and accurate judgments from untrained crowdworkers can be a challenge, particularly for tasks that require contextual information or domain knowledge. However, a study led by Kittur [31] found that crowdworkers were able to provide article quality assessments that mirrored assessments made by Wikipedians by providing clear definitions and instructions, and by focusing the crowdworkers attention on the aspects of the article that provided relevant evaluation criteria. Similarly, Sen et al. [46] demonstrated that crowdworkers are able to provide semantic relatedness judgments as scholars when presented with keywords related to general knowledge categories.

Our labeling approach aims to assess whether crowdworkers and experts (Wikipedians) agree in their understanding of verifiability policies—specifically, whether non-experts can provide reliable judgments on the reasons why individual statements need citations.

Recommending Sources. Our work is related to a body of bibliometrics works on citation analysis in academic texts. These include unsupervised methods for citation recommendation in articles [24], and supervised models to identify the purpose of citations in academic manuscripts[1]. Our work explores similar problems in the different domain of Wikipedia articles: while scholarly literature cites work for different purposes[1] to support original research, the aim of Wikipedia's citations is to verify existing knowledge.

Previous work on the task of source recommendation in Wikipedia has focused on cases where statements are marked with a *citation needed* tag [14–16, 44]. Sauper et al. [14, 44] focused on adding missing information in Wikipedia articles from external sources like news, where the corresponding Wikipedia entity is a salient concept. In another study [16], Fetahu et al. used existing statements that have either an outdated citation or *citation needed* tag to query for relevant citations in a news corpus. Finally, the authors in [15], attempted to determine the *citation span*—that is, which parts of the paragraph are covered by the citation—for any given existing citation in a Wikipedia article and the corresponding paragraph in which it is cited.

None of these studies provides methods to determine whether a given (untagged) statement *should* have a citation and *why* based on the citation guidelines of Wikipedia.

Fact Checking and Verification. Automated verification and fact-checking efforts are also relevant to our task of computationally understanding verifiability on Wikipedia. Fact checking is the process of assessing the veracity of factual claims [45]. Long et al. [36] propose TruthTeller computes annotation types for all verbs, nouns, and adjectives, which are later used to predict the truth of a clause or a predicate. Stanovsky et al. [47] build upon the output rules from TruthTeller and use those as features in a supervised model to predict the factuality label of a predicate. Chung and Kim [13] assess source credibility through a questionnaire and a set of measures (e.g. informativeness, diversity of opinions, etc.). The largest fact extraction and verification dataset FEVER [49] constructs pairs of factual snippets and paragraphs from Wikipedia articles which serve as evidence for those factual snippets. However,these approaches cannot be applied in our case because they make the assumption that any provided statement is of factual nature.

Research on the automated fact detectors in political discourse [23, 32, 39] is the work in this domain that is most closely related to ours. While these efforts have demonstrated the ability to effectively detect the presence of facts to be checked, they focus on the political discourse only, and they do not provide explanation for the models' prediction. In our work, we consider a wide variety of topics—any topic covered in Wikipedia—and design models able to not only detect claims, but also explain the reasons why those claims require citations.

[2]We use here the term "taxonomy" in this context as a synonym of *coding scheme.*

Table 1: A taxonomy of Wikipedia verifiability: set of reasons for adding and not adding a citation. This taxonomy is the result of a qualitative analysis of various sources of information regarding Wikipedia editors' referencing behavior.

Reasons why citations are needed	
Quotation	The statement appears to be a direct quotation or close paraphrase of a source
Statistics	The statement contains statistics or data
Controversial	The statement contains surprising or potentially controversial claims - e.g. a conspiracy theory
Opinion	The statement contains claims about a person's subjective opinion or idea about something
Private Life	The statement contains claims about a person's private life - e.g. date of birth, relationship status.
Scientific	The statement contains technical or scientific claims
Historical	The statement contains claims about general or historical facts that are not common knowledge
Other	The statement requires a citation for reasons not listed above (please describe your reason in a sentence or two)
Reasons why citations are not needed	
Common Knowledge	The statement only contains common knowledge - e.g. established historical or observable facts
Main Section	The statement is in the lead section and its content is referenced elsewhere in the article
Plot	The statement is about a plot or character of a book/movie that is the main subject of the article
Already Cited	The statement only contains claims that have been referenced elsewhere in the paragraph or article
Other	The statement does not require a citation for reasons not listed above (please describe your reason in a sentence or two)

3 A TAXONOMY OF CITATION REASONS

To train models for the Citation Need and Citation Reason tasks, we need to develop a systematic way to operationalize the notion of verifiability in the context of Wikipedia. There is currently no single, definitive taxonomy of reasons why a particular statement in Wikipedia should, or should not, have a supporting inline citation. We drew on several data sources to develop such a taxonomy using an inductive, mixed-methods approach.

Analyzing Citation Needed Templates. We first analyzed reasons Wikipedia editors provide when requesting an inline citation. Whenever an editor adds a *citation needed* tag to a claim that they believe should be attributed to an external source, they have the option to specify a reason via a free-form text field. We extracted the text of this field from more than 200,000 *citation needed* tags added by English Wikipedia editors and converted it into a numerical feature by averaging the vector representations of each sentence word, using Fasttext [8]. We then used k-means to cluster the resulting features into 10 clusters (choosing the number of clusters with the elbow method [28]). Each cluster contains groups of consistent reasons why editors requested a citation. By analyzing these clusters, we see that the usage of the "reason" field associated with the *citation needed* tag does not consistently specify the reason why these tags are added. Instead, it is often used to provide other types of contextual information—for example, to flag broken links or unreliable sources, to specify the date when the tag was added, or to provide very general explanations for the edit. Therefore, we did not use this data to develop our taxonomy.

Analyzing Wikipedia Citation Policies. As a next step, we analyzed documentation developed by the editor community to describe rules and norms to be followed when adding citations. We examined documentation pages in the English, French, and Italian language editions. Since each Wikipedia language edition has its own citation policies, we narrowed down the set of documents to analyze by identifying all subsidiary rules, style guides, and lists of best practices linked from the main Verifiability policy page, which exists across all three languages. Although these documents slightly differ across languages, they can be summarized into 28 distinct rules [3]. Rules that we identified across these pages include a variety of types of claims that should usually or always be referenced to a source, such as claims of scientific facts, or any claim that is likely to be unexpected or counter-intuitive. These documentation pages also contain important guidance on circumstances under which it is appropriate to *not* include an inline citation. For example, when the same claim is made in the lead section as well as in the main body of the article, it is standard practice to leave first instance of the claim unsourced.

Asking Expert Wikipedians. To expand our Citation Reason Taxonomy, we asked a group of 36 Wikipedia editors from all three language communities (18 from English Wikipedia, 7 from French Wikipedia, and 11 from Italian Wikipedia) to annotate citations with reasons. Our experiment was as follows: we extracted sentences with and without citations from a set of Featured Articles and removed the citation metadata from each sentence. Using WikiLabels[4], an open-source tool designed to collect labeled data from Wikipedia contributors, we showed our annotators the original article with all citation markers removed and with a random selection of sentences highlighted. Editors were then asked to decide whether the sentence needed a citation or not (Citation Need task), and to specify a reason for their choices (Citation Reason task) in a free-text form. We clustered the resulting answers using the same methodology as above, and used these clusters to identify additional reasons for citing claims.

[3]The full guideline summary and the cluster analysis can be found here: https://figshare.com/articles/Summaries_of_Policies_and_Rules_for_Adding_Citations_to_Wikipedia/7751027

[4]https://meta.wikimedia.org/wiki/Wiki_labels

Our final set of 13 discrete reasons (8 for adding and 5 for not adding) is presented in Table 1. In Section 4, we evaluate the accuracy of this taxonomy and use it to label a large number of sentences with citation-needed reasons.

4 DATASETS

In this Section, we show how we collected data to train models able to perform the Citation Need task, for which we need sentences with binary citation/no-citation labels, and the Citation Reason task, for which we need sentences labeled with one of the reason category from our taxonomy.

4.1 Citation Need Dataset

Previous research [17] suggests that the decision of whether or not to add a citation, or a *citation needed* tag, to a claim in a Wikipedia article can be highly contextual, and that doing so reliably requires a background in editing Wikipedia and potentially domain knowledge as well. Therefore, to collect data for the Citation Need task we resort to expert judgments by Wikipedia editors.

Wikipedia articles are rated and ranked into ordinal quality classes, from "stub" (very short articles) to "Featured". Featured Articles[5] are those articles that are deemed as the highest quality by Wikipedia editors based on a multidimensional quality assessment scale [6]. One of the criteria used in assessing Featured Articles is that the information in the article is *well-researched*.[7] This criterion suggests that Featured Articles are more likely to consistently reflect best practices for when and why to add citations than lower-quality articles. The presence of *citation needed* tags is an additional signal we can use, as it indicates that at least one editor believed that a sentence requires further verification.

We created three distinct datasets to train models predicting if a statement requires a citation or not[8]. Each dataset consists of: (i) *positive instances* and (ii) *negative instances*. Statements with an *inline citation* are considered as *positives*, and statements *without an inline citation* and that appear in a *paragraph with no citation* are considered as *negatives*.

Featured – FA. From the set of 5,260 *Featured* Wikipedia articles we randomly sampled 10,000 positive instances, and equal number of negative instances.

Low Quality (citation needed) – LQN. In this dataset, we sample for statements from the 26,140 articles where at least one of the statements contains a *citation needed* tag. The *positive instances* consist solely of statements with *citation needed* tags.

Random – RND. In the random dataset, we sample for a total of 20,0000 positive and negative instances from all Wikipedia articles. This provides an overview of how editors cite across articles of varying quality and topics.

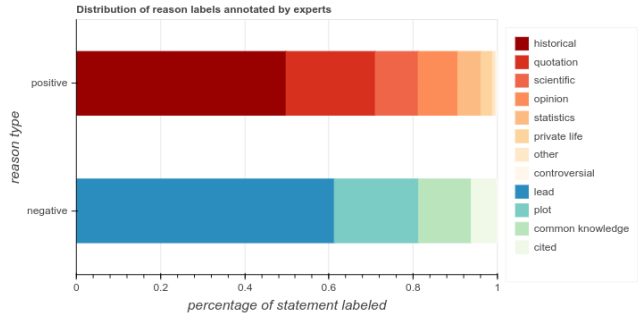

Figure 1: Distribution of labels assigned by Wikipedia Editors through the Wikilabels platform to characterize the reason why statements need citations.

4.2 Citation Reason Dataset

To train a model for the Citation Reason task,we designed a labeling task for Wikipedia editors in which they are asked to annotate Wikipedia sentences with both a binary judgment (citation needed/not needed) and the reason for that judgment using our Citation Reason Taxonomy. We used these annotations as ground truth for a larger-scale crowdsourcing experiment, where we

asked micro-workers to select reasons for why *positive* sentences require citations. We compared how well crowdworkers' judgments matched the Wikipedia editor judgments. Finally, we collected enough annotations to train machine learning algorithms.

4.2.1 Round 1: Collecting Data from Wikipedia Editors. To collect "expert" annotations from Wikipedia editors on why sentences need citations, we proceeded as follows.

Interface Design. We created a modified version of the free-text WikiLabels labeling task described in Section 3. We selected random sentences from Featured Articles, and removed citation markers when present. We presented the participants with the unsourced sentence highlighted in an article and asked them to label the sentence as needing an inline citation or not, and to specify a reason for their choice using a drop-down menu pre-filled with categories from our taxonomy. We recruited participants through mailing lists, social media and the English Wikipedia's Village pump (the general discussion forum of the English Wikipedia volunteer community).

Results. We collected a total of 502 labels from 35 English Wikipedia editors. Of the valid[9] annotated sentences, 255 were labeled as needing a citation (*positive*), and 80 as not needing a citation. Fig. 1 shows the breakdown of results by selected reason.

We found that the reason given for roughly 80% of the *positive* sentences is that they are "historical facts", "direct quotations", or "scientific facts". Furthermore, we observed that only a small percentage of participants selected the "Other" option, which suggests that our Citation Reason Taxonomy is robust and makes sense to editors, even when they are asked to provide these reasons outside of their familiar editing context.

[9]Due to a bug in the system, not all responses were correctly recorded.

Table 2: Example of sentences annotated with different categories by Wikipedia experts and Mechanical Turk contributors.

Non-Expert judgment	Expert judgment	Sentence extracted from Wikipedia Featured Article
historical	*quotation*	He argued that a small number of Frenchmen could successfully invade New Spain by allying themselves with some of the more than 15,000 Native Americans who were angry over Spanish enslavement
life	*historical*	Actor Hugh Jackman is also a fan of the club, having been taken to Carrow Road as a child by his English mother, though he turned down an opportunity to become an investor in the club in 2010
statistics	*historical*	The act, authored by Ohio senator and former Treasury secretary John Sherman, forced the Treasury to increase the amount of silver purchased to 4,500,000 troy ounces (140,000 kg) each month
quotation	*historical*	"This stroke", said Clark, "will nearly put an end to the Indian War." Clark prepared for a Detroit campaign in 1779 and again in 1780, but each time called off the expedition because of insufficient men and supplies

4.2.2 Round 2: Collecting Data from non-Experts. We adapted the task in Round 1 to collect data from crowdworkers to train a Citation Reason model.

Task adaptation. Adapting classification tasks that assume a degree of domain expertise to a crowdwork setting, where such expertise cannot be relied upon, can create challenges for both reliability and quality control. Crowdworkers and domain experts may disagree on classification tasks that require special knowledge [46]. However, Zhang et al.[51] found that non-expert judgments about the characteristics of statements in news articles, such as whether a claim was well supported by the evidence provided, showed high inter-annotator agreement and high correlation with expert judgments. In the context of our study, this suggests that crowdworkers may find it relatively easier to provide reasons for citations than to decide which sentences require them in the first place. Therefore, we simplified the annotation task for crowdworkersto increase the likelihood of eliciting high-quality judgments from non-experts. While Wikipedia editors were asked to both identify whether a sentence required citation and provide a reason, crowdworkers were only asked to provide a reason why a citation was needed.

Experimental Setup. We used Amazon Mechanical Turk for this annotation task. For each task, workers were shown one of 166 sentences that had been assigned citation reason categories by editors in round 1. Workers were informed that the sentence came from a Wikipedia article and that in the original article it contained a citation to an external source. Like editors in the first experiment, crowdworkers were instructed to select the most appropriate category from the eight citation reasons 1. Each sentence was classified by 3 workers, for a total of 498 judgments. For quality control purposes, only crowdworkers who had a history of reliable annotation behavior were allowed to perform the task. Average agreement between workers was 0.63% (vs random 1/8 =0.125).

4.2.3 Comparing Expert and Non-Expert annotations. The distribution of citation reasons provided by crowdworkers is shown in Fig. 2. The overall proportions are similar to that provided by Wikipedia editors in Round 1 (See Fig. 1). Furthermore, the confusion matrix in Fig. 3 indicates that crowdworkers and Wikipedia editors had high agreement on four of the five most prevalent reasons: *historical, quotation, scientific* and *statistics*. Among these five categories, non-experts and experts disagreed the most on *opinion*. One potential reason for this disagreement is that identifying whether a statement

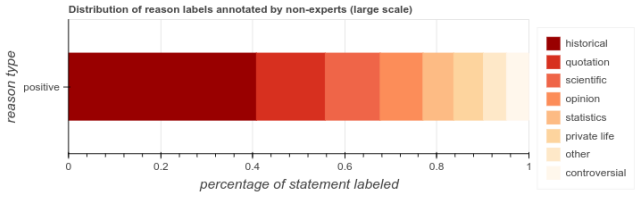

Figure 2: Citation reason distribution from the small-scale (166 sentences) crowdsourcing experiment.

is an opinion may require additional context (i.e. the contents of the preceding sentences, which crowdworkers were not shown).

The confusion matrix in Fig. 3) shows the percentage of different kinds of disagreement—for example, that crowdworkers frequently disagreed with editors over the categorization of statements that contain *"claims about general or historical facts."* To further investigate these results, we manually inspected a set of individual sentences with higher disagreement between the two groups. We found that in these cases the reason for the disagreement was due to a sentence containing multiple types of claims, e.g. a historical claim and a direct quote (see Table 2). This suggests that in many cases these disagreements were not due to lower quality judgments on the part of the crowdworkers, but instead due to ambiguities in the task instructions and labeling interface.

4.2.4 The Citation Reason Corpus: Collecting Large-scale Data. Having verified the agreement between Wikipedia editors and crowdworkers, we can now reliably collect larger scale data to train a Citation Reason model. To this end, we sampled 4,000 sentences that contain citations from Featured articles, and asked crowdworkers to annotate them with the same setup described above (see Sec 4.2.2). The distribution of the resulting judgments is similar to Fig. 2: as in Round 1, we found that the top categories are the *scientific*,*quotation* and *historical* reasons.[10]

[10]Our *Citation Reason corpus* is publicly available here: https://figshare.com/articles/Citation_Reason_Dataset/7756226.

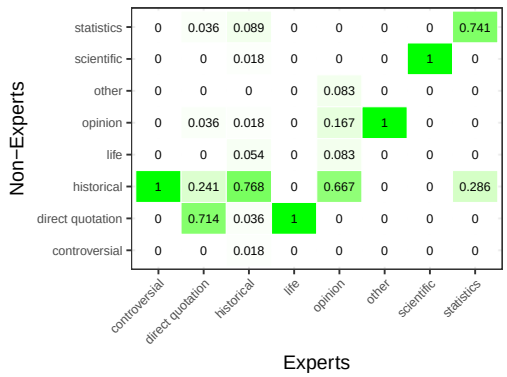

Figure 3: Confusion matrix indicating the agreement between Mechanical Turk workers ("non-experts") and Wikipedia editors ("experts"). The darker the square, the higher the percent agreement between the two groups

5 A CITATION NEED MODEL

We design a classifier to detect when a statement needs a citation. We proposea neural based Recurrent Neural Network (RNN) approach with varying representations of a statement, and compare it with a baseline feature-based model.

5.1 Neural Based Citation Need Approach

We propose a neural based model, which uses a recurrent neural network (RNN) with GRU cells[11] to encode statements for classification. We distinguish between two main modes of statement encoding: (i) vanilla RNN, fed with 2 different representations of a sentence (words and section information, indicated with RNN^{w} and RNN^{+S}), and (ii) RNN with global attention RNN_a (with similar representation).

5.1.1 Statement Representation. For a given Wikipedia sentence, for which we want to determine its citation need, we consider the words in the statement and the section the statement occurs in. To feed the network with this information, we transform sentence words and section information into features, or representations. Through the word representation we aim at capturing cue words or phrases that are indicators of a statement requiring a citation. Section representation, on the other hand, allows us to encode information that will play a crucial role in determining the Citation Reason later on.

Word Representation. We represent a statement as a sequence of words $s = (w_1, \ldots, w_n)$. We use GloVe pre-trained word embeddings [40] to represent the words in s. Unknown words are randomly initialized in the word embedding matrix $W_{glove} \in \mathbb{R}^{k \times 100}$, where k is the number of words in the embedding matrix.

Section Representation. The section in which the statement occurs in a Wikipedia article is highly important. The guidelines for *inline citations* suggest that when a statement is in the *lead section*, and that is referenced elsewhere in the article, editors should avoid multiple references [11]. Additionally, since sections can be seen as a topically coherent group of information, the reasons for citation will vary across sections (e.g. *"Early Life"*). We train the *section embedding* matrix $W_S \in \mathbb{R}^{l \times 100}$, and use it in combination with W_{glove}, where l is the number of sections in our dataset.

5.1.2 Statement Classification. We use 2 types of Recurrent Neural Networks to classify the sentence representations.

Vanilla RNNs. RNNs encode the individual words into a hidden state $h_t = f(w_t, h_{t-1})$, where f represents GRU cells [11]. The encoding of an input sequence from s is dependent on the previous hidden state. This dependency based on f determines how much information from the previous hidden state is passed onto h_t. For instance, in case of GRUs, h_t is encoded as following:

$$h_t = (1 - z_t) \odot h_{t-1} + z_t \odot \tilde{h}_t \quad (1)$$

where, the function z_t and $\tilde{h}_t$ are computed as following:

$$z_t = \sigma(W_z w_t + U_z h_{t-1} + b_z) \quad (2)$$

$$\tilde{h}_t = \tanh\left(W_h w_t + r_t \odot (U_h h_{t-1} + b_h)\right) \quad (3)$$

$$r_t = \sigma(W_r w_t + U_r h_{t-1} + b_r) \quad (4)$$

The RNN encoding allows us to capture the presence of words or phrases that incur the need of a citation. Additionally, words that do not contribute in improving the classification accuracy are captured through the model parameters in function r_t, allowing the model to ignore information coming from them.

RNN with Global Attention – RNN_a. As we will see later in the evaluation results, the disadvantage of vanilla RNNs is that when used for classification tasks, the classification is done solely based on the last hidden state h_N. For long statements this can be problematic as the hidden states, respectively the weights are highly compressed across all states and thus cannot capture the importance of the individual words in a statement.

Attention mechanisms [4] on the other hand have proven to be successful in circumventing this problem. The main difference with standard training of RNN models is that all the hidden states are taken into account to derive a *context vector*, where different states contribute with varying weights, or known with *attention weights* in generating such a vector.

Fig. 4 shows the RNN_a^{+S} model we use to classify a statement. We encode the statement through a bidirectional RNN based on its word representation, while concurrently a separate RNN encodes the section representation. Since not all words are equally important in determining if a statement requires a citation, we compute the *attention weights*, which allow us to compute a *weighted representation* of the statement based on the hidden states (as computed by the GRU cells) and the *attention weights*. Finally, we *concatenate* the weighted representation of the statement based on its words and section, and push it through a dense layer for classification.

The vanilla RNN, and the varying representations can easily be understood by referring to Fig. 4, by simply omitting either the section representation or the attention layer.

5.1.3 Experimental Setup. We use Keras [12] with Tensorflow as backend for training our RNN models. We train for 10 epochs (since the loss value converges), and we set the batch size to 100. We use Adam [29] for optimization, and optimize for *accuracy*. We set the number of dimensions to 100 for hidden states h, which represent the words or the section information.

[11] https://en.wikipedia.org/wiki/Wikipedia:Manual_of_Style/Lead_section

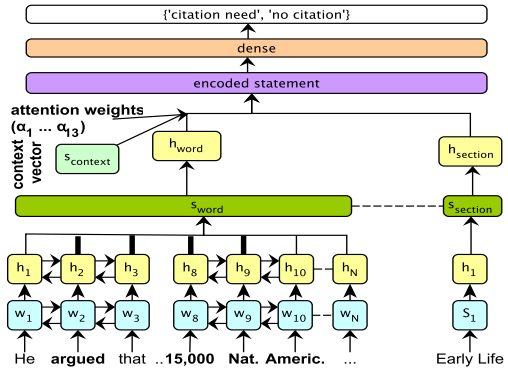

Figure 4: Citation Need model with RNN and global attention, using both word and section representations.

Table 3: Point-Biserial Correlation Coefficient between citation need labels and individual feature values

FA		LQN		RND	
Section	-0.621	*underline*	0.054	*say*	0.084
say	0.107	*say*	0.0546	*underline*	0.0842
underline	0.107	*believe*	0.042	*Section*	-0.072
realize	0.068	*disagree*	0.040	*report*	0.062
suggest	0.068	*claim*	0.039	*tell*	0.062

We train the models with 50% of the data and evaluate on the remaining portion of statements.

5.2 Feature-based Baselines

As we show in Table 1, where we extract the reasons why statements need a citation based on expert annotators, the most common reasons (e.g. *statistics*, *historical*) can be tracked in terms of specific *language frames* and *vocabulary use* (in the case of *scientific* claims). Thus, we propose two baselines, which capture this intuition of language frames and vocabulary. From the proposed feature set, we train standard supervised models and show their performance in determining if a statement requires a citation.

5.2.1 Dictionary-Based Baseline – Dict. In the first baseline, we consider two main groups of features. First, we rely on a set of lexical dictionaries that aim in capturing words or phrases that indicate an activity, which when present in a statement would imply the necessity of a citation in such cases. We represent each statement as a feature vector where each element correspond to the frequency of a dictionary term in the statement.

Factive Verbs. The presence of *factive verbs* [30] in a statement presumes the truthfulness of information therein.

Assertive Verbs. In this case, assertive verbs [25] operate in two dimensions. First, they indicate an assertion, and second, depending on the verb, the credibility or certainty of a proposition will vary (e.g. *"suggest"* vs. *"insist"*). Intuitively, *opinions* in Wikipedia fall in this definition, and thus, the presence of such verbs will be an indicator of opinions needing a citation.

Entailment Verbs. As the name suggests, different verbs entail each other, e.g. *"refrain"* vs. *"hesitate"* [5, 26]. They are particularly interesting as the context in which they are used may indicate cases of *controversy*, where depending on the choice of verbs, the framing of a statement will vary significantly as shown above. In such cases, Wikipedia guidelines strongly suggest the use of citations.

Stylistic Features. Finally, we use the frequency of the different POS tags in a statement. POS tags have been successfully used to capture linguistic styles in different genres [41]. For the different citation reasons (e.g. *historical*, *scientific*), we expect to see a variation in the distribution of the POS tags.

5.2.2 Word Vector-Based Baseline – WV. Word representations have shown great ability to capture word contextual information, and their use in text classification tasks has proven to be highly effective [22]. In this baseline, our intuition is that we represent each statement by averaging the individual word representations from a pre-trained word embeddings [40]. Through this baseline we aim at addressing the cases, where the *vocabulary use* is a high indicator of statements needing a citation, e.g. *scientific* statements.

5.2.3 Feature Classifier. We use a Random Forest Classifier [9] to learn Citation Need models based on these features. To tune the parameters (depth and number of trees), similar to the main deep learning models, we split the data into train, test and validation (respectively 50%,30% and 20% of the corpus). We perform cross-validation on the training and test set, and report accuracy results in terms of F1 on the validation set.

5.3 Citation Need Indicators

We analyze here how algorithms associate specific sentence features with the sentence's need for citations.

5.3.1 Most Correlated Features. To understand which sentence features are more related to the need for citation, we compute the Point Biserial Correlation coefficient [48] between the binary citation/no-citation labels and the frequency of each word in the baseline dictionary of each sentence, as well as the *Section* feature.

We report in Table 3 the top-5 most correlated features for each dataset. In featured articles, the most useful features to detect statements needing citation is the position of the sentence in the article, i.e. whether the sentence lies in the lead section of the article. This might be due to the fact that FA are the result of a rigorous formal process of iterative improvement and assessment according to established rubrics [50], and tend to follow the best practices to write the lead section, i.e. including general overview statements, and claims that are referenced and further verified in the article body. In the *LQN* dataset we consider as "positives" those sentences tagged as *Citation Needed*. Depending on the article, these tags can appear in the lead section too, thus explaining why the *Section* feature is not discriminative at all for this group of sentences. Overall, we see that *report verbs*, such as *say, underline, claim* are high indicators of the sentence's need for citations.

5.3.2 Results from Attention Mechanisms in Deep Learning. Fig. 5 shows a sample of positive statements from Featured Articles

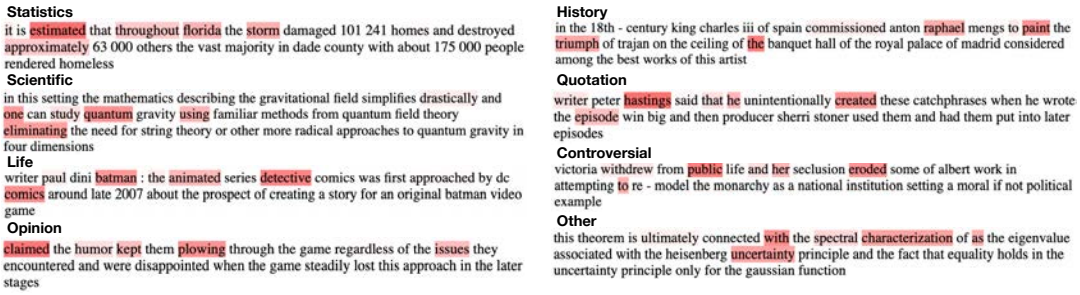

Figure 5: Attention mechanism for RNN_a^{+S} visualizing the focus on specific words for the different citation reasons. It is evident that the model is able to capture patterns similar to those of human annotators (e.g. *"claimed"* in the case of *opinion*.)

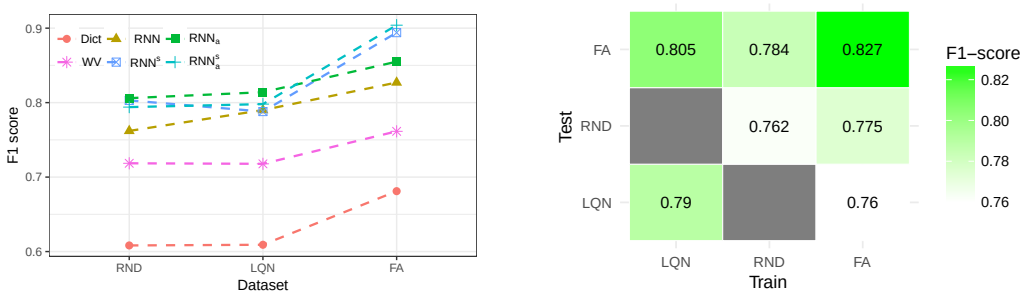

Figure 6: (a) F1 score for the different Citation Need detection models across the different dataset. (b) Confusion Matrix visualizing the accuracy (F1 score) of a Citation Need model trained on Featured Articles and tested on other datasets, showing the generalizability of a model trained on Featured Articles only.

Table 4: Accuracy (F1 score) of Citation Need classification models on Featured Article vs individual expert editor annotations on the same set of Featured Articles.

	no citation	citation	average
individual editor	0.608	**0.978**	0.766
RNN_a^{+S}	**0.902**	0.905	**0.904**

grouped by citation reason. The words are highlighted based on their *attention weight* from the RNN_a^{+S} model. The highlighted words show very promising directions. It is evident that the RNN_a^{+S} model attends with high weights words that are highly intuitive even for human annotators. For instance, if we consider the *opinion* citation reason, the highest weight is assigned to the word *"claimed"*. This is case is particularly interesting as it capture the *reporting verbs* [43] (e.g. *"claim"*) which are common in opinions. In the other citation reasons, we note the *statistics* reason, where similarly, here too, the most important words are again verbs that are often used in reporting numbers. For statements that are *controversial*, the highest attention is assigned to words that are often used in a negative context, e.g. *"erode"*. However, here it is interesting, that the word *"erode"* is followed by context words such as *"public"* and *"withdrew"*. From the other cases, we see that the attention mechanism focuses on domain-specific words, e.g *scientific* citation reason.

5.4 Evaluating the Citation Need model

In this section, we focus on assessing the performance of our model at performing the Citation Need task, its generalizability, and how its output compares with the accuracy of human judgments.

5.4.1 Can an Algorithm Detect Statements in Need of a Citation? We report the classification performance of models and baselines on different datasets in Fig. 6.

Given that they are highly curated, sentences from Featured Articles are much easier to classify than sentences from random articles: the most accurate version of each model is indeed the one trained on the Featured Article dataset.

The proposed RNN models outperform the featured-based baselines by a large margin. We observe that adding attention information to a traditional RNN with GRU cells boosts performances by 3-5%. As expected from the correlation results, the position of the sentence in an article, i.e. whether the sentence is in the lead section, helps classifying Citation Need in Featured Articles only.

5.4.2 Does the Algorithm Generalize? To test the generalizability of one the most accurate models, the RNN Citation Need detection model trained on Featured Articles, we use it to classify statements from the *LQN* and the *RND* datasets, and compute the F1 score over such cross-dataset prediction. The cross-dataset prediction reaches a reasonable accuracy, in line with the performances models trained and tested on the other two noisier datasets. Furthermore, we test the performances of our RNN_a model on 2 external datasets: the

Table 5: Citation reason prediction based on a pre-trained RNN_a^{+S} model on the *FA* dataset, and a RNN_a^{+S} which we train only on the Citation Reason dataset.

claim dataset from Konstantinovskiy et al. [32], and the CLEF2018 Check-Worthiness task dataset [39]. Both datasets are made of sentences extracted from political debates in UK and US TV-shows, labeled as positives if they contain facts that need to be verified by fact-checkers, or as negative otherwise. Wikipedia's literary form is completely different from the political debate genre. Therefore, our model trained on Wikipedia sentences, cannot reliably detect claims in the fact-checking datasets above: most of the sentences from these datasets are outside our training data, and therefore the model tends to label all those as negatives.

5.4.3 Can the Algorithm Match Individual Human Accuracy? Our Citation Need model performs better than individual Wikipedia editors under some conditions. Specifically, in our first round of expert citation labeling (Section 3 above), we observed that when presented with sentences from Featured Articles in the WikiLabels interface, editors were able to identify claims that already had a citation in Wikipedia with a high degree of accuracy (see Table 4), but they tended to *over-label*, leading to a high false positive rate and lower accuracy overall compared to our model. There are several potential reasons for this. First, the editorial decision about whether to source a particular claim is, especially in the case of Featured Articles, an iterative, deliberate, and consensus-based process involving multiple editors. No single editor vets all the claims in the article, or decides which external sources to cite for those claims. Furthermore, the decisions to add citations are often discussed at length during the FA promotion process, and the editors involved in writing and maintaining featured articles often have subject matter expertise or abiding interest in the article topic, and knowledge of topic-specific citation norms and guidelines [18]. By training on the entire corpus of Featured Articles, our model has the benefit of the aggregate of hundreds or thousands of editors' judgments of when (not) to cite across a range of topics, and therefore may be better than any individual editor at rapidly identifying general lexical cues associated with "common knowledge" and other statement characteristics that indicate citations are not necessary.

6 A CITATION REASON MODEL

In this Section, we analyze the *Citation Reason Corpus* collected in Sec. 4, and fine-tune the Citation Need model to detect reasons why statements need citations.

6.1 Distribution of Citation Reasons by Topic

Understanding if Wikipedia topics or article sections have different sourcing requirements may help contributors better focus their efforts. To start answering this question, we analyze citation reasons as a function of the article topic and the section in which the sentence occurs. We rely on DBpedia [3] to associate articles to topics and we show in Table 6 the most topics and article sections associated with each citation reason. We note that the distribution of citation reasons is quite intuitive, both across types and sections. For instance, *"direct quotation"* is most prominent in section *Reception* (the leading section), which is intuitive, where the statements mostly reflect how certain *"Athlete"*, *"OfficeHolders"* have expressed themselves about a certain event. Similarly, we see for *"historical"* and *"controversial"* the most prominent section is *History*, whereas in terms of most prominent article types, we see that *"MilitaryConflict"* types have the highest proportion of statements.

While the distribution of citation reasons is quite intuitive across types and sections, we find this as an important aspect that can be leveraged to perform targeted sampling of statements (from specific sections or types) which may fall into the respective citation reasons s.t we can have even distribution statements across these categories.

6.2 Evaluating the Citation Reason model

To perform the Citation Reason task, we build upon the pre-trained model RNN_a^{+S} in Fig. 4. We modify the RNN_a^{+S} model by replacing the dense layer such that we can accommodate all the eight citation reason classes, and use a *softmax* function for classification.

The rationale behind the use of the pre-trained RNN_a^{+S} model is that by using the much larger training statements from the binary datasets, we are able to adjust the model's weights to provide a better generalization for the more fine-grained citation reason classification. An additional advantage of using the model with the pre-trained weights is that in this way we can retain a large portion of the contextual information from the statement representation, that is, the context in which the words appear for statement requiring a citation.

The last precaution we take in adjusting the RNN_a^{+S} for Citation Reason classification is that we ensure that the model learns a balanced representation for the different citation reason classes.

Table 5 shows the accuracy of the pre-trained RNN_a^{+S} model trained on 50% of the Citation Reason dataset, and evaluate on the remaining statements. The pre-trained model has a better performance for nearly all citation reasons. It is important to note that due to the small number of statements in the Citation Reason dataset and additionally the number of classes, the prediction outcomes are not optimal. Our goal here is to show that the citation reason can be detected and we leave for future work a large scale evaluation.

7 DISCUSSION AND CONCLUSIONS

In this paper, we presented an end-to-end system to characterize, categorize, and algorithmically assess the verifiability of Wikipedia contents. In this Section we discuss the theoretical and practical implications of this work, as well as limitations and future directions.

7.1 Theoretical Implications

A Standardization of Citation Reasons. We used mixed methods to create and validate a Citation Reason Taxonomy. We then used this taxonomy to label around 4,000 sentences with reasons why they need to be referenced, and found that, in English Wikipedia, they are most often *historical facts, statistics or data about a subject, or direct or reported quotations*. Based on these annotations, we produced a Citation Reason corpus that we are

Table 6: Most common article topics and article sections for the different citation reasons.

Article Section						
quotation	**statistics**	**controversial**	**opinion**	**life**	**scientific**	**historical**
reception	history	history	reception	biography	description	history

officeholder	infrastructure	athlete	single	military	military unit	office holder
album	country	royalty	book	artist	band	settlement

making available to other researchers as open data[12]. While this taxonomy and corpus were produced in the context of a collaborative encyclopedia, given that they are not topic- or domain-specific, we believe they represent a resource and a methodological foundation for further research on online credibility assessments, in particular seminal efforts aiming to design controlled vocabularies for credibility indicators[51].

Expert and Non-expert Agreement on Citation Reasons. To create the verifiability corpus, we extended to crowdworkers a labeling task originally designed to elicit judgments from Wikipedia editors. We found that *(non-expert) crowdworkers and (expert) editors agree about why sentences need citations in the majority of cases*. This result aligns with previous research [31], demonstrating that while some kinds of curation work may require substantial expertise and access to contextual information (such as norms and policies), certain curation subtasks can be entrusted to non-experts, as long as appropriate guidance is provided. This has implications for the design of crowd-based annotation workflows for use in complex tasks where the number of available experts or fact-checkers doesn't scale, either because of the size of the corpus to be annotated or its growth rate.

Algorithmic Solutions to the Citation Need Task. We used Recurrent Neural Networks to classify sentences in English Wikipedia as to whether they need a citation or not. We found that algorithms can effectively perform this task in English Wikipedia's Featured Articles, and generalize with good accuracy to articles that are not featured. We also found that, contrary to most NLP classification tasks, our Citation Need model outperforms expert editors when they make judgments out of context. We speculate that this is because when editors are asked to make judgments as to what statements need citations in an unfamiliar article without the benefit of contextual information, and when using a specialized microtask interface that encourages quick decision-making, they may produces more conservative judgments and default to Wikipedia's general approach to verifiability—dictating that all information that's likely to be challenged should be verifiable, ideally by means of an inline citation. Our model, on the other hand, is trained on the complete Featured Article corpus, and therefore learns from the wisdom of the whole editor community how to identify sentences that need to be cited.

Algorithmic Solutions to the Citation Reason Task We made substantial efforts towards designing an interpretable Citation Need model. In Figure 5 we show that our model can capture words and phrases that describe citation reasons. To provide full explanations, we designed a model that can classify statements needing citations with a reason. To determine the citation reason, we modified the binary classification model RNN_a^{+S} to predict the eight reasons in our taxonomy. We found that using the pre-trained model in the binary setting, we could re-adjust the model's weights to provide reasonable accuracy in predicting citation reasons. For citation reason classes with sufficient training data, we reached precision up to $P = 0.62$. We also provided insights on how to further sample Wikipedia articles to obtain more useful data for this task.

7.2 Limitations and Future Work

Labeling sentences with reasons why they need a citation is a non-trivial task. Community guidelines for inline citations evolve over time, and are subject to continuous discussion: see for example the discussion about why in Wikipedia "you need to cite that the sky is blue" and at the same time "you don't need to cite that the sky is blue" [13]. For simplicity, our Citation Reason classifier treats citation reason classes as mutually exclusive. However, in our crowdsourcing experiment, we found that, for some sentences, citation reasons are indeed not mutually exclusive. In the future, we plan to add substantially more data to the verifiability corpus, and build multi-label classifiers as well as annotation interfaces that can account for fuzzy boundaries around citation reason classes.

In Sec. 5 we found that, while very effective on Wikipedia-specific data, our Citation Need model is not able to generalize to fact-checking corpora. Given the difference in genre between the political discourse in these corpora, and the Wikipedia corpus, this limitation is to be expected. We explored, however, two other generalizability dimensions: domain expertise and language. We demonstrated that, for this task, annotation can be effectively performed by non-experts, facilitating the solution of this task at scale and distributing it beyond expert communities. Moreover, we built a general multilingual taxonomy by evaluating policies from different Wikipedia language communities, and by testing its effectiveness with expert contributors from English, Italian, and French Wikipedia.

More broadly, this work is designed for multilingual generalizability. In the future, we aim to replicate the large annotation efforts across languages. This should be fairly straight-forward, since Featured Articles exist in 163 Wikipedia language editions[14]. Moreover, the RNN model can be fed with word vectors such as fasttext[8], which now exist in more than 80 languages [7] and that one can re-train with any language from a Wikipedia project.

Finally, in this study we consider the application of verifiability policies to a static snapshot of Wikipedia articles, not taking into account their revision

[12]URL hidden for double blind submission

[13]https://en.wikipedia.org/wiki/Wikipedia:You_do_need_to_cite_that_the_sky_is_blue

[14]https://www.wikidata.org/wiki/Q16465

history. We also used general text features, and limited the encyclopedic-specific features to the *main section* feature. We expect that the distribution of citation reasons may vary over the course of an article's development, as a function of how controversial or disputed particular sections are. Performing this analysis is beyond the scope of the current study, but it might surface important exceptions to our findings or uncover interesting editing dynamics.

7.3 Practical Implications

Our study also has practical implications for the design of collaborative systems to support information verifiability and fact-checking. Our results of a robust agreement between non-experts and experts around citation reasons suggests that this type of task can be effectively crowdsourced, potentially allowing systems to recruit non-experts to triage or filter unverified statements based on model predictions, and allowing subject-matter experts to focus their attention on identifying reliable sources for these statements, or improving articles or topics with the highest rate of unreferenced factual claims. On Wikipedia, existing microtasking tools such as CitationHunt[15] could be modified to surface unverified claims that have not yet been flagged *citation needed* by humans and provide users with model predictions to guide their research, while also allowing users to provide feedback on those predictions to refine and improve the model. The model could also be used to surface article or statement-level information quality indicators to Wikipedia readers, using scores or lightweight visualizations, as suggested by Forte and others [2, 18], to support digital literacy and to allow readers to make more informed credibility assessments. Finally, downstream re-users of Wikipedia content, such as search engines and social media platforms, could also draw on model outputs to assign trust values to the information they extract or link to.

Beyond Wikipedia, our work complements existing attempts to assess how experts and non-experts assess the credibility of digital information, [51] and suggests that it is possible to develop robust *verifiability taxonomies* and automated systems for identifying unverified claims in complex information spaces even without substantial domain knowledge. Such capabilities could support large-scale, distributed fact checking of online content, making the internet more robust against the spread of misinformation and increasing the overall information literacy of internet users.

ACKNOWLEDGMENTS

We would like to thank the community members of the English, French and Italian Wikipedia for helping with data labeling and for their precious suggestions, and Bahodir Mansurov and Aaron Halfaker from the Wikimedia Foundation, for their help building the WikiLabels task. This work is partly funded by the ERC Advanced Grant ALEXANDRIA (grant no. 339233), and BMBF Simple-ML project (grant no. 01IS18054A).

ABSTRACT

We present a seamless challenge-response authentication protocol which leverages on the variations of html5 canvas rendering made by the software and hardware stacks. After a training phase that leads to feature extraction with deep learning techniques, a server becomes able to authenticate a user based on fresh canvasses, hence avoiding replay attacks. The whole authentication process is natively supported by any mainstream browser, stateless on client side and can be transparent to the user. We argue that those features facilitate deployment and composition with other authentication mechanisms without lowering the user experience. We present the threat model against which our protocol is expected to live and discuss its security. We also present a prototype implementation of our protocol and report on a real-word experimentation that we ran in order to analyze its efficiency and effectiveness.

KEYWORDS

convolutional neural networks, authentication, html5 canvas, 2FA, usable security

1 INTRODUCTION

Although paramount for security, user authentication is often a hindrance for users: typing in a password, connecting a security token or interacting with a dedicated device is seen as a frustrating and time-consuming step. As a result, users more often than not are tempted to use time-saving shortcuts – bad or identical passwords, access card left next to device… – damaging for security, or to give up the transaction if the "reward" is not deemed to be worth the effort, resulting in losses for the provider. In this sense, seamless authentication protocols represent an appealing target.

Recently, browser fingerprinting [4], and in particular canvas fingerprinting [19] have been introduced as a means of identification. Put simply, the idea is that browser-specific features such as the supported fonts, software version or, for canvas fingerprinting, rendering of vector graphics can provide sufficient information to allow distinguishing a device from another, and hence to recognize a user coming back after a previous visit. Yet, to the best of our knowledge, this technique has been used only for identification – in the sense of recognizing a user – and not for authentication – in the sense of gaining confidence that a user is indeed who he pretends to be.

This paper represents a first attempt in this direction. Using canvas fingerprinting and deep learning techniques, we propose a challenge-response protocol taking place between a server and a standard web browser and operating in way that is transparent for the user. Intuitively, in an initial phase, the server asks the browser to perform several drawings and, through the use of deep learning, "learns" specifics about how the browser draws. As part of a later authentication process, the browser receives from the server a challenge describing a new drawing to perform. The server then passes the new drawing through the, now trained, deep learning model and if it recognizes the same specifics in the resulting image, authentication is deemed successful. The challenge-response process of SWAT aims at offering protection against stolen credentials, or offline replay attacks by malicious servers.

Our contributions are the design, the implementation and the evaluation of SWAT, a new protocol for user-friendly authentication based on canvas extraction of hardware/software dependencies. More specifically, we offer:

- An open-source implementation of SWAT for the Django Web framework. Our implementation covers (i) the data collection needed for the machine learning phases, (ii) the learning phase itself, implemented as a cron job that verifies every minute if new users registered and (iii) the authentication phase if a learned model is available for a given user.
- Experiments and evaluation of the efficacy of SWAT given real-world collection of user data.
- A discussion about real-world applications of SWAT, as well as its expected security benefits. We emphasize SWAT's security in a threat model that shows an interesting complementary with standard authentication systems, supporting the use of SWAT as a second authentication factor.

Our protocol takes advantage of standardized web technologies. In consequence, SWAT is natively supported by Web Browsers and is designed to be fast and easy to deploy.

Roadmap. Section 2 provides the necessary background for canvas fingerprinting and deep neural networks. Then, we describe the

SWAT protocol: how the client and server side conjointly perform the authentication as well as the threat model supported by our protocol. Section 4 covers an experimental analysis of our protocol, with real-world collection of data and analysis of the accuracy of the authentication. Section 5 describes various usage scenarios. Finally, Sections 6-8 discuss related work and future work before concluding.

2 BACKGROUND

2.1 Canvas fingerprinting

Mowery and Shacham [19] designed a new fingerprinting method based on browser font and WebGL rendering. This method exploits the surprising output variation of the HTML5 <canvas>. The <canvas> element provides, within a web page, an area in which the programmer can draw using Javascript. The variation depends on the operating system running the browser, the type of CPU or GPU, the graphic driver, the browser brand and its version.

The fingerprinting method works as follows: some Javascript code recovers the context of a canvas element within the webpage and draws a text and a text's scene. The goal is to generate a drawing impacted by as much software and hardware components as possible. The programmer, using common high level API functions, produces a drawing and then converts it to a base64 representation of the image. Then, a collision-resistant hash function receives this representation as an input and outputs a different value (the fingerprint) for any small change within pixel position or color of the image.

This method has been extensively used as a stateless tracker [1, 5], because the same user should produce the same hash output when drawing the same text and text's scene twice. In this paper, we try to take advantage of canvas's variation to the benefit of web users.

2.2 Deep Neural Networks

A natural candidate for extracting useful information from canvas drawings in an automated fashion is deep learning. Deep learning is a subfield of machine learning research which has demonstrated huge success in computer vision tasks like classification, localisation and segmentation [12, 13, 15, 27, 28].

Typically in machine learning, algorithms receive input features and produce, hopefully, useful outputs. The input features are usually manually defined and depend on the application domain. Consider for example an image classification task in which the algorithm needs to decide what object is displayed in an image. The input in this case would be defined in terms of a set of features defined on the pixels of the input image. It is easy to realize that defining manual features in the pixel space is extremely difficult. Representation learning can help alleviate this problem by providing the means to build models that can extract useful information from data.

Deep learning is a type of learning representation which follows a structured approach to extracting information from input data. It accomplishes this by using several layers to build representations of increasing complexity with initial layers dealing with primitive types, while the next layers deal with more complex objects composed of primitive types. For more in depth information regarding deep learning we refer the reader to Goodfellow *et al.* [10].

2.2.1 Fully Connected. Figure 1 shows a typical fully connected network. Its layers are comprised of scalar output values called *neurons* which are arranged in a hierarchical fashion. Information flows from the input all the way to the output with in-between layer outputs being the input to the following layer. Information does not flow back hence this network structure is also called a *feed-forward network*. The output of an individual neuron is called its activation which is typically non-linear (deep networks of linear activations are equivalent to single layer networks), hence it is referred to as the *non-linearity*. The activations of the last layer (output) is the prediction of the network given the first layer (input); all other layers are not directly observed and are conveniently called *hidden layers*.

Let $X = (x_1, x_2, x_3, \ldots, x_n)$ be a vector of inputs and $w = (w_1, w_2, w_3, \ldots, w_n)$ a vector of weights and b a bias. Then the output, or activation, of a given neuron is calculated by

$$a = \sigma(w \cdot x + b), \tag{1}$$

in which σ is the non-linearity. Currently the most used non-linearity is the rectified linear unit, or ReLU [21]. The ReLU function is defined as $\sigma(x) = \max(0, x)$ and it has been shown to result in strong gradients that allows much faster training for deep networks.

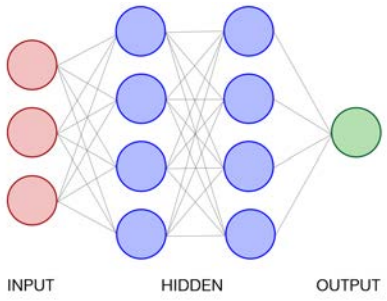

Figure 1: Fully Connected Neural Network.

What we want to find is the set of weights and biases that bring the outputs of the network closer to the desired output. Specifically, given network predictions $\hat{y} = (\hat{y}_1, \hat{y}_2, \hat{y}_3, \ldots, \hat{y}_n)$ and targets $y = (y_1, y_2, y_3, \ldots, y_n)$, we want the network outputs to approximate the targets as closely as possible for all inputs $X = (x_1, x_2, x_3, \ldots, x_n)$. This can be formulated as an optimization problem where we try to minimize a loss function. In this work we are dealing with a binary classification problem hence we use the cross-entropy loss to train our model over all training examples M,

$$Loss = -\frac{1}{M} \sum_{i}^{M} \left[y_i \log \hat{y}_i + (1 - y_i) \log(1 - \hat{y}_i) \right] \tag{2}$$

In order to find the model parameters that minimise the loss function we use gradient descent. By taking the gradient of the loss function w.r.t. the model parameters we can find how these

parameters need to be changed to reduce the loss value. The parameters are initialised at random and are then iteratively updated by descending along the gradient surface until a suitable minimum value is reached. Of course computing the exact gradient for the loss function would have us iterate through the entire dataset which is prohibitively expensive. Instead what is typically used is mini-batch gradient descend in which a subset of the training data is used to approximate the gradient at each step.

2.2.2 Convolutional Neural Networks. Convolutional neural networks [8, 18], CNNs, is the state-of-the-art technique when dealing with problems of computer vision in machine learning. Typical, fully connected networks, in which every neuron in layer l is connected to every neuron in layer $l+1$ ignore a very important aspect when dealing with images as input; spatial information. Every pixel in a fully connected network is treated independently when in most cases, pixels spatially located close to each other is important information that needs to be captured. CNNs provide the means to exploit the local structure in the input by learning local features. In deep architectures, earlier convolutional layers will learn to extract spacial features such as lines, edges and so on, while later layers will learn to combine those to form more distinct features, such as a face or a dog.

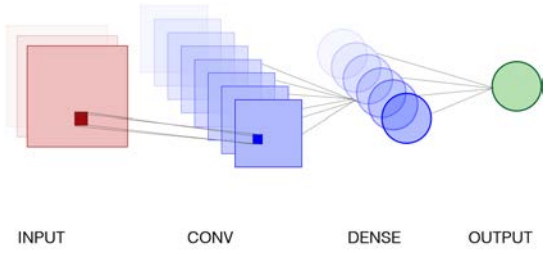

Figure 2: Convolutional Neural Network.

Figure 2 shows a schematic representation of a CNN. Typically a CNN is built by a series of convolutional layers, non-linearities, pooling layers and finally the output. The input to the CNNs presented in this work is an image. At each layer the input is convolved with a set of weights called *filters* to produce *feature maps*. Different feature maps i.e. layer outputs, are convolved with different sets of filters, but filters are shared within the same feature map. It is those sparse interactions and parameter sharing that greatly reduce the number of parameters of the model, its computational and memory complexity.

Equation 3 show the operation that defines the l-th feature map

$$a^l = \sigma\Big(\sum_m w_m^l * x + b^l\Big), \tag{3}$$

where we sum over all features maps, w_m^l are the filter weights to be learned, b is the bias, $*$ represents the cross-correlation operation (in deep learning known as "convolution"), and σ represents the element-wise activation function which as discussed previously is typically a ReLU. Popular kernel choices in most cases, and dependent on the input size, are $3 \times 3, 5 \times 5, 7 \times 7$. A pooling layer usually follows which aggregates the values of neighboring neurons based on their maximum, or average value. This results in the model being invariant to small translations in the input and is an important aspect if we only care about the presence of a feature and not its placement. Typically pooling layers have a stride of 2 i.e., they aggregate values that are spaced 2 neurons apart. This results in a reduction of neurons allowing the following convolutional layer to have a larger field of view of the input. For more in depth information regarding convolutional networks and their applications we refer the reader to [10].

3 SWAT

3.1 Overview

Authentication is usually based on an agreed token that is recognized by an identity provider and that a user uses to prove this identity. This token can take many forms with many different extraction methods. These are commonly divided in the following well-known classification: something we know, something we have and something we are.

In our case, the token can be seen as "the way the user draws in canvas" and by the user, we mean his/her full stack of hardware and software. Our method to extract this token and to send it toward the identity provider shows a unique advantage: it requires no interaction with the user and all recent browsers are compatible without any additive software to plug-in. This technique falls into the "something we have" category, however offering a better usability than other methods classified into the same category.

The SWAT authentication protocol is a challenge-response protocol that takes advantage of canvas's high variation and deep learning's feature extraction to provide a user-friendly layer of authentication. We can abstract SWAT as three independent phases: P1: data collection, P2: learning phase and P3: authentication phase. Phases P1 and P2 must be completed once for each stack of hardware and software owned by a user. When P1 and P2 are complete, the authentication phase can be performed as often as needed.

The data collection phase can be performed in a stealthy way to the user. While we advocate for transparency, scenarios may exist where a stealth collection of data is preferable. Such choice would be left to the identity provider, but could also be integrated as part of user preferences.

In our proof of concept implementation, the browser generates 2000 35x280x4 images based on random texts sent by the server (as a matter of fact, writing in canvas appears to be one of the most browser-sensitive features we observed). We extract those images from a `<canvas>` element, and convert them to a base64 representation which we send to the server.

Once the data collection (P1) is finished, we start extracting features in the learning phase (P2). We use a CNN to extract the user's features and build a binary classification model for each user. This is in contrast to what we usually see in the literature where one end-to-end model is trained with multiple classes. The reason we have decided to follow the path of per-user model is rooted in a more efficient training procedure for our authentication system. If we employed an end-to-end model trained on all users, then

every time a new user would register to our system, we would need to re-train the entire network; a process which takes time and resources. By having a binary classification process where we train a model per user, we do away with that problem. Our current CNNs are simple enough to spend less than 3 minutes of learning with a decent accuracy and almost no over-fitting. We have designed our CNN this way to focus on usable research and show that this authentication method could be deployed, even at a large scale for systems handling a large pool of users.

Finally, in the authentication phase (P3), the browser and the server play a (stealthy) challenge-response protocol, where the server asks to draw several texts and text's scenes. The server then uses the binary classification built during P2 to assess whether the browser's answer matches its user's model. To easily verify the validity of the client's response and prevent a replay attack, the server produces locally the same drawing as the one he asked from the browser and compares it to the response received from the browser using the method of least squares. Even though the two images will not be identical – this is the very essence of SWAT – they should be close enough for the least square difference to be small when based on the same challenge.

We provide in this paper a full stack implementation of the protocol outlined above and we describe, in the section below, each piece in details. We do not see SWAT as a replacement for existing strong authentication methods, as it does not guarantee as much security as a strong password for instance. However, we believe that SWAT is an interesting candidate to be part of a layered multi-factors authentication system, such as password+SWAT or other methods, mostly depending on the level of security needed and the threat model.

3.2 Client side

The client side of the SWAT protocol is mostly responsible for 1) drawing the random canvas asked by the server and 2) extracting a representation of the canvas as a png image. The Javascript code then sends the image representation to the server. As thousands of images are generated and sent during the collection phase, it might take up to a few minutes to complete. A "stop and resume later" strategy for the collection phase is possible, but the user needs to authenticate with another method to resume.

```
function generateRandomCanvas(txt) {
  var canvas =  document.getElementById("canvas");
  canvas.width = 280, canvas.height = 35;
  var ctx = canvas.getContext("2d");
  ctx.clearRect(0,0, canvas.width, canvas.height);
  //drawing the new canvas
  ctx.font= "18px 'Arial'";
  ctx.textBaseline = "alphabetic";
  ctx.fillStyle = "#069";
  ctx.fillText(txt, 2, 15, 280);
  ctx.fillStyle = "rgba(102, 204, 0, 0.7)";
  ctx.fillText(txt, 4, 19, 280);
  ctx.fillStyle = "#069";
  ctx.fillText(txt, 2, 23, 280);
  ctx.fillStyle = "rgba(102, 204, 0, 0.7)";
  ctx.fillText(txt, 4, 27, 280);
  ctx.fillStyle = "#069";
  ctx.fillText(txt, 2, 31, 280);
  ctx.fillStyle = "rgba(102, 204, 0, 0.7)";
  ctx.fillText(txt, 4, 35, 280);
}
```

Listing 1: javascript code to generate a canvas content

Figure 3: Example of a canvas drawn by SWAT

During the authentication phase, the client receives a few texts to draw from the server (E.g. Figure 3). This process takes less than a second, does not require any interaction with the user and can be designed to be invisible.

3.3 Server side

The prototype implementation we developed [25] is a Django plugin using the Python deep learning *Keras* API [14] as the front-end to the server-side programmer and *Tensorflow* as the back-end. The collection phase stores every *base64* encoded *.png* image into a database for each user. Once we have enough different users, the system starts to learn by pooling each user's generated images and a set of random images from other users. For each user, we have 2000 images labelled as "yes" (all collected images) and 2551 random images from the database labelled as "no". We choose those numbers such that, when the system splits the set of images into a training set and a validation set, we obtain a training set size as a multiple of the batch size for efficiency reasons.

The system trains and saves one model per user as a binary classification model. During the authentication phase, we load the model associated to the claimed user's identity and we feed the model with the few fresh images that we asked to draw. For each input image, the model outputs a prediction value. In theory, if the claimed user's identity is right, the predicted value should be high. The closer the prediction is to 1, the more confident we are about the image belonging to the right user.

A user identity may have multiple learned models, namely one for each of his stacks of hardware/software (e.g. chrome browser and firefox on his laptop). The user should succeed the authentication for one of the learned model but not for the others.

3.4 Threat model and security

We now discuss the type of adversary against whom SWAT is resistant as well as how the protocol could be combined with other forms of authentication to protect against several threats without giving up on usability.

In contrast to security notions provided in cryptography, the non-forgeability of valid canvas for a given user cannot be linked to a computationally hard problem. The forgeability of SWAT can be reduced to the following adversarial game: given a set of valid canvasses for an identity and given a challenge, draw a canvas that obtains a high prediction value with non-negligible probability. If the adversary wins this game, then we have an active attack against SWAT. Assessing the resistance of SWAT against such an active adversary is an open research problem, which involves analyzing how deep learning (and other) strategies could allow him to reconstruct the model based on partial information and with a non-negligible success probability. As a preliminary step, in this paper we consider

only the case of passive attackers, that is, attackers who follow the protocol but do not actively try to forge a canvas based on a more sophisticated strategy.

The SWAT protocol aims to protect against the following problems:

- **Passive eavesdropping and replay attacks**: since SWAT is a challenge-response protocol, a consumed canvas cannot be replayed to gain access to the authenticated channel. Therefore, the SWAT protocol may be interesting to use in addition to other authentication methods that do not protect against those problems.
- **Stolen credentials**: The SWAT protocol is a stateless protocol, hence the information needed to authenticate cannot be collected on a user device.

Under the assumption that an indistinguishable forgery cannot be performed, our canvas challenge-response approach mitigates the following issues:

- **Database leakage**: If the database of a service gets compromised, it should not give the opportunity to an attacker to forge a valid canvas and obtain a valid credential.
- **Website attacker**: If a website collects drawings against the will of a user, it should not help to forge a valid canvas, except through an on-line man-in-the-middle attack. As a partial mitigation, we observe that Firefox recently added a user approval on canvas extraction [7] based on a Tor Browser's functionality which would reduce the likelihood of such risk.

Some threats remain out of scope for this protocol:

- **Active man-in-the-middle attack**: such as a website attacker that tricks a user into completing a challenge for another service. Due to the design of SWAT, the tricked user would not notice any completed challenge toward another service.
- **Hardware/software cloning**: given the software stack of a target, and given the information related to the exact hardware the target owns, an adversary would be able to build a machine that would successfully authenticate him.

This protocol is not designed for high security and we would discourage a standalone use to protect sensible information. However, this protocol closes the security gap that some other authentication methods have, such as weak passwords. More generally, when a protocol relies on an attached secret to perform the authentication, it is always weak against the leakage of such a secret. SWAT may prevent the leakage of a password, a cryptographic key or the theft of a security token from providing the thief with a direct access to the secure environment. This protocol may offer the time needed to the user to react and recover new strong credentials.

4 EXPERIMENTAL ANALYSIS

4.1 Methodology

Our main objective is to obtain a seamless, user interaction-free layer of authentication which user intensive applications could use to enhance their account security system. For this purpose, the main constraint we impose to the evaluation of our prototype is to have a relatively fast training phase to comply with realistic utilization of this protocol. By realistic utilization, we mean realistic training cost and sufficient efficacy.

We started by developing a framework for the multi purposes of data collection and evaluation, as well as for protocol demonstration. We chose CNN architectures in such a way that the learning phase takes less time than the collection phase (less than 1 minute). We do not argue in this paper for an optimal architecture suited for our protocol, since we believe that the optimum is bounded by the resource availability of the identity provider: the more resources the identity provider owns, the more complex CNN architectures they could employ. We made the choice to experiment with two different architectures to demonstrate the trade-off between result efficacy and cost of the training phase.

We opened the data collection process within the main author's social network, and we explain in Section 4.2 the steps taken to avoid any pollution (i.e., injection of wrong data) of the database. We evaluate our architectures' accuracy by splitting the set of available canvases for a given user in a training set and a validation set. During the evaluation, one of our goals was to study the impact of having common pieces of software on the prediction value. For example, what is the chance for user A running Mac OS X to score a high prediction on behalf of user B also running Mac OS X? To answer those questions, we collected meta-information about participating users and ran the authentication phase for each user over every other user in our dataset.

We finally investigate different solutions to accept or reject authentication attempts from the output of the classifier.

4.2 Data Gathering

We built a web interface [26], to gather real user data over a few weeks. In total, 118 collections have been done and among them, 109 fully completed the collection phase. We discarded the uncompleted involvements for this analysis, leaving us 109 remaining datasets. Alongside the 2000 images collected for each participant, we collected some metadata such as the operating system family and the browser family.

The data gathering has been made public on social networks, hence we had to design the gathering with security issues in mind. We evaluated worst-case scenarios and came up with a few countermeasures against them. The most serious threat we may face during a public data gathering is database pollution. We consider a database polluted when wrong data is indistinguishable from correct data and would change the expected result during our analysis (e.g., increasing false positives). First, we have to define what would be "wrong" data for our purpose and how such pollution may happen (intentionally or non-intentionally). Then, working to avoid the non-intentional pollution is the bare minimum. We also make intentional pollution difficult for unskilled people. However, protecting the data collection against skilled people is a challenging problem and is out of the scope of this work. We assume skilled people did not pollute our database to influence our results.

We consider the database polluted when two different recorded identities are the same machine (same stack of hardware and software). The interface to the data gathering has been made as simplistic as possible in order not to discourage users: we asked participants to provide an email address and to click on a button. Then,

the data collection proceeded, displaying the percentage of data collected to the participant. So, what could go wrong? We have to consider every possible and problematic action a human might take:

- Doing the data gathering multiple times with the same email on the same machine.
- Doing the data gathering multiple times with different emails on the same machine.
- Stopping the data collection.
- Registering an identity but blocking the data collection. This could be unintentional due to some browser addons that are suspicious with canvas image extraction.

We prevent the first two bullets points by relying on a stateless attribute: we compute a browser fingerprint that should be unique to each browser. This fingerprint is transmitted with the provided identity. If the fingerprint matches another identity in the database, we display an error. Otherwise, the identity is accepted and a data collection begins. We could have used a cookie but it would be less protective against unskilled malicious users who might know that cookies are often used to "remember" and how to delete them. Finally, we asked users to complete a captcha to participate. Skilled malicious users may be slowed down or at the best, discouraged to fill our database with junk data. For the last two bullets, we discarded any user who have not finished the data collection. We did not notice any strange behaviour during the data gathering and, backed by our methodology, we are confident that our database has not been polluted.

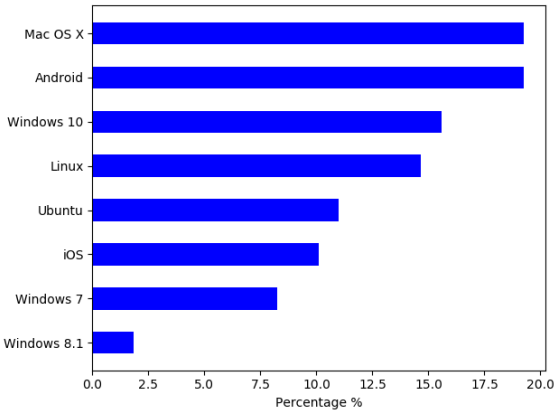
Figure 4 shows the distribution of Operating System and Browser families from our participating users. The main operating systems and browsers are well represented with a social bias toward Unix-based system (due to a non-negligible fraction of colleagues and friends within the participants) and many different families have been collected, including smartphones, which is what we need to validate our result over the global software and hardware ecosystem.

4.3 CNN Architectures

Table 1 shows the two CNN architectures we use to evaluate our protocol. For each user, Arch 1 provides a learning phase under one minute, and Arch 2 provides a learning phase under three minutes with a docker virtual machine using 12 cores of Intel(R) Xeon(R) CPU E5-2670 v3 2.30GHz. It can be expected to be much faster with dedicated instruction sets on the hardware, which are available on the market, or by deploying the models in GPU clusters. These performances allow an identity provider to derive a user specific model in less than a minute for any registered user.

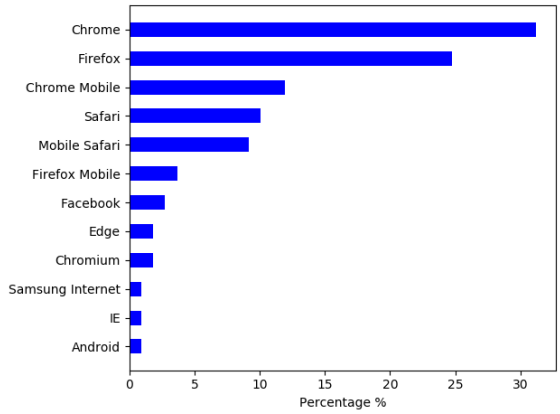
4.4 Results

4.4.1 CNN Accuracy. SWAT is designed to produce one CNN binary classification model for each registered user. The efficiency of our trained models is based on the accuracy of the chosen CNN architecture, as well as on the quality of the derived model that each user obtains. We may wonder what efficiency the CNN architecture achieves, and more importantly, what set of criteria might be used to define an efficient architecture. We define here the criteria that are important for our protocol:



(1) The model accuracy: how well does the CNN derived model perform for each user? We consider both the accuracy of the training set and the accuracy of the validation set.
(2) The gap between best accuracy results and worst accuracy results.
(3) The over-fitting: how large is the gap between trained results and validation results?
(4) The number of epochs and the time for each epoch: how fast does the model learn?

The learning speed may be more or less important, depending on the targeted security level and on the amount of computational power that is available: high security requirements and high computational power availability push for the use of a more complex architecture, which leads to better results in terms of accuracy and best/worst performance gaps. We chose to work with fast architectures, showing how well we can perform at a moderate cost, without designing our solution around a specific hardware specification for our learning algorithm. This choice is guided by our main objective: offering a <realistic new authentication layer which can be deployed even for usage intensive applications.



In Figure 5, we observe a median validation test reaching over 95% accuracy. The learning and validation sets contain canvas in the "yes" class and canvas in the "no" class chosen randomly from the database, and the accuracy is defined as the number of correct predictions over the total number of predictions. Figure 5b shows more over-fitting in the worst-case user (i.e., over all users and all runs), which indicates the need to collect more than 2000 canvas for that CNN architecture: because of the deep structure of the architecture, it may capture unique information about the training set which might not be representative of the user specific features.

4.4.2 True Positive Predictions. Figure 6 shows our classification's prediction results for new canvases during authentication. This figure shows the output of the authentication phase for legitimate authentications of each identity. The prediction result is not binary, it is a probability score for the canvas to belong to the 'yes' class. As can be seen on the figure, the second architecture shows a higher prediction distribution than the first one. We believe that there are two main reasons explaining this difference: we do not use max pooling in the second architecture and we have a deeper neural network. Indeed, max pooling is destructive (i.e., it discards information in favor of computational efficiency), and the deeper the network is, the more information it captures. However, those results alone are not enough to justify that the second architecture fits our authentication problem better. We also need to evaluate how a particular user performs against others. Ideally, we should obtain a 0 probability prediction for these situations.

4.4.3 False Positive Predictions. A high prediction result for true positive canvases would not be interesting if the CNN predicts also a high result of $user_i$'s canvas over $user_j$'s learned model. We need to evaluate this avenue to get a more precise idea of the effectiveness of this authentication method. Figure 7 shows CDFs of how well our CNNs perform for each user over all other users within our database. In Figure 7a, 'all' labeled lines compare our

(b) Browser of each user of our database

Figure 4: Percentage of observed OS family and Browser family in our data collection

	CNN		
Parameters	Arch 1	Arch 2	Search space
Optimizer	Adamax	Adamax	SGD, Adam, Adamax (default values)
Conv2D layers	3	17	3..20
Filters	4/layer	4/layer	4/8/16
Padding	valid valid same	valid (all)	valid, same
Dense	256 1	256 1	64/128/256/512 1
Flatten	yes	yes	-
Activation func	relu	relu	relu, tanh
Kernel init	Glorot normal	Glorot normal	-
Maxpooling	After each Conv2D	-	-
Pool Size	3x3 3x3 5x5	-	3x3 / 5x5
Batch size	256	256	64/128/256
Training epochs	100	100	50/100

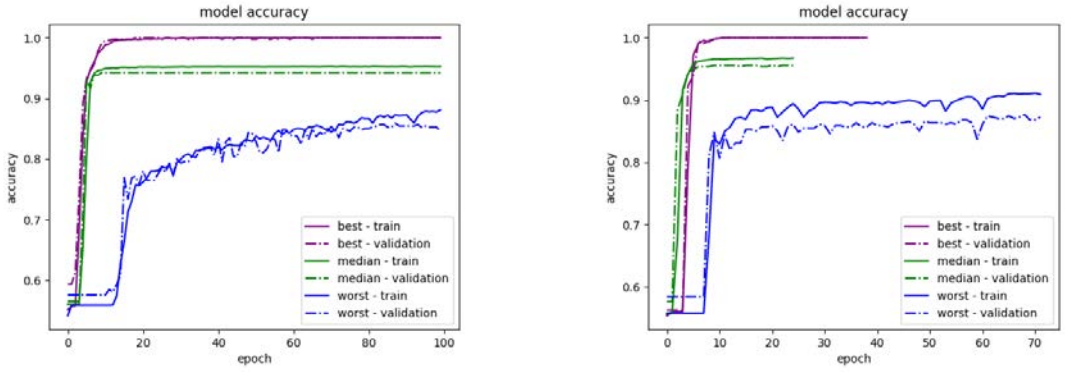

Table 1: Parameters choices for two architectures. Arch 2 is designed to offer better efficacy at a performance cost, which highlights the trade-off efficacy/performance of the various CNN architectures we could use

two architectures for all users, which shows that our CNN Arch 2 performs better as expected from the result of the previous section. Considering the 'all' labeled line, it gives us some intuition about the performance of this authentication method. Nevertheless, results about SWAT's performance in the real world may be better, because of two important points:

- Our data collection does not reflect the true distribution of hardware/software stacks which people own. Indeed, as we described in our Section 4.2, our data collection is biased toward Unix-based systems due to the author's social environment.
- Our results depends on the CNN used, and there is still strong potential for more efficient architectures.

This suggests that SWAT can achieve usable performances with a low training cost, and can potentially behave much better when deployed in a more realistic scenario by a company with the necessary computational resources.

We may also observe that users tend to obtain a higher score against other users running the same Operating System (Figure 7a) or the same Browser (Figure 7b). This result seems intuitive, as SWAT takes advantage of the various differences in the software/hardware stacks of users. When some parts of this stack are common, the CNN successfully extracts common features and may believe more easily that they are the same user. Another argument in favor of this interpretation can be observed with Mac OS X or iOS results: Due to less diversity in the hardware and software stack, Mac OS X

(a) Learning phase for Arch 1

(b) Learning phase for Arch 2

Figure 5: Model accuracy evaluation on CNN architectures

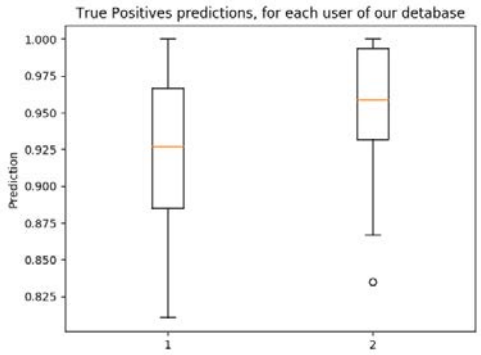

Figure 6: True positive prediction of CNN's architecture Arch 1 and CNN's architecture Arch 2

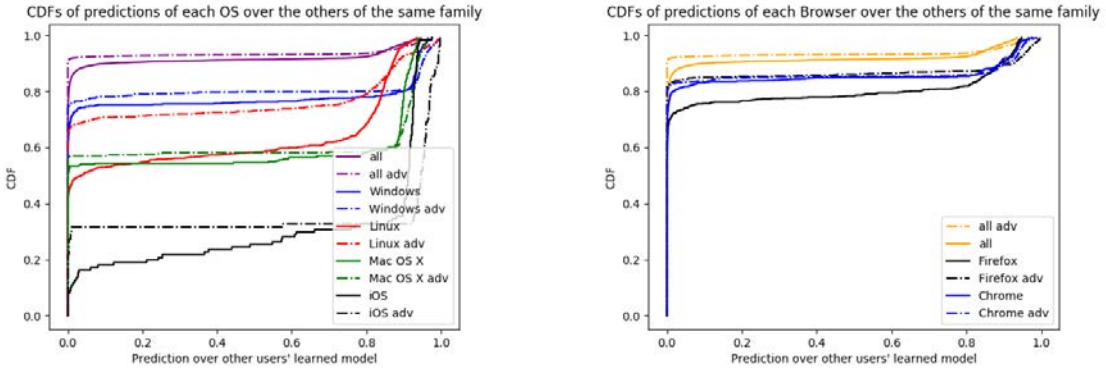
and iOS users are more likely to score high against each other (i.e., around 40% of our Mac OS X users score a high prediction against other Mac OS X users). We observe that this is less true as we move toward more complex CNN architectures, as showed by the results of the deeper CNN architecture.

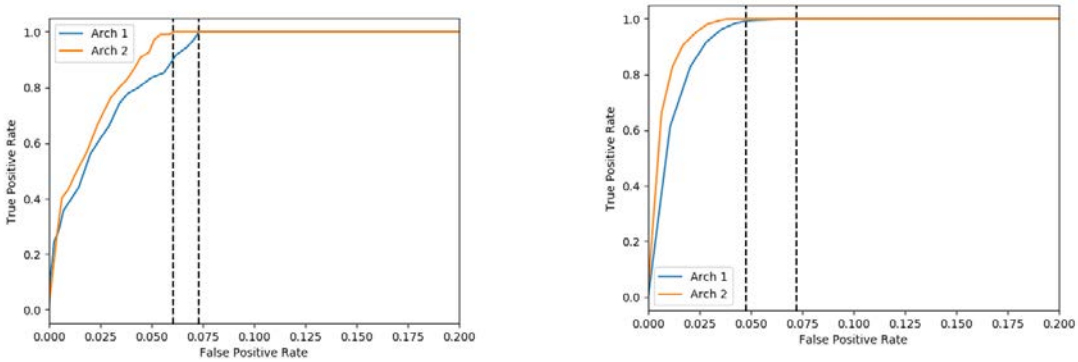


4.4.4 Accepting or Rejecting Authentication. An important question remains to be answered: how should we decide if an authentication is valid? The simplest and more straightforward technique would be to decide one global threshold which minimizes false positives and guarantees a true positive, based on our data. A second idea would be to use a threshold for each user, based on the result of their training phase. Indeed, since we derive one model per user, each of them produces a slightly different accuracy, as depicted in Figure 5. Therefore, having a model-based threshold to accept an authentication should give better results because some of the most accurate models can benefit from a higher threshold. A third and last idea would be to use, instead of a threshold, a validity interval for which we consider the authentication successful. Compared to the simple threshold, the validity interval would prevent $user_i$ from successfully authenticating as $user_j$ if $user_i$ obtains a much higher result.

Figure 8 shows the efficiency of our CNN architectures with ROC curves given two varying decision-making parameters: a global and unique threshold and a model-based interval for valid predictions. Since we know from the training phase which prediction value the valid user should obtain, we may use this information for the decision process to accept or reject an authentication attempt. This information is exploited with the model-based interval for valid prediction.

Figure 8a shows ROC curves for our two architectures given a global threshold varying from 0 to 1. For a TPR of 1, our CNN Arch 1 achieves $\approx 7,4\%$ of FPR and sets a global threshold to accept authentication to $\approx$ 0.81. The other deeper architecture Arch 2 achieves a TPR of 1 and $\approx 6\%$ of FPR, and sets a global threshold to accept authentication to ≈ 0.83. Figure 8b shows the result with a better heuristic to accept or reject authentication attempts. For each learned model, we accept an authentication attempt if the prediction is within an interval centered around the median value of the learning set's predictions. Figure 8b shows that this heuristic reduces the FPR to $\approx 5\%$. This improvement is motivated by two observations: first, by looking at Figure 7, we see that different users can score a high prediction for a given identity, even higher than the true identity itself. Hence, accepting authentication attempts simply based on exceeding a threshold is in fact allowing false positives. The second observation is that the prediction value is stable across several authentications of a same identity: if a training phase ends up giving a 0.85 prediction value to the canvas of one's identity, then this identity will score around 0.85 for each authentication. This stability characteristic allows a high TPR for small intervals.

4.5 Security Discussion



The current performance analysis of SWAT shows a non-negligible risk of a false positive. SWAT cannot hope to compete with the $\sim 2^{-128}$ security bounds provided by typical cryptographic tools, but this not its objective. Indeed, SWAT is not aimed to be a first-factor authentication, unless user friendliness is the critical property of the system (in such case, weak authentication is still better than

(a) Splitting users per OS families.

(b) Splitting users per Browser families

Figure 7: Prediction value over other registered users (i.e., $user_i$'s learned model evaluates $user_j$'s canvasses). "adv" labels refer to result for Arch 2, while the others refer for Arch 1

(a) Variation of a global threshold in interval [0, 1]

(b) Variation of the size of a model-based interval around the accuracy of each model predicted at the learning phase.

nothing). Rather, we expect SWAT to be useful in a multi-factors context where it would help to prevent direct access to the attacker if, for example, a password is leaked. In summary, SWAT enhances the security by a complementary threat resilience to existing authentication systems, without lowering the user experience if the identity provider implements a transparent usage of the protocol. We suggest in the next section a couple of potentially interesting usage scenarios.

5 POSSIBLE USAGE SCENARIOS

5.1 Web Authentication

A SWAT API could be built for various web frameworks. This work provides one implementation for the high-level Python web framework Django. With such an API, web developers could enhance the security of their application with multi-factor authentication, such as password + SWAT. With both authentication mechanisms covering different threat models, the benefits would be transparent for the users.

Another interesting use case would be to enhance the industry-standard protocol for third party authentication (Oauth2 [11]) with the ability to authenticate with SWAT. Identity providers such as Facebook, Google or Github are well-positioned and own the resource to develop and deploy our protocol in a transparent way for their users. For example, users may perform the learning phase when using the services offered by these Internet giants, and benefit from the increased security when connecting to others web services through Oauth.

5.2 IoT Authentication

Many IoT devices interact with smart phones and could benefit from our protocol inside dedicated applications as well. However, this would require the learning phase to be remote (not on the IoT device) and the learned model to be shared with the IoT device

afterwards. In many settings, weak but user-friendly authentication is desirable and this protocol offers such an opportunity.

5.3 Game Launcher

The Game industry has known a huge growth since the free-to-play model was introduced. Hacking and frauds is now common against gamer accounts. One way to improve the current landscape would be the increase the authentication security in game launcher to prevent account theft and in-game content theft. Several game companies, like Blizzard, offer in-game bonuses when users improve their account security with a hardware token. Nevertheless, hardware tokens are not widely used. SWAT could be an interesting opportunity to deploy massively multi-factor authentication on game launchers, while not damaging the user-friendliness of their game.

6 RELATED WORK

Since Peter Eckersley's initial "device fingerprinting" analysis [4], work has spawned with various categories of goals. Laperdrix *et al.* [17] consider a few: *Client-side diversity* which tries to evaluate uniqueness of fingerprinting methods [4][17][9].

Fingerprinting adoption on the web and server-side scripts which evaluates the surface of the web under fingerprinting methods. Under this category, FPDetective [2] identified new scripts and techniques to fingerprint users. Acar *et al.* [1] investigated canvas fingerprinting, evercookies and use of cookie syncing on a large-scale study. Englehardt and Narayanan [6] pushed the analysis to 1 million websites, found sophisticated fingerprinting methods and showed how to crawl and analyze a huge amount of information in a reliable way.

Advanced solutions to collect additional fingerprintable attributes is the category focusing on developing new fingerprintng methods. Canvas fingerprinting [19] or leaking battery information through the HTML5 API [23] are good examples of work in this category, and show how much we deeply need to better understand our application environment to improve privacy.

Resilience to fingerprinting methods is a category of work where anti-fingerprinting strategies are investigated but could potentially break the accuracy of our authentication protocol [22][3][16]. As discussed in Future work, Section 7, defending against tracking while preserving beneficial usage of the output variation of the canvas API might be an interesting research direction.

Closer to what is performed in this paper is the category of *frictionless authentication* [24] where the users authenticate without performing any intentional authentication actions [20]. The usability obtained in frictionless authentication is granted through continuous monitoring of the claimed identity to spot any divergence from the expected user behavior. However, this raises some serious privacy concerns.

Our work, as far as we know, is the first attempt to use the output variation of some HTML5 API to the benefit of the user.

7 FUTURE WORK

7.1 Increasing drawing variations

Our work leverages on Mowery *et al.* [19] text and text's scene variation to distinguish users. Recent work by Gómez-Boix *et al.* [9] shows how to draw more complex canvas which would likely increase the accuracy of our authentication protocol. Smart utilization of the Canvas API to cover a broader surface of the software and hardware stack can be considered as a side problem that may contribute to various works, like our proposal, but also to the understanding of browser fingerprinting diversity.

7.2 Privacy please?

Different service could collude and match users as being the same identity. Future work could address this privacy issue and complicate such intersection attack given sets of canvas collected by different services. Such a privacy property seems however difficult to obtain with a stateless client side protocol. The current research for privacy-preserving browsing experience attempts to break the linkage between sessions of the output of HTML5 API [16]. This line of work would break our protocol and its benefit, but we could imagine opt-in per-service when the usage of distinguishable information is intended for a true user-centered benefit, which is in line with the current approach of browsers (e.g., Firefox opt-in to enable canvas extraction).

7.3 Active attackers

Our current analysis is based on canvasses produced in a genuine way. An adversary may proceed in a different way: when facing a challenge response, and assuming that he has access to previous responses to different challenges he may try to combine those responses in order to forge a fresh one. More generally, an adversary could use image processing software to create a canvas forging system. Investigating this direction would be interesting to evaluate the security of SWAT in the more demanding setting of active adversaries.

8 CONCLUSION

We presented SWAT: an authentication protocol with a focus on usability, server-side performance and ease of deployment. SWAT provides interesting security properties in a multi-factor authentication scenario, protecting against passive eavesdropping and replay attacks as well as defending against stolen credentials. We highlighted in the analysis the existence of a trade-off between authentication accuracy and resource endowment, and showed that we achieve a high TPR for a low FPR even for small resource endowment. We discussed SWAT's security usefulness in a multi-factors context and for various scenarios. A SWAT protocol is not bound the the strict use of the Canvas API. Any other API which can take an input, and output variations depending on user specific software or hardware would be interesting candidate to increase the authentication accuracy.

ABSTRACT

The commencement of EU's General Data Protection Regulation (GDPR) has led to massive compliance and consent activities on websites. But did the new regulation result in fewer third party server appearances? Based on an eight months longitudinal study from February to September 2018 of 1250 popular websites in Europe and US, we present a mapping of the subtle shifts in the third party topology before and after May 25, 2018. The 1250 websites cover 39 European countries from EU, EEA, and outside EU, belonging to categories that cover both public-oriented citizen services, as well as commercially-oriented sites. The developments in the numbers and types of third party vary for categories of websites and countries. Analyzing the number of third parties over time, even though we notice a decline in the number of third parties in websites belonging to certain categories, we are cautious about attributing these effects to the general assumption that GDPR would lead to less third party activity. We believe that it is quite difficult to draw conclusions on cause-effect relationships in such a complex environment with many impacting factors.

1 INTRODUCTION

Mainly driven by privacy concerns, much research has been dedicated on examining the presence and implications of contacts with third-party servers when users browse websites. EU's General Data Protection Regulation (GDPR[1]) aims to give users more control over the collection and distribution of their personal information, also on websites. As one sign of the relevancy of GDPR to websites, the European advertiser's lobby organization (IAB Europe[2]) has proactively assisted and informed their members on the implications of GDPR [14], e.g. by providing an open source consent framework. Before the enforcement of GDPR, the future of third parties and advertising was also a hot debate topic in the advertising industry [5, 17, 26, 36]. As every provider serving users from the EU were compelled to review their use of cookies and other person-identifiable data-exchange with third parties, the assumption in the industry was that GDPR would lead website providers to review and reduce the number of third party servers [25]. Correspondingly, a number of companies started to offer the monitoring of third party activity on behalf of website providers, as well to legalize the data collection by obtaining user consents. The much ado in the web industry in relation to GDPR provokes thus the question whether the activity level of third party HTTP responses changed with GDPR. Do users meet fever third party servers when browsing the WWW?

This paper presents the results of an ongoing longitudinal study of strategically selected websites, from European countries in and outside the EU/EEA, and from USA. The websites have been selected to represent those categories that have been found to show either very high or very low numbers of third party[3] URLs [10]. Earlier works have observed that sites which belong to government organizations, universities, and non-profit entities have a low number of TPs, while sites with editorial content have a high number of TPs, since *"they are pressured to monetize page views with significantly more advertising"* [10]. In this work, we examine this observation with a longitudinal dataset spanning across the commencement of GDPR and across different countries.

Our intuition is that the picture is more differentiated than what has been studied so far, as many high-traffic public organizations' websites, such as public service media companies or public transportation companies, feature advertising and are deeply integrated in media ecosystems [22, 30, 37]. We analyze if these citizen-serving websites may thus, with respect to the number of TPs, have similarities with commercial high-traffic websites. As an example, public service media organizations promote themselves as *"islands of trust and quality in the multimedia environment"* [7]. They argue that citizens have high level of trust in public service media [8, 9]. Arguably, websites published by public entities should be expected to protect users' privacy particularly well, in order to maintain

[1] EU General Data Protection Regulation (GDPR) – https://eugdpr.org/
[2] IAB Europe – https://www.iabeurope.eu/
[3] In the rest of the paper we refer to third parties as "TPs".

the integrity of the public organization as being independent and sovereign in relation to private actors. As public organizations are funded by tax or – in cases of public service media – via a license fee, involvement with advertising blurs the public/private distinction. Indeed, advertising in public service broadcasting is subject to heavy regulations [33]. In a digital context, users may pay twice for the same public service: first via the tax and then with their data being transferred to the third party web services. The extended discussion of public organizations' use of third party services is however not the aim of this paper, but to test our assumption of websites morally obliged to a low number of third party contacts, we include law firms as examples of private websites that could have an interest in signalling a high level of privacy.

Our contributions: Having collected HTTP requests and responses 21 times over eight months for a strategic selection of 1250 European and US websites, we can analyze the fluctuations in number of TPs before and after the commencement of GDPR on May 25, 2018. Thereby, we provide empirical evidence for the discussion whether GDPR would lead to fewer TPs. At a general level, we can conclude that the amount of TPs on web pages have slightly declined, but the picture is more complex and contradictory when we study the developments for respectively categories of sites and TPs. This finding adds details to findings provided by [21] and [10]. We cannot support the general assumption that the GDPR has led to fewer TPs, since we cannot find strong evidence for any correlation. As a second contribution, we characterize the differences between websites offered by public and private organizations from the TP perspective, initiating a discussion on public organizations' use of TPs. Finally, we intend to publish the data to allow other research groups further analysis.

2 RELATED WORKS

The involvement of third-party (TP) advertisers or trackers in websites and mobile apps have interested many researchers [1, 2, 6, 10, 18, 20, 29, 31, 32, 34, 35]. In 2014, Acar et al. presented one of the first large-scale studies of third-party trackers in web pages, showing that *the web never forgets* [1]. The authors show that trackers use different and complex ways to integrate in a website, so that it is difficult to distinguish them accurately from genuine content. In a more recent work, Lerner et al. perform an *archaeological analysis* of tracking practices in the web, analyzing websites from 1996 to 2016 from the Internet Archive[4], showing that the first web trackers date back to 1996 [18]. Unsurprisingly, the study finds that the number and complexity of TPs have increased since their first appearance in 1996. Furthermore, through a large-scale automated analysis of third-party privacy policies, Libert et al. show that reading and understanding privacy policies is far from easy, and users are not presented with the needed information allowing them to take relevant decisions on what data to share [20].

One of the largest measurements of third-party presence was conducted in January 2016, where Englehardt and Narayana developed OpenWPM[5], an automated script that uses Firefox web-browser to visit websites through the Selenium[6] automation tool. OpenWPM collects and stores several browsing data, such as HTTP requests and responses, in a database for later analysis. The authors used the tool to visit one million unique websites via 90 million web page requests [10]. The selected websites represented the one million most popular websites in the world, according to the internet measuring service Alexa[7]. Following the categorization of websites made by Alexa, the authors found that news websites are among those with the highest number of third-parties, while websites from public organizations, NGOs, and universities are among those websites with the lowest number of third-party web-server contacts. In this study, the authors found over 81,000 unique third-party servers. However, they notice that only 123 of these were present at more than 1 percent of the visited sites [10].

Many studies have used OpenWPM for crawling and analyzing the web. Among these, Binns et al. assess the power of third party trackers through business collaboration [2], Mazel et al. compare privacy protection methods [23], Brookman et al. analyse cross-device tracking [3], and recently, Rodriguez et al. have analyzed tracking cookies in the EU [27].

To understand the inter-dependencies in the business ecosystem of media production, Lindskow analyzed the TPs presence at 41 US-American news publishers, identifying 1,356 business partners [22]. The study shows that *digital news publishers function as integrators of resource flows from hundreds of business partners of different types and sizes and that each of these partnerships involves complex resource exchanges and strategic dependencies.* The author's focus is thus not on privacy, but on business networks. However, they provide useful insights into dividing the TPs in different categories, identifying and analyzing six categories, as follows: *i)* News content elements, *ii)* News content, *iii)* Editorial tools, *iv)* Measurement, *v)* Advertising, and *vi)* Supporting resources.

Starov et al. analyzed the identifiers that third-party trackers store in users' devices to uniquely distinguish between users, showing that there are many websites that use the same identifiers, allowing the authors to cluster websites that looked unrelated to each other [32]. Falahrastegar et al. [12] make an early contribution to map the anatomy of the third party ecosystem, with a focus on user tracking.

Recently, with the advent of GDPR, many researchers have started analyzing the possible effects that GDPR is having on the web. Libert et al. [21] present a fact-sheet on third-party cookies of 204 news websites from seven EU countries. The pages were visited in April and July 2018 (pre- and post-GDPR), using a crawling system developed by one of the authors in a previous work [19]. The authors observe that the percentage of web pages that contain third-party content decreases with only two percent from April to July 2018, dropping from 41 to 40 third-parties per page. Conversely, they notice that there is a drop of 22 percent in the number of cookies, with variations among the seven countries.

Very recently, Iordanu et al. performed a massive analysis of a large-scale traffic flow from final users to third-party trackers [16]. The authors implemented a browser extension and distributed it to 350 real users, creating this way a reliable dataset. Then, they generalized their analysis methodology by extending it to datasets from four large Internet Service Providers (ISPs) containing data

from more than 60 million users. The study was performed during a period of four months before the implementation of GDPR. Among other results, this work shows that around 3% of the flowing traffic is related to sensitive user data, which might violate the GDPR requirements. Nevertheless, the authors show that trackers collecting sensitive data of users in the EU keep them primarily within the EU (in 90% of the cases).

In this work, we perform a large-scale analysis of third-party HTTP responses within a period of time that covers the pre- and post-GDPR era, specifically from February to September 2018. Firstly, we manually select more than 1300 websites of different categories from 39 countries, so that we have a reliable and controlled coverage of countries of interest and website purpose. Then, we use OpenWPM [11] to automatically visit the websites and some randomly selected sub-pages, creating a dataset composed of 21 crawls/harvests[8]. We then analyze the possible effects of GDPR, by comparing the changes of the TPs characteristics in the visits performed before and after GDPR.

3 RESEARCH DESIGN

In this section, we give a description of the tools we use to perform the data collection and the methodology we follow for selecting the websites to analyze, the cleaning of the data, and the classification of the third-parties.

3.1 Selection and classification of websites

The search for websites to be analyzed reflects our strategic selection of those website categories where third-party trackers have shown either high or low interest.

3.1.1 Identifying website categories. Considering the analysis and results of Englehardt et al. [10] and Libert et al. [21], we look for types of websites where either a high or a low number of TPs should be expected. From these studies, we can observe that there is a significant correlation between the ownership of the website, as being either private or public, and the number of TPs [10]. Indeed, while a user of commercially-oriented websites may expect a high presence of third party web servers, a user of a publicly owned citizen-oriented websites should expect none or very few third parties. As such, our website selection process reflects the distinction between websites offered by **public** and **private** organizations as a first criterion.

Then, the second selection criteria is the **country of origin** of the websites. We target primarily websites from the European countries, distinguishing between the EU, EEA (Extended Economic Area[9]), and non-EU sites. However, we also include few websites located outside Europe, mainly from US. To identify the country of a website we use its country code top-level domain, and if that is not available we perform a WhoIs look-up[10] to find the registrant organization's country.

Then, we identify eleven **categories of websites** that people visit more often, starting from and extending the list proposed in [10]. So, we include examples of shopping sites, hotel, travel and holiday sites, gaming and gambling sites, video-on-demand sites,

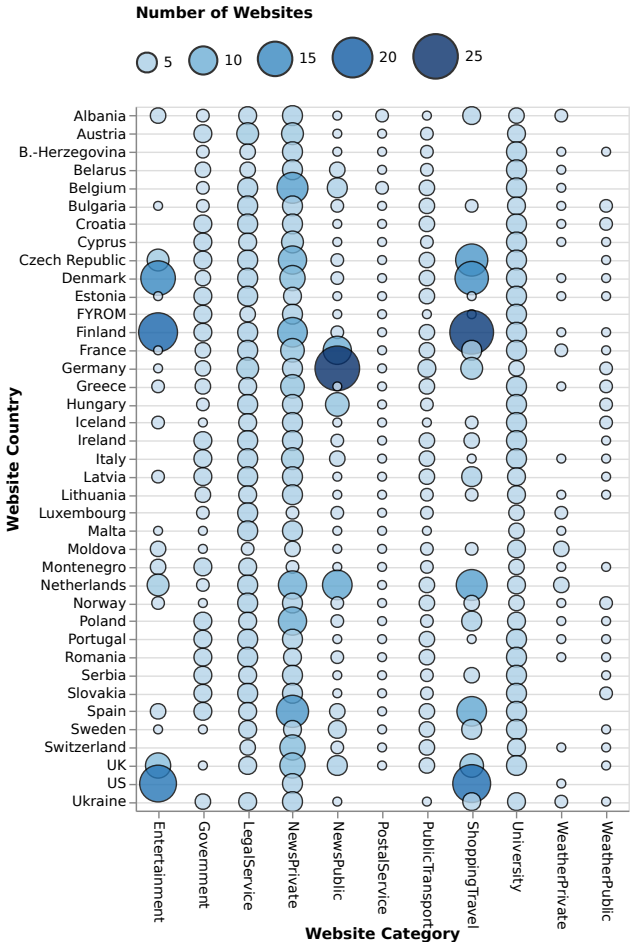

Figure 1: Number of websites per country and category selected for the analysis in this work.

general entertainment, and life-style magazines. In the analysis we have collected all these sub-categories in a single main category "Shopping and Travel". Moreover, we collect websites from European countries from law firms and attorneys, assuming that we would find an example of private websites with a low number of TPs. Furthermore, we consider governmental organizations, universities, public transportation, postal services, and state-funded weather services as public services websites, assuming that we would not observe a high number of TPs. For governmental organizations we specifically selected ministries and public administration sites.

Finally, we consider the news websites, which, differently from previous works, we explicitly divide them into public and private. We make this distinction considering the fact that there are huge differences among news/media organizations, particularly in Europe, where some are publicly owned and financed via a license fee, tax and in some cases also advertisement, whereas others are privately owned and financed by subscription, advertisement and in some cases public support. Similarly, we also distinguish between public weather websites from governmental/public organizations,

[8] In this paper, we use the terms *crawl* and *harvest* interchangeably.
[9] www.efta.int/eea
[10] https://whois.icann.org/en

and websites from private providers. To the best of our knowledge, this is the first work that makes this clear distinction.

As such, we identify the following categories: *i)* Entertainment, *ii)* Government, *iii)* Legal Services, *iv)* News Private, *v)* News Public, *vi)* Postal Services, *vii)* Public Transport, *viii)* Shopping and Travel, *ix)* University, *x)* Weather Private, and *xi)* Weather Public.

3.1.2 Selection of websites. To find the relevant websites for each category, we have used various methods: via search engines, via user involvement, via related research, and via lists of membership. Differently from previous works, which use Alexa[11] to classify a website as belonging to a category, we manually look at each website and classify it with human intervention. We believe that, compared to Alexa's lists, the manual classification allows us to have a higher level of certainty about the websites' category, given that we do not have access to Alexa's criteria for the categorization.

To identify public service media news websites we use the list of members of the European Broadcasting Union, a lobby organization for public service media[12]. As for private media, we take the top-5 most popular news sites listed in the Reuters Institute Digital News Report 2017 [24]. For countries not covered in the Reuter's report, we use the Alexa web service[13]. For websites in other categories than news, we manually identify them using Google Advanced Search[14], filtering by region/country, getting the top 5 websites not already in our list. Moreover, to broaden the collection of websites further, we perform a web survey asking users from our personal network to mention the most popular websites from their countries in the following categories: news, lifestyle/magazine, shopping, travel & hotels, entertainment, and gaming. From 17 users we obtained 279 unique websites: 62 news sites, 42 magazine/lifestyle sites, 67 shopping sites, 62 travel & hotel and accommodation sites, 23 entertainment sites, 20 gaming sites, and 3 sites outside these categories.

Overall, we were able to carefully select a total of 1,363 websites from 39 different countries, divided into 11 categories, as shown in Figure 1. As can be observed from the distribution, we are aware that not all categories are equally well represented for all countries, as well as some categories are represented with more websites in some countries than in others. This bias is an implication of our main study goal, which aims at having at least five websites from each country in these categories: *i)* private news, *ii)* universities, *iii)* ministries, *iv)* law firms. As for the categories of public transportation, postal service, and public weather, for some countries we found fewer sites than in some other. For public service media we included all public service organizations, even if multiple as in the case of Germany. The variability in the other categories, i.e. Entertainment and Shopping & Travel, is then due to user involvement.

3.1.3 Selection of subpages. To ensure a broad capture of possible TPs on the websites we have generated a list of subpages to visit. We have done so by collecting random URLs from the 1,363 sites, producing in total +50,000 URLs. From these, we randomly select ten subpages to be visited for each site. On average, we have visited 9.35 pages from each site. Some sites do not have subpages, since one single page provides all the necessary information. This is the case e.g. for weather information and public transport (journey planners and timetables). In total, the script visited 12,778 subpages from the 1,363 websites for each of the 21 harvests, capturing all the HTTP requests and responses. For each website and subpage visit we collect the set of unique third party URLs.

[13]https://www.alexa.com
[14]https://www.google.dk/advanced_search

3.2 Data collection and cleaning

3.2.1 Sampling period. We selected a long sampling period for the large-scale crawling, in order to be able to detect the effects of GDPR in terms of possible and expected deviations in the number of different types of TPs on the different categories of websites over time. As such, the sampling period spans across the GDPR commencement, which was on May 25, 2018, with 8 harvests from February to May and 13 harvests from May 25 to September.

3.2.2 Website harvesting. To perform the automatic website crawling we setup a virtual machine (VM) with 5 CPUs and 8GB of memory running Ubuntu. We installed the widely used OpenWPM framework and configured it to use four vanilla Mozilla Firefox browsers in parallel, meaning that we did not in any case register or log in with a user account while visiting the websites. Moreover, we did not give consent to any storage of cookies or other types of privacy-related requests, as the interaction with the web pages only took place automatically via the script. In this way, the behavior of the script consequently imitates a user who ignores all user privacy consent messages from the websites. However, we did not install any extension on the browser that would stop the websites from storing or reading cookies. We did not erase any cookie after a harvest was performed, so that on next visits the websites could behave normally by accessing the stored information. Finally, it is worth mentioning that the physical machine on which the VM was deployed is located in the EU, meaning that the visited websites must comply with GDPR.

3.2.3 Data cleaning and selection for analysis. Through the 21 harvests, we collected in total 31,493,575 HTTP responses from the 12,778 subpages of the 1,363 websites, averaging 1,431,526 HTTP responses per harvest.

Before analyzing the data, we performed a cleaning process that led to 83 websites to be removed from the dataset. The reasons for excluding these URLs are the following: *i)* Some of them redirected to a website already in our collection, thus risking to produce duplicated entries; *ii)* Some of them, suggested by the survey users, were from countries outside Europe (Japan, Korea, Hong Kong, Panama), from which we have no other or very few websites; *iii)* Finally, to consolidate our eleven main analytic categories of websites (see Figure 1), we have discarded few websites that did not fall into any of the main categories.

Thus, in the rest of the paper we analyze and present our findings regarding 1,250 websites from 39 countries from the EU, EEA, countries outside EU/EEA, and from the USA, and divided into 11 categories, as shown in Figure 1.

3.3 Categorization of the TPs

In this section we present some results related to the overall number of third-parties observed in our datasets and to the methodology we

TP Category	No. of Unique URLs

Unidentifiable	347

Table 1: Number of unique TP URLs for each TP category.

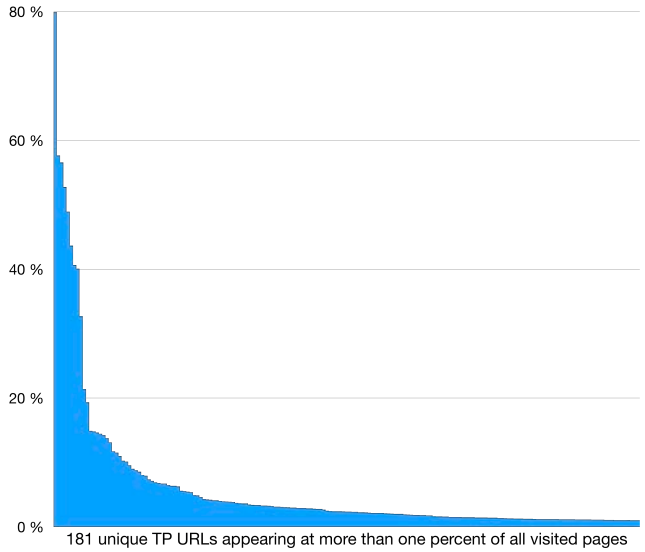

Figure 2: The presence in percent for the most omnipresent TPs of all pages.

pursued on classifying them into different categories. To identify the third-party URLs we look at all HTTP responses and extract all those URLs that are different from the website URL that was being visited. From this analysis we find 3,128 unique third-party URLs.

Then, we manually categorize the TPs by visiting the unique URLs. If we find a readable website, we attempt to determine the type of services offered by the TP by reading their descriptions of services, products, and mission statements. If the original TP URL redirects to another website, e.g. a company website, we analyze the description of products and services of that company. Otherwise, if the URL is not accessible and returns an error message, such as *HTTP 404 Not Found* for example, we classify the TP URL as *Unidentifiable*. Following this procedure, we were able to identify with high accuracy the 14 TP categories listed in Table 1, where we also show the number of TPs per each category. The details of each category are the following:

Advertising contains all the various services related to sale of ads and analysis of user profiles, such as: Programmatic advertising services, Personalization services, Recommender systems, Real-time bidding platforms, Demand-side and Sell-side platforms, Data management platforms and data integration, Data brokers and data trading, Re-targeting systems, User trackers, Ad-servers, Advertising agencies, Ad-verification systems, Brand-integrity, attribution and anti-fraud systems, Marketing automation, Content & native advertisement services, Cross-device user identification systems, and Video-based advertising.

Analytics contains different types of services used to understand user behavior and gather user feedback: Audience measurement, AI-powered analysis of user behavior, Audience Intelligence, Semantic profiling, Audience research (qualitative), Customer flow, Marketing analytics, Quality of Service monitoring and Web performance optimization, Attention optimization tools for Publishers, and Customer feedback.

Content includes all types of elements shown on the web page, not being advertising. That includes content embedded from other websites, not part of the media company/organization.

Cybersecurity specifically focuses on services that perform internet infrastructure surveillance.

Distribution technology includes content delivery networks, cloud services, and streaming services.

Editorial contains services specifically aimed at editors, e.g. recommender systems designed for publishers.

Plug-in contains web services that integrate content from other services into the visited site.

Privacy contains services that monitor website compliance with GDPR and cookie use on the visited site.

Programming contains services that deliver code to the rendering of the web page.

Publisher encompasses all servers that are owned by the media organizations including collaborating media organizations.

Retail includes all-purpose web-portals, job-seeking portals, shopping platforms, real-estate brokers, and consumer products (advertisers).

Unidentifiable includes those URLs that do not return a valid and readable HTML page when visited in the browser, but a *404* or *forbidden* error message or a blank page. Our working assumption is that a large portion of the unidentifiable TPs are advertising related, delivering the ads to be displayed, measuring and verifying the exposure, or tracking the user across websites and other devices. This assumption is based also on an expert interview that we conducted with the CTO of an advertising technology company in December 2017[15].

4 RESULTS

Our research design allows analysis of the collected data along different dimensions. Indeed, the categorization of both the visited websites and third party URLs, combined with 21 samples (harvests)

[15] Jacob Knobel, former CTO of Densou.dk, also cited in [30]

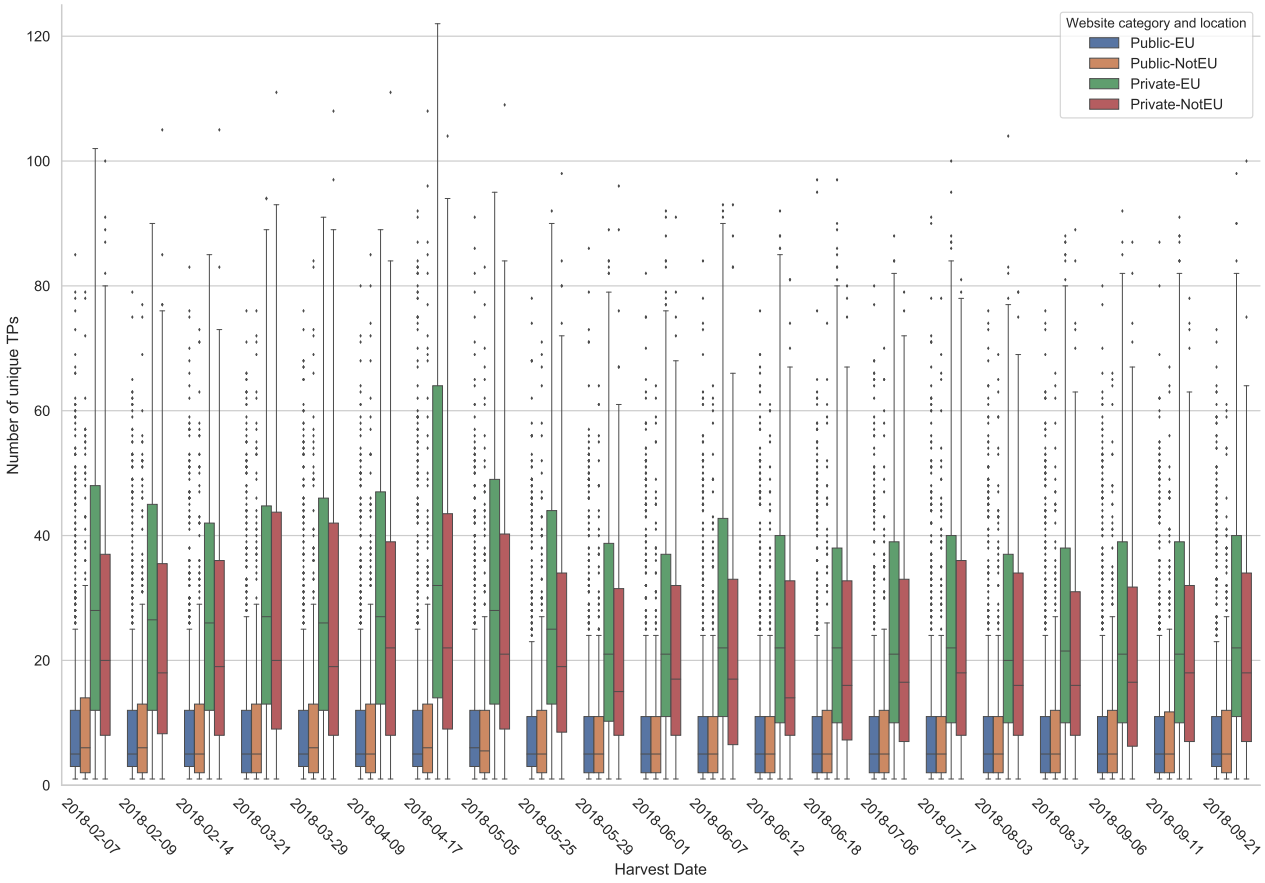

Figure 3: Number of TPs with respect to the website being public or private and its EU membership (EU/NotEU). In this graph we consider EEA countries together with the EU ones.

over a time span of eight months, gives us the opportunity for a detailed investigation over different feature combinations.

Firstly, as the sampling period spans across the commencement of GDPR, we can compare pre- and post GDPR levels for the presence of TPs. Moreover, the categorization of the visited sites into countries, groups of countries, and types of site, together with the categorization of the TPs, allows us to create a detailed picture of the developments. Furthermore, we can look at groups of sites, such as EU and EEA countries compared with sites from outside the EU/EEA area, and extend the investigation by also differentiating the websites in private and public ones. Finally, on a more detailed level, we can also look at the variations in the number of TPs for different categories of sites, for different countries, and for different types of TPs.

4.1 Analyzing the Number of TPs for Categories of Sites

In total, we found 3,128 unique third party URLs, appearing on at least one web page in all our 21 harvests. During all the observations, we found that:

- After May 25, 675 unique TPs disappeared, of these 63 were present in all harvests before May 25.
- 644 new unique TPs appeared after May 25, of these 36 were present in all harvests after May 25.
- 2096 TPs were present in all 21 harvest on at least one website.
- 408 TPs appeared only in one harvest at one website.

If we consider a list with the top-20 TPs, we find similarities with earlier works showing the dominance of the giant companies [10, 21, 28]. From our data, we find that this includes nine TP URLs controlled by Google *(google-analytics.com, doubleclick.net, googleapis.com, google.com, gstatic.com, google.dk, googletagmanager.com, googlesyndication.com, googletagservices.com, googleadservices.com)*, two TPs controlled by Facebook *(facebook.com, facebook.net)*, Amazon's CDN *(cloudfront.net)*, and the competitor CDN *(cloudflare.com)*, the advertising companies Adnexus *(adnxs.com)*, *criteo.com*, *adform.net*, the analytics companies *scorecardresearch.com (TMRG) and gemius.pl*, and the omni-present *twitter.com*. These URLs represent the beginning of a very long tail where only 151 TPs have a share of one percent or more of the pages, while the remaining 968

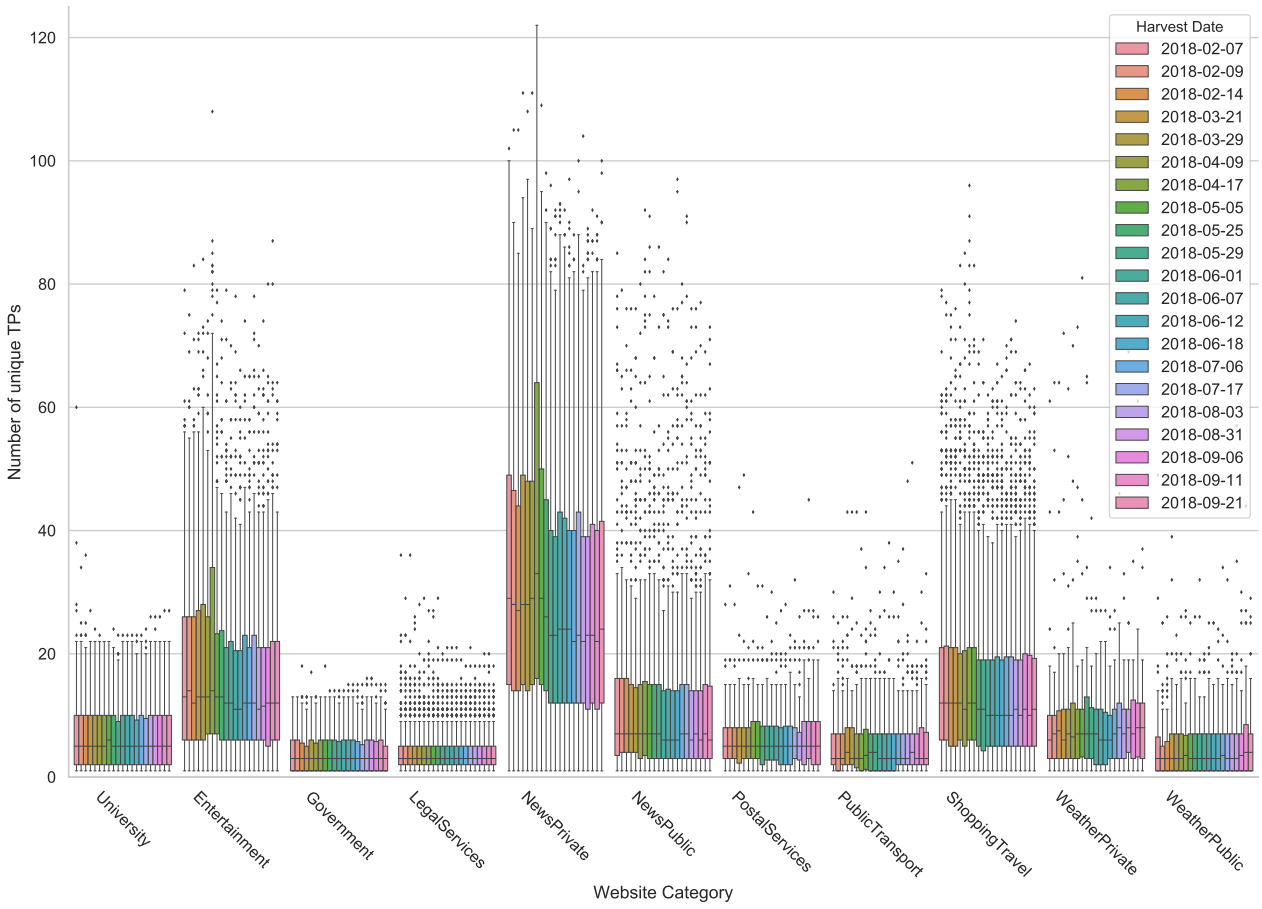

Figure 4: Number of TPs per website category with respect to the harvest date.

TPs have a share of less than one percent. The cut long tail of the top 151 TPs is presented in Figure 2.

In Figure 3, we analyze the variations of the TPs by dividing the websites into private/public and EU/NotEU, where EU in this case includes also the EEA countries, while *NotEU* includes websites from countries outside the EU/EEA. The figure shows, for each harvest, the distribution of the number of TPs embedded in each website represented as box plot, showing the minimum, the median, the maximum, the first and third quartile, and the outliers. From the figure, we can firstly see that the **public websites have far fewer TP URLs than the private ones** in all the harvests. Secondly, we can see that there is a **difference between private EU and NotEU websites**, while there is not much difference when considering the public websites. When considering the variations over the observed time, we can see a rather **stable picture for the public sites**, regardless being from the EU or not. In comparison, the **private sites present large fluctuations**, but with fewer outliers. Moreover, these data suggest that the **private websites present a slight decrease of the number TPs** after the commencement of GDPR, while the public ones are hardly affected.

Next, we continue our investigation trying to identify the responsible private websites that cause the decrease in the number of TPs after GDPR. In Figure 4, we present the distribution of the number of TPs for website category, grouped by harvesting date. As also observed above, this figure shows clearly and with more details that **public websites** (i. e. categories *University, Government, PublicTransport, PostalServices, NewsPublic,* and *WeatherPublic*) **present a low level of TPs and a low level of fluctuations**, with the exception of some outliers. Of these public categories, the news websites present the highest number of TPs and the highest variations. When it comes to **private websites**, *LegalServices* present a similar constant low level of TPs as the public ones, followed by the *WeatherPrivate*, while ***Entertainment, NewsPrivate,* and *ShoppingTravel* present the highest number and variations of TPs**.

To quantify the variations over time, we perform the linear regression of the average number of TPs for all website categories for each harvest. The regression lines are presented in Figure 5 and more details are presented in Table 2. From these results we can confirm that the ***NewsPrivate, Entertainment,* and *ShoppingTravel* categories show a clear decline in average numbers**

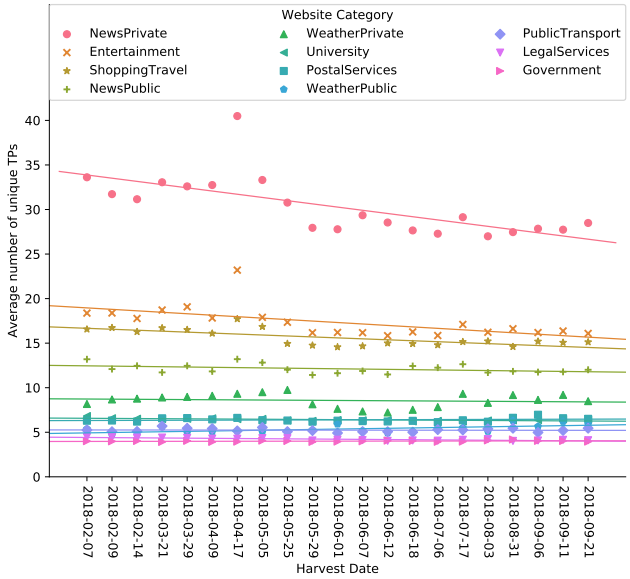

Figure 5: Average number of TPs per each website category during the harvesting period. The line represents the linear regression of the number of TPs, showing the tendency of the changes. The slope coefficients and the intercepts for each line are given in Table 2.

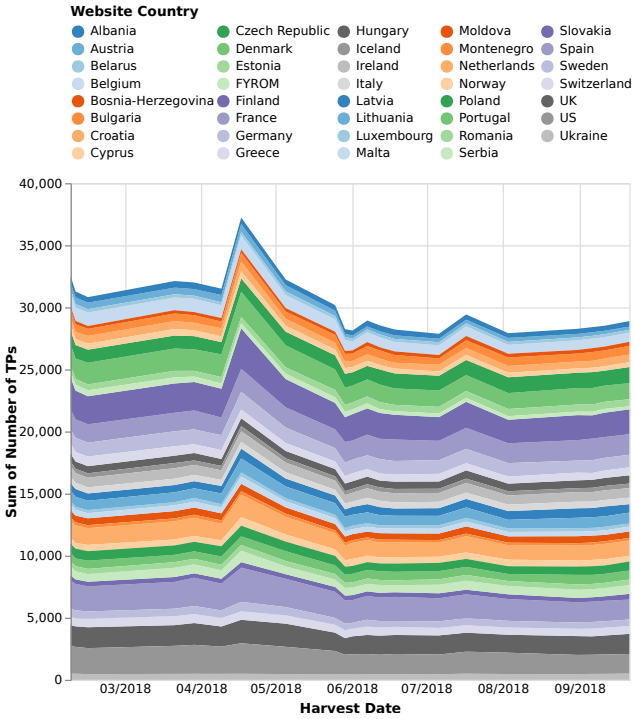

Figure 6: The total number of unique TPs at websites from 39 countries over time.

Private/Public	Website Category	Slope	Intercept
Private	NewsPrivate	-0.360	35.0
Private	Entertainment	-0.164	19.5
Private	ShoppingTravel	-0.107	17.0
Private	LegalServices	-0.019	4.5
Private	WeatherPrivate	-0.016	8.8
Public	NewsPublic	-0.033	12.6
Public	University	-0.015	6.6
Public	PublicTransport	-0.002	5.3
Public	Government	+0.003	4.0
Public	PostalServices	+0.008	6.3
Public	WeatherPublic	+0.043	4.8

Table 2: Coefficients of the regression lines of Figure 5.

of unique TPs per site visit, while for the other categories the decline is small. Moreover, for three categories of public websites, namely *PostalServices*, *Government*, and *WeatherPublic*, we see a slight, although we believe insignificant, growth in the number of unique TPs per site.

4.2 Countries Perspective

As a next analysis, we consider the individual countries and try to see the effects of GDPR over time. In Figure 6, we present the developments in the total number of unique TPs for each site we have visited from the different countries. This graph shows again that overall there has been a slight decline of the total number of TPs, but does not easily allow for a detailed quantification of the changes for each country. For this reason, we calculate for each country the average number of TPs for the harvests performed before and after GDPR and represent the changes as a percentage in Figure 7. The results show big variation among countries, with Estonia having the biggest growth and Austria having the biggest decline. 21 EU countries have fewer TPs after GDPR, while 7 EU countries have more TPs. Both EEA countries, Norway and Iceland, present a decline. Among the eight European countries outside EU/EEA, seven have a decline, while only Bosnia-Herzegovina has a growth.

4.3 Analyzing the distribution of the TPs

In this section, we present the analysis of the distribution of TPs in the different categories and the changes in each category over time (refer to Section 3.3 and Table 1 for more details about TP categorization). In Figure 8, we show a stream graph of the total number of TPs observed during each harvest. From the figure we identify major fluctuations in the *Unidentifiable* and *Advertising* third party categories. This is obviously due to the fact that these are the biggest categories, so it is easier to spot the changes.

To quantify the variations as we did for the countries, we look at the changes in percent and compare the visits after GDPR with those from before. The results for the categories with a declining trend are the following: *Cybersecurity (-51,16%), Privacy (-34,07%), Unidentifiable (-18,56%), Analytics (-11,28%), Advertising (-11,26%), Retail (-10,34%), Content (-6,50%), Distribution technology (-5,91%),*

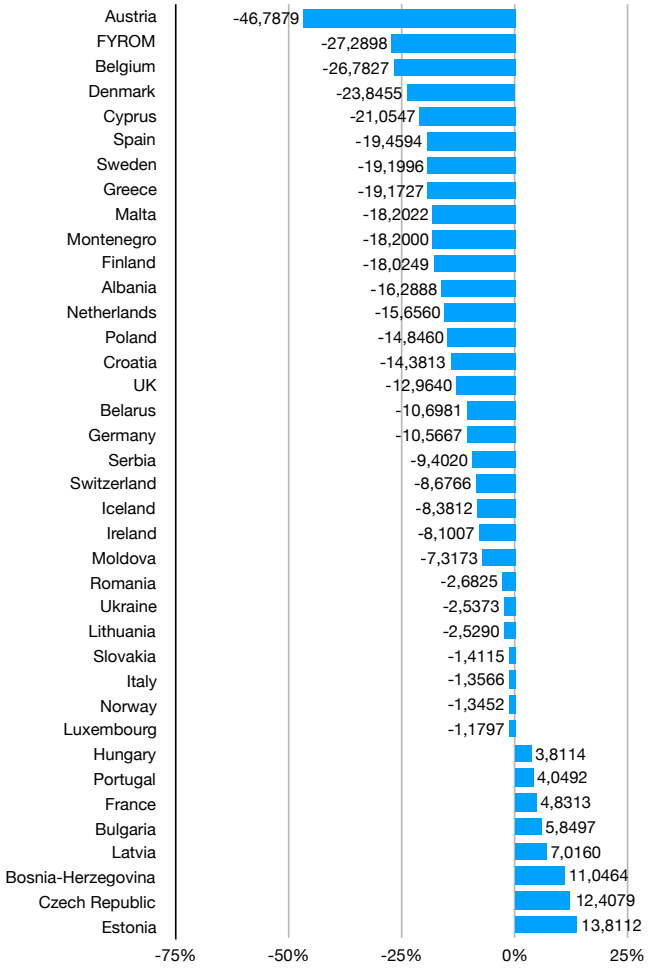

Figure 7: Comparing pre- and post May 25 average numbers of unique TPs for countries, listed as change in percent.

Social Media (-5,79%), *Publisher (-5,77%)*, and *Plug-In (-2,07%)*. We see a growth only in the categories *Programming (+2,73%)* and *Search Engines (+8,32%)*. However, as some of the categories have very few unique TPs the above changes should be considered with care. When considering single websites, we noticed that not all websites have a fluctuating number of TPs: for 241 websites (91 private and 148 public), the number of TPs is constant for all visits.

4.4 The Relation between Categories of Websites and TPs

The advantage of categorizing both websites and TPs is that we can also examine their mutual relation. Figure 9 shows, with a logarithmic representation, the occurrence of unique TPs of different categories in different categories of websites. The heat map considers all visits during all the harvests aggregated. The **most intense relationship can be seen in the lower right corner, where private media and advertising intersect**. We can also notice that the presence of advertising-related TPs is quite high

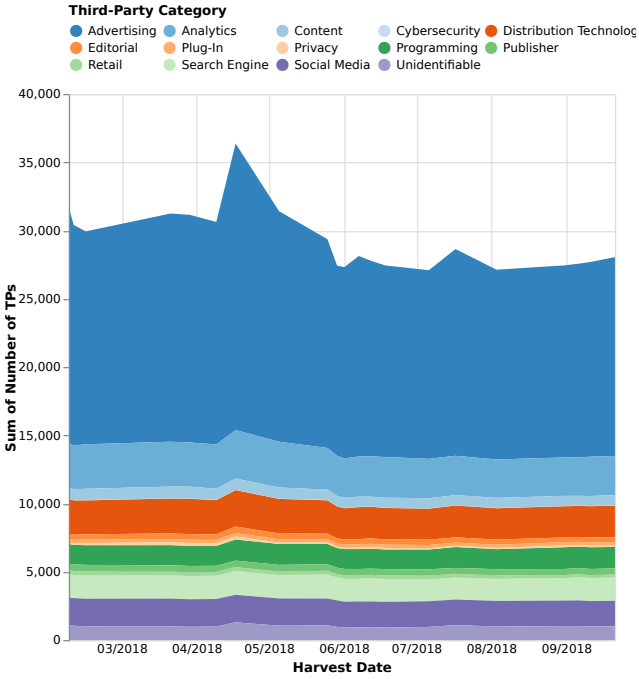

Figure 8: The total number of TPs distributed in categories.

in all the other types of sites, especially on public service media pages, on shopping/travelling, and entertainment sites. We can also notice that some TP categories are only found at some types of visited sites: The TP categories *Editorial* and *Publisher* are unique to the media websites. Other categories, such as *Cybersecurity* and *Privacy*, are low both in the number of unique TPs and in distribution and can thus not be expected to be prominently represented in the heat map. As a potentially more controversial finding, we see occurrences of both TP categories *Retail* and *Advertising* being present in the website categories *University*, *Government*, *Weather-Public*, *PostalServices*, and *PublicTransport*. That indicates that on the level of third-party ecosystems, **the borders between public and private institutions are to a certain degree dissolved**, with a possible user-tracking across the public-private border.

4.5 Interpretation

The different categories of websites have both *i)* a different behavior during the sample period and *ii)* a different pattern in the distribution of websites with many or few TPs. When we again look at Figure 4, we can see that the number of TPs for some categories of websites remains unchanged over the sampling period, while others have fluctuating amounts of TPs. Further detailed analyses on the level of individual pages and individual TPs may clarify the pattern. By looking at Figure 4, we can also see that the categories are showing a different span between the website in the category with the fewest TPs, and the website in same category with the most TPs. For websites in categories such as *Entertainment, NewsPrivate, NewsPublic*, or *ShoppingTravel*, this calls for a differentiated analysis. Possibly, for each of the categories websites with respectively few

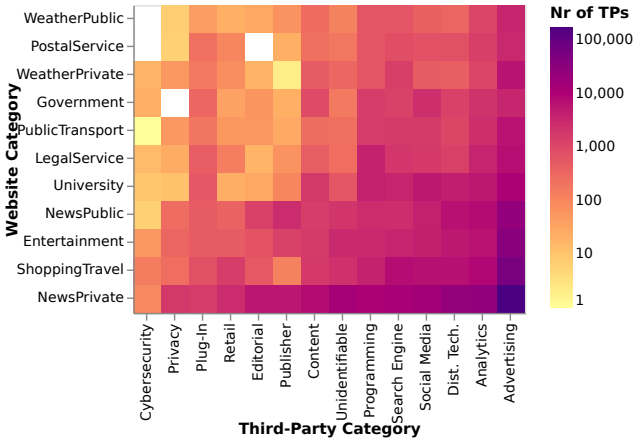

Figure 9: The intensity of the relation between categories of websites and categories of TPs on a logarithmic scale.

or many TPs may have more in common (also TPs) with websites in other categories. Again, this calls for an analysis of the appearance pattern for individual TPs across websites. An assumption, that can be supported by our findings, is that the fluctuations are mostly related to advertising and unidentifiable TPs, as shown in Figure 8.

Looking at the amount of TPs over time, we cannot see a decline for most categories of sites, and for others only a small decline. The assumption that GDPR would lead to a remarkable decline cannot be supported, as the fluctuations are too many for most of the categories of sites. Only for the categories *NewsPrivate*, *Entertainment*, and *ShoppingTravel* we could see a significant decline. However, to interpret this as an effect of GDPR may be problematic, since drawing strong conclusions on cause-effect relationships in such a complex environment with many impacting factors, such as online advertising and web page compilation, is difficult.

One hypothesis could be that advertisers prefer to reduce the amount of TPs to ease the obstacle of obtaining consent. Another hypothesis could be that the decline is caused by a technological change in the advertising industry. Indeed, the advertising industry is currently changing the methods for conducting the real time bidding for the sale of advertisements on web pages [15]. The old method conducts the bidding from the user's browser, producing - in the case of a difficult bidding process - a large number of HTTP requests and responses to real-time bidding platforms and their associated *Supply-side* and *Sell-side* platforms, among other third parties [4, 13]. The new server-side header bidding does not involve the user's browser, but takes place between the publisher website (the first party) and the servers of the bidding platforms. While the privacy exposure may be as big as before, the user will experience fewer HTTP requests from her browser [15]. Further research is however needed to assess the uptake of server-side header bidding by publishers and other websites displaying advertisements. Based on our current research it is thus problematic to associate the decline in advertising-related and unidentifiable TPs with the introduction of GDPR.

5 DISCUSSION

Our analysis shows that the number of third party servers a user will meet at different websites in many cases fluctuates from visit to visit. It is thus difficult to draw the conclusion that GDPR should have resulted in a user meeting fewer third parties when browsing a website. Furthermore, attributing the general decline we see to GDPR is problematic, as the implementation of GDPR coincides with another change in the ecosystem of third party services, namely the uptake of server-side header bidding for online advertisements [15] (see the previous section). Further analyses is however needed to shed light on these changes.

One can interpret the third party activities in different ways. The literature has mainly looked at these from a privacy perspective, focusing particularly on the tracking of users across websites. Through our categorization of third parties, based on text analysis of services offered by the third party company, we can however see that user tracking, segmentation, and user profiling have become standard products offered for sale to any advertiser. That does not make the privacy issue less pressing, but it shows that tracking has become industrialized.

Another way to interpret the third party activities is to see them as sign of an ever more integrated world wide web; a business ecology of services that co-produce the experiences to users, an interpretation aligned also with previous works [22]. That approach raises two discussions: one on *dependence* and one on *efficiency*.

The dependence discussion, initiated by Lindskow et al. [22], focuses on media companies' dependency on external collaboration in order to reach their audiences and monetize the contact. The outsourcing of production of the website content through a deep integration in the third party service ecology, diminishes the power and freedom of the media institutions. They operate on top of an infrastructure composed by a complex network of third party services, a network which has become the gateway to users.

The efficiency is a rather technical discussion on improving page loading times, initiated by the advertising industry. The answer has been to conduct the bidding for advertisements on the server-side, between the media organization's server and the bidding platforms with their affiliated network of services. The study of third-party interaction in the browser may however in the future not provide us much information of the exchange and analysis of our user data.

6 CONCLUSIONS AND FUTURE WORK

Our longitudinal large-scale study of the third-party server interactions at websites has shown that no clear effect of GDPR can be seen. Fluctuations of the number of TPs during the eight months harvesting period can be observed for most categories of websites, with some categories, such as private news, shopping/travel, and entertainment, presenting a visible decline. Other categories have a stable or even slightly growing number of unique third-party web services. The detailed study on the level of different countries adds nuances to the distinction between EU/EEA countries and other non-EU countries and the USA. Particularly, we see a difference between private websites from within the EU/EEA and from outside. Furthermore, our research shows large differences between privately owned websites and publicly owned websites, with the

former having many TPs embedded and the latter having low but growing amount of TPs.

As future work, we intend to analyze the relations between single third party servers and single websites, possibly employing machine learning techniques to uncover hidden patterns and relations. Furthermore, we will also continue harvesting the selected websites, potentially also extending the list. Finally, we will also focus on further analyzing the utilization of third party services in publicly owned websites.

ABSTRACT

Causal inference using observational data on multiple treatments is an important problem in a wide variety of fields. However, the existing literature tends to focus only on causal inference in case of binary or multinoulli treatments. These models are either incompatible with multiple treatments, or extending them to multiple treatments is computationally expensive. We use a previous formulation of causal inference using variational autoencoder (VAE) and propose a novel architecture to estimate the causal effect of any subset of the treatments. The higher order effects of multiple treatments are captured through a task embedding. The task embedding allows the model to scale to multiple treatments. The model is applied on real digital marketing dataset to evaluate the next best set of marketing actions. For evaluation, the model is compared against competitive baseline models on two semi-synthetic datasets created using the covariates from the real dataset. The performance is measured along four evaluation metrics considered in the causal inference literature and one proposed by us. The proposed evaluation metric measures the loss in the expected outcome when a particular model is used for decision making as compared to the ground truth. The proposed model outperforms the baselines along all five evaluation metrics. It outperforms the best baseline by over 30% along these evaluation metrics. The proposed approach is also shown to be robust when a subset of the confounders is not observed. The results on real data show the importance of the flexible modeling approach provided by the proposed model.

1 INTRODUCTION

This paper provides a scalable approach for estimation of individual treatment effect using observational data in the setting where any subset of treatments from a set of treatments can be applied. The main motivation for this work is to provide a scalable approach for running counterfactual experiments on the effect of marketing actions on likelihood of conversion of a customer. The goal is to use the model for personalized online marketing actions. This problem is modeled as a causal treatment effect estimation problem where a subset of treatments can be applied. This setting is relevant for problems in a wide array of domains such as Economics [5], Medicine, Public Policy [14].

The prescribed approach for estimating causal effect is to conduct a randomized control trial. Unfortunately, running a randomized control trial is expensive and often not possible. Easy availability of observational data makes causal inference using observed data an attractive alternative to costly experiments. However, it is often the case that treatments in observational data were not assigned randomly. For example, a customer is targeted with an advertisement based on propensity of the customer to click the ad. Formally, the assignment of a treatment to a customer is not independent of the outcome. This can lead to misleading estimates of treatment effect [12]. In this particular example, the effect of the targeted advertisement will be overestimated when outcomes of "treated" and "untreated" customers are compared without any adjustment for the biased assignment. In addition to the biases due to assignment, there is likely a selection bias where an individual is self-selecting to be part of a treatment group [2, 16].

There is a large literature in various fields on causal inference using observational data. The Rubin Causal Model [29] and conditioning on observables [18], are two popular approaches to handle the bias due to assignment or selection on observables. There are recent papers that extend these models by using deep learning models (see [19, 31]). These approaches do not apply when the assignment or selection is based on unobserved variables. Selection on unobserved can be due to a user self-selecting treatment(s) on the basis of her wants and needs. These unobserved variable are called latent confounders. Under the assumption that there are observable proxies which can be used to recover these latent confounders, the causal effect is identifiable. Recent papers have used deep generative models to recover the causal effect in a setting where latent variables determine assignment [25, 34]. These models have shown promising result. Our approach follows this line of literature.

The main focus of this literature is the setting where the treatment is a binary [25] or a multinoulli [34] variable. The case where treatment can be any subset out of a set of treatments is less studied. The approach to deal with multiple treatments seems to be either to treat each subset as a separate treatment [24] or derive multiple treatment effect as a function of the treatment effects of the individual treatments in a subset. As an example for the latter, in a linear regression setting the effect of two treatments can be modeled as a sum of the individual effect of the two treatments plus an extra coefficient for the joint effect. Both of these approaches have drawbacks. Treating each subset as a separate treatment do not use the information across treatments. Besides, it is not a scalable approach if the model requires separate models for each treatment (see [19, 25, 31, 34] for such models). Another issue is that all subsets of treatments might not be observed. For example, in the real dataset used in this paper there are five treatments, which implies $2^5 = 32$ total subsets of the treatments. Only 26 out of 32 subsets are observed. Out of these 26 subsets, 8 are observed less than 10 times, 10 are observed between 10 to 100 times, and only 8 are observed more than 100 times. This makes it difficult for a large number of existing models to be applicable for the task at hand. The approach to impose a particular structure on the treatment effect of a subset has the obvious drawback that the functional form can be wrong.

Our approach overcomes both of these drawbacks. Our main contribution is that we use a task embedding [15] to scale the model presented in [25] for multiple treatments. We explicitly model the latent variables and the structure of the causal problem using a variational autoencoder [20]. The effect of multiple treatments is incorporated by using a task embedding to model the interdependence between the treatments. A task embedding allows a flexible representation of a task by multiplying a vector of zeros and ones, representing which treatments are applied, and a weight matrix which is learned. The resulting vector is passed on to the following layers of the network. The dimensions of the weight matrix are equal to the number of treatments times a constant which is a hyperparameter of the model. If two treatments have similar effect, then the columns corresponding to the two treatments will take similar values. If two treatment have similar values only for a subset of the observed covariates, this can also be represented by the task embedding. We call this model Task Embedding based Causal Effect Variational Autoencoder (TECE-VAE). The model is robust even when some of the subsets of treatments are not observed and uses information across observed subsets of treatments. The simple tweak of the architecture by incorporating a task-embedding provides a powerful tool to deal with multiple treatments.

The proposed approach, TECE-VAE, shows improved performance over a wide variety of competitive baselines. The model is compared against deep causal models as well as traditional models that have shown to work well under different settings. The baselines also include models that have done well in causal effect estimation competitions. The proposed approach is compared with the baselines on a semi-synthetic dataset with three treatments. The choice of the number of treatments in the semi-synthetic data is due to the difficulty in scaling some of the baselines to more than three treatments. Note that the proposed approach scales well to multiple treatment. Hence, the results are conservative from the perspective of the proposed model.

The result on semi-synthetic dataset shows that TECE-VAE improves upon the best baselines by over 30% on a variety of metric, including one proposed by us. Another set of experiments tests the robustness of the model when some of the covariates representing hidden confounders are not observed. The proposed approach continue to work well on the reduced set of covariates when 20%, 40%, 60% of the covariates are removed from the dataset. We also apply the model on a real world dataset to solve a real causal inference problem. The results indicate that assignment bias is a problem and explicitly modeling the latent variables is helpful.

Next, the literature related to this work is discussed.

2 RELATED WORK

In our setting, the assignment is based on observable as well as on latent variables. We make an assumption that there are proxies observed for the latent variables.

The closest paper to our work is [25]. This paper uses a Variational Autoencoder (VAE) [21] to model and estimate the joint distribution of the observed proxies, treatments, unobserved latent variables, and the outcome. Following Rubin's potential outcomes framework, this model uses a private path for each treatment. The assignment model decides which of these paths is taken. Due to a large number of potential outcomes where all combinations are not observed, this approach is not directly applicable in our setting.

There are other papers that have used deep models for causal inference. Johansson *et al.* [19] introduced Balancing Linear Regression (BLR) and Balancing Neural Network (BNN), which is used for counterfactual inference in the case of binary treatments. They formulate the problem of counterfactual inference as a domain adaptation problem. Shalit *et al.* [31] introduced Counterfactual Regression (CFR) and Treatment-Agnostic Representation Network (TARNet) for estimating individual treatment effect (ITE) from observational data in the case of binary treatments. The causal inference models in these papers use an architecture with private paths for each treatment. The reason given for choosing private paths is to preserve the effect of a treatment amidst the noise due to non-treatment covariates. This might happen because the number of non-treatment features is very large compared to the treatment features. Our model, TECE-VAE, does not use treatment specific private paths. Instead, we use a task embedding to represent each

combination of tasks. Even though the semi-synthetic data and the real world dataset have a large number of non-treatment feature, the estimated ITE in not noisy.

There are other recent papers that have used deep generative models for causal inference. Yoon *et al.* [34] introduced Generative Adversarial Nets for inference of Individualized Treatment Effects (GANITE), an approach using Generative Adversarial Network (GAN) [10] to estimate the individualized treatment effects in case of multiple treatments. We were not able to obtain the code for GANITE, hence excluded this model from the baselines.

In addition to the deep model, other models which are considered for comparison come from the set of models that have performed well in a causal inference competition [6]. These models are Random Forest (RF) [3], Gradient Boosting Machine (GBM) [8], and Bayesian Additive Regression Trees (BART) [4]. These are tree-based supervised learning approaches that work well in causal inference tasks [6]. The third one, BART, is a computationally intensive approach that took about 12 hours for one run on our semi-synthetic dataset. These approaches extend easily to multiple treatment. While the first two are not proposed as causal models, these can recover causal effect by conditioning on observable covariates.

In summary, the existing literature, with naive extensions for a subset of treatments, often introduces scalability issues since the number of possible subset of treatments increases exponentially with number of available treatments. Moreover these approaches might fail to account for the interdependence among the treatments. We address this gap in the literature by proposing a scalable model that addresses the problem of estimating individual treatment effect when any subset of the available treatments can be applied.

The next section describes the proposed approach in detail.

3 METHOD

The causal structure in Figure 1 depicts latent confounders ($\boldsymbol{z}$) that determine who gets what possible combination of treatments ($\boldsymbol{t}$). The latent confounders also influence the outcome (y). The proxy variables, denoted by $\boldsymbol{x}$, are noisy representations of latent confounders ($\boldsymbol{z}$) that are observed. In the context of online marketing, the casual structure can be described as follows: $\boldsymbol{x}$ represents observed online behavior of customers and $\boldsymbol{t}$ denotes the treatments which a marketer can apply (for example sending an e-mail, offering discount etc.) to improve the likelihood of conversion. In such a scenario, the unobserved intent or purpose $\boldsymbol{z}$ guiding such online behavior $\boldsymbol{x}$, not only influences the conversion rate y, but also marketer's choice of actions $\boldsymbol{t}$. Hence, $\boldsymbol{z}$ confounds both y and $\boldsymbol{t}$.

It has been established that the proxy variables ($\boldsymbol{x}$) should not be treated as usual confounders ($\boldsymbol{z}$) because it induces bias [9, 11, 13, 22, 27]. Since $\boldsymbol{z}$ is not observed, we estimate a representation of $\boldsymbol{z}$ and use it to control for confounding effects of the latent confounders to obtain an unbiased estimate for the causal effect of $\boldsymbol{t}$ on y.

We use variational autoencoder (VAE) for causal effect estimation. The formulation is influenced by Louizos *et al.* [25]. As noted earlier, we use task embedding to represent different subsets of treatments instead of using private paths. VAE allows recovery of the distribution of the latent confounders under the assumption that the proxies are observed for the latent confounders. Recent

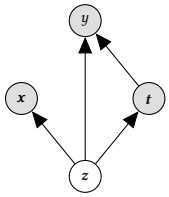

Figure 1: Causal graph where $\boldsymbol{x}$ represents observed proxies for confounders $\boldsymbol{z}$; $\boldsymbol{t}$ are treatments and y is outcome.

work on multiple treatments [33] show that weaker assumptions are sufficient to recover the causal effect of treatment when multiple treatments are applied. Under the assumption that there is no single cause confounder, the distribution of the latent confounders can be recovered from the assignment of the treatments in the observed data [33]. Note that we still need proxies for *all* latent confounders in case of *binary treatment*. Wang *et al.* [33] implies that the proxies for the latent confounders are not needed to identify the causal effect in case of *multiple treatments*. Inspired by this result, we also test the model when only a subset of the proxies are observed.

We can recover individual treatment effect under the causal model in Figure 1 if we can find the joint probability distribution $p(\boldsymbol{z}, \boldsymbol{x}, \boldsymbol{t}, y)$ [25, 26]. Using the causal structure, this joint probability distribution can be reduced to the product of the probability distributions $p(\boldsymbol{t}|\boldsymbol{z})$, $p(\boldsymbol{x}|\boldsymbol{z})$, $p(y|\boldsymbol{t}, \boldsymbol{z})$, and $p(\boldsymbol{z})$. These conditional probabilities are estimated using TECE-VAE.

First, let us introduce notations for describing the model. Let the total number of treatments be k. A subset of the treatments is denoted by a k-dimensional vector $\boldsymbol{t}$. Each element in the vector is a binary variable indicating whether a particular treatment is applied. For example, for $k = 5$, if the first and the third treatments are applied then $\boldsymbol{t} = [1, 0, 1, 0, 0]$. Let the dimension of the vector $\boldsymbol{x}$ be m. The proxy variables, $\boldsymbol{x}$, can be continuous, categorical, or binary. We denote these three types of variables by $\boldsymbol{x_c}$, $\boldsymbol{x_f}$ and $\boldsymbol{x_b}$, respectively. Similarly, the number of variables for each type is denoted by m_c, m_f and m_b, respectively. Finally, let $\boldsymbol{z}$ be a d length vector denoting unobserved latent confounders. The length of the latent confounders, d, is a hyperparameter. Experiments show that the results are not sensitive to the choice of d. This is a comforting result because the dimension of $\boldsymbol{z}$ is not known and sensitivity to the choice of d can make the application of the model to the real data less useful.

The proposed variation of VAE, like other autoencoder models, has a decoder and an encoder component. The causal VAE part is a specific architecture where the VAE mimics the dependencies shown in Figure 1. The design choices made in the architecture are either standard practices followed in VAE literature or are explicitly identified to be the contributions of this study. The details of the encoder and the decoder are presented next.

3.1 Encoder

In this part of the VAE, we recover the distribution of the latent counfounders $\boldsymbol{z}$. The posterior of $\boldsymbol{z}$ depends on $\boldsymbol{x}$, y and $\boldsymbol{t}$. Different parts of the network compute different probability distributions. Let g_i be the output of the layer as labeled in Figure 2. The treatment vector $\boldsymbol{t}$ is modeled as a vector of k Bernoulli random variables

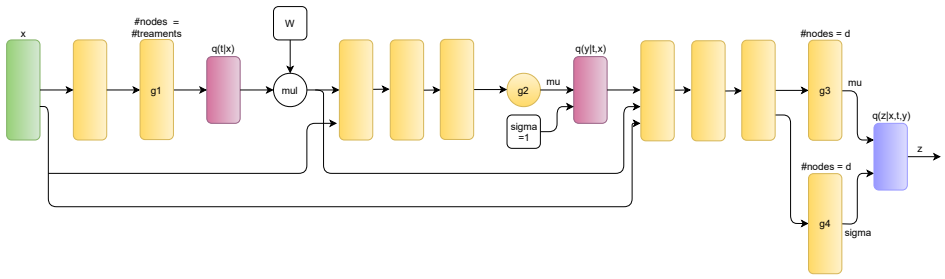

Figure 2: Encoder TECE-VAE, the encoder network takes input x to generate distribution for z. The green box refers to the input layer, input x is fed into yellow boxes that contain the network parameters to be trained. Purple boxes denote sampling step for various distributions. Note that weight matrix W is shown by an unshaded box.

which are independent given $\boldsymbol{x}$. Using the input $\boldsymbol{x}$, we obtain parameters for the distribution, $q(\boldsymbol{t}|\boldsymbol{x}) = \prod_{i=1}^{k} Bern(q_{\boldsymbol{t},i})$, where $q_{\boldsymbol{t},i}$ is the output of the layer labeled as g_1 in Figure 2.

The treatment vector, $\tilde{\boldsymbol{t}}$, is obtained by sampling from distribution $q(\boldsymbol{t}|\boldsymbol{x})$. Subsequently, we obtain a representation of the treatment vector $\tilde{\boldsymbol{t}}$ using the task embedding. The representation, denoted by $\boldsymbol{\tau}$, is obtained by projecting the k-dimensional treatment vector onto a k'-dimensional space ($\boldsymbol{\tau} \in \mathcal{R}^{k'}$) using an embedding matrix $\mathbf{W} \in \mathcal{R}^{k' \times k}$, $\boldsymbol{\tau} = \mathbf{W}\tilde{\boldsymbol{t}}$. The embedding weights, $\mathbf{W}$, are learned. Note that the embedding matrix $\mathbf{W}$ is shared between the encoder and decoder, in the next subsection it is shown how the decoder makes use of the embedding matrix. The dimension k' of the task embedding vector is a hyperparameter of the model. Such embeddings have been used in learning a curriculum of tasks in the domain of reinforcement learning [15]. By appropriately adjusting the dimensions of the embedding matrix $\mathbf{W}$, our model scales well for a large number of treatments. Furthermore, the use of task embedding accounts for the relationship between the treatments.

After finding $\boldsymbol{\tau}$, we concatenate it with $\boldsymbol{x}$ and feed it to the network to obtain parameters for $q(y|\boldsymbol{t},\boldsymbol{x})$ through g_2. For continuous y, we model $q(y|\boldsymbol{t},\boldsymbol{x})$ as $\mathcal{N}(\mu_{y_q}, 1)$. In case of binary outcomes, it is modeled as a Bernoulli distribution. We sample $\tilde{y}$ from the obtained distribution.

$$q(y|\boldsymbol{t},\boldsymbol{x}) = \mathcal{N}(\mu_{y_q}, 1), \quad \mu_{y_q} = g_2, \quad \boldsymbol{\tau} = \mathbf{W}\tilde{\boldsymbol{t}}$$

Finally, to compute posterior of $\boldsymbol{z}$ we estimate the mean and the variance using $\tilde{y}$, $\boldsymbol{x}$ and $\boldsymbol{\tau}$. The outputs i.e. $\mu_{\boldsymbol{z},i}$ and $\sigma_{\boldsymbol{z},i}$ are the outputs of the layers labeled g_3 and g_4 respectively.

$$q(\boldsymbol{z}|\boldsymbol{x},\boldsymbol{t},y) = \prod_{i=1}^{d} \mathcal{N}(\mu_{\boldsymbol{z},i}, \sigma_{\boldsymbol{z},i}), \quad \mu_{\boldsymbol{z},i}, \sigma_{\boldsymbol{z},i} = g_3, g_4 \tag{1}$$

The required joint probability distribution is the product of the probability distributions $p(\boldsymbol{x}|\boldsymbol{z})$, $p(\boldsymbol{t}|\boldsymbol{z})$, $p(y|\boldsymbol{t},\boldsymbol{z})$, and $p(\boldsymbol{z})$. Of these four terms, the distribution of latent confounders, $\boldsymbol{z}$, is output of the encoder part of the network. In the decoder network, we estimate the other three conditional probabilities.

3.2 Decoder

The latent confounder vector $\boldsymbol{z}$ is assumed to be vector of independent, univariate normal variables. The random variables that makeup the vectors $\boldsymbol{x_c}$, $\boldsymbol{x_f}$, and $\boldsymbol{x_b}$ are assumed to be independent of each other given $\boldsymbol{z}$ [25]. Every proxy variable in $\boldsymbol{x_c}$ is taken to be a univariate normal given $\boldsymbol{z}$. Similarly, every proxy variable in $\boldsymbol{x_b}$ is modeled as a Bernoulli(p) and every proxy variable in $\boldsymbol{x_f}$ is

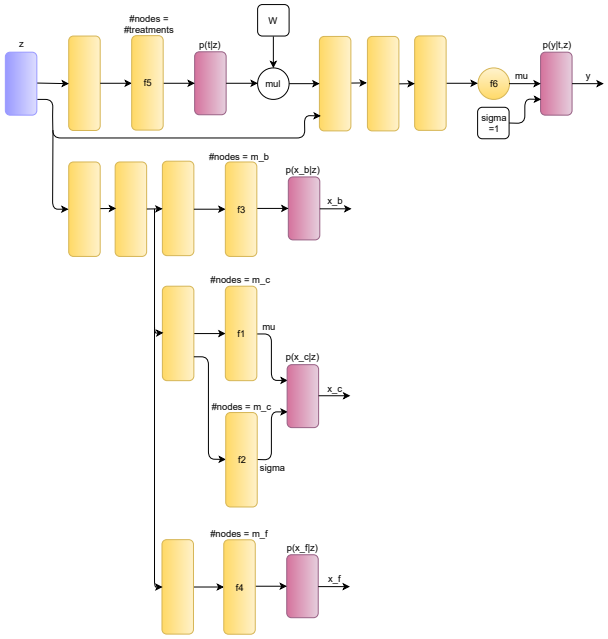

Figure 3: Decoder for TECE-VAE, the decoder network takes input z to reconstruct x, t and y. The input layer is depicted in blue, input z is fed into yellow boxes that contain the network parameters to be trained. Purple boxes denote sampling step for various distributions. Note that weight matrix W is shown by an unshaded box, this is the same matrix as used in the encoder network.

modeled as a categorical random variable that is independent of others conditional on $\boldsymbol{z}$.

Figure 3 shows the architecture of the decoder network. Different parts of decoder network predict different conditional distributions. Let f_i be the output of the layer as labeled in Figure 3. The decoder network works as follows: $\boldsymbol{z}$ is input to the network and the output of the layers labeled f_1 and f_2 are the parameters of the distribution $p(\boldsymbol{x_c}|\boldsymbol{z})$. Similarly, f_3 and f_4 output parameters for the binary and the categorical variables, respectively.

$$p(\boldsymbol{x_c}|\boldsymbol{z}) = \prod_{i=1}^{m_c} \mathcal{N}(\mu_{\boldsymbol{x},i}, \sigma_{\boldsymbol{x},i}), \qquad \mu_{\boldsymbol{x},i}, \sigma_{\boldsymbol{x},i} = f_1, f_2 \tag{2a}$$

$$p(\boldsymbol{x_b}|\boldsymbol{z}) = \prod_{i=1}^{m_b} Bern(p_{\boldsymbol{x},i}), \qquad p_{\boldsymbol{x},i} = f_3 \tag{2b}$$

$$p(\boldsymbol{x_f}|\boldsymbol{z}) = \prod_{i=1}^{m_f} Cat(\boldsymbol{q_{x,i}}), \qquad \boldsymbol{q_{x,i}} = f_4 \tag{2c}$$

Similar to encoder network the treatment vector $\boldsymbol{t}$ is represented by k Bernoulli random variables which are independent given $\boldsymbol{z}$. The conditional probability, $p(\boldsymbol{t}|\boldsymbol{z})$, is given by:

$$p(\boldsymbol{t}|\boldsymbol{z}) = \prod_{i=1}^{k} Bern(p_{\boldsymbol{t},i}), \qquad p_{\boldsymbol{t},i} = f_5 \tag{3}$$

Now, $\boldsymbol{x_c}$, $\boldsymbol{x_f}$ and $\boldsymbol{x_b}$ are sampled from corresponding distributions to obtain $\tilde{\boldsymbol{x}}$. Similarly $\tilde{\boldsymbol{t}}$ is sampled from $p(\boldsymbol{t}|\boldsymbol{z})$. For continuous y, we represent $p(y|\boldsymbol{t},\boldsymbol{z})$ as $\mathcal{N}(\mu_{y_p}, 1)$ and in case of binary outcomes we instead approximate with a Bernoulli distribution. In order to obtain $p(y|\boldsymbol{x},\boldsymbol{t},\boldsymbol{z})$ we transform the sampled $\tilde{\boldsymbol{t}}$ to $\boldsymbol{\tau}$ using the same embedding matrix $\mathbf{W}$. Next, $\boldsymbol{x}$, $\boldsymbol{z}$ and $\boldsymbol{\tau}$ are concatenated into a single vector which is then used to obtain the parameters for $p(y|\boldsymbol{t},\boldsymbol{z})$ as output of the layer f_6.

$$p(y|\boldsymbol{t},\boldsymbol{z}) = \mathcal{N}(\mu_{y_p}, 1), \quad \mu_{y_p} = f_6 \tag{4}$$

With equations 1, 2, 3 and 4, we can compute the joint probability distribution. We use variational inference to train the encoder-decoder. Note that during the training, we sample from $q(\boldsymbol{t}|\boldsymbol{x})$ and $p(\boldsymbol{t}|\boldsymbol{z})$. However during testing, if we want to find the effect of a particular combination of treatment, $\boldsymbol{t'}$, then we do not sample from these distributions. We instead directly pass $\boldsymbol{t'}$, which will be transformed into a state embedding. Also, observe that the embedding weights, $\mathbf{W}$, are the same for both the encoder and decoder. We have used variational inference algorithm available in the Python library Edward [32] for the training. The loss function is same as equation 10 in [25]. L2 regularization is added to the loss function, we then minimize this loss to estimate the model. The next section describes the datasets used for experimentation and associated proxy variables $\boldsymbol{x}$, outcome y, associated treatment vector $\boldsymbol{t}$ and confounders $\boldsymbol{z}$ for these datasets.

4 DATASETS

The proposed approach has been applied to three datasets. The first one is a user-conversion dataset for a product company that sells software subscriptions. This dataset contains outcomes for the marketing actions observed in the data. However, the evaluation of a causal model requires outcome for all potential marketing actions - observed or unobserved - for each customer. To evaluate the model, two semi-synthetic datasets are created using the covariates of the user-conversion dataset. The three datasets are described next.

User-Conversion Dataset: This dataset is constructed from the event level logs of the interaction events between a user and the organization's website as well as marketing actions. These interaction events come from four different data sources - web-analytics data, display ad impression data, email interaction data, and product usage data. We merge these data sources. Web-analytics data is stored in the form of a clickstream that records the online activities of an user on the company's website. Roughly, there is one row of data for each URL visited on the company's website. These visits include pages with information on the product features, product help, download trial versions or checkout. Each row contains information about the user's device, geography, source of visit, URL, time-stamp, product purchased etc. The display ad data provides information on ad impression on company's own website as well as other websites. This dataset stores which ads were shown to the user and whether the user clicked on the ad and many other ad-related properties. The email interaction dataset consists of email related information that was sent by the organization to the user. This dataset includes information such as whether a user opened the email, clicked on a link in the email, unsubscribed to emails from the company, description of the email, etc. Finally, product usage data contains information on a user's interactions with company's applications. Each row of the data stores information on the events such as application launch, application download etc. Each dataset described above uses the same identifier for the user, this identifier is used for merging the datasets.

The problem of a marketer working for the company is to decide the best subset of the treatments that can be applied to each user over the next three weeks. The set of treatments consists of five marketing actions which a marketer can potentially apply to each customer with varying degree of control. These are: 1) show paid search ads, 2) start a social media campaign, 3) send emails, 4) show ads on company's own website, and 5) show ads on other websites. One of the approaches to find the best set of actions is to estimate the `ITE` for each subset of the treatments. The action corresponding to the highest value of the `ITE` will be the optimal action for the user. The user-conversion information comes from the purchase events stored in web-analytics data. A user is said to be converted if he/she decides to makes a purchase in form of subscription to the company's product in the considered time-period.

In a supervised learning problem, the empirical design is such that the covariates are observed as of a time point. The outcome of interest or the target variable for the supervised model is observed for a period of time after the time point at which the covariates are observed. In our setting, where a marketer wants to ask counterfactual questions, with the goal of taking an action, the period of covariate observation is followed by a period during which applied treatments as well as the outcome are observed. The covariate observation period is three weeks in the user-conversion data. The applied marketing actions and the outcome event during the following three weeks are observed. Note that the marketing actions during the first three weeks will be part of the observed covariates, $\boldsymbol{x}$. The marketing actions applied after the purchase during the latter three week periods are ignored.

Once we have the stitched data and different periods for observing the user information, treatment applied $\boldsymbol{t}$ and conversion outcome y in place, we process the stitched data to create $\boldsymbol{x}$, $\boldsymbol{t}$ and y. The features $\boldsymbol{x}$ include Recency-Frequency-Monetary variables [7] as well as few columns are included as is. The recency features mainly accounted for how recently had the user interacted with the organization. The examples include how recently had the customer used a mobile application, interacted with an online-advertisement, opened a marketing email etc. The frequency features account for how often do these interactions occur. For instance, how frequently does a user launch an application, click on online-ads, check emails etc.

The set of five marketing actions are the treatments, $\boldsymbol{t}$. The treatments are assigned by the marketer to a user or self-selected by a user. For instance a marketer can send promotional emails to attract the customers for subscription or a customer can decide to search where a marketer can show a search ad. The outcome

variable y denotes if the user made a purchase. The purchase event in the data is subscription of the product.

In summary each row of the data contains user features $\boldsymbol{x}$, the treatment they were subjected to $\boldsymbol{t}$ and the outcome y if they subscribed to company's products/services. The dataset comprises of close to 1.2 million users. Due to the low percentage of the subscribers in the data, the negative class was down-sampled to create a balanced distribution of the subscribers and non-subscribers for training the models. The total number of features are 144. Out of these, 116 are continuous, 16 are Bernoulli, and 12 are categorical.

Semi-Synthetic Data: The original user-conversion dataset, as described above, contains the outcome corresponding to the observed subset of the treatments. However, for evaluating the models the outcome for every subset of the treatments is needed. This requires a dataset which contains outcome y for every subset of the treatments for each user. While the real-world dataset has five treatments, the synthetic data is limited to only three treatments. The number of treatments are limited to only three because we found it extremely hard to train many of the baseline models for five treatments.

Some of the baselines such as `BNN` [19], `BLR` [19], `CFR WASS` [31], and `TARNet` [31] train separate models for each subset of the treatments. In similar vein, `CEVAE` [25] employs separate paths for each subset of treatments. This implies that the number of parameters to be trained increases exponentially with the number of treatment. The problem is exacerbated by the fact that the number of observations in the data for each subset of the treatments is highly skewed. In the original user-conversion dataset, not all treatment subsets occur with the same frequency, some are frequently occurring treatments while some show up very rarely. This unbalanced distribution in the original dataset is shown in Figure 4. It shows a power distribution with no observation for 6 subset and a very few observations for another 10 or so subsets of marketing actions. This implies that for the treatment subset with fewer observations, the models will not be trained well, and the results will be poor.

Due to difficulty in estimating some of these baselines when the number of treatments are high, we restrict the total number of treatments to three. A dataset with fewer treatments is a conservative approach because it favors the baselines which are meant for a binary treatment.

Two semi-synthetic datasets are created to test how the different models perform in a setting that mimics the power law distribution of the observed subsets of the treatment vs when each subset appears uniformly. The frequency of the treatments in the uniform scenario is not completely equal but the differences are not stark. With these two settings, we not only test for the setting observed in a real world dataset like user-conversion data but also for the scenarios where the distribution for treatments is relatively uniform.

Three treatments imply a total of eight possible subsets of treatments. For evaluation of the causal effect, we need the `ITE` for each subset of the treatments for each individual user. Note that, to test the models in our setting (i.e. causal structure in Figure 1), we need observed proxies $\boldsymbol{x}$, latent confounders $\boldsymbol{z}$, observed treatments $\boldsymbol{t}$ assigned based on $\boldsymbol{z}$, and observed outcome y (for every treatment subset) determined by $\boldsymbol{z}$ and $\boldsymbol{t}$.

For generating the semi-synthetic datasets, we take the observed features, $\boldsymbol{x}$, from the user-conversion data. These are the observed proxies for the two semi-synthetic datasets. The semi-synthetic datasets are created using the following three steps:

(1) *Latent Confounder Creation:* Create latent counfouders $\boldsymbol{z}$ from the observed proxies $\boldsymbol{x}$.
(2) *Treatment Assignment Function:* Create the observed treatments as a function of the latent confounders for each user.
(3) *Outcome Function:* Create the observed outcome for each user and treatment subset as a function of the latent confounders and each treatment subset. Only the outcome corresponding to the observed treatment in step 2 is used for estimation. Other outcomes act as the ground truth for evaluation of the model.

Latent Confounder Creation: The observed proxies are then fed to an autoencoder [30] to model the hidden confounders. The middle layer of the autoencoder is used as the latent confounders. The size of the middle layer of the autoencoder is chosen to be 20. The latent values for each observation are used to generate the treatment to be assigned to each individual and the corresponding effect for each treatment. Note that the data generation approach used follows the causal structure in Figure 1, however, the data generating process is very different from the proposed model. Even the chosen dimensions of $\boldsymbol{z}$ for estimation and data generation are different. Next, the data generating process for obtaining the observed treatments and outcome is described in detail.

Treatment Assignment Function: As explained above, an autoencoder is used to obtain the latent confounders for each user. The Let Z be a matrix with n rows and d columns that contains the values of the latent confounders for each observation. Here n is the total number of observations and d is the total number of latent confounder variables. We set d to be 20 for the synthetic dataset. Let $\boldsymbol{t}_i$ be a row vector of length equal to the number of treatments. It specifies which subset of treatments was applied to i^{th} individual. Let k be the number of treatments. As discussed above, it is set to three. The outcome, $\boldsymbol{y}_i$, is a row vector that contains the `ITE` for each subset of the treatments for the i^{th} individual. The size of this vector is equal to the total number of possible treatment subsets, which is $2^3 = 8$ in this case.

We take a matrix θ, with d rows and the number of columns equal to the number of treatments. Each row $\theta_{\mathbf{i}}$ of θ is sampled from a standard multivariate normal distribution (mean is zero and covariance matrix is an identity matrix), i.e. $\theta_{\mathbf{i}} \sim \mathcal{N}(\mathbf{0}_{kX1}, \mathcal{I}_{kXk})$ where $i = 1, \ldots, d$.

We define a matrix μ, which is the difference between the matrix product of Z and θ and its mean taken across all the observations for balanced dataset. We subtracted each row of $Z \times \theta$ by the column-wise mean of $Z \times \theta$, which is a vector is size k. Let $mean_{all\ observations}(Z \times \theta)$ be a $n \times k$ matrix, with n duplicated rows containing column wise mean. For generating data with power law, -3 is added to all the elements of μ.

$$\mu = Z \times \theta - mean_{all\ observations}(Z \times \theta)$$

We took a covariance matrix Σ with k rows and k columns. The values that we chose are as follows:

$$\Sigma = \begin{bmatrix} 1 & 0.6 & 0.4 \\ 0.6 & 1 & -0.3 \\ 0.4 & -0.3 & 1 \end{bmatrix}$$

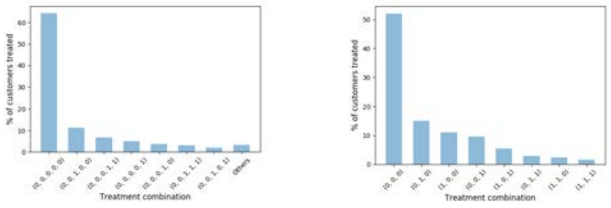

Figure 4: Distribution of treatments for user-conversion data (left) and unbalanced semi-synthetic data (right). Note that user-conversion dataset has 32 possible treatment subsets, we show top-7 in the graph while remaining 25 are aggregated to form *others* category. Unbalanced semi-synthetic dataset has 8 possible treatment subsets.

We define a row vector ϵ_i sampled from a multivariate normal distribution with mean μ_i (which is the i^{th} row of the matrix μ) and covariance matrix Σ.

An element of $\boldsymbol{t'(i)}$ is equal to 1 if the corresponding element in ϵ_i is greater than 0, otherwise 0. Hence $\boldsymbol{t'(i)}$ is a k-dimensional vector representing the treatments assigned to the i^{th} individual.

Outcome Function: We take a column vector $\boldsymbol{\beta}$ with length (d), where d denotes number of the latent confounder variables. Each element of $\boldsymbol{\beta}$ is sampled from a uniform distribution on the real interval [-10,10]. Let Z_i denote a column vector containing the i^{th} row of Z. We take a vector $\boldsymbol{\gamma}$ of size k. Each element of $\boldsymbol{\gamma}$ is sampled from a uniform distribution on the real interval [0,4]. Let y_{ij} denote the outcome of the i^{th} individual on applying j^{th} treatment vector $\boldsymbol{t}_j$.

The simulated outcome variable $y_{i,j}$ is given by the following equation:

$$y_{i,j} = {Z_i}^T \times \boldsymbol{\beta} + {\boldsymbol{t}_j}^T \times \boldsymbol{\gamma} + \xi_{i,j},$$

where ξ_{ij} is sampled from a normal distribution with mean as zero and variance as 10% of the absolute value of the sum of ${Z_i}^T \times \boldsymbol{\beta}$ and ${\boldsymbol{t}_j}^T \times \boldsymbol{\gamma}$. Hence for every individual i, the proxies($\boldsymbol{x}_i$), the treatment vector $\boldsymbol{t'(i)}$ and corresponding outcome $\boldsymbol{y}_i(\boldsymbol{t'(i)})$ forms the part of the training data. Figure 4 on the right shows the obtained treatment distribution for unbalanced semi-synthetic dataset.

The datasets described in this section are used to compare the proposed model with the baselines. In the next section we describe the details of the baselines and evaluation metrics.

5 EXPERIMENTS

In this section we describe experiments that compare the proposed approach to the existing treatment effect estimation techniques. Some of the baselines considered for the experiments extend naturally to multiple treatments, while others require some modification in the code. This section describes the changes made, the choice of hyperparameters and the evaluation metrics used for the experimentation.

5.1 Baselines

The baselines that naturally extend to multiple treatments are: k-nearest neighbor (k-NN), Random Forest (RF) [3], Gradient Boosting Machine (GBM) [8], and Bayesian Additive Regression Trees (BART) [4]. To implement k-NN, RF, and GBM, the python library scikit-learn [28] was used. To implement BART [4], the R package BayesTree[1] was used.

Other baseline models were created for binary treatment. These models are: Balancing Linear Regression (BLR) [19], Balancing Neural Network (BNN) [19], Counterfactual Regression with Wasserstein distance (CFR WASS) [31], Treatment-Agnostic Representation Network (TARNet) [31], and Causal Effect VAE (CEVAE) [25]. The available implementations for these models are not directly applicable to the multiple treatments setting. All of these baseline models except the last one were extended to multiple treatments setting, as done in [34]. All possible subsets of treatment can be taken as separate treatments and encoded as one-hot vectors. There are 2^k distinct treatment subsets so the size of one-hot vector is also 2^k. The models addressing the binary treatment-effect problem can be extended to multiple treatments by considering the problem as 2^k binary treatment-effect problems. And so the number of models required will be 2^k. The models that are extended to multiple treatment are BNN [19], BLR [19], CFR WASS [31], and TARNet [31]. We extended CEVAE [25] to handle multiple treatments. The number of distinct paths required is equal to the total number of treatment subsets 2^k, one path for each treatment subset.

For BNN [19], BLR [19], CFR WASS [31], and TARNet [31], the publicly available code[2] was used. For CEVAE [25], the publicly available code from github[3] was used. For the implementation of our model, Tensorflow [1] and Edward [32] were used. We used 63-27-10 % as train-validation-test split. We used the architecture as shown in figure 2 and 3. Unless specified we use 200 neurons per layer with *tanh* activation function. The size of $\boldsymbol{z}$ for CEVAE and TECE-VAE is 25. This was chosen based on experiments that showed that a large range of values for the dimension for $\boldsymbol{z}$ gives similar results. Figure 5 plots various evaluation metrics for different choices of the dimension of $\boldsymbol{z}$. The evaluation metrics do not change as the dimension of $\boldsymbol{z}$ is varied from 10 to 40.

These baselines as well as the proposed approach are compared using five causal inference evaluation metrics described next.

5.2 Evaluation Metrics

In the existing literature on binary treatments, the evaluation metrics used were RMSE of the estimated Individual Treatment Effect (ITE) [19], and absolute error in estimated Average Treatment Effect (ATE) [19, 25, 31]. These papers also report Precision in Estimation of Heterogeneous Effect (PEHE) [19, 25, 31] following [17]. We have used the evaluation metrics used in past as well as a few more that capture different aspects of a causal model used for choosing best subset of actions for each user. The evaluation metrics are described next.

The first two metrics - *RMSE* and *Absolute Error* - measure the difference between the ground truth and the estimated individual treatment effect (ITE) of the treatments. These metrics are used to evaluate the causal models in the multiple treatment effect literature [34]. In case of semi-synthetic data, the outcomes for all subsets

[1]The R package can be found at https://cran.r-project.org/package=BayesTree.

[3]Code available at https://github.com/AMLab-Amsterdam/CEVAE.

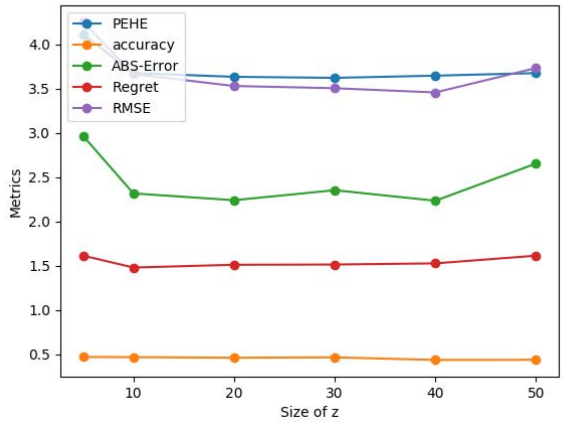

Figure 5: Values of various evaluation metrics for different dimensions of z, averaged over first three replications for unbalanced semi-synthetic data.

of the treatments are available in the data, and hence we calculate RMSE of the estimated outcomes for all subsets of the treatments. RMSE is defined as:

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\frac{1}{|T|}\sum_{j\in T}(y_{i,j} - \hat{y}_{i,j})^2}$$

where, T is the set of all possible combinations of treatments, n is the number of observations, $y_{i,j}$ is the true outcome when j^{th} subset in T is applied on i^{th} observation, and $\hat{y}_{i,j}$ is the predicted outcome when j^{th} subset in T is applied on i^{th} observation. We also calculate absolute error in the same way as RMSE.

$$Absolute\ Error = \frac{1}{n}\sum_{i=1}^{n}\frac{1}{|T|}\sum_{j\in T}|y_{i,j} - \hat{y}_{i,j}|$$

The third metric, *Average PEHE Error*, measures the average of the RMSE between the actual and estimated difference between ITE for each treatment with no treatment ITE. This metric is used in binary treatment literature. We have extended it to multiple treatments setting. The subset with no treatments being applied is chosen as control and PEHE is calculated for each subset of all possible combinations of treatments with respect to control. Then, the error in PEHE is calculated for each treatment subset.

$$Error\ in\ PEHE_j = \sqrt{\frac{1}{n}\sum_{i=1}^{n}((y_{i,j} - y_{i,0}) - (\hat{y}_{i,j} - \hat{y}_{i,0}))^2}, j \in (T - T0)$$

where, $T0$ is the subset with no treatments being applied (control) Average PEHE error is the mean of error in PEHE for all the subsets of all possible combinations of treatments.

$$Average\ PEHE\ Error = \frac{1}{|T|}\sum_{j\in(T-T0)} Error\ in\ PEHE_j$$

These three metrics measure the accuracy of the estimated causal effect with respect to the actual values. However, these do not capture the loss suffered due to the estimation error. To measure the loss with respect to the actual ITE, we propose a metric which is similar to the regret metric used in the Bandit literature [23]. Unsurprisingly, we call this metric *Regret*. It measures the loss due to using a particular causal inference model with respect to the ground truth. This is something that a marketer targeting customer for improving bottom line will deeply care about.

$$Regret = \frac{1}{n}\sum_{i=1}^{n}(y_{i,t_i} - y_{i,\hat{t}_i})$$

where, t_i is the true best action for i^{th} observation, and $\hat{t}_i$ is the predicted best action for i^{th} observation. In addition to these four metrics, we also compare micro averaged F-score which compares the best action implied by an estimated model with the ground truth best action for each customer using the usual supervised learning metric - the F-Score.

Next section presents the results and discussions for these experiments.

Table 1: Out-of-sample metrics for the various models in the case of Unbalanced data. Bold indicates the model with the best performance for each metric.

Model Name	*RMSE*	*Absolute Error*	*Ave PEHE Error*	*Regret*	*Micro − Ave F − score*
RF	9.12 ± 0.84	5.35 ± 0.49	8.23 ± 0.94	3.40 ± 0.23	0.19 ± 0.03
k-NN	8.40 ± 0.49	5.09 ± 0.27	5.05 ± 0.30	5.71 ± 0.43	0.06 ± 0.01
GBM	6.71 ± 0.57	4.12 ± 0.35	6.29 ± 0.61	2.21 ± 0.18	0.40 ± 0.06
BLR*	15.74 ± 0.82	10.58 ± 0.65	5.41 ± 0.35	3.96 ± 0.46	0.11 ± 0.04
BNN-2-2*	15.43 ± 0.77	10.58 ± 0.59	5.51 ± 0.30	2.82 ± 0.38	0.22 ± 0.07

TECE-VAE	**4.01 ± 0.19**	**2.44 ± 0.12**	**3.95 ± 0.20**	**1.60 ± 0.18**	**0.51 ± 0.06**

* Original code modified for multiple treatments.

Table 1 compares the proposed approach with the baselines. This table present result on the semi-synthetic dataset that captures the skewness in the number of observation for each subset of treatments. There are 10 datasets created by changing the seed for the random draws. The evaluation metrics for each model are calculated on each of these 10 datasets. Table 1 presents mean and standard deviation of the evaluation metrics over the 10 runs. Note that we did not include the results for BART model because it takes about 12 hours for each run on the semi-synthetic data. The results for BART are included in Table 2 where the evaluation metrics are based on only one replication of the semi-synthetic dataset.

As shown in Table 1, the proposed approach TECE-VAE outperforms the baselines along each metric for the test data. The results for the training data are similar. Hence, the comparisons for the training data are not shown. The results are available on request. In the test data, TECE-VAE outperforms the closest baseline in terms of RMSE and Absolute Error, TARnet, by 21% and 39% respectively. This is a large improvement over the baselines. The implication is that, if one is interested in the *ITE* for each treatment, TECE-VAE provides a significant improvement over the baselines. In terms of *PEHE* and *Regret*, TECE-VAE outperforms the closest baselines by 33% and 38% respectively. As noted earlier, *Regret* measures the loss due to applying the optimal subset of treatment for each customer using a particular causal inference model instead of the

6 RESULTS AND OBSERVATIONS

6 RESULTS AND OBSERVATIONS

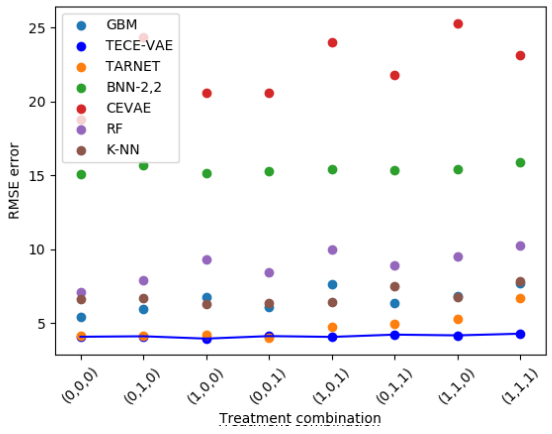

Figure 6: RMSE for each treatment subset averaged over 10 replications of unbalanced semi synthetic data. Treatments are sorted in descending order by the number of observations in the data.

ground truth optimal treatments. This result shows that by using TECE-VAE the outcome, as measured by *Regret*, improves by at least 38%. The last metric is Micro F-Score which measures accuracy of best ITE given by a causal model with respect to the ground truth optimal ITE. TECE-VAE outperforms the baselines along this metric as well.

Since, the number of observations for each subset of the treatments is different, a natural question is how the performance of the model varies by the number of times a particular subset of the treatments is observed. Figure 6 plots the *RMSE* metric for each treatment subset. The x-axis in the figure is sorted in decreasing order by the number of observation in the data. For example, the treatment subset (0,0,0) corresponds to no treatment and it is observed in the data for 39891 out of 69431 users; whereas the treatment subset (1,1,1) is observed only 9 times. As expected, the difference in the performance of TECE-VAE and other models increases as the number of observation for a treatment subset decrease. This result reinforces the assertion that the baseline models are not equipped to handle multiple treatments. Another observation from Figure 6 is that the performance of TECE-VAE as compared to TARnet starts to diverge around treatment subset (1,0,1). This subset of the treatments is observed 7244 times in the data, which is a large number. This implies that a large number of observations is needed to get comparable performance between the best baseline and TECE-VAE. As noted earlier, the main reason the model performs well is due to representation of treatments using a task embedding.

One question remains is how does TECE-VAE performs in a dataset where the distribution of the observed treatments is not skewed. To answer this question, we compared the models on a semi-synthetic dataset with uniform distribution of treatment subsets. Note that this dataset should be more favorable to the baseline techniques because many of these models estimate separate parameters for each treatment. The analysis on this dataset, presented in Table 2, shows that the proposed approach is among the top two models along all metrics. At the same time, the large difference between TECE-VAE and the baselines disappears. One interesting observation is that GBM, which is a supervised learning model and doesn't explicitly model the latent variables, works well when the observed treatment subsets are balanced. There are three important observations. First, if the number of treatments are balanced and the variance of the estimate is not needed, one can use GBM and expect reasonable results. Second, since GBM is available out of the box and easy to train, it should be an important baseline for any causal effect estimation model. Third, the comparison between TECE-VAE and CEVAE, where former uses a task embedding and latter uses private paths, reveal the benefits of representing treatments using a task embedding. Note that the number of treatments as well as number of observations per treatment subset are chosen to favor the baselines such as CEVAE. Even in this setting, TECE-VAE outperforms CEVAE along all evaluation metrics.

The next set of experiments are conducted to test the robustness of the proposed approach. The experiments so far assume that the complete set of proxies for the latent confounders is observed. However, in practise proxies for all latent confounders might not be observed. This call for testing the robustness of the proposed approach when a fraction of proxies are not observed. For this set of experiments, the semi-synthetic data generation process as well as the train-validation-test split is same as above. During model estimation, a fraction of proxies, $\boldsymbol{x}$, are not used for estimation. The comparisons are done for following four scenarios - all proxies observed, 20%, 40%, 60% proxies not observed. The proposed approach is compared against two baselines - TARnet and GBM. These two baseline models have been the second best models along two metrics - *RMSE*, which measures the accuracy of the estimate of ITE, and *Regret*, which measures the loss due to using an estimated decision rule as compared to the ground truth decision rule. Figure 7 contains the results of these experiments. Each point in Figure 7 is an average of 10 runs where a different, randomly selected, subset of the observed proxies is removed. The repetitions ensure that the evaluation metrics do not suffer from the sampling bias. The comparison of the *RMSE* of the ITE for the three models shows similar trend with TECE-VAE being the best model. The comparison along the *Regret* metric shows interesting results. TECE-VAE performance stays similar to 0% hidden proxies

Table 2: Out-of-sample metrics for the various models in the case of Balanced data. Bold indicates the model with the best performance for each metric.

Model Name	*RMSE*	*Absolute Error*	*Average PEHE Error*	*Regret*	*Micro − Averaged F − score*
k-NN	5.069	2.791	3.608	2.899	0.174
RF	4.516	2.430	3.449	2.147	0.261
GBM	3.781	2.072	3.434	1.617	0.440
BART	3.531	1.905	3.397	**1.533**	**0.450**
BLR*	15.305	11.207	3.440	1.985	0.193
BNN-2-2*	**3.142**	**1.848**	3.525	1.805	0.338
CFR WASS*	3.228	1.973	3.509	2.306	0.173

TECE-VAE	**3.190**	**1.886**	**3.189**	1.656	0.298

* Original code modified for multiple treatments.

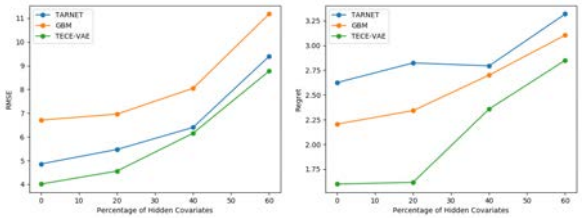

Figure 7: RMSE and Regret by 0%, 20%, 40%, and 60% covariates hidden, averaged over 10 replications for unbalanced semi-synthetic data.

results. TECE-VAE performance stays similar to 0% hidden proxies when 20% proxies are removed. The other two models show deterioration in performance. These results show that the proposed model is robust when a subset of proxies are not observed. Even the baselines are robust, albeit to a lesser degree. These results are in line with work recent which shows that in the case of multiple treatment the causal effect can be identified even when the latent confounders or proxies are not observed [33]. The intuition is that the assignment of multiple treatment provides information about the underlying latent confounders. A flexible model is able to utilize the observed assignment to recover the otherwise unobservable confounders and control for them to recover the causal effect. A deep generative model such as VAE provides a probabilistic factorization of the observed space in the form on the distribution of z. Wang *et al.* [33] show that such a representation identifies the unobserved confounders. The causal effect of multiple treatments is identified by controlling for this estimated representation of the input space.

User-Conversion Data: TECE-VAE is applied to the user- conversion dataset described in Section 4. The five treatments in this dataset are Search Ad, Social Ad, email sent, display ad in own domain, display ad outside own domain. The business question is to find the optimal subset of the treatments for each customer. Here, optimality is defined as the largest increase in the probability of achieving the desired outcome, which is a software subscription in this case. One might argue that some of the treatments cannot be chosen by a marketer. For example, a user searches and clicks on a search ad based on his or her own volition. It is not obvious how a marketer can influence this behavior. This is a valid point. However, the models are not used to directly target but inform targeting strategies. The counterfactual questions are hypotheticals asked to inform a decision. For example, TECE-VAE can be used to identify customers who can be influenced by a search ad. The profile data and search keywords of these customers can be used to find the profile of similar customer which can be used for targeting. A marketer can increase targeting of these keywords. Similarly, a customer matching the profile of someone influenced by a display ad can be sent display ad as and when the customer visits a website.

The results from the model show a few interesting findings. First, the prediction error as measured by RMSE of the predicted outcome is lower for TECE-VAE (0.397) than GBM (0.428) and RF (0.417), two popular supervised learning models. The RMSE of the observed outcome is not a suitable for evaluating a causal inference model. However, a causal inference model that fits the observed data is always desirable. One possible reason for the better performance might be due to explicit modeling of the latent state in TECE-VAE and use of a task embedding.

Second, the raw estimates of the treatment, as measured by the difference between the average conversion percentage for the consumer with treatment applied and for the consumer without any treatment, overestimates the effect of the treatment as compared with the average treatment effect measured by the model. For example, the raw estimate and the average treatment effect (ATE) for the treatment "Search Ad" are 46.5% and 21.8%, respectively; for "Social Ad" 37.8% and 13.8%, respectively; for "display ad outside own domain" 44.4% and 22.2%, respectively; for "display ad in own domain" 49.4% and 34.0%, respectively; and for "email sent" 22% and -3.42%, respectively. These difference in the two estimates show the extent of assignment and self-selection bias present in data. The effect of "email sent" is lowest among the treatments in both estimates. The ATE estimated using the model is a small but negative value! This neither means that this effect is negative for all individuals nor that sending email with other treatments in not optimal.

Third, the marketing actions that are actually applied are rarely optimal. The optimal marketing action suggested by TECE-VAE is actually observed only for 0.034% of the users. This might be due to the fact that some marketing action such as sending an email are easier than making someone actually search for an ad. However, the model shows that some marketing actions, such as sending and email or targeting with a social media campaign, might have a negative impact.

Fourth, in the test data only 15 out of a total of 32 subsets are optimal for at least one customer. Out of these only 8 subsets of the treatments are optimal for more than 50 users. None of these 15 optimal subsets are single treatment subsets. The subset that is optimal for the largest number of users is to apply all treatments but a social media campaign. Another important observation is that the effect of multiple treatments is not linear. For example, effect of showing an ad on own domain to everyone is a 11% points increase is likelihood of conversion. Whereas for a search ad to everyone increases the probability of subscription by 8% points. When the two treatment are applied jointly to everyone the increase in the probability is 23% points.

In summary, the results on real data show that the raw estimates from the data are highly biased, the use of model can lead to a large increase in the outcome metric, and the effect of multiple marketing actions is non-linear. These observations underline the need for a flexible model to to estimate ITE.

7 CONCLUSION

This paper provides a scalable approach for estimation of individual treatment effect using observational data in a setting where a subset from a set of treatments can be applied. We use task embedding to scale the model presented in [25] for multiple treatments. TECE-VAE is robust to unobserved treatments and uses information across treatments. We show the improvement in a variety of of experiments. TECE-VAE is compared against multiple baseline models that have shown to work well under different setting. The baselines also include models that have done well in causal effect estimation

competitions. TECE-VAE is applied on a real world dataset to solve a real causal inference problem.

ABSTRACT

In this paper, we present *a semi-automated, "human-in-the-loop" framework for attribute design* that assists human analysts to transform raw attributes into effective derived attributes for classification problems. Our proposed framework is optimization guided and fully agnostic to the underlying classification model. We present an algebra with various operators (arithmetic, relational, and logical) to transform raw attributes into derived attributes and solve two technical problems: (a) the **top-k buckets design** problem aims at presenting human analysts with k buckets, each bucket containing promising choices of raw attributes that she can focus on only without having to look at all raw attributes; and (b) the **top-l snippets generation** problem, which iteratively aids human analysts with top-l derived attributes involving an attribute. For the former problem, we present an effective exact bottom-up algorithm that is empowered by pruning capability, as well as random walk based heuristic algorithms that are intuitive and work well in practice. For the latter, we present a greedy heuristic algorithm that is scalable and effective. Rigorous evaluations are conducted involving 6 different real world datasets to showcase that our framework generates effective derived attributes compared to *fully manual or fully automated methods*.

1 INTRODUCTION

Attribute design (also known as feature engineering) is one of the most challenging aspects of a data science pipeline, and is considered to be an "arduous process for data scientists"[1] [3, 14], where the raw attributes often need to be transformed into derived attributes that can be more effective for building predictive models such as classifiers. For example, in a healthcare setting involving large, high dimensional and heterogeneous electronic health records (EHR) datasets, an attribute such as the average length of prior hospitalization can be very useful to build effective predictive or classification models on future hospitalization (i.e., readmission) [4]); however, such attributes are not readily available in the raw dataset. For example, Table 1 shows that the average length of hospitalization needs to be computed per hospitalization window considering admission and discharge date, and taking the average of these windows.

The state-of-the-art attribute design techniques fall into one of these two extremes: (a) *fully manual*, painstakingly slow and heavily reliant on domain expertise, often requiring data scientists to go through a repetitive trial-and-error exercise until the set of designed attributes are satisfactorily effective or (b) *fully automated* techniques (some notable systems are, Data Science Machine [18][2], ExploreKit [20][3], One Button Machine [23], or Featuretools[4]). Such methods are not model agnostic, require substantial time to identify derived attributes that are opaque to the human analyst.

In this paper, we investigate a semi-automated "human-in-the-loop" framework that is agnostic to any classification model. Our work is inspired by a handful of recent works [8, 36, 50] which propose a conceptual framework and empirically argue that attribute design by involving human analysts can effectively substitute for either of the two extremes (fully manual or fully automated). However, these do not study how to optimize human involvement in the process or how to guide it.

Proposed Framework: Our proposed framework is developed around three fundamental aspects.

Model agnostic measure: We adopt a principled and quantifiable measure of the effectiveness of a derived attribute that is agnostic to the specifics of any underlying classification model. We consider *Mutual Information* (MI in short) [38] to determine

[1] https://www.itproportal.com/features/dont-let-feature-engineering-stagnate-your-ml-projects/
[2] https://people.csail.mit.edu/kalyan/dsm/
[3] https://github.com/giladkatz/ExploreKit
[4] https://docs.featuretools.com/#minute-quick-start

the predictive ability of an attribute. Intuitively, MI is a symmetric measure that captures "correlation" between a pair of attributes and quantifies how much information is contained in one attribute about the other. We are interested in producing derived attributes that have high MI with the target variable (or the class label). MI is known to have several desirable properties: (a) MI is proved to have certain qualitative guarantees when chosen for attribute selection for multiple popular classification models, such as Naive Bayes [38], or linear regression [12]; (b) prior works have also shown that MI optimizes important properties in attribute selection, such as; relevance, complementarity, and redundancy [38] and (c) finally, as we shall show later in the paper, MI satisfies upward closure [6] which is useful for designing effective algorithms.

Attributes algebra: The second aspect of our framework is an algebra that dictates how raw attributes (numerical or categorical) are to be combined to produce the derived attributes. We study arithmetic, logical, and relational operators. Our initial example of average length of prior hospitalization is an example of arithmetic operator, whereas an example of the logical operation is the following Boolean attribute: *elderly* AND *diabetic* OR *covered under medicaid*. A patient is more vulnerable to future hospitalization if she gets an "yes" on this attribute. A logical operator on the other hand is *obesity* that is set to True, when $BMI > 30$.

Guiding human analysts: The third aspect of our framework is the investigation of how to optimize the involvement of humans in the attribute design process and ensure their efforts are successful. This is motivated by a handful of recent works that argue that humans must not be left unguided in the attribute design process [8, 36, 50], Simply presenting the entire set of raw attributes or hundreds and thousands of raw records to the human analysts might overwhelm them. We propose to present each analyst with small summarized portions of the raw data and raw attributes that is likely to be most helpful for the human to analyze and create useful attributes from. We formulate two technical problems that need to be addressed:

(1) Top-k buckets design: We present each analyst with only k (a small number) *buckets*, each with at most x attributes, that are most predictive. For example, when $x = 3$, a useful bucket that is likely to have predictive qualities may contain {elderly, diabetic, covered-by-medicaid}. We show that generating these buckets is NP-hard. We provide an exact algorithm, `ExBKT`, and an even more efficient heuristic algorithm called `RandomizedBKT` that performs random walks on the attribute lattice to design the top-k buckets. However, just producing buckets that are highly predictive (high MI) may not be enough. We propose `RandomizedCovBKT` that finds top-k buckets that are not only effective wrt MI, but also they together cover many "good" raw attributes of the dataset.

(2) Top-l snippets generation: Even after the buckets of raw attributes have been generated, the human analyst may have to sift through large volumes of data (i.e., the tuples with those raw attribute values) to design good derived attributes, and this task may still be overwhelming. Thus, we propose an interactive procedure by which an analyst may approach this task. Given a bucket, the analyst starts designing a derived attribute (i.e., an algebraic expression involving the raw bucket attributes) interactively (i.e, term by term). At each iteration, our framework recommends l *snippets*, i.e., it suggests the l best ways to extend the partially created derived attributes using the algebra. More formally, at a given iteration the snippet generation process suggests how to augment the partially composed derived attribute by length j, i.e., combining j new raw attributes with the derived attribute developed thus far. For instance, if *elderly* has already been selected by the analyst, and if $j = 1$, an example snippet will suggest a visual distribution that shows how *elderly* AND *diabetic* correlates with the prediction target variable *hospital readmission*.

Evaluations: Rigorous evaluations are conducted considering 6 real world datasets by comparing our solutions with two fully automated methods (ExploreKit and Featuretools), and a fully manual domain expert guided attribute design process, as well as intuitive baselines. Our experimental results demonstrate that we scale up to $7x - 20x$ faster compared to fully automated (ExploreKit) and the fully manual process, while ensuring similar quality (average improvement 14%). By leveraging the domain expert, our framework avoids falling into the pitfall where derived features could actually be detrimental to the performance (unlike FeatureTools). It also has other appealing properties, such as being easily parallelizable, and exhibiting "anytime behavior" whereby it gives meaningful results at any point of execution. Our scalability results demonstrate that both bucket design and snippet generation procedures are efficient and can work interactively with the human in the loop.

In summary, the paper makes the following contributions:

- Proposed Framework: We initiate the study of a model agnostic semi-automated attribute design framework (Section 2) that judiciously involves human analysts in the loop.
- Technical contributions: We formalize two technical problems around the framework and present several theoretical and algorithmic results (Sections 3 and 4).
- Experimental Results: We conduct extensive experiments to demonstrate both effectiveness and scalability of our proposed solutions (Section 5).

2 PRELIMINARIES AND FORMALISM

In this section, we describe our data model, present our framework, and formalize the technical problems.

Example 2.1. We present a toy running example in Table 1 that provides longitudinal data of a heart failure datamart in a hospital. The objective is to build a classifier that predicts whether a patient getting discharged from the hospital will be readmitted within 6 months of discharge, considering predictors from base attributes (first 10 columns) and derived attributes (designed using the base attributes). The data is augmented by adding the last column, representing the class label per patient per admission instance.

2.1 Data Model

Base attributes, records, and target variable: A given dataset is comprised of a set $\mathcal{A}$ of n attributes and m records, as well as an additional target attribute (column) Z. These attributes are referred to as base or raw attributes. In this work, we consider all major types of attributes including numeric, Boolean, and categorical. Our proposed approach can work for a wide variety of predictive modeling tasks including classification and regression (we refer to them classification in general). Depending on the nature of the

patient-id	admission date	dis. date	gender	BMI	income	medicaid	senior	diabetic	primary-diagnosis	readmission
p1	10-1-2013	10-23-2013	M	32.5	low	Y	Y	Y	Congestive heart failure	N
p1	5-2-2014	5-10-2014	M	32.2	low	Y	Y	Y	Heart Attack	Y
p2	5-12-2014	5-14-2014	F	26.7	medium	N	N	N	Arrhythmia	N

p4	12-12-2017	12-14-2017	F	23.4	medium	N	N	N	Arrhythmia	N
p4	9-2-2018	9-29-2018	F	27.8	medium	N	N	N	Heart Attack	Y

Table 1: Example 2.1 toy heart failure datamart

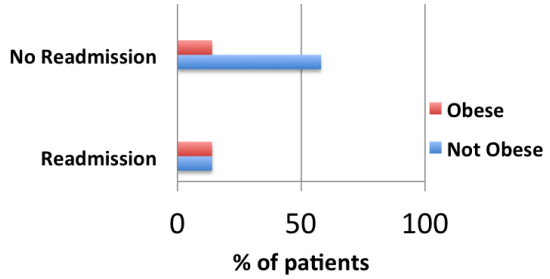

Figure 1: A snippet on Obesity

problem, Z is a continuous variable (regression problem), or has discrete values (classification problem). Using Example 2.1, $n = 10$ and $m = 7$, Z corresponds to readmission within 6 months of discharge (discrete).

Algebra, $\mathcal{L}$: A set of operators (arithmetic, relational and logical) which are applied to one or more base attributes to combine them. When the base attributes are numeric, we consider arithmetic operators to combine them: addition (+), subtraction (−), multiplication (x), division (/). For Boolean attributes, we consider logical operators, AND, OR. We also support all relational operators that compare two base attributes or a base attribute with a constant (e.g. $A_i > A_j$ or $A > 100$). Our framework is flexible enough to support arbitrary operators. We also support aggregate operators over a set of tuples.

Derived Attribute, d: An attribute that combines two or more base attributes using the algebra $\mathcal{L}$. Using Example 2.1, we can create a derived attribute *length of stay* by subtracting discharge date from the admission date. Another derived attribute *obesity* can be obtained through the relational operator > as $BMI > 30$.

Independent variable, dependent variable: A base attribute or a derived attribute is an independent variable (V) in our problem as that is used to predict the target variable Z, which is the dependent variable. Our overall intention is to craft a set of derived attributes as independent variables that are highly "predictive" to the target (dependent) variable.

Mutual Information (MI): We are interested in calculating "predictiveness" of an independent variable V to the target variable Z. For that, we use Mutual Information (MI) that captures information theoretic "correlation" (indeed there exists a relationship between MI and correlation [25] between two random variables that quantifies the amount of information obtained about one through the other). When V and Z are discrete [5], $MI(Z, V)$ is defined as follows:

$$MI(Z,V) = \sum_{z \in Z} \sum_{v \in V} p(z,v) \log \frac{p(z,v)}{p(z)p(v)} \quad (1)$$

where $p(z, v)$ is the joint probability function of Z and V, and $p(z)$ and $p(v)$ are the marginal probability distribution functions of Z and V respectively. Of course, V could be a single base attribute, a small set of base attributes, or a derived attribute.

2.2 Proposed Framework

Our proposed framework consists of two technical steps. We first design a set of k buckets, each with at most x base attributes. Given a bucket and the algebra $\mathcal{L}$, the analyst then starts composing a small number of derived attributes from the bucket. This next step is referred to as *snippet generation*, and works iteratively with the analyst until she decides to stop. In each step in snippet generation, the analyst extends the currently composed derived attributes by a small amount. Our algorithmic contributions are focused on these two steps. In Section 3, we analyze the Top-k buckets design problem and describe our solutions. In Section 4, we present our solutions for the Top-l snippets generation problem.

Definition 2.2. **Score of a bucket, $sc(b)$:** For a bucket b with $A_1, A_2, \ldots A_x$ base attributes, the score of b, i.e., $sc(b)$ is the MI between Z and the Cartesian product of the base attributes that are part of b.

$$sc(b) = MI(Z, [A_1 \times A_2 \times A_3 .... \times A_x]) \quad (2)$$

Using Example 2.1, $sc(gender, senior) = MI(readmission, [gender \times senior])$

Definition 2.3. **Coverage of a set of buckets:** coverage of a set of buckets $Cov(b_1, b_2, ..b_k)$ is the size of the union of the base attributes that are present in these buckets.

$$Cov(b_1, b_2, ..b_k) = |b_1 \cup b_2 \cup ....b_k| \quad (3)$$

Using Example 2.1, if $k = 2, x = 2$, $b_1 = [gender, senior]$, $b_2 = [medicaid, gender]$, then $Cov(b_1, b_2) = 3$.

Definition 2.4. **Snippet, s:** A snippet s is a visual representation of a joint distribution between Z and a derived attribute d^s in the snippet.

Figure 1 shows one such snippet between obesity and hospital readmission.

[5]We consider the numeric variables are appropriately discretized, when needed

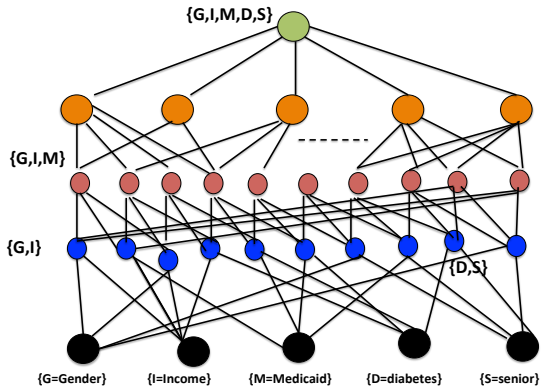

Figure 2: Attribute Lattice

Definition 2.5. **Score of Snippet, $Sc(s)$:** Score of a snippet is the MI between Z and derived attribute d^s in the snippet s, i.e., $MI(Z, d^s)$.

Using Figure 1, $Sc(obesity) = MI(readmission, obesity)$.

2.3 Problem Definitions

Problem 1: Top-k-Buckets Design: Given a set of attributes A, number of required buckets k and maximum number of attributes in each bucket x, our objective here is to design Top-k buckets based on MI, i.e., finding the k-buckets (each with at most x attributes) with the highest MI and present those buckets to the the human analyst to investigate further for creating derived attributes.

We also investigate the top-k coverage aware bucket generation problem, where the objective is to create "high quality" buckets *that together cover* all base attributes that have high MI with the target variable.

Problem 2: Coverage Aware Top-k buckets: The objective is to create Top-k buckets such that the score of each bucket, $sc(b)$ in Top-k is above a certain threshold δ and $Cov(b_1, b_2, ..b_k)$ is maximized.

Problem 3: Top-l Interactive Snippets Generation: Each step of the interactive snippet generation takes as inputs a bucket b, an integer j, the currently composed set of derived attributes $\mathcal{D}'$, the algebra $\mathcal{L}$; and produces l snippets with highest scores, where each derived attribute d_i'' in snippet s_i is created by extending d_i', that is, by adding j additional attributes that are part of b, involving $\mathcal{L}$.

3 TOP-k BUCKETS DESIGN

Top-k Buckets Design takes x (the maximum size of each bucket), k (the number of buckets), the dataset (base attributes A, target variable Z, and the records), and produces Top-k buckets, each of size at most x that are highest in MI with Z.

Theorem 3.1. *The Top-k Buckets Design Problem is NP-hard, for an arbitrary x and k.*

Proof. (Sketch): As shown in [46], for an arbitrary maximum bucket size x and number of buckets k, the problem of identifying the number of distinct buckets of maximum size x (that have maximal MI in our case) is #P-Hard. Therefore, the enumeration problem of finding top-k buckets of maximum size x is NP-hard. □

Intuitively, the bucket design problem bears similarity with the itemset mining problems based on association rules (support) or other correlation measures [1], such as Chi-Square [6]. WRT our problem, a base attribute could be considered an item, and therefore mining a bucket with at most x-base attributes is akin to mining an itemset with at most x items that satisfy a certain property. Thereby, the Top-k buckets generation problem seemingly appears similar to Top-k itemset mining problems.

Most popular and effective algorithms in this problem space make use of the *upward or downward closure property of the itemsets* based on the underlying measures (for example, support is downward closed, while chi-square is upward closed [6]). These properties enable efficient algorithm design for the itemset mining problems.

Popular algorithms such as Apriori [1] make use of this property extensively in mining frequent itemsets. They execute in a bottom-up manner by discarding any itemset from consideration whose subsets are not frequent based on the support threshold [1].

However, designing an Apriori [1] type of algorithm is impractical for our problem for several reasons: firstly, because *MI is not downward closed;* secondly, because our problem does not have a *support threshold* like Apriori, and finally because our problem has *more constraints* (x and k) as inputs.

Lemma 3.2. *Mutual Information is upward closed.*

Proof. Without loss of generality, let us assume Z is the target variable and A_1, A_2, A_3 are three base features. We have to prove $MI(Z, [A_1, A_2]) \leq MI(Z, [A_1, A_2, A_3])$.

Based on MI definition [26]:

$$MI(Z, [A_1, A_2]) = H(Z) - H(Z|[A_1, A_2]) \tag{4}$$

where $H(Z|[A_1, A_2])$ is the conditional entropy of Z given A_1, A_2.

Using Equation 4, we therefore prove $H(Z|[A_1, A_2]) \geq H(Z|[A_1, A_2, A_3])$.

$H(Z|[A_1, A_2, A_3])$

$$\begin{aligned}
&= \Sigma_{a_1,a_2,a_3} p(a_1, a_2, a_3) \times \\
&\Sigma_z p(z|a_1, a_2, a_3) \log p(z|a_1, a_2, a_3) \\
&\leq \Sigma_{a_1,a_2,a_3} p(a_1, a_2) \times p(a_3) \Sigma_z p(z|a_1, a_2) \times \\
&p(z|a_3) \log p(z|a_1, a_2) \log p(z|a_3) \\
&\leq H(Z|[A_1, A_2]) \times \Sigma_{a_3} p(a_3) \Sigma_z p(z|a_3) log p(z|a_3) \\
&\leq H(Z|[A_1, A_2])
\end{aligned} \tag{5}$$

Therefore, $H(Z|[A_1, A_2]) \geq H(Z|[A_1, A_2, A_3])$, proving $MI(Z, [A_1, A_2]) \leq MI(Z, [A_1, A_2, A_3])$. □

An Apriori-Like Algorithm is Impractical. Since MI is upward closed, a level-by-level algorithm such as Apriori must be done in a top-down fashion for our problem, as opposed to the typical bottom-up fashion. Our problem has an additional constraint on the maximum bucket size that requires the algorithm to climb to level x first before it can start generating possible buckets. Moreover, our bucket generation problem does not come with any provided threshold of MI. Instead, it has the number of buckets constraint k. Therefore, it has to start at level x (which will have $\binom{n}{x}$ number of buckets of size x) with the highest MI value possible as the threshold and determine all the size x buckets that satisfy the threshold. If the

number of generated buckets is less than k, it then has to reduce the MI threshold value systematically until a total of exactly k buckets have been generated. Naturally, to faithfully reproduce Apriori for our problem, one has to make several runs of the algorithm, until exactly k buckets have been produced. Clearly, such a process is computationally impractical for large n, x, and k.

Next, we describe our solutions for this problem - first an exact algorithm (ExBKT) that produces the top-k buckets of at most size x with the highest MI, and then random walk based algorithms that are highly efficient and work well in practice.

3.1 Exact Algorithm

Algorithm ExBKT extensively exploits a few observations that we make about MI. In particular, while computing the MI of a set of attributes with the target variable Z, we observe that one can produce effective *lower and upper bounds* on MI. These bounds shall allow us to design a bottom up algorithm that goes level by level and effectively prunes a set of candidate attributes (buckets) by using upper bounds. The observation is rather simple - between two subsets of candidate buckets, if one has higher lower bound of MI than the other bucket's upper bound of MI, then the former bucket should get promoted as the winner between these two buckets. Algorithm ExBKT makes use of this observation to prune buckets that are never going to be part of the top-k results. Before we describe this algorithm in detail, we describe how to effectively compute lower and upper bound (LB and UB respectively) of MI of a set of attributes (candidate buckets).

Theorem 3.3. *Upper Bound: Given a set of t base attributes $A_1, A_2, \ldots A_t$ and the target variable Z, $MI(Z, [A_1, A_2, \ldots A_t]) \leq H(Z) + H(A_1, A_2, \ldots A_t)$*

Proof.

$$\begin{aligned} MI(Z, [A_1, A_2, \ldots A_t]) &= H(Z) - H(Z|[A_1, A_2, \ldots A_t]) \\ &= H(Z) - H(Z, [A_1, A_2, \ldots A_t]) + \\ & H(A_1, A_2, \ldots A_t) \text{ since } [H(Y|X) = H(X, Y) - H(X)] \end{aligned} \quad (6)$$

Therefore,

$$MI(Z, [A_1, A_2, \ldots A_t]) \leq H(Z) + H(A_1, A_2, \ldots A_t) \quad (7)$$

Applying the chain rule of entropy, the right hand side of the inequality could be expressed further as $H(Z) + H(A_1) + H(A_2|A_1)$ $+H(A3|A_1A_2) + \ldots H(A_t|A_1, A_2, \ldots A_{t-1})$ □

Theorem 3.4. *Lower Bound: Given a set of t base attributes $A_1, A_2, \ldots A_t$ and the target variable Z, $MI(Z, [A_1, A_2, \ldots A_t]) \geq MI(Z, [A_1, A_2, \ldots A_{t-1}])$*

Proof. This comes directly from lemma 3.2. □

Algorithm Description: Algorithm ExBKT runs in a bottom-up fashion. It starts at the bottom of attribute lattice with singleton base attributes as buckets, and gradually walks up the lattice, level by level. For illustration purposes, consider only 5 attributes from Example 2.1, abbreviated $\{G, I, M, D, S\}$. The bottom layer refers to the 5 singleton base attributes and their computed MI wrt the target variable Z. Once the score of each of size 1 bucket is computed, then in the next level, the algorithm combines two base attributes and computes 10 buckets of size 2. For each bucket b_i, it maintains two scores: the lower bound score of b_i, $sc^{lb}(b_i)$ derived from Theorem 3.4 and the upper bound score of b_i, $sc^{ub}(b_i)$ derived from Theorem 3.3. Between two buckets b_i and b_j, if the upper bound of b_i (i.e., $sc^{ub}(b_i)$) is smaller than the lower bound of score of b_j (i.e., $sc^{lb}(b_j)$), then b_i and all of its supersets get dropped from further consideration. Using Figure 2, if $sc^{lb}\{G, I\}$ is larger than the upper bound score $sc^{ub}\{M, D\}$, then the latter bucket gets dropped from further consideration. Additionally, all buckets that contain $\{M, D\}$ as some base attributes do not need to be considered. If $x = 3$, then the algorithm continues to climb up the attribute lattice to the next level, finding buckets with at most size 3 base attributes, but applies pruning between the buckets using the lower and upper bound as before. Once it finishes the traversal, it produces the top-k buckets with the k-highest MI with the target variable. The pseudo-code is described in Algorithm 1.

Algorithm 1 Algorithm ExBKT

```
inputs: 𝒜, m records, x, k, target variable Z.
output: Top-k buckets, each of size at most x.
compute all buckets of size 1 and their score.
i = 2
while  i ≤ x do
    Compute sc^ub(b) and sc^lb(b) of each bucket b;
    IF  sc^ub(b_w) ≤ sc^lb(b_y)
        Drop b_w and any superset of b_w
    i = i + 1
end while
```

Lemma 3.5. *Algorithm ExBKT produces the exact top-k buckets.*

Proof. (sketch:) The intuitive argument is that ExBKT only drops a bucket and its super-set if its upper bound score is not larger than the lower bound score of other buckets, which will produce the exact solution, because of Lemma 3.2. □

Running Time: In the worst case ExBKT may take $O(n^x)$, hence it is exponential. However, in practice, the pruning can be very effective and the algorithm converges much sooner.

3.2 Random Walk Based Algorithms

While ExBKT works well in practice, it has an exponential running time in the worst case. Furthermore, ExBKT is not easily extensible when we have to optimize any other criteria in addition to MI. Specifically, for our proposed problem *Coverage Aware Top-k buckets*, ExBKT can not be adapted to generate the best k-buckets with the highest coverage. Therefore, we propose faster heuristic alternatives that provide good solutions most of the time.

Our proposed Algorithm RandomizedBKT is motivated by random walk on the attribute lattice [6] and has a unified solution for both *Top-k buckets Design* and *Coverage Aware Top-k buckets Design* problems. The core idea is to compose a bucket of size x, by performing a random walk on the attribute lattice (refer to Figure 2). An attribute is added to a bucket by using weighted sampling without replacement. The weight of an attribute is based on the optimization criteria. A bucket is formed by performing a random walk on the attribute lattice, until its maximum size x has been reached. This

random walk is repeated, until k-unique buckets have been derived and any additional criteria (e.g., threshold δ for the latter problem) has been satisfied. With this high level description above, now we describe how to compute the weight of an attribute in different scenarios. For the *Top-k buckets Design* problem, the weight of an item is directly proportional to its MI, i.e., $weight(A) = MI(Z, A)$.

The *Coverage Aware Top-k buckets Design* problem requires that in addition to MI threshold δ, the coverage of the Top-k buckets also must be maximized. The weight of an attribute is a ratio; it is proportional to its MI, but inversely proportional to the number of times it is present in other buckets that have been computed thus far. Indeed, this latter criteria is designed to ensure high coverage.This condition can be extended to include feature cost as well, so that costly features are assigned lower preference. As before, the algorithm terminates when we obtain top-k unique buckets. Using Figure 2, if $k = 5$ and $x = 2$, when the random walk produces the 5th bucket, if M has appeared in all other 4 buckets, the weight of M is dampened by a factor of 4 even if it is high in MI with readmission. The pseudo-code is described in Algorithm 2.

Algorithm 2 Algorithm `RandomizedBKT`

inputs: set of base attributes $\mathcal{A}$, m records, target variable Z, x, k, δ (for the coverage aware problem)
output: Top-k buckets of size at most x
$\mathcal{B} = \{\}$
while $|\mathcal{B}| < k$ **do**
  while $size(b_i) < x$ **do**
    $weight(A) = MI(Z, A)$ ▷ for the top-k variant
    $weight(A) \propto \frac{MI(Z,A)}{\#A \text{ has been used before}}$ ▷ for the Coverage aware variant
    Sample A based on $weight(A)$ and add it to b_i
  end while
  IF $sc(b) < \delta$ ▷ only for the Coverage aware variant
    Drop b
  $\mathcal{B} = \mathcal{B} \cup b$
end while

Running Time: Each run of `RandomizedBKT` takes at most $O(n)$ time. The total running time of the algorithm is dominated by the number of different random walks that needs to be performed before it returns k buckets.

4 TOP-l INTERACTIVE SNIPPETS GENERATION

Recall that we propose snippet generation as an interactive process that continues until the human is done crafting the attributes. Each step of this process takes as inputs a bucket b, an integer j, the currently composed set of derived attributes $\mathcal{D}'$, and the algebra $\mathcal{L}$ to produce l snippets with highest scores (MI with Z), where each derived attribute d_i'' in snippet s_i is created by extending d_i' by adding j additional attributes that are part of b, involving $\mathcal{L}$. Each of these l snippets are recommended to the human as visual distributions to aid her design derived attributes.

Therefore, our computational challenge is to produce l snippets effectively in each step involving each $d_i' \in \mathcal{D}'$. A natural choice is to investigate a greedy algorithm that builds the final derived attribute bottom-up by selecting the best base attributes from the bucket and combining them with the best operators to recommend a snippet. In order for this greedy algorithm to provide any provable guarantee, this greedy selection process needs to satisfy certain properties. For example, given four attributes A_i, A_j, A_r, A_s, if $MI(Z, A_i) > MI(Z, A_r)$, and $MI(Z, A_j) > MI(Z, A_s)$, then it seems intuitive that if we combine the two attributes with higher MI (A_i, A_j) with an operator, the resulting derived attribute should have higher MI than the combination of the other two attributes (A_r, A_s) using the same operator. Unfortunately, as we prove below with counter examples, such a property fails to hold *even for very simple operators such as arithmetic addition.* This makes the snippet generation more challenging than the previous step of bucket generation.

A_i	A_j	A_r	A_s	Z
1	-1	0	0	0
2	-2	1	0	1
3	-3	0	1	0
4	-4	1	1	1

Table 2: Example where $MI(Z, A_i + A_j) < MI(Z, A_r + A_s)$

Lemma 4.1. *Given four attributes A_i, A_j, A_r, A_s, if $MI(Z, A_i) > MI(Z, A_r)$, and $MI(Z, A_j) > MI(Z, A_s)$, $MI(Z, A_i + A_j)$ may or may not be greater than $MI(Z, A_r + A_s)$*

Proof. (Sketch): We prove this by counter examples. We present two examples - one shows $MI(Z, A_i + A_j) < MI(Z, A_r + A_s)$ and the other shows the inequality other way. Table 2 shows the first scenario. To create the second scenario, if we replace A_j with 5, 6, 7, 8 in the 4 different rows respectively, we have $MI(Z, A_i + A_j) > MI(Z, A_r + A_s)$. □

Proposed Algorithm: Our proposed algorithm `GSnippet` is a greedy algorithm - it still generates a snippet bottom up in each step. Given a bucket b, it first sorts the base attributes in the bucket in descending MI. Then given j (the number of additional attributes to extend a partially created derived attribute d_i'), it finds the top-j attributes in b that are not in d_i'. These are the candidate set of attributes for the snippets that involve d_i'. After that, it attempts to combine these j attributes considering all the operators in $\mathcal{L}$ with d_i'. It ranks each of these created combinations and produces the l-combinations as snippets that have the top-l MI score with Z. Algorithm 3 presents the pseudo-code.

The reason that `GSnippet` exhaustively considers all the operators in $\mathcal{L}$ (and cannot make any greedy or more efficient look-ups) is because of Lemma 4.1. In order to avoid exhaustive search, other alternative metrics to MI need to be explored that can guarantee upper/lower bound for features combined under algebraic operators. Nevertheless, as we shall show in our experiment, `GSnippet` runs at interactive speeds and produces effective recommendations for the human analyst.

Using Example 2.1, if $b = \{admission.date, dis.date\}$, $l = 1$, $j = 2$, $\mathcal{L} = \{+, -, \times, /\}$, and current $d = \{\}$ (i.e., empty), then `GSnippet` will rank $admission.date + dis.date$, $admission.date -$

dis.date, *admission.date* × *dis.date*, *admission.date*/*dis.date*, and take the one which has the highest MI with readmission.

Algorithm 3 Algorithm `GSnippet`

inputs: bucket b, a derived attribute d'_i, target variable Z, j, l, $\mathcal{L}$
output: Top-l snippets involving d'_i
Sort attributes in b in descending order of MI
Select set S with top-j attributes from b that are not in d'_i
$C = S \bigcup d'_i$
Combine $c_i \oplus c_j \oplus .... \oplus d'_i, \oplus \in \mathcal{L}, c_i \in C$
Rank each combination wrt *MI*
Return top-l

Running Time: Each run takes $O(|\mathcal{L}|^j log l)$ time, the majority of which is spent on brute-forcing on the operator set $\mathcal{L}$.

5 EXPERIMENTAL EVALUATION

We conducted comprehensive experimental analysis to compare our proposed approach with fully automated methods, as well as fully manual (domain expert guided) solution. We investigated both quality and running time in this process.

5.1 Experimental Setup

Hardware and Platform. All our experiments were conducted on a quad-core 2.2 GHz machine with 16 GB of RAM and 1 TB of hard disk. We used Python to implement our algorithms and used scikit-learn for building the classification models.

Datasets. We evaluated our algorithms against a wide variety of datasets that are considered to be popular choice for attribute design problems. Due to lack of space, we report our results on 5 datasets from UCI repository and one from Kaggle. They cover a diverse array of domains (agriculture, medicine, and e-commerce) and contain attributes that are amenable to constructing derived features. Table 3 has more details.

DataSet	# Records	# raw attributes
pollen	3848	5
delta_elevators	9517	6
mammography	11183	6
space	3107	6
diabetes	768	8
home	506	14

Table 3: Reported datasets characteristics

Compared Methods. *(1) Fully Automated Methods.* We implemented two fully automated state-of-the-art approaches for comparison - Featuretools[6] and ExploreKit[7]. They both have open source repositories that allow us to evaluate them fairly.

(2) Our proposed algorithms. These are the solutions that are presented in Sections 3 and 4.

[6]https://docs.featuretools.com/#minute-quick-start
[7]https://github.com/giladkatz/ExploreKit

(3) Buckets Design Baseline algorithms. We compared our proposed buckets design algorithm against an intuitive baseline algorithm (referred to as `Greedy`) that groups attributes on mutual information. It started with an empty bucket and x attributes were added through importance sampling greedily, where the importance is proportional to the marginal increase in MI. The process was repeated k times.

(4) Fully manual method. In this scenario, a domain expert was involved in crafting the derived attributes. We present a case study towards that in Section 5.5.

Evaluation of our proposed framework. Our proposed framework has two steps: the first one, top-k buckets design, is fully automated and does not require any human involvement. We have described three algorithms for that. The second step, top-l snippets generation, proposes the list of top l snippets for each of the derived attribute chosen by the human analyst. The human analyst can either accept the choice, select another snippet or even construct a new one. This process is repeated interactively. The framework continues to retain the top-l choices, if no human guidance is given and is fast enough to be done in near real-time. Finally, the designed derived and the base attributes are passed through existing popular classification models with an average of 10 runs.

Parameter Settings. *x, k, j, l, random walk:* We varied the size of a bucket x between 2 to the maximum number of base attribute with the default value being 5. The snippet extension parameter j is set to 1. Finally, both k and l were set to 5 by default. We ran the random walk for 1000 iterations and picked top-k from it.

Classification models. While our process is classifier agnostic, for the purpose of comparison, we considered two popular classifiers, Support Vector Machines (SVM) and Random Forests (RF). For the latter, we use 100 trees using a depth of 2. Training and testing are performed with a 70% − 30% split of the data, akin to ExploreKit.

Algebra. By default, we used only arithmetic operators. We then varied the grammar to include logical, relational and other aggregate operators. Overall, our approach can support all the operators described in both ExploreKit and Featuretools.

Performance Measures. *Qualitative measures.* For measuring the classifier performance, we reported the Area Under the Curve (AUC). This has been used in prior work such as ExploreKit as it provides a holistic view of the classifier and attribute design. Higher the AUC, better the classifier performance. We reported the percentage improvement in AUC with base(raw) attributes and base+derived attributes. For example, if the classifier had an AUC of 0.7 with base attributes but 0.8 with base+derived attributes, the improvement is $\frac{0.8-0.7}{0.7} = 14\%$.

Scalability measure. We used time in seconds to evaluate the efficiency of our algorithms.

5.2 Summary of Results

Our experimental analysis answered the following key questions:

- **How did our proposed framework compare against fully automated or fully manual solutions?** We found that we scale significantly better ($10x - 20x$ faster than ExploreKit, $7x$ better than fully manual) than both of these extremes, with comparable AUC improvements (on an average 14%). Due to human involvement, it also avoided the worst case

Table 4: AUC improvement and runtime comparison with fully automated methods using SVM

behavior of the automated methods (FeatureTools showed decrease in performance at times). Sections 5.3, 5.5 present these results.

- **How did our proposed algorithms compare?** We observed that we attained higher qualitative performance, while being scalable compared to other baselines. The exact algorithm `ExBKT` produced optimal buckets, while `RandomizedBKT` was much faster and produced results comparable to `ExBKT`. `Greedy` was inferior in quality. We focused on the coverage variant of `RandomizedBKT` so as to provide a diverse set of buckets

Data	EK-RF	Time (s)	FT-RF	Time (s)	MI-RF (s)	Time
pollen	10.56%	10233	-3.71%	40	-1.00%	42

Table 5: AUC improvement and runtime comparison with fully automated methods using RandomForest

to the human analyst. Algorithm `GSnippet` was interactive to the human analyst and works in real time. Section 5.4 presents these results.

- **What kind of attributes did our proposed framework generate?** We observed that the attributes produced by our framework were intuitive and meaningful to human analyst. Section 5.5 presents some of these results.

5.3 Comparison with fully automated methods

We compared the performance of our proposed approach against automated systems in both classifier performance and efficiency. Tables 4 and 5 show the results for SVM and RF classifiers respectively. On an average, the AUC improvement of the classifiers were more than 14% through attribute design. Our proposed framework was almost 10x-20x faster than ExploreKit, comparable with FeatureTools (but FeatureTools caused sudden decline in AUC at times with the derived attributes).

5.4 Analysis of presented algorithms

In this section, we present quality and running time study of our algorithms with the baselines, described in Section 5.1. We note that the implemented baselines were inferior in AUC improvements, hence we only present running time of our solutions.

Comparison with Baselines. We began by comparing our algorithms for bucket construction : an exact algorithm `ExBKT`, a random walk based algorithm handling coverage `RandomizedBKT` and `Greedy`. Figures 3 and 4 show the results. As expected, `ExBKT` took substantial amount of time but gave the best results. `RandomizedBKT` was much faster and provided almost identical results for AUC improvement. `Greedy` was very efficient but qualitatively inferior.

Varying Number of Operators in the Algebra. We began by supporting arithmetic operators ($+, -, \times, /, \%$) and then systematically added more logical, relational and aggregate operators. As expected, increasing the number of operators causes a slow down in our approach. Recall that our first stage of bucket generation was agnostic to both classifier and grammar. The resulting buckets often contained only a handful of attributes and hence our algorithm was quite fast even for a large number of operators. This can be seen in Figure 9 where the improvement is (sub)-linear in the number of operators. Figure 6 shows the corresponding impact on AUC. This shows that the additional operators often only provides negligible improvement in AUC. We conjuncture that for most attributes, only a small set of operators are most relevant.

Varying Bucket Size x. Next, we varied the maximum number of attributes x in each bucket. The impact of k (the number of buckets to return) was minimal. Our algorithms have a natural anytime property where it can be stopped at any time and pick the best k buckets. x affected the length of the random walk and had a major impact on runtime and AUC. Figures 7 and 10 show the result. As expected, increasing bucket size improved the AUC but it stagnated quickly. This confirmed with our hypothesis that most derived attributes often consist of few base attributes. The bucket size must not be too small - otherwise, we might miss meaningful group of attributes. It must also not be too large - otherwise, we might expend runtime for no meaningful improvement of AUC. We found a value of 5 to be good both from runtime perspective and the required cognitive impact on the human analyst. The runtime increased almost linearly with larger bucket size.

Varying Snippet Size j. In our final set of experiments, we varied the snippet size. Here we also noted that the impact of l (the number of snippets to return) was minimal. Figures 8 and 11 show the results. As expected, increasing snippet size had minimal impact on AUC. The improvement more or less topped out at snippet of size 3. This once again confirmed our hypothesis that derived attributes were often constructed from a handful of base attributes. The increase in time for larger snippet size was mostly linear.

Varying Number of Attributes. In order to highlight the scalability of our algorithms, we varied the number of base attributes by duplicating some of the base attributes randomly. Figure 5 shows the impact on running time of our exact and random walk based algorithm. As expected, the running time increased dramatically for `ExBKT` while the increase was marginal for `RandomizedBKT`. Our approach was scalable to large increase in the number of columns. The impact of increasing number of rows were rather minimal.

5.5 Comparison with fully manual method

We present a case study comparing a fully manual approach (a typical trial-and-error based attribute design exercise a data scientists goes through) and our approach. We used the popular Boston dataset from Kaggle [8] that seeks to predict house prices from from features like its area, number of bedrooms, etc.

We involved a data scientist to construct the derived attributes and she came up with the following 6 additional derived attributes after extensive analysis. lstat / tax, ptratio / tax, dis * rad / tax, black * crim, rm * (zn + indus) and (nox * indus) / tax. The interpretation of these attributes are presented in Table 6. The data scientist took about 10 hours to manually craft these 6 derived attributes, out of which 3 hours were needed to understand and explore the data. The remaining 7 hours were needed for a trial and error process, where the expert tried many possible derived attributes, analyzed the correlation, tweaked the attributes, and repeated the process. While another data scientist with similar expertise was guided by

[8] https://www.kaggle.com/c/boston-housing/data

Attribute	Interpretation
lstat	lower status of the population (percent).
tax	full-value property-tax rate per $10,000.
ptratio	pupil-teacher ratio by town.
dis	weighted mean of distances to five Boston employment centres.
rad	index of accessibility to radial highways.
black	$1000(Bk - 0.63)^2$ where Bk is the proportion of blacks by town.
crim	per capita crime rate by town.
rm	average number of rooms per dwelling.
zn	proportion of non-retail business acres per town.
nox	nitrogen oxides concentration (parts per 10 million).

Table 6: Boston home dataset attributes

our framework, she took *only* 1 *hour* to craft the same 6 derived attributes. For both cases, we observed an AUC improvement of 14%. This case study anecdotally showcase that our proposed framework is capable to drastically reduce the latency (7 hour vs 1 hr, i.e, $7x$ improvement) by aiding the domain expert.

6 RELATED WORK

Human-in-the-loop Query Answering : A growing number of systems make use of lay workers (known as crowdsourced workers) using commercial platforms (e.g., AMT and CrowdFlower) or for academic use. Examples of applications include not only sentence translation, photo tagging and sentiment analysis, but also query answering (CrowdDB [11], Qurk [28], Deco [32], sCOOP, FusionCOMP, MoDaS, CyLog/Crowd4U), entity resolution (such as CrowdER [40]), planning queries [19], perform matching [41], or counting [27]. A series of works [39–43] have proposed variations of crowdsourced join to address entity resolution task for query answering. Authors in [7, 9, 13, 21, 33, 47] have proposed various techniques of performing crowdsourced version of top-k item selection. Crowdsourcing based filtering has been extensively introduced in [30, 31]. Crowdsourced *find* focuses on selecting one or more qualified items [34, 44]. Unlike these works, we involve humans for attributes design, which occurs at a later stage of the data science pipeline — therefore these prior works do not extend to our problem.

Human-in-the-loop Supervised Modeling: Machine learning literature has involved humans to obtain labels [5, 15, 16, 37] primarily for the classification problem. Active learning involving humans (expert as well as lay workers) has also been discussed in recent works such as [10, 29, 45, 49]. These works utilize humans for accurately predicting class labels, thus the humans function as an added module to help the algorithm steer toward the correct assignment of class labels. The main distinction between these works and ours is that, these works leverage human mainly for data labeling and not for attribute design.

Attribute Design: How to develop automated methods for designing/engineering attributes (commonly referred to as as feature engineering) has been discussed in recent works [2, 18, 20, 22, 23, 48], primarily in machine learning literature. Attribute engineering tools, such as, ExploreKit, Featuretools, Data Science Machine, One Button Machine [17, 18, 20, 23, 24, 35] rely on fully automated approaches. Typically they take longer to run and do not offer adequate explainability or intuition, as the discovered attributes remain opaque to the human analyst interested in broader ad-hoc data exploration. They also ignore the availability of humans to guide their exploration. Finally, the effectiveness of most of these tools depend on the underlying classification model, whereas, we present a model agnostic approach. Nevertheless, we use some of these tools in our experimental analysis for comparison purposes. A very few recent works [8, 36, 50] propose a conceptual framework and describe how to involve humans for designing attributes to improve the accuracy of predictive machine learning models, such as classifiers. While we borrow inspiration from these recent works [8, 36, 50], we present the framework with mathematical rigor and investigate optimization opportunities.

7 CONCLUSION

We present an optimization guided semi-automated model-agnostic "human-in-the-loop" framework for designing derived attributes by leveraging humans. The main contribution of our work is to provide an optimization guided framework for data scientists that will help them to craft meaningful derived attributes much quicker than a fully manual method. On the other hand, running time of the fully automated techniques vary greatly; for example, FeatureTools is significantly faster compared to ExploreKit, but they all have the limitations of producing derived attributes that are opaque. Contrarily, the derived attributes produced by our framework are interpretable.

We present two computational problems inside our proposed framework - *top-k buckets design* and *top-l snippets generation* problems. We present effective solutions for solving both problems. We compare our proposed approach with two fully automated state-of-the-art tools, as well as fully manual domain expert designed derived attributes. Our rigorous quality evaluations using 6 real world datasets demonstrate that we are as effective as *fully automated methods* and we scale up significantly better compared to a fully manual solution involving two domain experts. Our scalability results demonstrate that both bucket design and snippet generation are interactive and ensure real time response with the analysts. As an ongoing problem, we are investigating how to revisit these problems when the datasets contain significant missing values. We are also investigating how to involve multiple domain experts in buckets design and snippets generation problems.

ABSTRACT

Triplestores are data management systems for storing and querying RDF data. Over recent years, various benchmarks have been proposed to assess the performance of triplestores across different performance measures. However, choosing the most suitable benchmark for evaluating triplestores in practical settings is not a trivial task. This is because triplestores experience varying workloads when deployed in real applications. We address the problem of determining an appropriate benchmark for a given real-life workload by providing a fine-grained comparative analysis of existing triplestore benchmarks. In particular, we analyze the data and queries provided with the existing triplestore benchmarks in addition to several real-world datasets. Furthermore, we measure the correlation between the query execution time and various SPARQL query features and rank those features based on their significance levels. Our experiments reveal several interesting insights about the design of such benchmarks. With this fine-grained evaluation, we aim to support the design and implementation of more diverse benchmarks. Application developers can use our result to analyze their data and queries and choose a data management system.

1 INTRODUCTION

The last years have witnessed a significant growth in the use of Linked Data and Semantic Web technologies. This growth has motivated the development of new triplestores with increasingly more efficient RDF storage and SPARQL query processing mechanisms. Accordingly, various benchmarks [2, 5, 8, 11, 14, 16, 18, 24, 27, 30, 31, 33] have been proposed to evaluate the querying performance of these triplestores. However, due to heterogeneity of RDF datasets and SPARQL queries, real-world applications often require customized deployments and experience different workloads when deployed in real environments [22]. Thus, designing a one-fit-all benchmark or selecting the most suitable benchmark for any given use-case and workload is not a straightforward task [12, 21, 24].

This work highlights key features of triplestore benchmarks pertaining to the three main components of benchmarks, i.e., datasets, queries, and performance metrics. State-of-the-art triplestore benchmarks are analyzed and compared against these features. Particularly, we consider triplestore benchmarks that rely on the native capabilities of the triplestores and do not require further reasoning over queries to get complete results. We also analyze the data and query logs of five real-world datasets selected from three different domains so as to provide a comparison with real-world datasets and queries. Our contributions are as follows.

(1) We identify key design features of SPARQL triplestore benchmarks based on our systematic survey on the state-of-the-art.
(2) We provide a detailed comparative analysis of the queries and datasets of 11 representative triplestore querying benchmarks: Train Benchmark [30], FEASIBLE [24], WatDiv [2], DBpedia SPARQL Benchmark (DBPSB) [18], FishMark [5], Bowlogna [11], SP2Bench [11], Berlin SPARQL Benchmark (BSBM) [8], BioBench [33], LDBC Social Network Benchmark Business Intelligence workload (SNB-BI) [31], and LDBC SNB Interactive workload (SNB-INT) [14].
(3) We analyze real data and corresponding user queries of five real-world datasets – DBpedia,[1] Semantic Web Dog Food (SWDF),[2] NCBI Gene,[3] SIDER,[4] DrugBank[5] – and compare them with the selected triplestore benchmarks.
(4) We measure the impact of various SPARQL query features (e.g., result sizes, triple patterns selectivity and number of join vertices) on the overall query execution time and rank these features according to their significance. In addition,

we demonstrate that state-of-the-art triplestore benchmarks vary greatly, and highlight their current limitations.
(5) We performed extensive experiments and measure the impact of dataset *structuredness* (a well-known RDF dataset metric [12] formally defined in Section 2.1.1) on the overall query execution time as well as on the result sizes.

The rest of this paper is organized as follows: We provide an overview of the key RDF datasets and SPARQL query features that need to be considered while designing triplestore benchmarks based on a review of the state of the art. We then present a systematic survey of the current benchmarks for triplestores. The subsequent comparison of selected representative SPARQL benchmarks based on key data and query features identified in the survey is followed by a discussion of our results and some concluding remarks. The data and results presented in this evaluation are available online at https://github.com/dice-group/triplestore-benchmarks. The complete results can be reproduced and new benchmarks can be easily compared using the scripts provided at the project page.

2 BENCHMARK DESIGN FEATURES

In general, triplestore benchmarks comprise three main components: (1) a set of RDF datasets, (2) a set of SPARQL queries, and (3) a set of performance metrics. This section presents key features of each of these components that are important to consider in the development of triplestore benchmarks. Most of these features originate from state-of-the-art research contributions pertaining to triplestore benchmarks.

2.1 Datasets

Datasets used in triplestore benchmarks are either synthetic or selected from real-world RDF datasets [24]. The use of real-world RDF datasets is often regarded as useful to perform evaluation close to real-world settings [18]. Synthetic datasets are useful to test the scalability of systems based on datasets of varying sizes. Synthetic dataset generators are utilized to produce datasets of varying sizes which can often be optimized to reflect the characteristics of real-world datasets [12]. Previous works [12, 20] highlighted two key measures for selecting such datasets for triplestores benchmarking: (1) Dataset Structuredness, (2) Relationship Specialty. However, observations from the literature (see e.g., [12, 23]) suggest that other features such as varying number of triples, number of resources, number of properties, number of objects, number of classes, diversity in literal values, average properties and instances per class, average indegrees and outdegrees as well as their distribution across resources should also be considered.

2.1.1 Dataset Structuredness: Duan et al. [12] combine many of the aforementioned dataset features into a single composite metric called dataset *structuredness* or *coherence*. This metric measures how well a dataset's classes (i.e., `rdf:type`) are covered by the different instances of the dataset. The structuredness value for any given dataset lies between $[0, 1]$, where 0 stands for lowest possible structure and 1 points to a highest possible structured dataset. They conclude that synthetic datasets are highly structured while real-world datasets have structuredness values ranging from low to high, covering the whole structuredness spectrum. Formally, dataset structuredness is defined in the form of class coverage. The coverage of a class C, denoted by $CV(C)$, is defined as follows [12]:

Definition 2.1 (Class Coverage). Let D be a dataset. Moreover, let $P(C)$ denote the set of distinct properties of class C, and $I(C)$ denote the set of distinct instances of the class C. Let $I(p, C)$ count the number of entities for which property p has its value set in the instances of C. Then, the coverage of the class $CV(C)$ is

$$CV(C) = \frac{\sum_{p \in P(C)} I(p, C)}{|P(C)| \cdot |I(C)|}$$

In general, RDF datasets comprise multiple classes with a varying number of instances for different classes. The authors of [12] proposed a mechanism that considers the weighted sum of the coverage $CV(C)$ of individual classes. For each class C, the weighted coverage is defined below.

Definition 2.2 (Weighted Class Coverage). The weighted coverage for a class C denoted by $WTCV(C)$ is calculated as:

$$WTCV(C) = \frac{|P(C)| + |I(C)|}{\sum_{C' \in D} |P(C')| + |I(C')|}$$

By using Definitions 2.1 and 2.2, we are now ready to compute the structuredness of a dataset D.

Definition 2.3 (Dataset Structuredness). The overall structuredness or coherence of a dataset D denoted by $CH(D)$ is defined as

$$CH(D) = \sum_{C \in D} CV(C) \cdot WTCV(C)$$

2.1.2 Relationship Specialty. In datasets, some attributes are more common and associated with many resources. In addition, some attributes are multi-valued, e.g., a person can have more than one cellphone number or professional skill. The number of occurrences of a predicate associated with each resource in the dataset provides useful information on the graph structure of an RDF dataset, and makes some resources distinguishable from others [20]. In real datasets, this kind of relationship specialty is commonplace. For example, several million people can like the same movie. Likewise, a research paper can be cited in several hundred of other publications. Qiao et al. [20] suggest that synthetic datasets are limited in how they reflect this relationship specialty. This is either due to the simulation of uniform relationship patterns for all resources, or a random relationship generation process. The relationship specialty of a *relationship predicate* is defined as follows:

Definition 2.4 (Predicate Relationship Specialty). Let d be the distribution that records the number of occurrences of a *relationship predicate* r associated with each resource and μ is the mean and σ is the standard deviation of d. The specialty value of r denoted as $\kappa(r)$ is defined as the Pearson's Kurtosis value of the distribution d.

$$\kappa(r) = \frac{n(n+1)}{(n-1)(n-2)(n-3)} \cdot \frac{\sum_{x_i \in d}(x_i - \mu)^4}{\sigma^4} - \frac{3(n-1)^2}{(n-2)(n-3)}$$

Where n is the number of available values, i.e., sample size. The relationship specialty of a dataset is defined in the form of a weighted sum of specialty values of all relationship predicates:

Definition 2.5 (Dataset Relationship Specialty). The relationship specialty of dataset D denoted by $RS(D)$ is calculated as follows:

$$RS(D) = \sum_{r_i \in R} \frac{|T(r_i)| \cdot \kappa(r_i)}{\sum_{r_j \in R} |T(r_j)|}$$

where $|T(r_i)|$ is the number of triples in the dataset having predicate r_i, $\kappa(r_i)$ is the specialty value of relationship predicate r_i.

The dataset structuredness and relationship specialty directly affect the result size, the number of intermediate results, and the selectivities of the triple patterns of the given SPARQL query. Therefore, they are important dataset design features to be considered during the generation of benchmarks [12, 20, 24].

2.2 SPARQL Queries

The literature about SPARQL Queries [2, 15, 23, 24, 26] suggests that a SPARQL querying benchmark should vary the queries with respect to various features such as *query characteristics*: number of triple patterns, number of projection variables, result set sizes, query execution time, number of BGPs, number of join vertices, mean join vertex degree, mean triple pattern selectivities, BGP-restricted and join-restricted triple pattern selectivities, join vertex types, and highly used SPARQL clauses (e.g., `LIMIT`, `OPTIONAL`, `ORDER BY`, `DISTINCT`, `UNION`, `FILTER`, `REGEX`). All of these features have a direct impact on the runtime performance of triplestores. We assume that the reader is familiar with the basic concepts of SPARQL, including the notions of a triple pattern, a basic graph pattern (BGP), and projection variables.[6] In the following, we define the remaining SPARQL features formally, i.e., the number of join vertices, mean join vertex degree, join vertex types, triple pattern selectivities, BGP-restricted and join-restricted triple pattern selectivities.

We represent any basic graph pattern (BGP) of a given SPARQL query as a *directed hypergraph* (DH) [25], a generalization of a directed graph in which a hyperedge can join any number of vertices. In our specific case, every hyperedge captures a triple pattern. The subject of the triple becomes the source vertex of a hyperedge and the predicate and object of the triple pattern become the target vertices. For instance, the query (Figure 1) shows the hypergraph representation of a SPARQL query. Unlike a common SPARQL representation where the subject and object of the triple pattern are connected by an edge, our hypergraph-based representation contains nodes for all three components of the triple patterns. As a result, we can capture joins that involve predicates of triple patterns. Formally, our hypergraph representation is defined as follows:

Definition 2.6 (Directed hypergraph of a BGP). The hypergraph representation of a BGP B is a directed hypergraph $HG = (V, E)$ whose vertices are all the components of all triple patterns in B, i.e., $V = \bigcup_{(s,p,o) \in B} \{s, p, o\}$, and that contains a hyperedge $(S, T) \in E$ for every triple pattern $(s, p, o) \in B$ such that $S = \{s\}$ and $T = (p, o)$.

The representation of a complete SPARQL query as a DH is the union of the representations of the query's BGPs. Based on the DH representation of SPARQL queries, we can define the following features of SPARQL queries:

[6] See https://www.w3.org/TR/sparql11-query/ for the corresponding definitions.

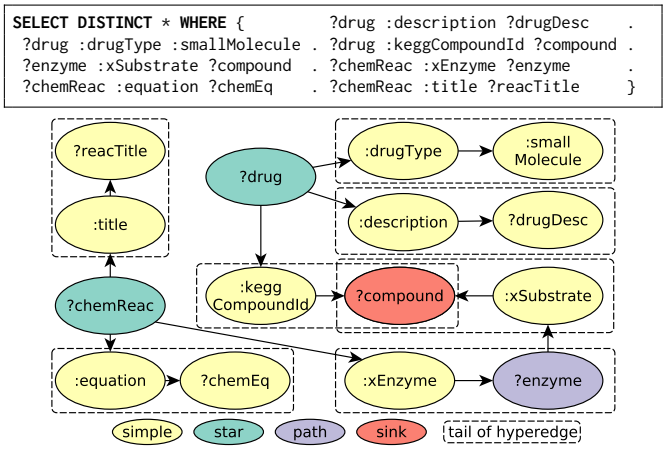

Figure 1: Directed hypergraph representation of a SPARQL query. Prefixes are ignored for simplicity.

Definition 2.7 (Join Vertex). For every vertex $v \in V$ in such a hypergraph we write $E_{\text{in}}(v)$ and $E_{\text{out}}(v)$ to denote the set of incoming and outgoing edges, respectively; i.e., $E_{\text{in}}(v) = \{(S, T) \in E \mid v \in T\}$ and $E_{\text{out}}(v) = \{(S, T) \in E \mid v \in S\}$. If $|E_{\text{in}}(v)| + |E_{\text{out}}(v)| > 1$, we call v a *join vertex*.

Definition 2.8 (Join Vertex Degree). Based on the DH representation of the queries the join vertex degree of a vertex v is $JVD(v) = |E_{in}(v)| + |E_{out}(v)|$, where $E_{in}(v)$ resp. $E_{out}(v)$ is the set of incoming resp. outgoing edges of v.

Definition 2.9 (Join Vertex Types). A vertex $v \in V$ can be of type *star*, *path*, *hybrid*, or *sink* if this vertex participates in at least one join. A *star* vertex has more than one outgoing edge and no incoming edges. A *path* vertex has exactly one incoming and one outgoing edge. A *hybrid* vertex has either more than one incoming and at least one outgoing edge or more than one outgoing and at least one incoming edge. A *sink* vertex has more than one incoming edge and no outgoing edge. A vertex that does not participate in joins is *simple*.

Definition 2.10 (Triple Pattern Selectivity). Let tp_i be a triple pattern of a SPARQL query Q and D be a dataset. Furthermore, let N be the total number of triples in D and $Card(tp_i, D)$ be the cardinality of tp_i w.r.t. D, i.e., total number of triples in D that matches tp_i, then the selectivity of tp_i w.r.t. D denoted by $Sel(tp_i, D) = Card(tp_i, D)/N$.

Definition 2.11 (BGP-Restricted Triple Pattern Selectivity). Consider a Basic Graph Pattern BGP and a triple pattern tp_i belonging to BGP, let $R(tp_i, D)$ be the set of distinct solution mappings (i.e., result set) of executing tp_i over dataset D and $R(BGP, D)$ be the set of distinct solution mappings of executing BGP over dataset D. Then the BGP-restricted triple pattern selectivity denoted by $Sel_{BGP\text{-}Restricted}(tp_i, D)$ is the fraction of distinct solution mappings in $R(tp_i, D)$ that are compatible (as per standard SPARQL semantics [3]) with a solution mapping in $R(BGP, D)$ [2]. Formally, if Ω and Ω' denote the sets underlying the (bag) query results $R(tp_i, D)$

and $R(BGP, D)$, respectively, then

$$Sel_{BGP\text{-}R.}(tp_i, D) = \frac{|\{\mu \in \Omega \,|\exists \mu' \in \Omega' : \mu and \mu' are\ compatible\}|}{|\Omega|}$$

Definition 2.12 (Join-Restricted Triple Pattern Selectivity). Consider a join vertex x in the DH representation of a *BGP*. Let BGP' belonging to *BGP* be the set of triple patterns that are incidents to x. Furthermore, let tp_i belonging to BGP' be a triple pattern and $R(tp_i, D)$ be the set of distinct solution mappings of executing tp_i over dataset D and $R(BGP', D)$ be the set of distinct solution mappings of executing BGP' over dataset D. Then the *x-restricted* triple pattern selectivity denoted by $Sel_{\mathcal{J}Vx\text{-}Restricted}(tp_i, D)$, is the fraction of distinct solution mappings in $R(tp_i, D)$ that are compatible with a solution mapping in $R(BGP', D)$ [2]. Formally, if Ω and Ω' denote the sets underlying the (bag) query results $R(tp_i, D)$ and $R(BGP', D)$, respectively, then

$$Sel_{\mathcal{J}Vx\text{-}R.}(tp_i, D) = \frac{|\{\mu \in \Omega \,|\exists \mu' \in \Omega' : \mu and \mu' are\ compatible\}|}{|\Omega|}$$

All of the above important query features were collected from the previous works [2, 15, 23, 24] in triplestores benchmarking. Finally, we combine all these important query features into a single composite metric called the *Diversity Score* of the benchmark queries, defined as follows.

Definition 2.13 (Queries Diversity Score). Let μ_i be the mean and σ_i the standard deviation of a given distribution w.r.t. the i^{th} feature of the said distribution. The overall diversity score *DS* of the queries is the average coefficient of variation of all the query features k analyzed in the queries of benchmark B:

$$DS = \frac{1}{k} \sum_{i=1}^{k} \frac{\sigma_i(B)}{\mu_i(B)}$$

2.3 Performance Metrics

Based on the previous triplestores benchmarks and performance evaluations [2, 5, 8, 10, 11, 14, 16, 18, 24, 27, 30, 31, 33] the performance metrics for such comparisons can be categorized as:

- **Query Processing Related**: The performance metrics in this category are related to the query processing capabilities of the triplestores. The query execution time is the central performance metric in this category. However, reporting the execution time for individual queries might not be feasible due to the large number of queries in the given benchmark. To this end, Query Mix per Hour (QMpH) and Queries per Second (QpS) are regarded as central performance measures to test the querying capabilities of the triplestores [8, 18, 24]. In addition, the query processing overhead in terms of the CPU and memory usage is important to measure during the query executions [27]. This also includes the number of intermediate results, the number of disk/memory swaps, etc.
- **Data Storage Related:** Triplestores need to load the given RDF data and mostly create indexes before they are ready for query executions. In this regard, the data loading time, the storage space acquired, and the index size are important performance metrics in this category [8, 11, 27, 33].
- **Result Set Related:** Two systems can only be compared if they produce exactly the same results. Therefore, result set correctness and completeness is important metrics to be considered in the triplestores evaluations [8, 24, 27, 33].
- **Parallelism with/without Updates:** Some of the aforementioned triplestores performance evaluations [8, 10, 33] also measured the parallel query processing capabilities of the triplestores by simulating workloads from multiple querying agents with and without dataset updates.

We analyzed state-of-the-art existing SPARQL triplestore benchmarks across all of the above mentioned dataset and query features as well as the performance metrics. The results are presented in Section 4.

3 SYSTEMATIC SURVEY

In this section, we present a systematic survey carried out to collect triplestore benchmarks and their selection criteria for further analysis. We conducted a public survey[7] through various relevant W3C Linked Open Data mailing list[8] and Semantic Web mailing list[9] with a request to participate email. We received 14 responses[10] regarding SPARQL triplestore benchmarks. Moreover, we used Google Scholar to retrieve published research work relating to the design of triplestore benchmarks and/or their performance evaluation. Initially, we selected 40 relevant papers[11] and evaluated them against our designed inclusion criteria. In our inclusion criteria we mandated that (1) the benchmark target the query runtime performance evaluation of triplestores, (2) both RDF data and SPARQL queries of the benchmark are publicly available or can be generated (3) the queries must not require reasoning to retrieve the complete results. After manual evaluation, we found 11 benchmarks (7 with synthetic and 4 with real data) that fulfilled our requirements. The sections below provide details of the selected benchmarks.

3.1 Synthetic Triplestore Benchmarks

The *Train Benchmark* (TrainBench) [30] uses a data generator that produces railway networks in increasing sizes and serializes them in different formats, including RDF. *The Waterloo SPARQL Diversity Test Suite* (WatDiv) [2] provides a synthetic data generator that produces RDF data with a tunable structuredness value and a query generator. The queries are generated from different query templates. *SP2Bench* [27] mirrors vital characteristics (such as power law distributions or Gaussian curves) of the data in the DBLP bibliographic database. *The Berlin SPARQL Benchmark* (BSBM) [8] uses query templates to generate any number of SPARQL queries for benchmarking, covering multiple use cases such as explore, update, and business intelligence. *Bowlogna* [11] models a real-world setting derived from the Bologna process and offers mostly analytic queries reflecting data-intensive user needs. The *LDBC Social Network Benchmark* (SNB) defines two workloads: (1) the *Interactive* workload (SNB-INT) measures the evaluation of graph patterns in a localized scope (e.g., in the neighborhood of a person), with the graph being continuously updated [14], and (2) the *Business Intelligence* workload (SNB-BI) focuses on queries that mix complex

graph pattern matching with aggregations, touching on a significant portion of the graph [31], without any updates. Note that these two workloads are regarded as two separate triplestore benchmarks based on the same dataset.

3.2 Triplestore Benchmarks Using Real Data

FEASIBLE [24] is a cluster-based SPARQL benchmark generator, which is able to synthesize customizable benchmarks from the query logs of SPARQL endpoints. The *DBpedia SPARQL Benchmark* (DBPSB) [18] is another cluster-based approach that generates benchmark queries from DBpedia query logs, but employs different clustering techniques than FEASIBLE. The *FishMark* [5] dataset is obtained from FishBase[12] and provided in both RDF and SQL versions. The SPARQL queries were obtained from logs of web-based FishBase application. *BioBench* [33] evaluates the performance of RDF triplestores with the real biological datasets and queries from five different real-world RDF datasets[13], i.e., Cell, Allie, PDBJ, DDBJ, and UniProt. Due to the size of the datasets, we were only able to analyze the combined data and queries of the first three.

3.3 Selected Real-World Datasets

As mentioned before, we aimed to analyze the data and queries of real-world datasets and compare them to those of the benchmark datasets and queries. The selection criteria for the real-world datasets were: (1) The RDF datasets must be publicly available, (2) the real queries posted by users of the datasets via SPARQL endpoints should be available. We were able to get real log queries of the Bio2RDF datasets,[14] DBpedia, and Semantic Web Dog Food. Our goal was to select real-world datasets from different domains. Hence, we selected DBpedia[15] and SWDF and three datasets – NCBIGene, Sider, DrugBank from Bio2RDF. The selection of the three Bio2RDF datasets was based on a recommendation from domain experts. The well-known DBpedia dataset is the RDF version of Wikipedia. The SWDF represents the publication from Semantic Web and Linked Data as RDF. NCBIGene provides genetic information from a wide range of species. SIDER contains information on marketed medicines and their recorded side-effects. DrugBank knowledge base contains information about drugs, their composition and their interactions.

Table 1 shows statistics from selected datasets of the benchmarks and real-world datasets. More advanced statistics will be presented in the next section. The table also shows the number of SPARQL queries of the datasets included in the corresponding benchmark or query log. It is important to mention that we only selected SPARQL `SELECT` queries for analysis. This is because we wanted to analyze the triplestore benchmarks for their query runtime performance and most of these benchmarks only contain `SELECT` queries [24]. For the synthetic benchmarks that include data generators, we chose the datasets used in the evaluation of the original paper that were comparable in size to the datasets of other synthetic benchmarks. For template-based query generators such as WatDiv, DBPSB, SNB, we chose one query per available template. For FEASIBLE, we generated a benchmark of 50 queries from DBpedia log to be comparable with a well-known WatDiv benchmark that includes 20 basic testing query templates, and 30 extensions for testing.[16]

Table 1: High-level statistics of the data and queries used on our evaluation. Both SNB-BI and SNB-INT use the same dataset and are therefore named as SNB for simplicity.

	Benchmark	Subjects	Predicates	Objects	Triples	Queries
Synthetic	Bowlogna [11]	2,151k	39	260k	12M	16
	TrainB. [30]	3,355k	16	3,357k	41M	11

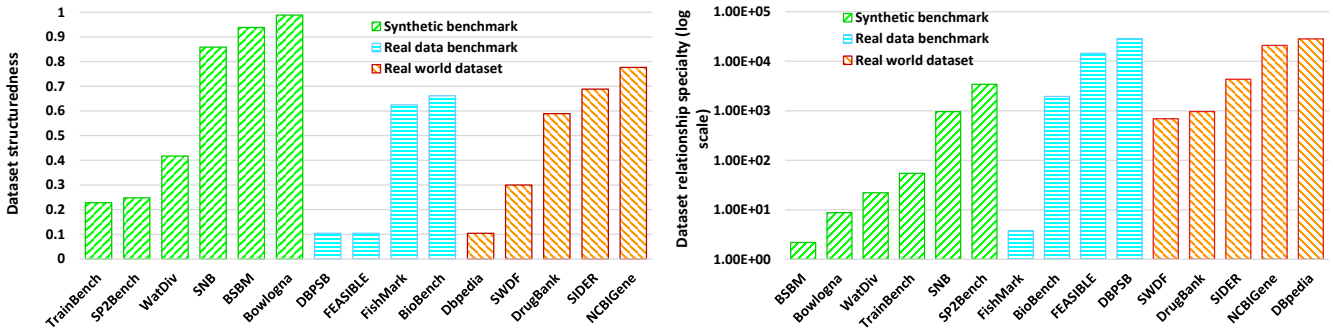
4 ANALYSIS OF THE BENCHMARKS

We present a detailed analysis of the datasets, queries, and performance metrics of the selected benchmarks and datasets according to the design features presented in Section 2.



4.1 Datasets

We presents results pertaining to the dataset features of Section 2.1.

4.1.1 Structuredness. Figure 2a shows the structuredness values of the selected benchmarks and real-world datasets. Duan et al. [12] establish that synthetic benchmarks are highly structured while real-world datasets are low structured. This important dataset feature is well-covered in recent synthetic benchmarks such as TrainBench (with a structuredness value of 0.23) and WatDiv, which lets the user generate a benchmark dataset of a desired structuredness value. However, Bowlogna (0.99), BSBM (0.94), and SNB (0.86) have relatively high structuredness values. The average structuredness value of the selected five real-world datasets is 0.49, and 0.65 for the 13 real-world datasets used in LargeRDFBench [23]. Finally, on average, synthetic benchmarks are still more structured than real data benchmarks (0.61 vs. 0.45).

4.1.2 Relationship Specialty. According to [20], relationship specialty in synthetic datasets is limited, i.e., the overall relationship specialty values of synthetic datasets are lower than those of similar real-world datasets. The dataset relationship specialty results presented in Figure 2b mostly confirm this behavior. On average, synthetic benchmarks have a smaller specialty score than real-world datasets (744 vs. 11098). The relationship specialty values of Bowlogna (8.7), BSBM (2.2), and WatDiv (22.0) are on the lower side compared to real-world datasets. The highest specialty value (28282.8) is recorded in the DBpedia dataset.

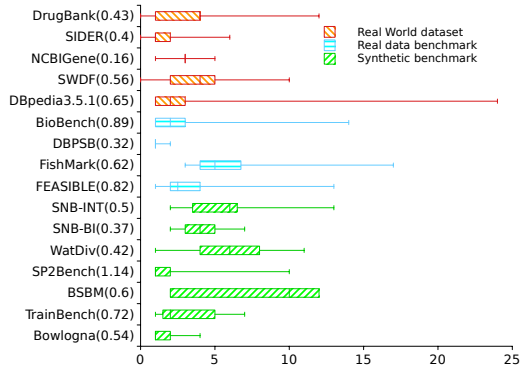
(a) Structuredness

(b) Relationship Specialty

Figure 2: Analysis of the datasets of triplestore benchmarks and real-world data.

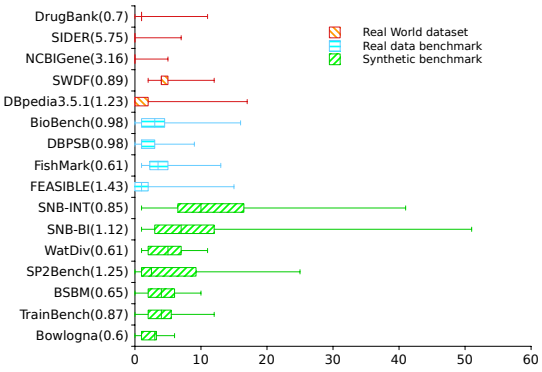
An important issue is the correlation between structuredness and the relationship specialty of the datasets. To this end, we computed the Spearman's correlation between the stucturedness and specialty values of all the selected benchmarks and real-world datasets. The correlation of the two measures is −0.5, indicating a moderate inverse relationship. This means that the higher the structuredness, the lower the specialty value. This is because in highly structured datasets, data is generated according to a specific distribution without treating some predicates more particularly (in terms of occurrences) than others.

4.2 Queries



This section presents results pertaining to the query features discussed in Section 2.2. Figure 3 shows the box plot distributions of real-world datasets and benchmark queries across the query features defined in Section 2. The values inside the brackets, e.g., the 0.89 in "BioBench (0.89)", show the diversity score (Definition 2.13) of the benchmark or real-world dataset for the given query feature.

Starting from the number of projection variables (ref. Figure 3a), the NCBIGene dataset has the lowest diversity score (0.16) and SP2Bench has the highest score of 1.14. The mean diversity score (across all benchmarks and real-world datasets) for this feature is 0.59 and hence the diversity scores of DBPSB, SNB-BI, SNB-INT, WatDiv, and Bowlogna are below the average value. Even though the diversity score of BSBM is above average, the distribution shows that the values mostly lie in the second quartile of the box plot. The average diversity score of the number of join vertices (ref. Figure 3b) is 1.39 and hence the diversity scores of the Bowlogna, FishMark, WatDiv, BSBM, TrainBench, BioBench, DBPSB, SNB-BI, and SNB-INT benchmarks are below the average value. It is important to mention that the highest number of join vertices recorded in a query is 51 in the SNB-BI benchmark. The average diversity score of the number of triple patterns (ref. Figure 3c) is 0.75 and hence the diversity scores of the FishMark, Bowlogna, BSBM, and WatDiv benchmarks are below the average value. The average diversity score of the result sizes (ref. Figure 3d) is 11.89 and hence the diversity scores of all benchmarks are below the average value. The average diversity score of the join vertex degree (ref. Figure 3e) is 1.08 and hence the diversity scores of all benchmarks except FEASIBLE are below the average value. The average diversity score of the triple pattern selectivity (ref. Figure 3f) is 3.17 and hence the diversity scores of all benchmarks except FEASIBLE are below the average. The average diversity score of the join-restricted triple pattern selectivity (ref. Figure 3g) is 1.39 and hence the diversity scores of all benchmarks except FEASIBLE and BSBM are below the average value. The average diversity score of the BGP-restricted triple pattern selectivity (ref. Figure 3h) is 4.11 and hence the diversity scores of all benchmarks except WatDiv are below the average value. The average diversity score of the number of BGPs (ref. Figure 3i) is 0.63 and hence the diversity scores of SNB-BI, SNB-INT, BSBM, SP2BENCH, TrainBench, WatDiv, and Bowlogna are below the average value.



The Linked SPARQL Queries (LSQ) [22] representation stores additional SPARQL features, such as use of `DISTINCT`, `REGEX`, `BIND`, `VALUES`, `HAVING`, `GROUP BY`, `OFFSET`, aggregate functions, `SERVICE`, `OPTIONAL`, `UNION`, property paths, etc. We make a count of all of these SPARQL operators and functions and use it as a single query dimension as number of LSQ features. The average diversity score of the number of LSQ features (ref. Figure 3j) is 0.30, and hence only the diversity scores of SNB and WatDiv are below average value. Finally, the average diversity score of the query runtimes is 12.87 (ref. Figure 3k), and hence the diversity scores of all benchmarks are below average value.

In summary, FEASIBLE's diversity scores are below the average values in 3 of the 11 features, followed by BioBench with 7/11. These are followed by SP2Bench, TrainBench, and BSBM with 8/11 each. The next is FishMark 9/11 and then Bowlogna, WatDiv, SNB-BI, SNB-INT, and DBPSB with 10/11 each. Figure 3l shows the overall (across all the features, ref. Definition 2.13) diversity scores of the benchmarks and real-world datasets. In the benchmarks category, FEASIBLE produces the most diverse benchmarks (diversity score 2.15), followed by BioBench (1.51), FishMark (1.33), WatDiv (1.32), Bowlogna (1.23), SP2Bench (1.22), BSBM (1.08), DBPSB (1.03), SNB-BI (0.90), SNB-INT (0.863) and TrainBench (0.79).

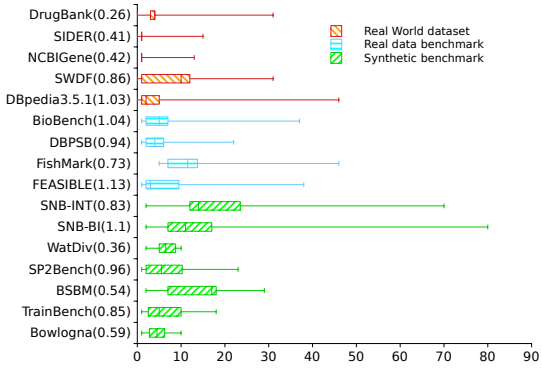


Table 2 shows the percentage coverage of widely used [22] SPARQL clauses and join vertex types for each benchmark and real-world dataset. We highlighted cells for benchmarks that either completely miss or overuse certain SPARQL clauses and join vertex types. TrainBench and WatDiv queries mostly miss the important SPARQL clauses. All of FishMark's queries contain at least one "Star" join node. The distribution of other SPARQL clauses, such as subquery, `BIND`, aggregates, solution modifiers, property paths, and

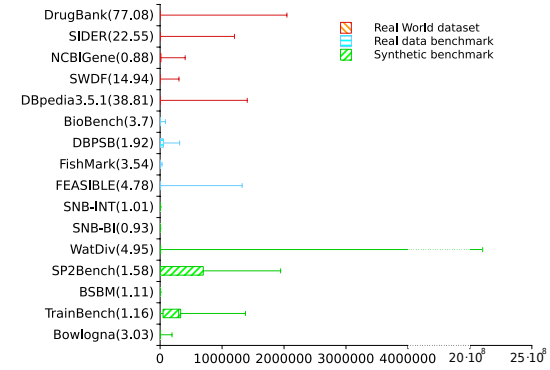
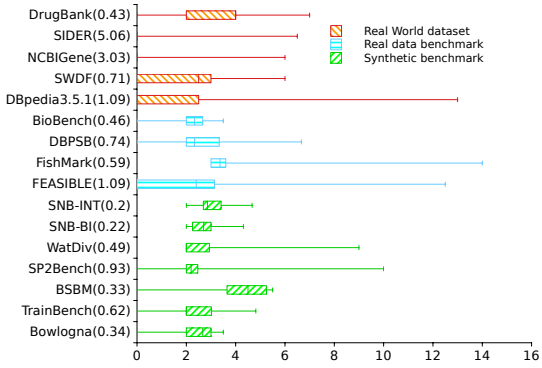
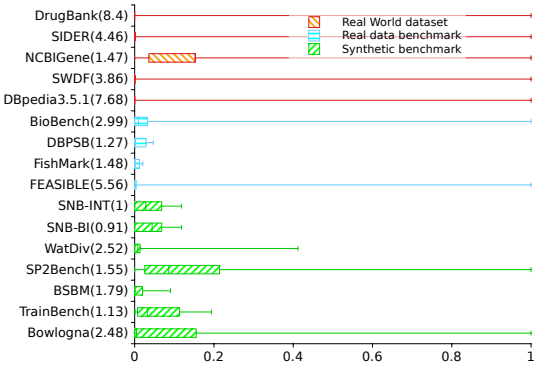


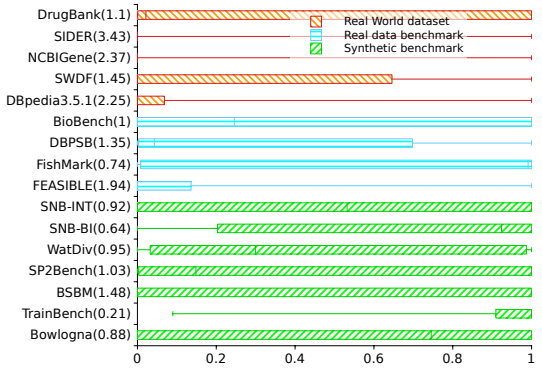
(a) No. of projection variables



(b) No. of join vertices



(c) No. of triple patterns



(d) Result size

services are provided in the LSQ versions of each of the benchmark queries, available from the project website.

4.3 Performance Metrics

This section presents results pertaining to the performance metrics discussed in Section 2.3. Table 3 shows the performance metrics used by the selected benchmarks to compare triplestores. The query runtimes for complete benchmark's queries is the central performance metrics and is used by all of the selected benchmarks. In addition, the QpS and QMpH are commonly used in the query processing category. We found that in general, the processing overhead generated by query executions is not paid much attention as only SP2Bench measures this metric. In the "storage" category, the time taken to load the RDF graph into triplestore is most common. The in-memory/HDD space require to store the dataset and corresponding indexes did not get much attention. The result set correctness and completeness are important metrics to be considered when there are large number of queries in the benchmark and composite metrics such as QpS and QMpH are used. We can see many of the benchmarks do not explicitly check these two metrics. They mostly assume that the results are complete and correct. However, this always might not be the case [23]. Additionally, only BSBM considers the evaluation of triplestores with simultaneous user requests with updates. However, benchmarks execution frameworks such IGUANA [10] can be used to measure the parallel query processing

Table 2: Coverage of SPARQL clauses and join vertex types for each benchmark in percentages. SPARQL clauses: `DIST[INCT]`, `FILT[ER]`, `REG[EX]`, `OPT[IONAL]`, `UN[ION]`, `LIM[IT]`, `ORD[ER BY]`. Join vertex types: Star, Path, Sink, Hyb[rid], N[o] J[oin]. Missing ● and overused ● features are highlighted.

		Distributions of SPARQL Clauses							Distr. of Join Vertex Type

4.4 Impact of Dataset Structuredness

The dataset structuredness has been regarded as one of the most important RDF dataset feature [12]. However, to the best of our knowledge, the impact of dataset structuredness on query runtimes and result set sizes has not been measured in the literature. To measure this impact, we need to create synthetic datasets of varying structuredness values, all following the same dataset description model or schema and comparably to each others in terms of their sizes. We then need to execute the same set of benchmark queries over the generated datasets and measure the result set sizes and query runtimes. The WatDiv benchmark data generator allows the control of the size of generated datasets as well as the structuredness values of individual entities. However, the task of generating the datasets with exact sizes and structuredness values are difficult to achieve due to the scaling and structuredness factors used to control the size and structuredness of the overall dataset. We generated 10 datasets of varying structuredness values given in Table 4.

We run complete WatDiv queries on the individual datasets by using Virtuso triplestore and measured the result set sizes and runtimes of individual queries. Figure 4 shows the impact of the dataset structuredness values on query runtimes and result set sizes. We can clearly see there is a positive correlation of dataset sturcturedness values and the query runtimes as-well-as result sizes, i.e. the higher the structuredness value of the dataset the higher the result sizes and query runtimes. The result also suggests that there is a direct correlation with the result sizes and the query runtimes.

4.5 Correlation of Query Features vs. Runtimes

In previous sections, we presented the results of some important SPARQL query features that should be considered while designing SPARQL benchmarks. These features were mostly taken from previous works [2, 18, 24] in SPARQL benchmarking. However, an important question to investigate is how significantly these features impact the query runtimes. To this end, we calculated Spearman's correlation of the said query features with the query runtime as shown in Table 5. Note that this table presents combined results obtained from Virtuoso and FUSEKI triplestores. We choose two triplestores as the query planner of the triplestore can greatly affect the query runtimes and hence biased the result towards a particular query planner. The overall results show that the number of projection variables (correlation 0.32) has the highest impact and BGP-restricted triple pattern selectivity (correlation 0.00) has the lowest impact on query runtimes. Yet, the result suggests that there is no single query feature that has a strong or very strong correlation with the query runtimes. This further suggests that the overall query runtime is impacted by a combination of different features.

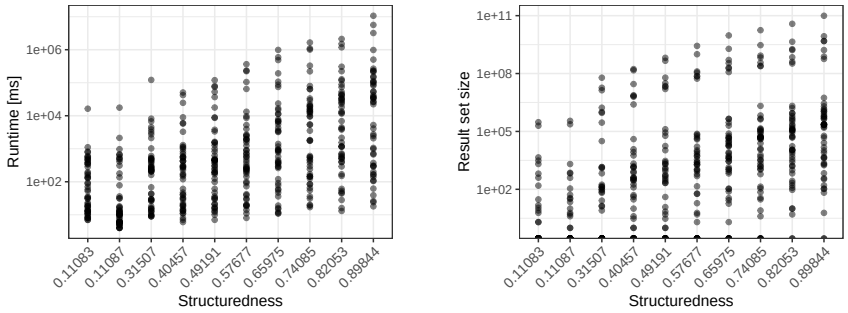

Table 4: WatDiv datasets with varying structuredness values. *DS:* Data Set, *SF:* the Structuredness Factor that controls the structuredness values of the entities used in the datasets.

DS	SF	Structuredness	Total Triples
1	0.1	0,110 878	103 394 017

5 RELATED WORK

Graph structure vs. query performance. The correlation between query runtime and workload metrics were studied in [17]. In addition to standard metrics, the authors introduced composite metrics such as the *absolute difficulty* (logarithm of the search space size), and the *relative difficulty*, which expresses how much worse a query engine does than the theoretical lower bound required by a certain query. The authors generated 12 graphs with different degree distributions along with 25+ queries of different shapes and measured their execution times. Then, they calculated the Kendall's τ rank correlation coefficient for $p < 0.001$ between each metric and the query execution times. The strongest correlation (+0.38) was exhibited by the *absolute difficulty* metric. The goal of gMark [4] is to define a *schema-driven workload generator* that synthesizes graph instances and queries for a given schema. The approach relies on controlling the diversity of the generated graphs and the difficulty of the generated workloads, using a *selectivity estimation* algorithm, which guarantees the selectivity of (certain) generated queries. The flexibility of their approach is demonstrated by generating workloads based on existing RDF benchmarks (SNB, SP2Bench, WatDiv).

Characterization of typed graphs. While this paper focuses on determining the correlation query execution time and graph metrics such as *relationship specialty* and *structuredness* (Sec. 2.1.1), other

(a) Structuredness vs. runtime **(b) Structuredness vs. result set size**

Figure 4: Correlation of structuredness value with runtimes and result set sizes. Note that the structuredness values are slighly off from the configured $[0.1, 0.2, \ldots, 1.0]$ values as the WatDiv generator can only target an approximate structuredness value.

metrics could also provide valuable insight. In particular, the tools of *network science* are often used to uncover the structural interplay between the nodes of a certain graph [9], which in turn could be used to predict the difficulty of querying such graphs. However, most works in the field only target the characterization of homogeneous, untyped networks, which omit a great deal of valuable information when trying to understand the structure of typed networks such as RDF graphs. Only recent research targeted the understanding of typed graphs, referred to as "multilayer", "multiplex", or "multi-dimensional" networks. The authors of [7] generalized the degree distribution to take edge types into account and introduced a set of typed connectivity metrics. Extending this work, the authors of [19] defined a set of additional metrics to characterize the effect of types on nodes and edge pairs. Meanwhile, paper [6] introduced variants of the local clustering coefficient that described the ratio of typed triangles in the network. Survey [1] summarizes the state-of-the-art on analyzing multilayer (edge-typed) networks. Typed graph metrics were used successfully in the context of *model-driven engineering* to describe the structure of system models and distinguish real graph models from synthetic ones [29, 32]. However, these were limited to graphs containing at most 1M nodes.

In the fields of *semantic web* and *database engineering*, a set of simple typed graph metrics were proposed in the context for *social network analysis* in [13]. The concept of "meta-path", a path with a given sequence of node/edge types and its related literature were investigated in survey [28]. Duan et al. [12] presented the structuredness values of several real-world datasets and synthetic benchmarks. RBench [20] introduced the relationship specialty metric and compared real datasets with datasets synthesized by data generators. WatDiv [2] introduced the Join-restricted and BGP-restricted triple pattern selectivities as important query features.

Our work. In this paper, we conducted a systematic survey to collect a current list of triplestore benchmarks. We collected important query and dataset features from state-of-the-art [2, 12, 20, 24] and added additional important query features such as the number of projection variables, the number of BGPs, the number of LSQ features, etc. We compared 11 triplestore benchmarks and 5 real-world datasets across the identified important data and query features. We also measured the correlation of the identified query features with the overall query runtime. To the best of our knowledge, there exists no such detailed analysis of triplestore benchmarks.

6 CONCLUSION AND FUTURE WORK

We performed a comprehensive analysis of existing benchmarks by studying synthetic and real-world datasets as well as by employing SPARQL queries with multiple variations. Our evaluation results suggest the following: (1) The dataset structuredness problem is well covered in recent synthetic data generators (e.g., WatDiv, TrainBench). The low relationship specialty problem in synthetic datasets still exists in general and needs to be covered in future synthetic benchmark generation approaches; (2) The FEASIBLE

framework employed on DBpedia generated the most diverse benchmark in our evaluation; (3) The SPARQL query features we selected have a weak correlation with query execution time, suggesting that the query runtime is a complex measure affected by multi-dimensional SPARQL query features. Still, the number of projection variables, join vertices, triple patterns, the result sizes, and the join vertex degree are the top five SPARQL features that most impact the overall query execution time; (4) Synthetic benchmarks often fail to contain important SPARQL clauses such as `DISTINCT`, `FILTER`, `OPTIONAL`, `LIMIT` and `UNION`; (5) The dataset structuredness has a direct correlation with the result sizes and execution times of queries and indirect correlation with dataset specialty. As future work, we endeavour to broaden the scope of our analysis by adding more types of SPARQL query benchmarks (e.g., using reasoning, querying streams) and investigating more typed graph metrics on benchmark data sets.

ABSTRACT

In this paper, we quantify the impact of self- and cross-excitation on the temporal development of user activity in Stack Exchange Question & Answer (Q&A) communities. We study differences in user excitation between growing and declining Stack Exchange communities, and between those dedicated to STEM and humanities topics by leveraging Hawkes processes. We find that growing communities exhibit early stage, high cross-excitation by a small core of power users reacting to the community as a whole, and strong long-term self-excitation in general and cross-excitation by casual users in particular, suggesting community openness towards less active users. Further, we observe that communities in the humanities exhibit long-term power user cross-excitation, whereas in STEM communities activity is more evenly distributed towards casual user self-excitation. We validate our findings via permutation tests and quantify the impact of these excitation effects with a range of prediction experiments. Our work enables researchers to quantitatively assess the evolution and activity potential of Q&A communities.

1 INTRODUCTION

Why and *how* some Question & Answer (Q&A) communities gain traction and attract activity from large numbers of users—while others do not—are questions of theoretical and practical relevance [31, 38]. Understanding how users become active in such systems, and how user activity evolves over time, can be considered an important stepping stone towards better modeling and shaping of online Q&A communities. This will allow to devise novel approaches to guide and encourage activity [12] and to support community managers in their community building efforts [2, 20].

User excitation. In this paper, we investigate *self-excitation* and *cross-excitation* of users in Q&A communities. Self-excitation reflects how a user's *own* past activity shapes her future activity, while cross-excitation reflects how *other users'* past activity influences future activity of a given user. Modeling temporal traces of user activity informs the inference of excitation effects and thus provides a first step towards deeper causal analysis of user excitation.

In the present work, we adopt point processes [7–9]—in particular Hawkes processes [14]—to leverage temporal traces of user activity as latent indicators of self- and cross-excitation. We empirically analyze 69 Stack Exchange Q&A instances where we fit a multivariate Hawkes process model[1]. With that, we are able to analyze self- and cross-excitation of users across: (i) communities with growing and declining activities, (ii) the topics of the conversations, (iii) activity types (e.g., question, answers), and (iv) activity source (e.g., power user, casual users). Subsequently, we characterize self- and cross-excitation as a function of community age. We then validate, with a range of statistical tests, the excitation effects we uncover, and we quantify their relative importance in the evolution of Q&A communities with a prediction experiment. We illustrate various types of excitation and how they generate user activity in Figure 1.

Findings. Our empirical findings emphasize the need for Q&A communities to maintain a steady core of highly cross-excited power users (i.e. very active users) reacting, particularly in a community's early stages, to the community as a whole. In thriving communities, casual users (less active users) shape each others' activity levels via cross-excitation. This suggests that growing communities are, in general, facilitating and embracing less active and casual users, thereby offering low barriers of entry. Additionally, we observe late-stage domination of self-excitation over cross-excitation, meaning

[1] We make our code available at https://github.com/tfts/Excitation_in_QA.

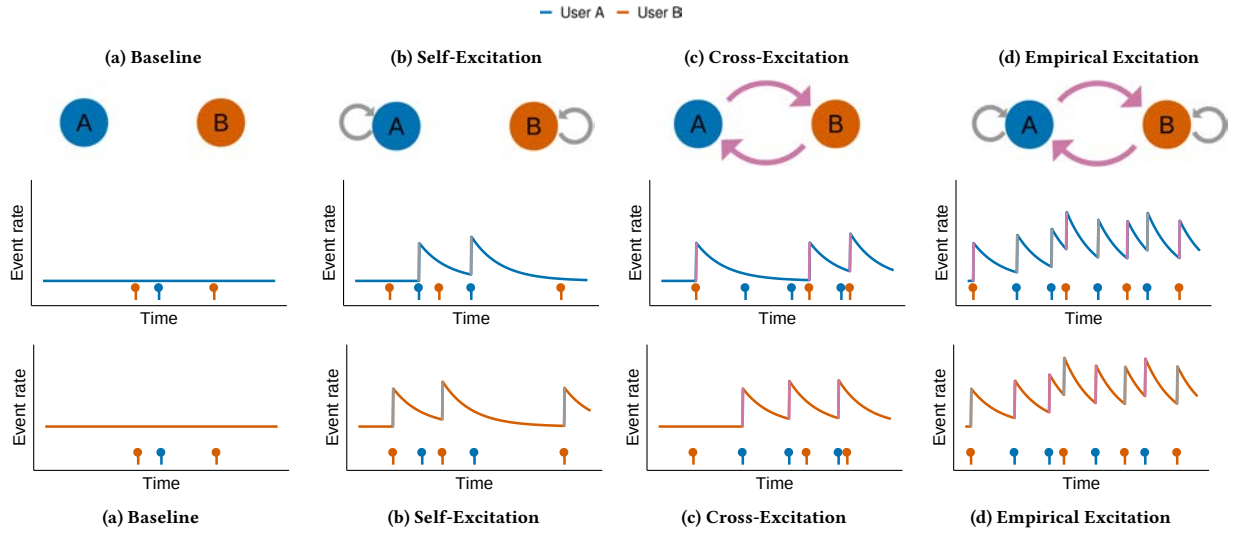

Figure 1: Excitation types. We distinguish between three drivers of user activity excitation: (a) Baseline, a constant base event rate level, (b) Self-Excitation, a proxy for increased propensity by a user to be active in the future following her past activity, and (c) Cross-Excitation, a boost to event rate triggered by activity of other users. The upper row of this Figure depicts the links between users A and B per excitation type, and the two lower rows the corresponding event rate as it reacts to the user's own and others' activity events, marked by the trees below each event rate line and colored by the corresponding user. The first three excitation types cover excitation components which combine to form (d) empirical excitation. This work characterizes and quantifies how each type of excitation manifests itself in Q&A communities and how excitation strength changes over time as a Q&A community develops.

that self-driven activity becomes a crucial factor in successful communities. This effect may serve as a long-term growth indicator, as this self-excitation dominance is most prominent in growing communities. Finally, we observe differences in user participation across distinct topics: Q&A communities dedicated to topics in the humanities (such as languages) are more driven by cross-excitation of power users, whereas those in STEM-related fields are not.

With our work we make the following contributions. First, we model self- and cross-excitation effects in successful and unsuccessful Q&A communities. Second, we empirically show how self- and cross-excitation manifests in communities defined by different levels of success and different topics. Third, our validation provides a foundation for building further predictive models of user activity in Q&A communities. Finally, we provide and illustrate an approach that allows community managers to quantitatively compare long-term dynamics of their online Q&A communities—in terms of user excitation—to well-established ones.

2 HAWKES PROCESSES

A point process can be broadly defined as a collection of points randomly located in some mathematical space. Temporal point processes employ the real line, representing time, as the underlying mathematical space. For the interested reader, the work by Daley and Vere-Jones [8, 9] and by Cox and Isham [7] are comprehensive references on point process theory.

In practice, temporal point processes model the arrival of discrete events over time with the help of a *conditional intensity function* λ^*, a stochastic model for the arrival of the next event given the event history. Hawkes processes [14] are a particular class of temporal point processes, which assume a particular functional form for the intensity function. Specifically, the intensity function of Hawkes processes is in itself a stochastic process and it explicitly encodes *self-excitation*, the increase in intensity caused by past events:

$$\lambda^*(t) = \mu + \sum_{t_i < t} \alpha e^{-\beta(t-t_i)}, \tag{1}$$

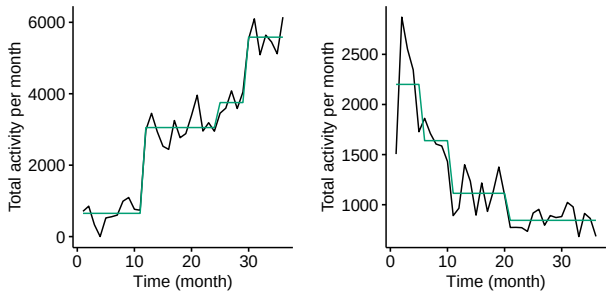
where $\mu > 0$ is the baseline intensity independent on the event history, and $\alpha, \beta > 0$ establish the dependence on previous events. In particular, each previous event at time t_i increases the intensity by α, the self-excitation factor. We choose to let the intensity jumps exponentially decay at the rate β, which is a commonly used functional form of intensity decay called an *exponential kernel*.

Equation 1 describes *univariate* Hawkes processes, as they consider only the effect of past events in future event times of the same event stream. The *multivariate* generalization of univariate Hawkes processes includes not only self-excitation but also *cross-excitation*. Cross-excitation is the intensity increase that an event in one event stream implies in another event stream. More formally, let $\boldsymbol{N}(t) = (N^1(t), N^2(t), \ldots, N^M(t))$ be a simple multivariate point process, where each of the $N^i(t)$ is a counting process in the i-th dimension. An M-variate Hawkes process with an exponential kernel is defined by the following intensity function:

$$\lambda^{*m}(t) \quad = \quad \mu_m + \sum_{n=1}^{M} \sum_{t_i^n < t} \alpha_{mn} e^{-\beta_{mn}(t-t_i^n)}. \tag{2}$$

We write μ_m as the baseline intensity in dimension m, α_{mn} as the cross-excitation on dimension m caused by an event in dimension n and the corresponding decay rate as β_{mn}. In matrix notation, we

write $\boldsymbol{\mu} \in \mathbb{R}^M$, $\boldsymbol{\alpha} \in \mathbb{R}^{M \times M}$ and $\boldsymbol{\beta} \in \mathbb{R}^{M \times M}$. Linniger [23] provides a more detailed treatment of multivariate Hawkes process theory.



Samples from multivariate Hawkes processes, which can be obtained via Ogata's thinning algorithm [27], generate self-excitation and cross-excitation effects of the kind depicted in Figure 1, where users A and B correspond to two dimensions of a Hawkes process and their event rate to the Hawkes process intensity. We observe, in both dimensions, intensity peaks corresponding to the sampled events, and we note the intensity decays exponentially until converging to the baseline intensity level $\boldsymbol{\mu}$.

Fitting Hawkes processes. Given an observed sequence of events $\{t_i\}$, we fit the parameters of Hawkes processes by maximizing its *log-likelihood*. Closed form expressions for the log-likelihood can be derived for many different types of intensity function kernels, including the exponential kernel that we assume. For a given $\boldsymbol{\beta}$, all other parameters of the process may be estimated by maximizing the log-likelihood via well-known convex optimization methods such as Levenberg-Marquardt [21]. However, fitting $\boldsymbol{\beta}$-s is a challenging task, since the likelihood functions of Hawkes processes with exponential kernels are either flat around the optimal $\boldsymbol{\beta}$ (see, for example, Upadhyay et al. [36]) or, in some other formulations of the kernel function, even non-convex in $\boldsymbol{\beta}$. In this paper, we propose an effective Bayesian hyperparameter optimization step, which allows fitting the decay-related and then the remaining parameters of a Hawkes process. Assuming $\beta_{m,n} = \beta, \forall_{1 \leq m,n \leq M}$ [12, 35], we apply the Tree of Parzen Estimators approach, as described by Bergstra et al. [4], on the convex optimization routine of log-likelihood for a given set of event sequences to estimate β. We perform 15 runs of the Bergstra et al. algorithm and keep the β yielding highest likelihood, since this effectively allows for convergence even in the presence of flat plateaus around local maxima of Hawkes likelihood as a function of β. Finally, using the learned β, we fit $\boldsymbol{\mu}$ and $\boldsymbol{\alpha}$.

Furthermore, practical fitting of Hawkes processes requires the fits to be done on *stationary* [23] periods of the corresponding count time series. Stationarity, in this context, refers to translation-invariance in the Hawkes process distribution, which implies a linear growth in the associated time series of event counts over time. However, in the time series representing activity in the Q&A communities we work with, we observe a range of non-stationary phenomena: exponential growth and decline and other sudden structural changes, such as level jumps. Therefore, we need to restrict the fitting procedure to stationary subsequences of an observed event stream. To that end, we use the time series structural change detection algorithm devised by Zeilis et al. [45]. Given a linear regression model, this algorithm returns optimal points in time for structural change in the regression model's fit to a given input time series. Using a constant regression model allows us to detect level changes in an input event count time series, and thus to segment it into stationary subsequences.

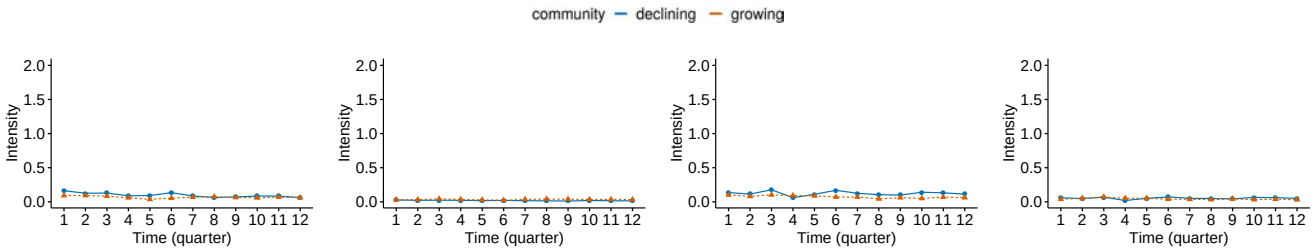
3 EXPERIMENTAL SETUP

We study user self- and cross excitation by empirically analyzing Stack Exchange instances. We distinguish activity in these datasets by two aspects: (i) activity content, which we define as questions and answers (with the latter including answers and comments), and (ii) activity source, meaning whether it originated from highly active (power) or less active (casual) users. Further, we explore the differences in excitation across communities, which we group according to two criteria: (i) growth pattern, and (ii) topical focus.

(a) Growing instance (electronics) **(b) Declining instance (cstheory)**

Figure 2: Exemplary *growing* (left) and *declining* (right) Stack Exchange instances. These two curves exemplify the monthly total activity time series of a *growing* (*declining*) instance, electronics (cstheory). Following Zeilis et al., we indicate stationarity in subsequences of both time series with the green lines. Note that *growth* (*decline*) in electronics (cstheory) was, at 757.62% (−61.63%), one of the highest (lowest) among Stack Exchange instances we analysed.

Datasets. Stack Exchange encompasses several Q&A communities, termed Stack Exchange instances, with each dedicated to Q&A on a single topic, such as computer science, the English language or movies. We extract user activity in all 159 Stack Exchange instances[2] (as of June 2017) as the timestamps of users' activity events: posts (i.e. questions) and replies (i.e. answers and comments). In a first step, we consider these instances' complete history, which spans the period from August 2008 to June 2017 and comprises a total of 22 million events. However, our analysis is independent from the calendar date a Stack Exchange instance originated, as we map the inception of each instance to a time scale starting at zero.



Before we group Stack Exchange instances according to our two criteria, growth patterns and topical focus, we discard all datasets with less than ten events in any period of three months, which ensures that we have enough events for the fitting procedure.

Growth pattern. In our first comparison by growth pattern, we analyze the first three years of existence of Stack Exchange instances, so we exclude datasets with durations shorter than three years. To better distinguish excitation effects driving overall activity increase or decrease in these communities, we then extract, from the remaining datasets, two groups of strongly *growing* and strongly *declining* datasets. The extraction criterion stems from our application of Zeilis et al.'s algorithm to find level structural changes in the time series of total activity count per month: We define a dataset as strongly growing (declining), if the percentage change in structural level from the first fitted window to the last fitted window is in the 80^{th} (20^{th}) percentile over all datasets. The grouping of Stack Exchange instances into *growing* and *declining* yields two groups of 22 datasets each, of which we provide descriptive statistics in Table 1. Note that the *growing* (*declining*) group only includes instances with strongly positive (negative) growth.

[2]The Stack Exchange dataset is available at https://archive.org/details/stackexchange.

Table 1: Dataset characteristics. We show the datasets per group sorted by activity growth (top and bottom three growth percentages per group shown in parenthesis), the total number of datasets per group (#), as well as ranges for a number of descriptive statistics: the activity total as the sum of all questions and answers, the age in years and the total growth as a percentage of the level of the first subsequence found by Zeilis et al.'s algorithm. We observe a clear separation in strongly positive and negative growths (and thus also total activity) in the major distinction we draw between datasets, *growing* vs. *declining*. This distinction is remarkably less pronounced in *STEM* vs. *humanities* instances, which both feature positive and negative growths.

Dataset Group	Datasets	#	Activity total	Age (years)	Growth (%)
Stack Exchange Growing	electronics (757.62%), ru (736.42%), codegolf (510.06%), chemistry, sharepoint, academia, puzzling, tex, codereview, blender, unix, money, gis, ux, crypto, security, stats, salesforce, dba, wordpress (182.28%), opendata (174.69%), askubuntu (169.29%)	22	[7987, 1489384]	[3.08, 7.83]	[169.29, 757.62]
Stack Exchange Declining	boardgames (−28.53%), fitness (−34.56%), sound (−35.01%), productivity, tridion, parenting, pets, craftcms, webapps, spanish, cooking, ham, bricks, gardening, cstheory, expressionengine, pm, skeptics, sustainability, genealogy (−80.26%), ebooks (−81.52%), stackapps (−82.7%)	22	[3301, 117474]	[3, 7.75]	[−82.7, −28.53]
Stack Exchange STEM	electronics (757.62%), chemistry (473.48%), stats (199.18%), biology, datascience, physics, astronomy, cs, space, cogsci, earthscience, engineering, reverseengineering (0.00%), softwareengineering (−21.28%), sound (−35.01%)	15	[15759, 745674]	[2.41, 8.75]	[−35.01, 757.61]
Stack Exchange Humanities	philosophy (122.45%), english (117.76%), chinese (23.17%), music, german, mythology, portuguese, christianity, esperanto, arabic, russian, writers, buddhism (−26.62%), french (−27.91%), spanish (−50.10%)	15	[87, 896631]	[0.17, 6.83]	[−50.10, 127.47]

(a) Baseline of Answers by Power Users (b) Baseline of Questions by Power Users (c) Baseline of Answers by Casual Users (d) Baseline of Questions by Casual Users

Figure 3: Low baseline excitation in *growing* and *declining* communities. Given the Hawkes process dimensions questions and answers per power and casual users, we depict the baseline parameters μ of the Hawkes processes fitted every three months over three years of *growing* (orange lines) and *declining* (blue lines) Stack Exchange instances. Error bars in this Figure and Figures 4 and 5 show bootstrapped 95% confidence intervals, many of which are too small to be visible. Note our use of the same scale in Figures (a)-(d) and throughout Figure 4: The relatively low baseline intensities in comparison to the effects depicted in Figure 4 stress that overall activity is driven by self- or cross-excitation rather than baseline intensity.

We plot the total monthly event counts for a selected dataset from each dataset group in Figure 2 to exemplify their activity curves and the detected structural level changes. Often, there are prolonged periods of stagnancy in one structural level, both in *growing* as well as *declining* datasets. Typically, such periods vary in length.

Topical focus. For the topical comparison, we study Stack Exchange instances dedicated to *STEM* (i.e. science, technology, engineering and mathematics) and *humanities* topics. To that end, we randomly picked a set of 15 Stack Exchange instances we manually classified as STEM topics, and another 15 as humanities. The instances in these two groups vary in size and age, and feature no distinctive growth patterns, although some *humanities* instances are smaller and have shorter overall durations than *STEM* instances (cf. Table 1). In this comparison, we also analyze instances' first three years, but we do not impose a minimum duration, which leads to fewer than 15 instances per group later in time. However, the number of instances per group remains comparable over time and reaches a minimum of nine instances per group by the third year.

Hawkes process application. In the Stack Exchange instances, we distinguish between more active and less active users, which we term *power users* and *casual users*. This definition mainly distinguishes a *core* of remarkably engaged power users typically found in Q&A communities [13, 24, 41] from casual users. Thus, for each dataset individually, we count the total activity per month per user, and per activity type (question or answer) and postulate that power users are those in the 90^{th} percentile of most active users for that month. This implies that this monthly group of power users is ever-changing, as users join and leave the communities or as the users' intrinsic motivation to contribute content rises and falls over time. Note that our results changed only minimally with different percentile thresholds (i.e., 85^{th} and 95^{th}) for power user classification. To measure self- and cross-excitation per user and activity event type, we map the event stream of question and answer activity to

four Hawkes process dimensions: questions by power users, questions by casual users, answers by power users and answers by casual users. For each such dimension, we work with the corresponding event timestamps at the resolution of a second.

We then follow the procedure outlined in Section 2 to fit four-dimensional Hawkes processes to each dataset group (Stack Exchange instances in the groups *declining* vs. *growing* and *STEM* vs. *humanities*). For each dataset group comparison, we begin by fitting overall β for all datasets over the first three years of their existence. Then, we perform structural level change fits on the total monthly event count, and observe a minimal window length of five months. According to our experimentation with different window lengths, specifically two to six months, we find a window length of three months is long enough to ensure we have enough events per window and do not overfit a particular window, while also short enough to capture granular changes in the evolution of the underlying Hawkes process distribution. Hence, we set the constant window length to three months (a quarter).

To measure variability in the evolution of the fitted models, we bootstrap, with 100 repetitions, the fitting procedure of all Stack Exchange instances per dataset group per window. From the resulting bootstrap distribution, we compute 95% confidence intervals for the mean value of each fitted Hawkes process parameter. We display the confidence intervals as error bars in Figures 3, 4 and 5.

4 EXCITATION EFFECTS

4.1 Comparison by growth pattern

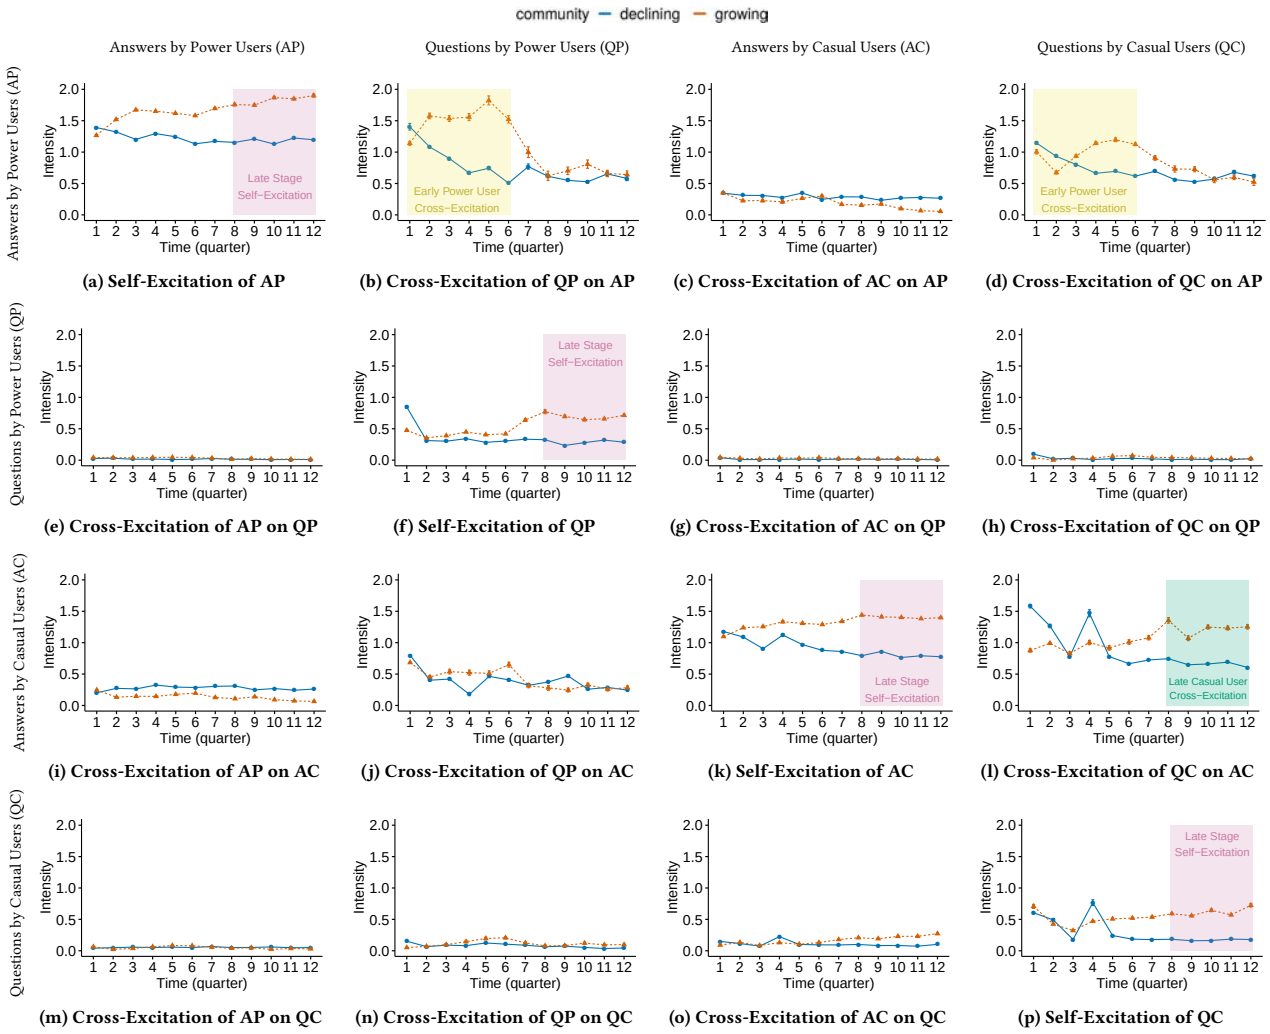
The β value, fitted over 44 datasets in the *growing* vs. *declining* comparison and the whole three year period, is 2.288, corresponding to an intensity half-life of about 0.3 hours (meaning that the intensity jump of magnitude α caused by either self-excitation or cross-excitation decays to $\alpha/2$ after about 18 minutes). With a single constant β, we restrict our model to capture distributional changes in terms of baseline, self- and cross-excitation intensities, allowing us to focus on these factors as direct proxies for the role of different user groups in overall activity intensity over time.

We visualize the evolution of all baseline parameter values for questions and answers by power users and casual users in *growing* (orange) and *declining* (blue) instances in Figure 3. We depict the corresponding self- and cross-excitation parameter values in Figure 4. Note that we employ the same scales throughout both Figures for better comparison.

Low baseline intensities. The Figures 3a through 3d show the baseline intensities ($\boldsymbol{\mu}$) fitted over time. We observe roughly constant baseline intensities throughout the whole period, for both *growing* and *declining* instances. Furthermore, the baseline intensities are rather low, especially in comparison with the self-excitation and cross-excitation effects ($\boldsymbol{\alpha}$) depicted in Figure 4.

Finding: Constant and low baseline intensities suggest Q&A communities thrive off self- and cross-excitation, representing interaction between different user (power and casual) and activity types (questions & answers), rather than featuring constant levels of activity over time, independent from other activity dimensions.

Early Power User Cross-Excitation (■). We continue our analysis with the Hawkes process dimension with the highest intensity values: intensity in answer activity by power users (*first row* in Figure 4, i.e. Figures 4a through 4d). We observe, in the early stages of *growing* instances, high impact of questions by both power as well as casual users on answer activity by power users (see yellow region highlighted in Figures 4b and 4d). In contrast, in *declining* instances, especially in the yellow highlighted region, questions by both types of users elicit declining numbers of answers by power users over time, and self-excitation in answers by power users dominates over all temporal windows. Regarding question activity by power users (*second row* in Figure 4, i.e. Figures 4e through 4h), there is a clear prevalence of self-excitation intensity with respect to other cross-excitation intensities. However, we observe, albeit minor, differences in the short and medium terms between *growing* and *declining* instances, as power users in *growing* instances are more encouraged to participate with new questions as a response to questions by casual users and answers by both (see inlines of Figures 4e, 4g, 4h).



Finding: These observations suggest strong activity by power users, as a response to questions by both power users as well as, crucially, casual users, is related to increased growth in the early stages of Q&A communities. This finding suggests the importance of an active core of users to jumpstart Q&A community development.

Late Casual User Cross-Excitation (■). In Figure 4's *third row* (Figures 4i through 4l), we highlight another type of effect: Answers and discussion by casual users is driven strongly by questions also from casual users, especially in the long-term as highlighted by the green region of Figure 4l. The main difference between *growing* and *declining* instances in this dimension is, besides the intensity magnitude difference, that this cross-excitation effect loses importance in the long-term in the *declining* instances, while overall it does not in *growing* instances. We point out one interesting effect in the *fourth row* (Figures 4m through 4p), which depicts the question intensity dimensions of casual users: In the long term, there is a small increase in questions by casual users after answers also by casual users in *growing* Stack Exchange instances (cf. quarters eight through twelve of Figure 4o).

Finding: Long-term cross-excitation from questions on answers by casual users is a key factor present in *growing* Stack Exchange instances and lacking in *declining* ones. We find contributions by casual users thus attract more participation by casual users, likely helping to sustain and even enhance activity levels. Hence, we identify openness from the community towards casual users in the form of healthy interaction between them as a sign of enduring community growth.

Late Stage Self-Excitation (■). In the diagonal of Figure 4, consisting of Figures 4a, 4f, 4k and 4p, we observe strong and growing self-excitation effects, which dominate over cross-excitation effects in the long-term. We indicate long-term with the pink region marking quarters 8 to 12, the last five quarters we fit. We note this effect is most predominant in *growing* communities. Further, for *growing* instances, notice that, for a given dimension (e.g. answers by power users, Figures 4a through 4d), the timing of the surge in self-excitation coincides in general with a decline in cross-excitation.

Finding: In *growing* Stack Exchange instances, we attribute the phenomenon of higher long-term self-excitation to steadily growing arrivals of questions and answers from power and casual users. As users react to a constantly and regularly growing pool of questions and answers, this makes distinction of direct interaction between

(a) Self-Excitation of AP (b) Cross-Excitation of QP on AP (c) Cross-Excitation of AC on AP (d) Cross-Excitation of QC on AP

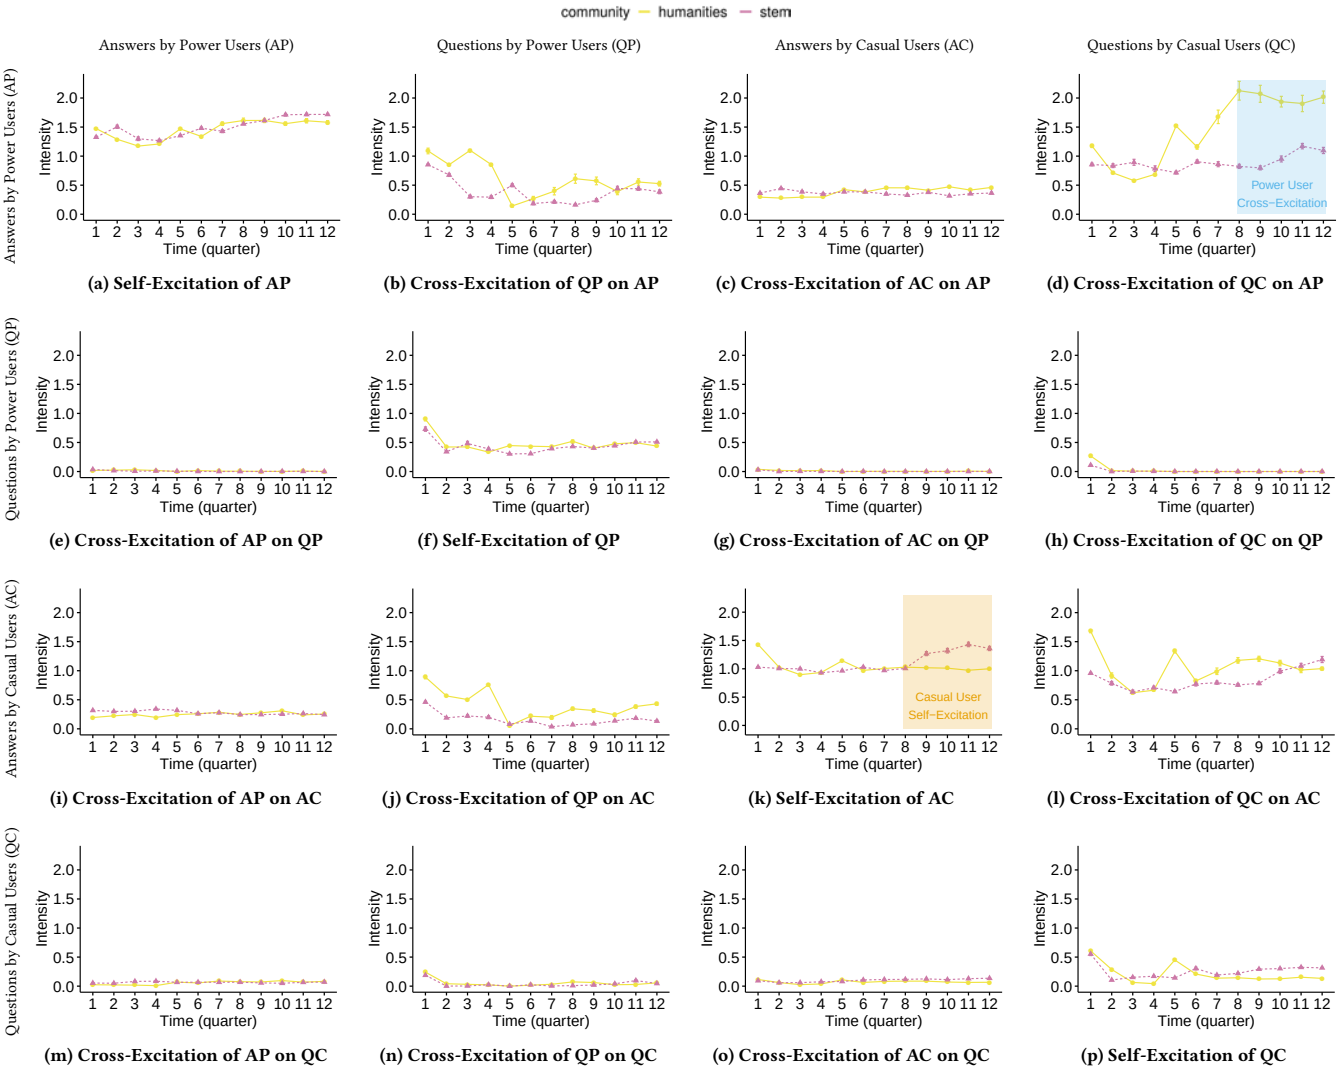

Figure 4: Excitation in *growing* vs. *declining* communities. Given the Hawkes process dimensions questions (Q) and answers (A) per power (P) and casual (C) users, we depict the α matrix of self-excitation (diagonal plots) and cross-excitation (off-diagonal plots) parameters of the Hawkes processes fitted every three months over three years of *growing* (orange lines) and *declining* (blue lines) Stack Exchange instances. The first and second row, respectively, show how answer and question intensities by power users are self- and cross-excited, and the third and fourth the influence on answer and question intensity by casual users as a result of self-excitation and cross-excitation. The yellow highlighted regions ( ) of Figures (b) and (d) depict the effects of questions by power and casual users on answers by power users and thus the crucial importance of power user cross-excitation in driving early stage dynamics of *growing* instances. In Figure (l) we observe another difference between the groups: *growing* communities also thrive off interaction between casual users, as shown by long-term cross-excitation of questions by casual users on answers by casual users (cf. green region of Figure (l)). In the long-term, self-excitation (pink highlighted regions of diagonal entries, i.e. Figures (a), (f), (k), and (p)) is the most dominant form of excitation in all four Hawkes process dimensions.

single questions and corresponding answers harder over time. The timing of this self-excitation surge may be of particular interest for Q&A community managers, who may be concerned about growth should they not observe this effect by the community's third year.

4.2 Comparison by topic

The comparison between *STEM* and *humanities* instances of Figure 5 shares a few commonalities with our previous findings on the *growing* and *declining* instance comparison: roughly constant and relatively low baseline intensities (not depicted due to limitations in space) and comparatively high long-term self-excitation. In this comparison, we obtained $\beta = 2.067$, which corresponds to an intensity half-life of 0.33 hours. These values are comparable to the ones we obtained previously, which may indicate a universal pattern of user activity decline across Stack Exchange instances.

Power User Cross-Excitation ( ) vs. Casual User Self-Excitation ( ). In the light blue highlighted region of Figure 5d,

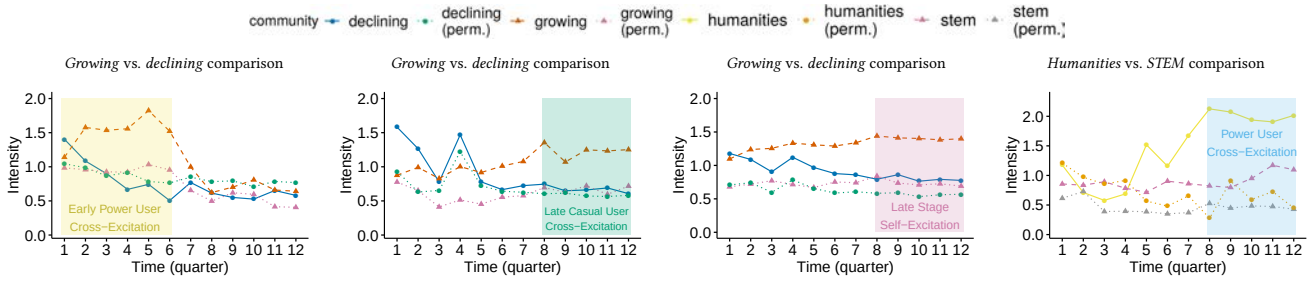

Figure 5: Excitation in *humanities* vs. *STEM*. Using the same notation and format as Figure 4, we depict the parameters of the Hawkes processes fitted every three months over three years of Stack Exchange instances dedicated to *STEM* (purple lines) and *humanities* (yellow lines) topics. We observe a more prominent role by power users in *humanities*, as indicated by by the more important role of power user cross-excitation originating from power users answering questions by casual users (cf. blue highlighted region ■ of Figure (d)). Furthermore, regarding casual user activity in *STEM* vs. *humanities* instances, we note the former's casual users feature more prominently in the long-term in the form of higher answer self-excitation (cf. orange highlighted region ■ of Figure (k)).

we stress the notable role of answer activity by power users in *humanities* instances. We observe answers by power users after questions from casual users is notably higher in *humanities* instances than in *STEM* instances (see Figure 5d). With the light orange region of Figure 5k, we underline the counterpart in casual user activity: There are higher long-term intensities in self-excitation of answers by casual users in *STEM* instances as compared to *humanities*.

Finding: In comparison with *STEM* Stack Exchange instances, *humanities* Stack Exchange instances are more reliant on cross-excitation by power users to address questions by both types of users. We observe more power user centric interactions in Stack Exchange instances in the *humanities*, while activity in *STEM* Stack Exchange appears more focused on casual users. Higher long-term self-excitation by casual users in *STEM* instances indicates stronger interactions between casual users. In turn, casual user activity is less dependent on power users in these instances. Overall, this finding suggests the existence of topic-dependent user type structures, which can be cast as measurable goals for community managers.

5 EVALUATION

In this section, we assess whether differences in excitation effects we observe in the evolution of *growing* vs. *declining* (*STEM* vs. *humanities*) instances result by chance or if there is some causal link between excitation, as measured with the Hawkes processes,

(a) Permuted Cross-Excitation of Questions by Power Users on Answers by Power Users

(b) Permuted Cross-Excitation of Questions by Casual Users on Answers by Casual Users

(c) Permuted Self-Excitation of Answers by Casual Users

(d) Permuted Cross-Excitation of Questions by Casual Users on Answers by Power Users

Figure 6: Permuting event sources destroys observed excitation effects. We illustrate the temporal evolution of selected cross-excitation effects of multivariate Hawkes process models fitted to both the original (solid lines) as well as the permuted event streams (dashed lines) of the *growing* vs. *declining* and *STEM* vs. *humanities* comparisons of Stack Exchange instances. The permuted event streams in the colored regions of this Figure feature only few of the differences of the original event streams, and, for differences that remain (e.g. of Figure (c)), they are of perceptibly lower magnitude. Hence, the absence of effects in permuted event streams strengthen the significance of our main findings.

and community growth (topical focus). Moreover, we evaluate the sizes of the observed effects by quantifying their impact on the future user activity.

Comparison of activity distributions. While the comparison of *growing* vs. *declining* instances aims to distinguish excitation effects in instances of increasing vs. decreasing and thus different total activity volumes, the *STEM* vs. *humanities* comparison is intended towards providing decoupled effects, which ideally should not be confounded with the excitation effects of *growing* vs. *declining* instances. However, in the *STEM* vs. *humanities* instance comparison, we highlight long-term self-excitation in answers by casual users, an effect which could be similar to the late stage self-excitation of *growing* vs. *declining* instances. Furthermore, if *humanities* instances simply featured overall higher answer-based activity levels by power users than in *STEM* instances, power users would also likely react stronger to questions by casual users, as opposed to them being an inherently more important backbone to questions by casual users.

Hence, we verify if the total answer-based activity distributions of both user types are similar in *STEM* and *humanities* instances. We compare the sample distributions of answers-based activity by power (and separately casual) users in *STEM* vs. *humanities* instances with the Kolmogorov-Smirnov two-sample test for their equality. As this test results in a p-value of 0.3855 (0.2305) for power (casual) users' activity distributions, we conclude there is not enough evidence to reject the null hypotheses of the probability distributions being equal at all usual significance levels. In turn, this test result indicates that the power and casual users' activity distributions are comparable, which supports our finding regarding the importance of the role power (casual) users play in *humanities* (*STEM*) Stack Exchange instances.

Permutation tests. To assess the significance of the excitation effects we conduct the following permutation test. First, we randomly permute the association of event types (questions by power users, questions by casual users, answers by power users and answers by casual users) to the corresponding time stamps per time window. This procedure keeps the amount of events per event type constant, but destroys the temporal connection between event types. Then, we refit the multivariate Hawkes processes over windows of these permuted event streams, and we repeat these two steps 100 times. Finally, we compare the difference in mean Hawkes process parameter values fitted on the permuted event streams to the original ones. If there is a notable difference between them, then this indicates that growth (or the evolution of the topical instances) does not come about by chance, but that differences in self-excitation and cross-excitation between *growing* vs. *declining* (*STEM* vs. *humanities*) communities play an important role in their temporal evolution. We depict the result of these permutation tests in Figure 6, in which previously described differences between *growing* vs. *declining* and *STEM* vs. *humanities* Stack Exchange instances are all either remarkably weaker or non-existent. We arrive at similar results with the permutation tests on the other effect not included in Figure 6 (namely casual user self-excitation, in the *STEM* vs. *humanities* comparison). Inspired by Chandrasekharan et al.'s [6] quantification of differences in permutation test distributions, we numerically summarize our permutation tests with a comparison of the absolute difference of *growing* vs. *declining* (*STEM* vs. *humanities*) Hawkes process parameter values fitted on the original event streams with the distribution of absolute differences in parameter values obtained on permuted event streams. If the difference in original values is extreme in relation to the distribution of permuted values in the effects' time spans, then this is further evidence the effects we observe are unlikely to arise by chance. We quantify "extreme" with the p-value, in this case the proportion of values from the permuted difference distribution greater than the original difference. Over the quarters per effect time span, almost all p-values are smaller than or equal to 0.01[3]. Thus, we find the existence of a weak causal link between excitation effects in Stack Exchange instances and their temporal evolution in terms of activity volume.

[3]Single exception: Early Power User Cross-Excitation in quarter one (p-value 0.04).

Table 2: Kolmogorov-Smirnov (K-S) distance between predicted and real interevent times, per predicted quarter, effect type, Hawkes process dimension and model variant. Lower K-S values are better. Distance values marked with an asterisk correspond to not rejecting equality of simulated and real interevent times. The Full model produces forecasts with lowest K-S distances and highest number of non-significant distances. Thus, as the Excitation Effects Removed model features higher K-S distances than the Full model, we find all excitation effects are important for prediction. To quantify the importance of each excitation effect, we observe removing Late Stage Self-Excitation (■) in the Excitation Effects Removed model is most detrimental for prediction performance (cf. high values in mid-section of four rightmost columns). Hence, Late Stage Self-Excitation is most important for prediction, followed by Early Power User (■) and Late Casual User (■) Cross-Excitation.

Prediction experiment. To quantify the impact of the observed excitation effects on future activity, we design the following prediction experiment. For each three-month time window (quarter) and for each *growing* and *declining* Stack Exchange instance, we fit three variants of the Hawkes process, with the same four dimensions as previously: answers by power users, questions by power users, answers by casual users and questions by casual users. The Hawkes process variants we consider are (i) a multivariate baseline model (i.e., a multivariate Poisson process), consisting of only baseline excitation $\boldsymbol{\mu}$ (Baseline in Table 2), (ii) a reduced model where we fit a full Hawkes process model but set the model parameters corresponding to the observed excitation effect to zero for quarters in which we observe a given excitation effect (i.e., we set cross-excitation of power users to zero for quarters one to five to remove the effects of Early Power User Cross-Excitation effect, then we set cross-excitation of casual users to zero for quarters eight to eleven to remove Late Casual User Cross-Excitation effect, and finally we set self-excitation of all users to zero also for quarters eight to eleven to remove the effects of Late Stage Self-Excitation effect) (Excitation Effects Removed), and (iii) a full Hawkes process model as defined in Equation 2 (Full), which we fit in the same manner as when uncovering excitation effects.

Overall, Hawkes process-based models such as ours are suited to forecast event timings, as classical machine learning approaches cannot make such time predictions (cf. e.g. Kurashima et al. [19]). Hence, for each variant of the Hawkes process, each Stack Exchange instance, and for each quarter that we fit, we predict the next quarter's event times by simulating the fitted process 100 times. To assess the model's performance we first compute the distribution of interevent times as well as event counts in all dimensions for each simulated and for given observed event sequences. Then, for each simulated quarter, we compute the mean of the Kolmogorov-Smirnov (K-S) test statistic to compare distributions of interevent times (and the root mean squared error (RMSE) to compare the event counts) between simulated and real events. We list the K-S test distance values for each predicted quarter in Table 2. We highlight, with an asterisk, values of the K-S test distance which correspond to not rejecting the hypothesis of equality of simulated and real interevent times at all usual significance levels.

We observe best K-S distance values overall for the Full model, indicating the overall importance of observed excitation effects at every developmental stage of a Stack Exchange instance for prediction experiments. Moreover, the very poor performance of the Excitation Effects Removed model, at times worse than the Baseline model, reinforces the importance of the effects we found for modeling and prediction. However, there seems to be a difference in the impact of different observed effects on the prediction performance. In particular, removing two cross-excitation effects (i.e., Early Power User Cross-Excitation and Late Casual User Cross-Excitation effect) from the models does not impair the performance of those models as strongly as the removal of Late Stage Self-Excitation effect. In Table 2's columns corresponding to the two Cross-Excitation effects, a comparison of predictions by the Excitation Effects Removed model with the corresponding predictions by the Full model reveals their differences in K-S distances lie in the interval $[-0.01, 0.04]$. In these cases, the Full model has only slightly better performance. On the other hand, the impact of the Late Stage Self-Excitation effect dramatically impairs the performance of the Excitation Effects Removed model. The differences between K-S distances in this case (cf. predictions by the Full model and the Excitation Effects Removed model in the Late Stage Self-Excitation columns of Table 2) range from 0.06 to 0.32, indicating a larger effect size of self-excitation than that of cross-excitation.

To further validate these results we perform another prediction experiment with a fourth variant of Hawkes processes. In this variant, we fit self-excitation only models by setting all cross-excitation parameters to zero. These additional experiments with a self-excitation model confirm previous observations: A model with only self-excitation achieves performances (as measured by

the K-S distance and by the event count RMSE) in general on par with those of the Full model and, in the Late Stage Self-Excitation effect, even surpassing its performance slightly.

For all model variants we come to comparable conclusions when measuring the RMSE between simulated and real event counts. Limited by space, we summarize these results: The average RMSE of the Full model is 638.17 events, an improvement of 59.91% (43.09%) upon the Excitation Effects Removed (Baseline) model.

6 LIMITATIONS

Although we experimented with slightly different percentiles in the user type distinction and the instance characterization and obtained qualitatively similar results, we recognize those are arbitrary thresholds, which impact the results if changed significantly. Our results are more robust to changes in window size of the activity event stream of the Q&A communities (e.g. to two, four or five months), since this hyperparameter controls for the granularity of our results. Nevertheless, the Hawkes process model itself could include time-varying parameters, as an alternative to this repeated fitting procedure we apply over fixed time windows.

The effect time spans we propose, namely a one-and-a-half-year-long early stage and a late stage starting in the last quarter of the second year of a Q&A community, stem from our empirical observations of large differences in excitation in specific temporal segments in the community comparisons. Pinpointing exact transition dates is beyond the scope of this work, as we focus on learning temporal user excitation effects.

We acknowledge that mapping each user's questions and answers event streams to a Hawkes process dimension may be a more realistic model. However, we argue that such a model would suffer from sparsity, high dimensionality and higher computational cost. Further, such a model might also not improve the excitation effect characterization, as it would also struggle with distinguishing sources of self- and cross-excitation in high-activity regimes.

Note that we avoid a discussion of how casual users become power users with our characterization of power users as the most active each month, regardless of their histories. We believe engagement reward systems such as badges play an important role in casual user's development in particular and user excitation in general [20], but we leave a detailed investigation of the role of reward systems on excitation effects for future work.

We also caution that our work indicates a *temporal* link between (i) specific community structures in terms of user types and their excitation and (ii) the overall development of activity volume in a Stack Exchange community. This work does not establish causality.

7 RELATED WORK

Research on Q&A communities. There is a considerable amount of authors [1, 10, 13, 24, 33, 41] analyzing the roles different types of users play in Web communities such as Q&A websites. In addition, several authors surveyed the motivation and behaviour of individual users [17, 26] of Q&A communities. While Mamykina et al. [24] and Furtado et al. [13] concentrate on uncovering and studying the roles of user types present in thriving Q&A communities, Danescu-Niculescu-Mizil et al. [10] and Yang et al. [41] explicitly focus on specific user types in Web communities and the user types' static and temporal characteristics. More broadly, Yang et al.'s work is part of a larger body of literature [28, 30, 46] on identifying experts in Q&A websites and characterizing their behavior. Our work leverages a comparable user type characterization to infer properties about the temporal evolution of communities themselves.

In approaches methodologically related to Zhang et al.'s [46], multiple authors [3, 25, 31, 38, 39, 43] study evolution dynamics of Web communities by relying on an explicit description of networks underlying a given Web community, and these networks often serve as a basis for dynamical systems models of the communities. In their study of Quora, another Q&A website, Wang et al. [39] analyze the role different social network structures play in Quora's community growth. Ribeiro [31] and Walk et al. [38] model users and activity in diverse Web communities including Q&A communities, with the former focusing on growth and decline of communities and the latter on the model's implications for self-sustainability in a community's activity. Matsubara et al. [25] and Zang et al. [43] study information diffusion and growth dynamics of Web communities.

Similarly to Matsubara et al.'s, Walk et al.'s and Zang et al.'s work, in this paper we also model growth and interaction dynamics of Q&A communities, but we do not assume an underlying network. We focus rather on excitation between groups of users, which we distinguish not on their expertise but on their overall activity levels. Furthermore, by encoding community lifecycles in Hawkes processes fitted to sequences of time windows, we extend the empirical discussion of Web community lifecycles [15, 42] and the critical mass literature [29, 32] to the Q&A community domain with measurable results.

Applications of Hawkes processes. Hawkes processes and their variations, as models for event streams with unequally spaced events in time, have found wide application in literature on different aspects of Web phenomena [12, 16, 36, 37, 44, 47, 48]. One such topic regards content popularity dynamics, in particular how to predict the influence of internal and external aspects of activity in social networks [12] and reshare popularity of items on the Web [47]. To infer causal links between users and user influence from user activity in social networks, Ver Steeg and Galstyan [37], Iwata et al. [16] and Zhou et al. [48] propose point process-related approaches, which cope with high dimensionality in number of users. Further, Upadhyay et al. [36] model the crowdlearning process of Stack Overflow users and characterize different user types by their expertise and learning curves. The work by Zang et al. [44] models and predicts the growth dynamics of individuals' ties in social networks and predicts its evolution.

Our work draws inspiration and methodological know-how from all above mentioned papers to expand on a topic closely related to Zang et al.'s: the development of not just the relatively small circle of an individual's social ties, but of excitation and interaction of user groups in Q&A communities. Furthermore, we contribute, to the growing body of work on fitting Hawkes process kernels [5, 22, 40, 49], a parsimonious Bayesian hyperparameter optimization method for fitting the decay parameter of exponential kernels in Hawkes processes. Finally, our extension of this fitting method to non-stationary multivariate event streams enables the extraction of temporal excitation effects from Q&A communities.

8 CONCLUSIONS

Summary. In this work, we modeled self- and cross-excitation in Q&A communities along several dimensions, including activity type, user engagement level, growth path and topical focus of a given community. We approached this task by fitting multivariate Hawkes processes to stationary temporal segments of Q&A communities' activity volumes. We found stronger cross-excitation of power (casual) users in early (late) stages of growing communities when compared to communities with declining total activity. Further, in growing communities, we observed self-excitation dominates in the long-term. Moreover, we uncovered strong long-term cross-excitation by power (casual) users in Q&A communities dedicated to topics in the fields of the humanities (STEM). We validated the presence of these excitation effects with statistical and permutation tests and we quantified their strength via prediction tasks.

Implications. Our work can support Q&A community managers in their ambition to promote sustainable community structures. To jumpstart community growth in its first six months, engaging a core of power users, for example in community building efforts, appears to be of crucial importance. In the medium- to long-term, we find community developers should carefully monitor and foster participation rather by casual users. While literature on critical mass in Web communities [29, 32] and studies on the user mix in Wikipedia [18, 34] also support this recommendation, we can afford further advice, as our casual cross-excitation analysis specifically underlines the importance of interaction between casual users. In practice, we believe adjusting reward or badge systems to encourage contributions by casual users, perhaps by welcoming newcomers or by easing their adjustment to community rules, would be of value to community development. Furthermore, community managers, which have not observed a surge in self-excitation by the third year of their communities, may have reason to concern over growth. Such excitation effects should be carefully monitored, as Q&A community growth may come at the cost of other community parameters [11]. Furthermore, our results indicate concrete implementations of these suggestions should depend on community topic, as it impacts excitation effects. Overall, our findings thus highlight the impact of timing in the user mix development.

Future work. Comparing other Q&A communities would allow to further generalize the results we obtained on Stack Exchange communities. Our work can be extended to uncover excitation effects in other domains, such as of Q&A instances in other languages or of other contribution types (e.g. open-ended vs. focused question), as our proposed approach is generic and can be readily extended.

ABSTRACT

In the medical domain, systematic reviews are a highly trustworthy evidence source used to inform clinical diagnosis and treatment, and governmental policy making. Systematic reviews must be complete in that *all relevant* literature for the research question of the review must be synthesised in order to produce a recommendation. To identify the literature to screen for inclusion in systematic reviews, information specialists construct complex Boolean queries that capture the information needs defined by the research questions of the systemic review. However, in the quest for total recall, these Boolean queries return many non relevant results.

In this paper, we propose automatic methods for Boolean query refinement in the context of systematic review literature retrieval with the aim of alleviating this high-recall, low-precision problem. To do this, we build upon current literature and define additional semantic transformations for Boolean queries in the form of query expansion and reduction. Empirical evaluation is done on a set of real systematic review queries to show how our method performs in a realistic setting. We found that query refinement strategies produced queries that were more effective than the original in terms of six information retrieval evaluation measures. In particular, queries were refined to increase precision, while maintaining, or even increasing, recall — this, in turn, translates into both time and cost savings when creating laborious and expensive systematic reviews.

1 INTRODUCTION

Systematic reviews are highly reliable sources of evidence, created by synthesising all relevant studies in a comprehensive literature review for a highly focused research question. Medical systematic reviews are held to a particularly high standard because of the role they play in both evidence-based medicine and health policy as a whole. Systematic reviews both inform how medical professionals diagnose and treat patients, and how governing bodies decide upon health management and policies [14].

With the rise of web-based databases of medical literature, now containing tens of millions of medical citations (often in the form of abstract, title, MeSH headings and metadata, which reference full studies of, for example, randomised controlled trials), it is becoming increasingly difficult and highly costly to identify relevant literature to include in a systematic review [29]. For example, one of the most popular web-based databases, PubMed, contains approximately 28 million citations of medical studies. While recall is paramount in that all potentially relevant citations must be retrieved, precision in the case of systematic review literature retrieval is still critically important. Systematic reviews can cost upwards of a quarter of a million dollars [17] and can take several months to complete. A large portion of this cost can be attributed to the screening phase, where there are typically many false positives (i.e., citations retrieved which are not relevant to the research question of the systematic review). For systematic reviews of highly specific areas of medicine, finding relevant studies requires a highly specific query which cannot be too broad (which minimises the false positive rate). For broad studies such as scoping reviews, the query cannot be too specific as to limit the number of relevant citations that are not retrieved (i.e., minimising the false negative rate). This balance of potentially relevant and potentially non-relevant citations is currently managed by the intuition and knowledge of highly trained and skilled information specialists who are deeply familiar with the search systems in which they formulate their queries, and often, but not always, also with the topic of the systematic reviews they are formulating queries for.

The queries that information specialists formulate are highly complex Boolean queries. Systematic review literature search is dependent on, and has always used, Boolean retrieval for two reasons: (i) the Boolean query syntax enables specialists searchers to have fine-grained control over exactly which citations are retrieved, and (ii) the Boolean query which is published alongside the review, is used for reproducibility purposes; for example, when the recommendation of a systematic review is in doubt or a review needs to be updated. Ultimately, the Boolean query controls the outcomes and decisions reached by a systematic review.

This paper investigates automatic methods for refining queries used to retrieve literature for systematic reviews. Prior work by Scells and Zuccon has investigated syntactic transformations of the Boolean query, and have empirically shown that these could improve the effectiveness of the queries originally formulated by

expert information specialists [24]. In their approach, a query was modified at the Boolean query language level — for example, by changing an *OR* operator into an *AND* operator for a specific Boolean clause. These transformations did not add or remove the original query terms. They did not perform query expansion or reduction, apart from making use of, or removing, the Medical Subject Headings (MeSH) explosion operator (which allows for the retrieval of citations that contain MeSH concepts subsumed by the concept specified in the query). In this work, we investigate whether semantic transformations (query expansion and reduction by drawing upon semantically similar terms) can further improve the effectiveness of the Boolean queries. Specifically, the context of this work is to refine existing Boolean queries that have been created for the explicit purpose of systematic review literature search. We define a good query refinement process as one where fewer citations are retrieved, but the number of relevant citations stays the same (or with very minor, tolerable reductions). In Information Retrieval terms, this equates to increasing precision, while maintaining or even improving recall. In the case where recall is improved, note that in the case of systematic reviews, a number of studies that are used to synthesise results are often found *outside* the search process, either by snowballing references (i.e., finding relevant studies by examining the references of retrieved citations), or having prior knowledge of the existence of relevant studies.

The methods proposed in this paper are envisioned not to replace the experience and knowledge of human searchers, but instead, to assist them formulate more effective queries (e.g., explicitly recommending more effective queries). To investigate this topic, we pose the following research questions:

RQ1: Which types of transformations are the most effective at refining Boolean queries in systematic review literature search?
RQ2: What impact do unjudged documents have on the effectiveness of refined Boolean queries in systematic review literature search?

To answer **RQ1**, we first devised a set of strategies to generate semantic and syntactic transformations within the Query Transformation Chain Framework of Scells et al. [24]. These were then applied to the original Boolean queries in an iterative fashion so as to generate a set of transformed query candidates. The generated candidate queries were then represented within a feature space, which was then used to automatically select a transformed Boolean query that was predicted to improve over the original query (if no improvement was predicted, then original input query was retained). We then selected the top query from the set of candidates with a query candidate selector function which maximised a target evaluation measure. The effectiveness of the query refinement was determined by comparing the original queries with the ones that were automatically refined.

To answer **RQ2**, we perform evaluation by considering the unjudged documents that may be retrieved by the automatically refined queries. We do so by considering two methods for computing which portion of the unjudged citations (i.e. the residual) should be used for computing relevance. The methods outlined for **RQ1** and **RQ2** are explained in detail in Section 3.

2 RELATED WORK

The modification or transformation of a query, such as query expansion and query reduction, but not limited to any semantic and syntactic modification (e.g., via synonyms of a term, adding related terms, removing unnecessary terms, correcting spelling mistakes) has been shown to significantly improve the effectiveness of a query [3, 6, 18, 30]. Previous work, however, has focused almost exclusively on non-Boolean queries (i.e., keyword queries).

In the professional search setting, Kim et al. [10] was able to generate Boolean queries using a decision tree method and then automatically suggest queries. A decision tree is generated by selecting unigrams from the top-k pseudo-relevant documents and nodes in the tree are selected with a probability of that term appearing or not in the pseudo-relevant set (leading to conjunction and negation). Queries are then suggested by training a learning to rank model on query performance predictor (QPP)-based features. Both general-purpose QPPs and Boolean query-specific QPPs are used. When general-purpose QPPs are used, only the query terms that are associated with conjunctions are considered. In the context of systematic reviews, Scells et al. [22] have shown that QPPs were not effective in predicting the performance of queries in this domain.

Karimi et al. [9] have found that simplifying field restrictions and operators, and removing clauses from keyword queries (not Boolean) provides significant improvements in recall for systematic review queries, while degrading precision only slightly. Keyword queries, however, have a major limitation: they do not capture complex information needs by restricting sets of documents; i.e., they operate in a best-match setting where ranking is important[1]. Another perspective is that keyword queries do not allow the information specialist explicit control over the set of documents retrieved.

Because Boolean queries are so deeply engrained in the scientific methodology of constructing systematic reviews, we focus on modifications or transformations that can be applied to Boolean queries. Scells et al. have also investigated the modifications to queries in a systematic review setting in two studies. One study found that integrating clinical labels into the retrieval model (i.e., annotating both queries and documents) significantly improved precision while slightly degrading recall [25]. The other study focused on improving existing Boolean queries with automatic candidate generation and selection [24]. While Scells et al. [24] use only syntactic transformations, we advance the state-of-the-art by integrating syntactic *and* semantic transformations of queries and then automatically selecting the best candidate.

3 METHODOLOGY

3.1 Query Transformation Chain Framework

A query transformation chain is the repeated application of one or more transformations to a query which results in a set of variations of the original query. A simplified example of a query transformation chain is shown in Figure 1, where three transformations (τ_1, τ_2, and τ_3) are applied to three clauses (c_i) of the original query q. This process of applying transformations to clauses of a new query continues until the stopping criteria of the candidate selection function is met. After the transformations are applied, a final, rewritten

[1] Although another task in this domain – screening prioritisation – would benefit from this.

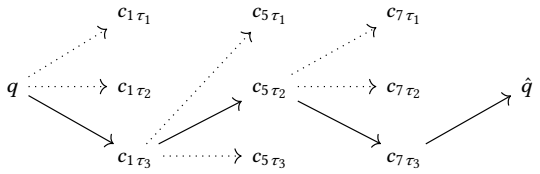

Figure 1: A query q transformed via a query transformation chain into a new query $\hat{q}$. Three transformations (τ_1, τ_2, and τ_3) are applied to clauses (c_i) of a query at each point in the chain. The path of each transformation chosen through the chain is indicated by a solid line. Only the path of transformations taken for $\hat{q}$ are shown.

query $\hat{q}$ is produced. A query chain can either be used to generate all possible variations of a query given the set of transformations, or at each application of transformations, a smaller subset of queries can be chosen. This candidate selection process is described in detail in Section 3.4.

3.2 Query Clause Transformations

Scells et al. [24] considered only syntactic transformations of a query. We extend that work by integrating several semantic transformations. Syntactic transformations are those that modify aspects of the query unrelated to the structure of a query: logical operators, or the fields keywords are restricted to. The other form of transformation is semantic, whereby aspects of a query are modified structurally (through the addition or removal of clauses). In this work, we use six types of transformations: two syntactic, and four semantic. In addition, four of the transformations can be applied to non-atomic clauses and three can be applied to atomic clauses. The six transformations we use in this work are presented in Table 1 with the classification (syntactic or semantic) and the applicability of the transformation (to atomic or non-atomic clauses). Each transformation is described in detail below:

(1) **Logical Operator Replacement** The logical operator replacement transformation syntactically replaces the Boolean operators in a query. For example, `(A **AND** B)→(A **OR** B)`. This transformation only considers `AND` and `OR` operators.
(2) **Field Restrictions** The field restrictions transformation syntactically modifies the fields an atomic clause is restricted to in Boolean search. For example,

```
(cancer[Title] AND lungs[Title])
                ↓
(cancer[Title/Abstract] AND lungs[Title])
```

This transformation produces the following modifications to fields: `title` to `abstract`, `title` to `title & abstract`, `abstract` to `title`, `abstract` to `title & abstract`, `title & abstract` to `title`, and `title & abstract` to `abstract`.
(3) **MeSH Explosion** MeSH is a medical ontology organised in a tree structure. Explosion is the subsumption of all nodes underneath a particular term node in the ontology. MeSH explosion can be considered a semantic transformation in that it implicitly adds terms to a query. This transformation toggles if a MeSH term should be exploded or not. Systematic review query languages all support some way for explosion to be toggled, normally in the retrieval model, thus not explicitly modifying the semantics of a query.
(4) **MeSH Parents** The MeSH parents transformation acts in the opposite direction of the explosion transformation: moving up one level in the tree (if possible), thus selecting a broader MeSH term. For example, if the MeSH term is `Skull Neoplasms`, then this transformation selects the parent term `Bone Neoplasms`.
(5) **Clause Removal** The clause removal transformation semantically modifies a query by removing a non-atomic clause from a query. This transformation will remove atomic clauses from a non-atomic clause until there are no more atomic clauses left (at which point the non-atomic clause that groups them is removed).
(6) **cui2vec Expansion** The cui2vec transformation is a semantic query expansion transformation that uses a pre-trained set of clinical concept embeddings [1] to find related keywords.[2] We first map keywords to concepts using QuickUMLS [27], restricting matches to preferred candidates. Next we find the top-k similar concepts (which are then used as expansions E) using the clinical concept embeddings via cosine similarity; scores are then normalised using the softmax function. A mapping derived by Jimmy et al. [7] is used to map concepts to their most common string. In our experiments, we expand to a maximum of five candidates. To integrate the new expansions into the Boolean query, we replace the original keyword with a logical `OR` operator that groups the expansions. The fields of the expansions are inherited from the original keyword. Finally, the original keyword that was used for expansion is then added to the atomic clauses in the new non-atomic clause.

Table 1: Classification (semantic or syntactic) and Applicability (transformation can be applied to atomic or non-atomic clauses) of transformations used in this work.

Transformation	Classification	Applicability
Logical Operator Replacement	Syntactic	Non-Atomic
Field Restrictions	Syntactic	Atomic
MeSH Explosion	Semantic	Atomic
MeSH Parents (new)	Semantic	Atomic
Clause Removal (new)	Semantic	Atomic
cui2vec Expansion (new)	Semantic	Atomic

3.3 Query Candidate Features

The ranking of query candidates requires discriminative features in order to select the most effective query. We use 39 features in total, described in Table 2. Two notable features which we consider to be novel are Δ, which computes the difference between measurements indicated in Table 2 with †, and ω_i which represents the ith transformation applied to a query in the query chain process.

[2] As the name suggests, the embeddings are for clinical *concepts* (rather than terms), identified as **Concept Unique Identifiers** (CUI) from the UMLS Metathesaurus. A single CUI may represent different names or *strings* in different source vocabularies of the UMLS Metathesaurus.

For performance and effectiveness reasons we do not include general purpose QPPs (Query Performance Predictors) as in similar work [10]. This is because: (i) most QPP measurements rely on costly retrieval statistics which becomes prohibitive with the number of queries that are generated, and (ii) previous work has shown that QPPs are often not correlated with retrieval effectiveness [5, 22] and thus may hamper the quality of ranking.

3.4 Query Candidate Selection

Query candidate selection is the process by which the next candidate to transition to in the query chain is chosen. The formalisation of candidate selection is described as follows. Following the generation of candidate queries $\hat{\mathbb{Q}}_q$ from the initial query q, the next candidate q^* is selected as the next transition in the query chain via the maximisation of function $f(\hat{q})$ where:

$$q^* = \underset{\hat{q} \in \hat{\mathbb{Q}}_q}{\text{argmax}}\, f(\hat{q}) \tag{1}$$

The candidate generation and selection process is repeated until the stopping criteria is met. Here, we define the stopping criteria with two objectives: (i) the query chain reaches a depth of five as in previous research [24], and (ii) the number of retrieved citations for a candidate query is zero.

When generating queries for training purposes, we only considered the stopping criteria when the depth of a chain reached the maximum length of five. We did this so that we would have sufficient negative training examples. In practice, this resulted in a severely imbalanced training set with the majority of examples being negative and only a small portion positive. In training models to maximise the candidate selection objective function, we discovered empirically that removing the majority of negative examples (i.e., rebalancing the positive and negative examples via negative sub-sampling) increased the effectiveness of ranking.

The maximisation function $f(\hat{q})$ can be learnt as a machine learning problem. In this work, we learn $f(\hat{q})$ as both a learning to rank task (similarly as in [24]) and a nearest neighbour task (new to this work). For both tasks, we train a different model for each evaluation measure that we seek to optimise. For the learning to rank task, we use DART: an ensemble of boosted regression trees which incorporates dropouts [21]. In our empirical testing we found this method to be the best for this task when compared to other state of the art techniques such as LambdaMART. For the nearest neighbour task, we create a model which records the most effective query in each topic (given an evaluation measure), and the distance to and reduction in effectiveness for all other queries in that topic. For an unseen set of candidate queries, each target query in the set is ranked by minimising the distance and maximising the score of the queries in the aforementioned model.

3.5 Sampling Query Candidates

In generating training data for automatic query candidate selection methods, we encountered an exponential growth in queries generated. This growth is computationally undesirable: for example, if on average 100 candidates are generated for a query, and the total length of a chain is 5 then a total of 10^9 queries would be generated (n^d where n is the number of candidates and d is the depth). Additionally, if on average it takes 30 seconds to generate a set of queries and features, then for that query it would take over 950 years to complete. For this reason, we sample queries to cut the total number of queries that are included for training. Note that the $O(n^d)$ complexity does not affect testing as we are not exploring the space of transformations for a query, rather we are ranking candidates, selecting and generating transformations for the top-1. Our sampling approach is as follows: for a seed query q, we generate a set of candidate queries $\hat{\mathbb{Q}}_q$; from this set, we randomly sample a minimum of 20 candidate queries and if there are more than 20 queries generated, we sample a further 10%. We then cut further by removing any identical queries that have already been processed. Finally, of the queries that are generated from the previous step, we randomly sample 10% of these new queries and repeat the process.

3.6 Evaluation

We perform evaluation as a standard ad-hoc search task. Relevance assessments are obtained from the studies that are reported in each systematic review as *included* (relevant), and *excluded* (non-relevant). Queries obtained through query refinement may retrieve citations that were not assessed by the reviews (i.e., unjudged); thus, relevance assessments are incomplete. At the first stage we assume all citations which were not judged as non-relevant. Remember, however, that unlike in traditional ad-hoc information retrieval evaluation, no pooling using a large variety of systems was executed: only one query and one system contributed to the relevance assessments — other, non retrieved but relevant citations may very well exist. Thus, later in the analysis of the results, we use two heuristics to bound the effect of unjudged documents on the effectiveness of the studied methods. To this aim, we use and further extend the intuition of residual analysis described for the rank bias precision measure [19]:

3.6.1 Optimistic Residual. The first heuristic consists of assuming all unjudged citations are relevant, as done for the computation of the heuristic in rank bias precision [19]. This value provides the upper bound on the value of the evaluation measure that would be obtained if all citations were assessed.

3.6.2 Maximum Likelihood Residual. The second heuristics attempts to provide a stricter bound than the optimistic residual. To do this, the relevance of an unjudged citation is set according to its probability of being relevant. To estimate this probability, we use the maximum likelihood estimation computed on the set of judged documents:

$$P(\texttt{relevant}|d) = \frac{|\texttt{relevant}|}{|\texttt{relevant}| + |\texttt{non-relevant}|}$$

This could be considered as a rough approximation of the number of relevant and non-relevant citations that would exist, if the relevance assessments for a query were complete. Intuitively, it provides a balance between the existing pessimistic view of unjudged citations and the aforementioned optimistic view of unjudged citations.

4 EXPERIMENTAL SETUP

Experiments were performed on a test collection of 125 systematic reviews [26]. The CLEF2017 TAR collection [8] was not used

Table 2: Features used in the candidate selection task. Applicability denotes to which types of clauses a feature is applicable to: *Atomic* refers to clauses which consist of a single keyword, *Non-Atomic* refers to clauses which group several atomic clauses with a logical operator, and *Both* indicates that the feature can be applied to either type of clause.

Feature	Description	Applicability
Depth	How deep in the query the transformation was made.	Both
Clause Type	The type of clause the transformation was applied to (atomic/non-atomic).	Both
Children Count	Number of sub-clauses a non-atomic clause has.	Non-Atomic
Transformation Type	The type of transformation (Table 1) made.	Both
Logical Operator Replacement Type	The type of operator this type of transformation modified.	Non-Atomic
MeSH Depth	The depth that the MeSH term was exploded from in the MeSH ontology.	Atomic
MeSH Parent	Whether a MeSH parent transformation is made.	Atomic
Restriction Type	Which type of field restriction was made when this transformation was applied.	Atomic
Clause Removal	Whether a clause removal transformation has been made.	Atomic
cui2vec	Whether a cui2vec Expansion has been made.	Atomic
cui2vec Expansions	The number of expansions that were made when this transformation was applied.	Atomic
MeSH Exploded	If the MeSH heading in an atomic clause is exploded or not.	Atomic
Truncated	If an atomic clause has a character replacement expression (e.g., wildcard).	Atomic
Retrieval Size†	Total number of citations retrieved by the query.	Both
# Boolean Clauses†	Total number of Boolean clauses in the query.	Non-Atomic
# Boolean Keywords†	Total number of atomic clauses (keywords) in the query.	Non-Atomic
# Truncated†	Total number of atomic clauses that have a truncated term.	Non-Atomic
# Fields†	Total number of fields in the query.	Both
# MeSH Keywords†	Total number of non-atomic clauses that contain a MeSH term.	Non-Atomic
# MeSH Exploded†	Total number of non-atomic clauses that have an exploded MeSH term.	Non-Atomic
# MeSH Non-Exploded†	Total number of non-atomic clauses that do not have an exploded MeSH term.	Non-Atomic
Average MeSH Depth†	The average depth MeSH terms in the query appear.	Non-Atomic
Maximum MeSH Depth†	The maximum depth MeSH terms in the query appear.	Non-Atomic
Δ	The difference of a feature between q and $\hat{q}$, where applicable (†).	Both
ω_i	n additional features that correspond to the sequence of transformations made.	Both

because that collection contains a smaller number of topics (50 in total) and therefore less training data. To perform the experiments, we used a framework to construct pipelines for each stage of the experiments [23]. These pipelines and the code for the experiments are made available online.[3]

4.1 Query Candidate Generation

In order to train a model to select candidate queries, training data is required. We achieve this by exploring the space of queries using the transformation processes described in Section 3.2 up to a depth of 5. The difference here, however, is that rather than choosing one query as a candidate query, all queries are chosen. That is, rather than choosing one query to transition to in the chain, we explore all possible transitions in order to generate training data. Because this process is exponential in nature, we sample using the method described in Section 3.5. In terms of training statistics, on average 7968 queries were generated from a seed query. The highest number of queries generated for a topic was 129,282 and the lowest was 70. The total number of training data points was 717,160.

[3] https://github.com/ielab/www19refinement

In the testing phase, where candidates for unseen queries are selected, the transformation process is the same as described in Section 3.2.

4.2 Query Candidate Selection

The topics are split into approximately 70% train (90 topics) and 30% test (35 topics). In the training process, 30% of the train set is used for validation. To perform automatic candidate selection, we train two methods: a learning to rank model and a nearest neighbour approach. The queries that are refined by the candidate selection process are evaluated with six information retrieval measures (precision, recall, $F_{0.5}$, F_1, F_3 and work saved over sampling (WSS)). These measures are typically used to evaluate retrieval in the case of systematic reviews [8, 20, 26]. As the candidate selection function seeks to maximise an evaluation measure, a model is trained for each of the evaluation measures considered in this work for both the learning to rank and nearest neighbour candidate selectors, for a total of 12 models.

4.2.1 Learning to Rank. The DART learning to rank model is trained within the QuickRank framework [2]. We parametrise the DART model with a tree size of 100, a drop-out rate of 0.8, with uniform sampling, tree normalisation, a learning rate (shrinkage) of 0.1, and

to optimise the ranking of queries using DCG@1.[4] We perform candidate selection using this model with the same ranking effectiveness metric (DCG@1). The choice of DCG@1 is motivated by the task of identifying the top-1 ranked candidate query to transition to in a query chain. We sample the training data by removing a large portion of negative examples (two-thirds) to train a DART learning to rank model, as we discovered empirically that negative examples degrade the ranking quality.

4.2.2 Nearest Neighbour. Our nearest neighbour approach first records the feature vectors and evaluation measure values for each query in the training set. Next, for a new unseen query, an evaluation measure value is approximated by searching for a query in the training set which minimises the distances between the two feature vectors and maximises the recorded evaluation measure score. The intuition here is to find the most effective query from the training set which is most similar to an unseen query. In order to find the top-1 candidate to continue the query chain, each generated candidate query is ranked by the approximated evaluation measure value described previously. For efficiency reasons, we only store the deltas of distance and score from the most effective query generated from each seed query. The entire training data is used to create a nearest neighbour model, as we empirically discovered that unlike learning to rank, with the nearest neighbour approach negative examples improved the ranking quality.

5 RESULTS AND ANALYSIS

The main results of the experiments are reported in Table 3, where statistical significant differences are computed using a paired two-tailed t-test with $p < 0.01$. Along with the results obtained when unjudged citations were considered not relevant, we also report results obtained by considering the optimistic and probabilistic (maximum likelihood estimation) residuals: these are indicated by the subscripts *r* and *mle*, respectively.

Overall, the results in Table 3 indicate that the automatic candidate selection methods identified refined queries that were better than the original query (Seed), for the chosen evaluation measures. Somewhat surprisingly for this task, the nearest neighbour candidate selector often outperformed the learning to rank selector, choosing candidate queries that more often refined the query, rather than degrading or broadening it. Notably, the nearest neighbour candidate selector that was trained to maximise the F_1 measure (indicated as $F1_n$ in Table 3) was the most effective at selecting queries that improve over the original seed queries in terms of precision, F_1, and F_3.

The summary of the effect each candidate selector has on the refined queries is presented in Table 4. These results suggest that, although the number of transformations that are made to queries is relatively small (sometimes less than five), the queries often differ significantly from the original seed queries. The final clauses included in the queries were impacted by the types of transformations that were allowed. The following mapping indicates which of the six transformations align with which headings in Table 4:

- Clauses, Keywords: *Clause Removal* & *cui2vec Expansion*
- # AND, # OR: *Logical Operator Replacement* (# NOT included for completeness)
- Fields, (Title, Abstract, MeSH, Other): *Field Restrictions*
- Exp. Mesh: *MeSH Explosion*
- Avg. MeSH, Max. MeSH: *MeSH Parents*

The query expansion method *cui2vec* used was not chosen often by the candidate selectors: on average, the selected queries did not contain more non-atomic clauses than the original seed queries (this is explored in more detail in Section 5.1).

To provide further insight into how each candidate selector model affects the resulting selected queries, Table 5 presents the average proportion of fields and Boolean operators in queries. As the number of clauses in each of the selected queries differ from each trained candidate selector, this table seeks to show the changes in the types of fields and types of Boolean operators in proportion to the size of the query (i.e., with respect to the total number of Boolean operators and fields). For example, the $F1_n$ selector (which consistently improved the effectiveness of queries over the original seed queries for all measures) tended to increase the number of Title fields while decreasing the number of Abstract fields, as well as increase the number of AND operators while decreasing the number of OR operators. These refinements to queries align with the intuition that using the Title field will yield fewer results than the Abstract (or both fields combined), and that the AND operator is more restrictive than the OR operator (the intersection of retrieved citations as opposed to the union).

In terms of directly optimising precision and recall, we further analyse the P_n, and R_l selectors, as each recorded the highest increase in precision and recall, respectively. The P_n selector showed a similar proportion of fields to $F1_n$, however the proportion of AND operators was lower and the proportion of OR operators was higher. The R_l selector had fewer Title *and* Abstract fields, and it removed atomic clauses that did not contain MeSH fields (this is implied by the fact that no transformation allowed MeSH terms to be added, and that it was possible for any clause to be removed with the *Clause Removal* transformation). In addition, this selector had a higher number of OR operators than AND operators. Finally, Table 4 shows that R_l is the only selector to increase the average MeSH depth, suggesting that this selector often applied the *MeSH Parent* transformation.

Next, we explore at a topic level the differences between candidate selectors and their effects on evaluation. Figures 4 and 5 present the topic-by-topic effectiveness of the selectors with respect to the target evaluation measures. The differences between the precision candidate selectors (i.e. the learning to rank selector and the nearest neighbour selector) is noticeable. The P_l selector in fact chose many queries which degraded the effectiveness in terms of precision. On the other hand, the P_n selector had (larger) gains for a similar number of topics, but when compared to the P_l selector, it shows both a reduced number of queries for which a loss was recorded, and a reduced amount of loss when losses happened.

On the other hand, the R_l and R_n selectors were more similar, and many of the same topics had improved effectiveness. The results of these figures reflect the intuition that refining a query to increase precision is more difficult than improving recall. To contrast the previous two figures, Figure 6 presents the effect the $F1_n$ selector

[4]The exact parameters used to train the model can be found in the experiment pipeline files.

Table 3: Comparison of the effectiveness of the original queries in the test set (Seed) and each of the candidate selectors. Reported are the average values across topics. Values in bold indicate the highest value in that column. Statistical significance (two-tailed t-test where $p < 0.01$) is indicated with $*$. Evaluation methods are abbreviated in the following manner: P→precision, R→recall, WSS→work saved over sampling. Residual evaluation can be identified with the $_r$ (optimistic) and $_{mle}$ (maximum likelihood) subscripts. The two candidate selection functions can be identified by the evaluation measure they optimise, and a corresponding letter: e.g., P_l corresponds to the learning to rank selector which maximised precision, and $F1_n$ corresponds to the nearest neighbour selector which maximised F1.

Table 4: Summary of the query refinement process. Shown in the table is the average difference in change of different aspects of queries obtained by each selector. A negative value indicates a reduction in the corresponding aspect, a positive value indicates an increase, and a zero value indicates that aspect was not changed. For comparison, the average values of the original *Seed* queries are reported as well. *Clauses* refers to the number of Boolean clauses in the query. *# AND*, *# OR*, and *# NOT* indicate how many of the corresponding operators were in the query. *Fields* indicates how many fields were in the query in total; this is further divided into how many of those were Title, Abstract, MeSH, or other (e.g., dates or publication type). *Exp. MeSH* indicates the number of MeSH terms that have been exploded, and *Avg. MeSH* & *Max. MeSH* indicate the average and maximum depth in the ontology of the MeSH terms. Two-tailed statistical significance where $p < 0.01$ between the Seed queries and the queries selected by each model is indicated with $*$.

	Clauses	# AND	# OR	# NOT	Fields	Fields (Title)	Fields (Abstract)	Fields (MeSH)	Fields (Other)	Keywords	Exp. MeSH	Avg. MeSH	Max. MeSH

had on each topic in terms of the six evaluation measures considered in this work. While many queries had improved precision and maintained or even increased recall (e.g., topic 83), approximately one third of queries had a reduction in recall. This suggests that there may not have been enough training examples for this selector to choose a candidate query that is likely to cause an increase in recall.

Figure 2: Comparison between the original query (left) and a transformed query (right) for topic 154. The transformed query was chosen using the $F1_n$ selector, and was the least effectively refined query. Note that on line 28 for both queries there is a carriage return as the line was too long.

Finally, we compare two example queries by examining the transformations that have been applied to them. The queries chosen for comparison are from topics 73 and 154. These topics were respectively the best and worst performing ones when query transformations were obtained through the $F1_n$ candidate selector (in the case of topic 154 it was chosen because the query for 106 was too long to fit into a column). The transformed query for topic 73 obtained a large increase in precision, while maintaining recall, while the transformed query for topic 154 obtained a minor decrease in precision and a large decrease in recall.

The original and the transformed query for topic 73 are shown in Figure 3. The transformations made to the query were that lines 59 and 75 were both removed, and lines 40, 46 and 75 (which become line 66 in the transformed query) had their operators changed (from OR to AND). The original and the transformed query for topic 154 are shown in Figure 2. The transformations made to its query were that lines 1, 3, and 27 had their fields changed from Title and Abstract to only Title, and the MeSH term of line 7 was expanded to its parent.

Upon examination of the queries in Figures 3 and 2, it is clear that they considerably differ in length: one may question whether the length difference (in number of clauses) is associated with the effectiveness difference — according to this hypothesis shorter queries would generally perform worse than longer queries. However, upon further analysis we found that this is not the case. In fact, the Pearson's r correlation between the F_1 evaluation measure and the number of Boolean clauses in each query was only $r = 0.175$. Similar results were obtained when considering the other evaluation measures used in this study, thus suggesting that there is no direct relation between query length in terms of number of Boolean clauses and retrieval effectiveness. This finding is similar to what

5.1 Impact of Semantic Transformations

To answer **RQ1**: '*Which types of transformations are the most effective at refining Boolean queries in systematic review literature search?*', a comparison between candidate selection transformations was made. The summary of query refinement are presented in Table 4. On average, none of the approaches selected queries which performed explicit query expansion. Indeed, a deeper analysis of the results identifies that none of the queries are longer than the original seed. This suggests that, in this context, query expansion may not be an effective way to refine a query. On the other hand, query reduction was chosen very often, more so by the learning to rank selector — which tended to remove clauses from queries more often than the nearest neighbour selector. While the candidate queries that had the *cui2vec Expansion* transformation applied were not chosen by either of the selectors, the *MeSH Parent* transformation was. The R_l selector chose queries with an average MeSH depth of 0.32 higher than the original seed query. This suggests that to maximise an increase in recall, this selector opted to chose a query that broadened the scope of MeSH keyword than to add new, somewhat related text-matching keywords. Overall the results indicate that, among the investigated transformations, *syntactic* transformations play a larger role in query refinement than *semantic* transformations.

5.2 Impact of Unjudged Citations

To answer **RQ2**: '*What effect do unjudged citations have on the effectiveness of refined Boolean queries in systematic review literature search?*', the evaluation measures and the estimates obtained with the two residual heuristics are compared. As reported in Table 3, these results show that the effect of unjudged citations is not significant. When a selector chooses candidate queries that perform

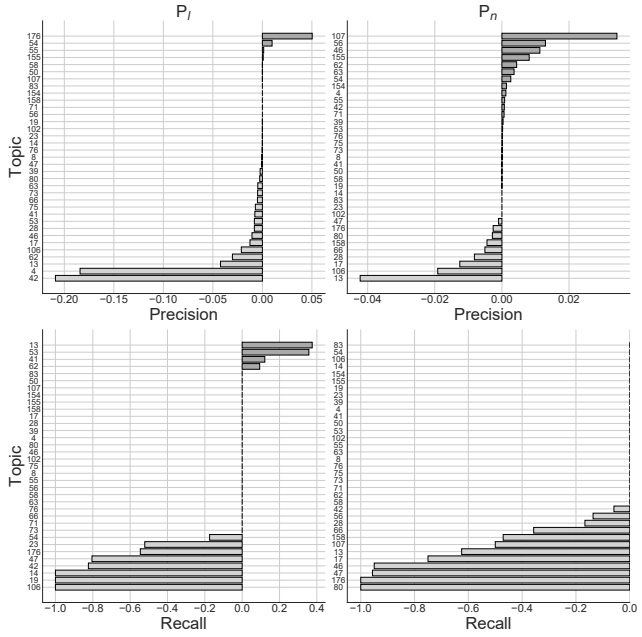

Figure 4: Per-topic gains in precision (top) and recall (bottom) over the Seed query for the candidate selectors which maximised precision (P_l and P_n).

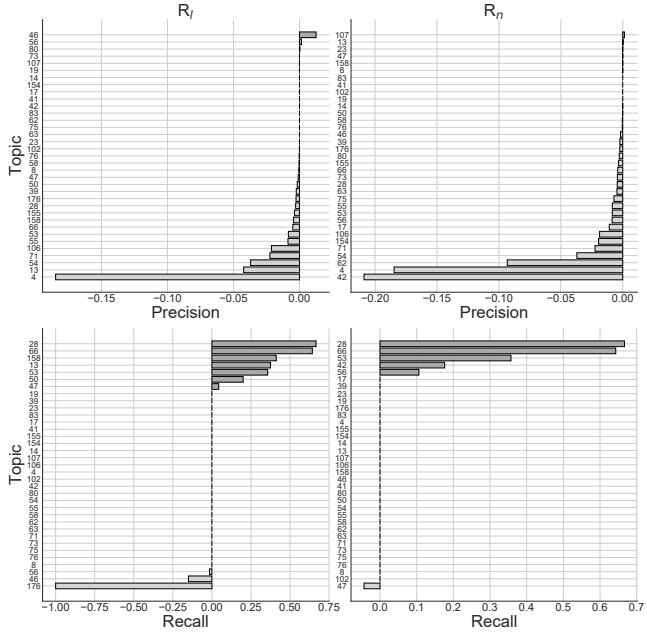

Figure 5: Per-topic gains in precision (top) and recall (bottom) over the Seed query for the candidate selectors which maximised recall (R_l and R_n).

statistically significantly worse for an evaluation measure, the residual *mle* results are also significantly worse. Nonetheless, Table 3

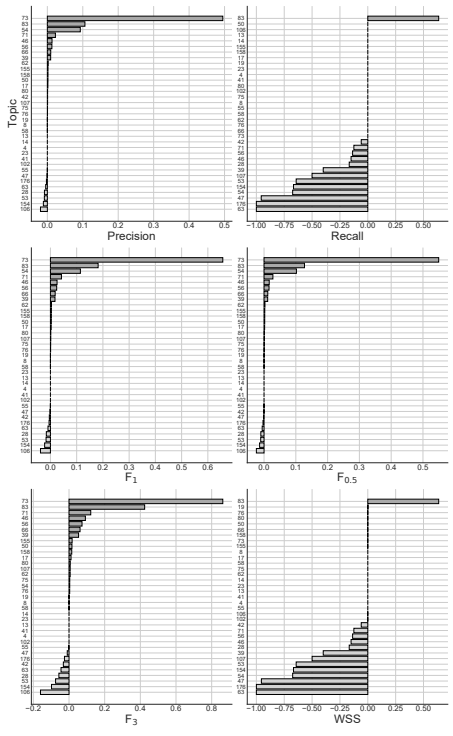

Figure 6: Per-topic gains over the Seed query in the evaluation measures considered in our study. Here we considered the nearest neighbour candidate selector that maximised F1 ($F1_n$.)

still shows that in many cases, effectiveness increases when unjudged citations are factored into evaluation. For example, the P_n selector does not obtain increases in precision over the seed queries, when unjudged citations are considered non-relevant. However, when using the *mle* heuristic, precision is higher, though with the *r* heuristic, precision is also lower. In fact, from analysing the *r* heuristic, we can determine that the P_n selector retrieves many more non-relevant citations than the P_l selector. For these reasons, estimates for residual should be considered when performing high-recall tasks such as this; or in tasks that modify or change queries in some way. This is especially important when relevance assessments are largely incomplete, and no system variation was considered when forming the pool for assessments: this was the case for systematic review collections available for Information Retrieval research [8, 26].

6 CONCLUSIONS

This paper presented three novel semantic transformations that integrate with previous work on systematic review query generation. In addition, we cast the task of query generation from previous work [24] to query refinement — where newly generated queries should improve precision while maintaining or improving recall. To this end, we employed two new candidate selector functions, one based on learning to rank, and one based on a nearest neighbour algorithm. Both candidate selectors were trained to maximise six evaluation measures. When evaluating query refinement, we also revealed that the refinement retrieved unjudged documents; we accounted for these in the evaluation by computing the residuals of the evaluation measures. We did so by considering both an optimistic residual and a probabilistic residual (based on maximum likelihood estimation). Our results showed that the nearest neighbour model was able to more effectively select query refinements than the learning to rank approach. Our experiments have shown that the explicit query expansion method (*cui2vec Expansion*) proposed in this work is not viable for query refinement (as candidates with other transformations outrank it). However, the explicit query reduction method (*Clause Removal*), and to a lesser extent the implicit query expansion method (*MeSH Parents*) can, in fact, be used to help refine queries.

The detailed analysis of how each set of selected queries was transformed by candidate selectors suggested that the syntactic transformations were in fact more suited to refinement than semantic transformations. Our experiments also showed that the effect of unjudged citations on evaluation is significant: unjudged citations should be accounted for in some way when performing evaluation.

Future plans for the task of automatic query refinement for systematic review literature search will focus on exploring other methods for candidate selection and other features, as well as improving the sampling of queries in the exploration/generation phase for collecting training data. With this in mind, the current sampling method leads to a large imbalance of negative to positive training samples. One promising sampling method could be to sample each query with a set of "known-relevant" seed documents. These are used in systematic review literature search by information specialists to guide the query generation process. Recently, a seed-driven approach to ranking has been shown to reduce the workload of the screening task [15]. We also plan to further study other techniques for semantic query transformation, such as query reduction [13]. Query reduction techniques for professional search have been shown to be successful in other contexts, both in the clinical domain [11, 12, 28], and outside of the medical field [4, 16].

The proposed method for automatic query refinement has the potential to vastly reduce the time spent creating systematic reviews. The searching and screening processes contribute to a significant period of time and money in the systematic review creation process. By reducing the total number of citations to screen by automatically refining already highly effective queries, the time spent screening citations and therefore the total cost of a systematic review can be reduced. These reductions lead to faster and more up-to-date evidence based medicine which in turn lead to more accurate clinical decisions and better health outcomes.

ABSTRACT

Network traffic classification is an important tool for network administrators in enabling monitoring and service provisioning. Traditional techniques employed in classifying traffic do not work well for mobile app traffic due to lack of unique signatures. Encryption renders this task even more difficult since packet content is no longer available to parse. More recent techniques based on statistical analysis of parameters such as packet-size and arrival time of packets have shown promise; such techniques have been shown to classify traffic from a small number of applications with a high degree of accuracy. However, we show that when employed to a large number of applications, the performance falls short of satisfactory. In this paper, we propose a novel set of bit-sequence based features which exploit differences in randomness of data generated by different applications. These differences originating due to dissimilarities in encryption implementations by different applications leave footprints on the data generated by them. We validate that these features can differentiate data encrypted with various ciphers (89% accuracy) and key-sizes (83% accuracy). Our evaluation shows that such features can not only differentiate traffic originating from different categories of mobile apps (90% accuracy), but can also classify 175 individual applications with 95% accuracy.

1 INTRODUCTION

Global mobile data traffic has witnessed astonishing growth over the last half-decade; having multiplied 18-fold since 2011, it is forecasted to account for 20% of all IP traffic by 2021 [1]. The sheer scale and enormous diversity of this traffic has engendered exceptional challenges for network administrators and service providers. One major goal of network administrators is providing differentiated quality of service (QoS) based on the traffic category (also known as service differentiation). The decision of how much bandwidth to provide where, may depend on either preferences of users in the network, or the policies adopted by the enterprise served by the administrator. The first step of such a solution is the classification of traffic originating from various applications. This task, however, has been rendered significantly difficult in case of mobile applications, due to the lack of unique traffic signatures.

Unlike in the case of traditional web traffic, mobile app traffic cannot be segregated based on the presence of obvious signatures (e.g., server address, app port number, unique identifiers in packet content, etc. [12]). In fact, the majority of mobile apps tunnel data over HTTP and HTTPS [24, 28], which use the same port (80 and 443 for HTTP and HTTPS respectively) for all traffic. Also, in case of sub-networks, all traffic is addressed to and from a common IP address (that of the gateway device), rendering IP-based traffic classification infeasible. The most difficult hurdle seems to be the increasing adoption of encryption. Encrypted traffic renders DPI-based efforts to identify signatures from packet content ineffective [26].

One popular way of circumventing this problem is using statistical analysis to classify application traffic [7, 27, 46]. Features such as packet-size, inter-arrival time of packets, etc. have been known to prove beneficial in classifying one type of traffic from another. However, these approaches are under the scanner, and techniques have already been proposed to thwart such attempts. For example, a recent study proposed using packet-size and arrival time obfuscation to confuse a trained classifier [41]. The authors implement their system as a proxy which can fragment and regulate packet departure in a way such that one category of traffic looks exactly like another. In the presence of such techniques, it is necessary to devise strategies which are immune towards obfuscation attempts.

In this paper, we propose a novel set of bit-sequence similarity based features, which leverage footprints left by encryption implementations to achieve traffic classification. A recent study reveals that in case of mobile platforms (and specifically the Android OS), there exists significant diversity in the implementation of TLS/SSL, with a vast majority of those implementations falling

short of the adequate security standards [41]. This phenomenon is mainly due to the *app store* model adopted by major platforms such as Google Android and Apple iOS, which enables developers with little to no expertise to implement security in a host of applications. TLS deployment requires configuring a complicated end-to-end architecture, with numerous 'knobs and buttons'; different permutations of these options adopted by the developers result in a wide array of cipher suites, key-sizes, and certificate management styles getting associated with mobile applications. Additionally, security implementations also depend extensively on the computational capabilities of the mobile devices; while high-end smartphones support the most secure standards, lower-end phones may only support weaker cipher suites, or none at all.

We observe that the differences in encryption implementations of mobile applications in the wild, leave footprints in the encrypted data generated by them, which can be harnessed using a set of novel bit-sequence based features. These features leverage the difference in the randomness of bits, when data is encrypted using different cipher algorithms and key-sizes. We argue that the tell-tale differences in randomness, although weak when data bits are assumed to be in a temporal sequence, begin emerging strongly when the sequence is transformed to the frequency domain (using Fast Fourier Transform). We substantiate this claim with a series of *standard randomness tests*[1] on 11 ciphers, the most noteworthy of which is the *Discrete Fourier Transform* based 'Spectral Test' [36]. This test exhibits the highest standard deviation in randomness scores (~ 0.38) across the ciphers, suggesting its suitability in classifying data generated by different ciphers. We proceed to train a classifier using the aforementioned features, on an offline dataset consisting of data encrypted with 11 different ciphers, and 3 different key-sizes, and obtain 89% (for different ciphers) and 83% (for different key sizes) accuracy in the best case, respectively.

Armed with this set of discriminative features, we propose a mechanism based on machine learning, which can enable classification of mobile network data into source applications. We achieve 71% accuracy in classifying packets from 175 Android apps using only these features, which improves to 95% when augmented with previously defined packet-level features. In comparison, a classifier trained only on baseline features, is able to exhibit only 62% accuracy. Additionally, this technique is not only resistant towards obfuscation, but is also simple to implement, since it requires computing the Fast Fourier Transform of a bit-stream (specialized hardware is available for such tasks [6]), and some additional computation.

The key contributions of this paper include:

(1) We propose and validate a set of novel bit-sequence based features, which enable classification among data encrypted with 11 ciphers and 3 different key-sizes, with 89% and 83% accuracy (best case), respectively (§2).
(2) We substantiate the efficacy of the bit-sequence based features in discriminating among diverse security implementations, by performing multi-class classification of network traffic originating from 175 mobile apps. While previously studied packet-level features (which serve as our baseline) account for only 62% accuracy, our proposed bit-sequence based features alone achieve 71% accuracy, which is boosted significantly (95% in the best case) in conjunction with packet-level features (§3).

[1]Recommended by the National Institute of Standards and Technology (NIST), US Department of Commerce for evaluating suitability of a random bit generator in cryptographic applications [4].

2 BIT-SEQUENCE BASED FEATURES

In this section, we substantiate the notion that data encrypted with different cryptographic system configurations yield different degrees of randomness. We show that it is possible to harness these differences in randomness, and construct "features" (in machine learning parlance) which are useful in extracting sensitive information from encrypted data, e.g., the cipher algorithm or the key-size.

2.1 Background

Secure cryptographic systems are characterized with certain desirable properties, namely (1) the *avalanche effect*, and (2) the *completeness* property. The avalanche effect mandates that a small change (even a bit) in the plaintext should create significant changes (alter a large number of bits) in the ciphertext [25]. The completeness property demands that *all* bits in the plaintext should affect *each* bit in the ciphertext [34]. The broader intent behind these properties is the generation of sufficient randomness in the encrypted data, such that an attacker is unable to exploit any patterns useful in deciphering the plaintext or the encryption key.

However, cipher implementations are seldom perfectly random; existing literature shows that different cipher implementations are characterized with different degrees of randomness [8, 23, 35, 44, 52]. An important measure of the strength of a cipher is therefore the amount of randomness it can induce in the data encrypted with it. While a large number of statistical tests are available to determine randomness, the National Institute of Standards and Technology (NIST), USA recommends a specific set of 15. A candidate cipher is evaluated based on whether the randomness (as determined by these tests) in bits generated due to encryption with it, is sufficiently high to be suitable for cryptographic applications [4]. In this section, we perform these 15 tests on data generated by different ciphers, and validate that the degrees of randomness are indeed different.

2.2 Randomness Analysis of Ciphers

We evaluate the randomness induced by different ciphers on data encrypted by them, by subjecting the data to a set of 15 recommended statistical tests, as mentioned before.

Randomness tests: We perform the following randomness tests: (1) Monobit test, (2) Block frequency test, (3) Independent runs test, (4) Longest runs test, (5) Spectral test, (6) Non-overlapping patterns test, (7) Overlapping patterns test, (8) Universal test, (9) Serial test, (10) Approximate entropy test, (11) Cumulative sums test, (12) Random excursions test, (13) Random excursions variant test, (14) Matrix rank test, and the (15) Linear complexity test. These tests have been defined and standardized in the NIST standard *SP 800-22* [4] [2]. The tests evaluate different properties of the test data which may indicate presence of patterns in the data (e.g., high frequency of specific bit-strings, too many zeros or too many ones, etc.). The score reported for each test is the test statistic *p-value*

[2]The descriptions of these tests have been omitted for the sake of brevity.

Table 1 Results of 15 randomness (recommended by NIST [4]) tests on data encrypted with 11 ciphers. The green row represents the randomness scores for the *Spectral Test*, which is touted as the most powerful test of randomness [36] and also shows the higest std. deviation across tests.

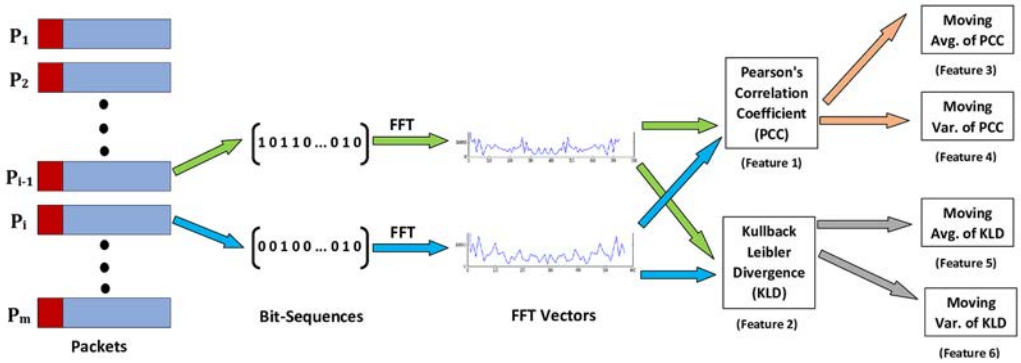
which is a function of the observed (encrypted) data. The *p-value* indicates the probability that a perfect random number generator would have produced a sequence (in terms of the property assessed by a particular test) less random than the tested sequence. If *p-value* = 1 for a test then the tested sequence is deemed to have perfect randomness, while if *p-value* = 0 then the sequence may be adjudged as completely non-random.

Ciphers: As candidates for the randomness tests, we consider 7 symmetric-key ciphers (e.g., AES, ARC2, ARC4, Blowfish, CAST, DES, and DES3), 2 asymmetric ciphers (e.g., PKCS#1 OAEP and PKCS#1 v1.5), and the XOR cipher. The variety in types of ciphers ensures generalizability. We also consider unencrypted data as the 11^{th} category for these tests (we refer to this as a cipher here onward for ease of explanation).6 The implementations of the considered ciphers are as available in the Python library `PyCrypto` [3].

Setup: We synthesize random data blocks of 1504 bytes each, which is approximately the MTU (maximum transmission unit) of a network packet. We use the `random.SystemRandom` class provided by Python for this purpose. We generate and encrypt 1000 such data blocks (or packets) for each cipher mentioned above. In case of the symmetric ciphers, we use a fixed key sized 128 bits. We use the Cipher-Block Chaining (CBC) encryption mode in all cases (of symmetric ciphers). For the asymmetric ones, we generate a 1024 bit RSA public/private key pair using `OpenSSL`, and then extract the public key; this public key is then used for encryption. The encrypted data generated by each cipher is converted into a separate bit-stream and fed as input to the randomness testers. We implement the randomness testers based on the Python library `r4nd0m` provided by NIST [2].

Results: The results of the randomness tests are provided in Table 1. We report scores, which are *p-values* (as mentioned before), with a precision of only up to 4 places after the decimal point. Therefore, a score of 0.0000 may not indicate a *p-value* of exactly zero, but a value which is lesser than 0.00005 (since we round up). Most tests find unencrypted data and data encrypted with XOR less than satisfactory (very low *p-value*) for usage in practical cryptographic systems, as expected. More importantly, we observe that there are discernible differences in the randomness values for data generated by the 11 ciphers considered, with respect to most of the tests. It is meaningful to ask therefore: *which test should one focus on if she intends to classify data based on the cipher used to encrypt it?* We attempt to answer this question next.

Towards identification of classification features: Of the 15 tests considered in the aforementioned experiment, the test known as the ***Spectral Test*** (also called the *Discrete Fourier Transform (DFT) Test*) is of special significance both in the literature and in this work. The roots of this test lie in a work by Coveyou et al. which suggested employing Fourier analysis to analyze the quality of random number generators [19]. Donald Knuth formalized the *Spectral Test* based on this idea and touted the test as "by far the most powerful test known", since certain weak ciphers which pass all other tests have been known to invariably fail this particular test [36]. We also observe that this test (highlighted with green in Table 1) shows the highest standard deviation in scores across all ciphers, which is indicative of high variability. Buoyed by these observations, we choose the DFT-based *Spectral Test* as the basis of defining classification features for traffic encrypted with different encryption parameters.



2.3 Defining Bit-Sequence Based Features

Having zeroed in on the basis of feature extraction, i.e., the DFT-based *Spectral Test*, we proceed to examine how we can define features which can effectively classify encrypted data based on encryption parameters.

Role of Fast Fourier Transform (FFT): FFT is an efficient algorithm for computing the DFT of a signal (or sequence). FFT transforms the input sequence (a bit sequence in our case) from the temporal domain to the frequency domain; the result is a vector containing the intensities of each frequency component in the original sequence. Based on our observations in the previous subsection, we already know that analyzing the FFT vectors generated from encrypted data (as done in the *Spectral Test*) is beneficial in gleaning out the randomness present in encrypted data. However, *how does one use FFT effectively to leverage this property and subsequently enable classification?*

The case for packet pairs: Randomness is likely to be induced in an individual app packet from two sources: (1) the content encapsulated in the packet, and (2) encryption. Our aim in this work is to capture the randomness due to encryption only. This requirement drives us to consider a pair of packets instead of individual packets; the idea is to eliminate the randomness due to differences in content,

Figure 1 Feature Extraction: Pictorial description of the methodology used to extract the 6 defined bit-sequence based features

as far as possible. Content similarity is likely to be the maximum in *consecutive packets* generated by an application, rather than any random pair of packets. For example, in the case of a video app, consecutive packets are likely to carry two consecutive frames of a video. Therefore, in this work, we consider consecutive packets for defining our features. We discuss possible scenarios arising out of this requirement from an implementation perspective, and ways to address those, in § 3.2.
