A two-step CNN based hybrid approach was proposed in [27] for detecting racist and sexist speech using the same data set as [33]. In particular, the first step is aimed at detection of abusive language, whereas the second step is aimed at identification of the abusive language type (racist and sexist). In comparison of the two-step approach with the one step approach, the experimental results reported in [27] show that the use of hybrid CNN led to the best performance through the one-step approach and the use of LR led to the best performance through the two-step approach, where the one-step approach performed marginally better than the two-step approach. In [40], a gated recurrent unit layer was incorporated into CNN by locating this added layer after the pooling layer and a drop out layer was used for optimaizing the training of embeddings. The experimental results show that the proposed approach led to advances in the classification performance on 6 out of 7 data sets, in comparison with previous baseline results.

On the basis of the above review, we consider text embedding as the state of the art method of feature extraction. Moreover, probabilistic learning approaches including DT, NB, SVM, GBT and DNNs are considered as the state of the art ones for classifiers training.

3 PROPOSED FRAMEWORK OF CYBERHATE DETECTION

In this section, we present the proposed three-level framework for cyberhate detection, which involves polarity classification (hate or non-hate) in level 1, multi-task classification for identification of the hate speech types in level 2 and detection of topics and contexts of hate speech in level 3. Then we focus on level 2 for the problem formulation and the illustration of the procedure of the proposed fuzzy ensemble approach in the setting of multi-task learning.

The proposed framework essentially aims at different levels of abstraction for hate speech detection tasks and reduction of the complexity of a single task in a single level. There has been a plenty of works done on general detection of hate speech as a task involved in level 1, as reviewed in Section 2. However, to the best of our knowledge, very few works have been focused on identifying the presence or absence of multiple types of hate speech as a task involved in level 2. Different types of hate speech have potential intersectionality [9], which indicates that the hate speech type identification task can not be simply formulated as a traditional multi-class classification problem based on the assumption of mutual exclusion of different classes. In other words, multi-label classification would be a more appropriate formulation.

Multi-label classification is typically achieved through training classifiers in the setting of supervised learning. However, mutlilabelling of hate speech data is practically much less feasible, as stressed in Section 1. Therefore, we will introduce a new formulation of the problem in Section 3.1 to enable multi-label classification in the setting of semi-supervised learning and propose a fuzzy ensemble approach for hate speech type identification in the setting of mutli-task learning in Section 3.2.

3.1 Problem Formulation

In general, a single-labelled data set D involving n labels could be produced by taking the positive instances from n different binary data sets $D_1, D_2, ..., D_n$. In this way, each set of positive instances is associated with one of the n labels and the n sets of positive instances are merged into a new single-labelled data set D.

In the setting of semi-supervised multi-label learning, the problem is formulated as n Positive-Unlabelled (PU) learning sub-problems (Eqs. (1) and (2)), respectively, for identifying n labels (types of hate speech), similar to the Binary Relevance based problem transformation. In particular, for each single-labelled instance, it is considered as an unknown case that the instance is relevant or not to the other $n-1$ labels, i.e. it is treated as unlabelled regarding other labels.

$$h(\cdot) = \bigwedge_{j=1}^{n} \{h_j(\cdot)\} \tag{1}$$

$$h_j(\cdot) = \begin{cases} +1, & \text{if } h_j(\cdot) = l_j; \\ -1, & \text{otherwise.} \end{cases} \tag{2}$$

In the above context, for each predefined label $l_j \in LS$, instances that are assigned this label l_j are considered to be a set of positive ones, whereas the other instances are considered to be a set of unlabelled ones regarding the label l_j (i.e. a mixed set of potentially both positive and negative instances). The above two sets of instances are used for an independent binary classification task for each label l_j in the setting of PU learning [13, 16–18], which has been popularly adopted for semi-supervised single-label classification.

PU learning is a special type of semi-supervised learning, which does not involve labelled negative instances in the training set and can be achieved through three strategies as surveyed in [38]:

(1) The first strategy involves a two-step operation by identifying reliable negative instances from the unlabelled set and then adopting supervised learning on the positive instances and the reliable negative instances.
(2) The second strategy involves weighting the positive and unlabelled instances and then estimating the conditional probability of the positive class given the input vector of an instance.
(3) The third strategy involves simply treating the unlabelled training instances as highly noisy negative ones, assuming that the majority of the unlabelled instances belong to the negative class.

In the context of hate speech type identification, we take the third strategy since the positive (target) class is typically the minority one. For each binary classifier h_j trained in the setting of PU learning, the output +1 shown in Eq. (2) indicates the case that the target type l_j of hate speech is detected from an instance x_i. In contrast, the other output -1 indicates the case that the binary classifier h_j fails to detect the target type l_j of hate speech.

For adopting probabilistic approaches, it is not feasible to achieve the above setting of semi-supervised multi-label learning without transformation of the original single-labelled data. In particular, a single-labelled data set needs to be transformed into n binary data sets in the setting of Binary Relevance, i.e. from each binary data set D_j, the instances assigned label l_j are treated to be the positive ones and the other instances are treated as unlabelled ones, so a binary classifier h_j is trained to identify the label l_j.

In contrast, for adopting the proposed fuzzy approach, the above data transformation is not needed, since it is an instance based generative approach of fuzzy rule learning, which aims at considering iteratively whether each instance $x_i \in l_j$ is covered by an existing rule of the label l_j or another label $l_g \neq l_j$. More details on the fuzzy approach are shortly given in Section 3.2.

In the classification stage, it is possible that more than one binary classifier gives a positive output (i.e. a label $l_j \in LS$ rather than its negation $\neg l_j$) for the same instance x_i, so the instance is finally assigned multiple labels. If the target label l_t is originally assigned to the instance x_i as the ground truth and the binary classifier h_t successfully identifies that the instance x_i belongs to the label l_t, then it would be judged as successful detection of the target type l_t of hate speech from the instance x_i, regardless of the correctness of assigning other labels to the instance x_i. Also, it is possible that none of the binary classifiers provides a positive output, which would be simply identified as the case that the binary classifier h_t fails to detect the presence of the target type l_t of hate speech and none of the other types of hate speech is detected.

In the new problem formulation shown in Eqs. (1) and (2), two new metrics are proposed, which are referred to as 'detection rate' (Eq. (3)) and 'irrelevance rate' (Eq. (4)), respectively. The two terms given for the two metrics are inspired from two possible cases in information retrieval tasks, where the retrieved documents may be the target ones successfully detected or the irrelevant ones incorrectly identified. In Eq. (3), $|l_j|$ represents the number of instances

that are annotated the label l_j and $|l_j \cap \hat{l_j}|$ is the number of instances that are annotated the label l_j by people and are assigned either a single label l_j or multiple labels including l_j by classifiers. In Eq. (4), $|\hat{l_j}|$ is the number of instances that are assigned the label l_j by classifier h_j and $|\neg l_j|$ represents the number of instances that are annotated as $\neg l_j$ (i.e. the number of negative instances).

$$P = \frac{|l_j \cap \hat{l_j}|}{|l_j|} \tag{3}$$

$$R = \frac{|\hat{l_j}|}{|\neg l_j|} \tag{4}$$

In the context of hate speech types identification, non-hate speech instances should be used as negative ones (belonging to $\neg l_t$), since single-labelled hate speech instances (annotated label l_t) are not provided with ground truth on the absence of each other type $l_j \neq l_t$ of hate speech and thus cannot be used as negative instances for evaluating the overall confidence of relevantly assigning an instance $x_i \in l_t$ a label $l_j \neq l_t$ in addition to the label l_t.

3.2 Procedure of Multi-task Learning

The proposed multi-task learning approach is essentially based on the mixed fuzzy rule formation algorithm [7] with modifications, and the procedure of this algorithm is illustrated as below:

It involves a sequential and constructive generation of new rules and modification of existing rules in an instance-by-instance manner, i.e. each instance is checked, and a new rule is added into the rule set or some existing rules are modified. For each class label l_j, a subset of fuzzy rules is trained in a single task and the rule subset is treated as a binary classifier h_j trained for identifying the label l_j. Therefore, the training of the whole set of fuzzy rules for all class labels is undertaken in a multi-task learning manner.

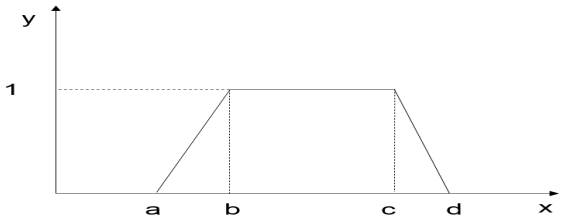

Figure 1: Trapezoidal Membership Function [20]

In the whole procedure, each rule r_t involves n membership functions (for n rule antecedents) and two additional parameters w and λ to be defined, where w represents the number of instances covered by rule r_t and λ is a so-called anchor that remembers the original instance triggering the generation of this rule r_t. A membership function generally involves four parameters a, b, c, d as shown in Fig. 1, where the interval $[b, c]$ represents a core region showing hard boundaries for an element to fully belong to a set and the rest represents a support region (a, b) or (c, d) showing soft boundaries for an element to partially belong to a set.

At each of a number of epochs, once each instance $x_i \in l_j$ is checked, one of the following cases needs to be identified:

- Covered: if an instance $x_i \in l_j$ is covered by a rule r_t, then the membership function defined for each rule antecedent needs to be adjusted to let the instance x_i obtain a membership degree of 1 to the rule r_t [7, 11].
- Commit: if the instance $x_i \in l_j$ is not covered by any rules, a new rule is generated and a membership function is initialized for each rule antecedent [7, 11].
- Shrink: if an instance $x_i \in l_j$ is covered by a rule r_t of label $l_g \neq l_j$, then conflict avoidance should be taken using some shrink heuristics [11].

Following the above procedure, a set of fuzzy rules is trained, which involves n subsets of rules for the n labels. The presence or absence of each target type of hate speech can be identified from each new instance through fuzzification, inference and defuzzification. The fuzzification operation is simply to map the value v_{ik} of each feature f_k of an instance x_i to a membership degree $\mu_{A_{tk}}(v_{ik})$ to a fuzzy set A_{tk} defined in a rule antecedent for f_k. The inference operation is adopted to compute the firing strength of each rule r_t by using a T-norm (e.g. the min function shown in Eq. (5)) and to derive the overall membership degree of the instance x_i for each label l_j (the presence degree of each type of hate speech) by using one of the T-conorms [11], e.g. the max function shown in Eq. (6).

$$T(\mu_{A_{t1}}(v_{i1}), \mu_{A_{t2}}(v_{i2}), ..., \mu_{A_{td}}(v_{id})) = \min_{k=1}^{d}\{\mu_{A_{tk}}(v_{ik})\} \tag{5}$$

$$S(\mu_{r_1}(x_i), \mu_{r_2}(x_i), ..., \mu_{r_q}(x_i)) = \max_{t=1}^{q}\{\mu_{r_t}(x_i)\} \tag{6}$$

It is proposed to use multiple fuzzy norms (dual pairs of T-norms and T-conorms) for training multiple classifiers. Fuzzification and inference are operated independently using each single classifier. However, the defuzzziciation operation is modified to suit identifying the presence or absence of each hate speech type from a new instance x_i according to a threshold (normally 0.5) of the overall membership degree for each label l_j, i.e. Eq. (7) shows that defuzzification is operated by fusing the m fuzzy classifiers through taking the maximum of the membership degrees $\{\mu_{l_j}^{h_1}(x_i), \mu_{l_j}^{h_2}(x_i), ..., \mu_{l_j}^{h_m}(x_i)\}$ computed through classifiers $\{h_1, h_2, ..., h_m\}$ for each label l_j.

$$\mu_{l_j}^{Ensemble}(x_i) = \max_{f=1}^{m}\{\mu_{l_j}^{h_f}(x_i)\} \tag{7}$$

$$\mu_{l_j}^{Ensemble}(x_i) = \frac{1}{m}\sum_{f=1}^{m}\{\mu_{l_j}^{h_f}(x_i)\} \tag{8}$$

The maximum fusion rule (Eq. (7)) is adopted instead of others such as the mean rule (Eq. (8)), in order to minimize the risk of missing a target type of hate speech to be detected from a tweet, while the type of hate speech is actually present. In other words, if one classifier in a fuzzy ensemble identifies that the membership degree for the target label (hate speech type) is high enough, the fusion of multiple classifiers in the ensemble would make sure the fused membership degree for the target label is high enough. In particular, if the fused membership degree $\mu_{l_j}^{Ensemble}(x_i)$ of instance x_i for a label l_j is greater than the predefined threshold, it would be judged as the case that the target type l_j of hate speech is detected successfully from the instance x_i.

4 EXPERIMENTAL STUDY

In this section, we report an experimental study on identification of hate speech types using four data sets collected for four target types of hate speech, namely: religion, race, disability and sexual orientation. The proposed fuzzy ensemble approach is evaluated by comparing with the state of the art probabilistic approaches such as SVM and DNNs, alongside the use of embedding features. The details on the data sets are described in Section 4.1 and the experimental setup and results are presented in Section 4.2.

4.1 Data

The data sets were collected from Twitter for a period immediately following selected 'trigger' events, which were: for religion, the attack on Lee Rigby in Woolwich, London on 22 May 2013 by Islamist Extremists; for race, the presidential re-election of Barack Obama starting November 6th 2012; for disability, the opening ceremony of the Paralympic games in London, UK on 29th August 2012; and for sexual orientation, the public announcement by Jason Collins on 30th April 2013 - the first active athlete in an American professional sports team to come out as gay. Each event produced datasets between 300,000 and 1.2 million, from which we randomly sampled 2,000 to be human coded. Coders were provided with each tweet and the question: 'is this text offensive or antagonistic in terms of religion/race/sexual orientation/disability?' They were presented with a ternary set of classes - yes, no, undecided.

The results of the annotation exercise produced four 'gold standard' data sets as follows: Religion - 1,901 tweets, with 222 instances of offensive or antagonistic content (11.68% of the annotated sample); Race - 1,876 tweets, with 70 instances of offensive or antagonistic content (3.73% of the annotated sample); Disability - 1,914 tweets, with 51 instances of offensive or antagonistic content (2.66% of the annotated sample); and Sexual Orientation - 1,803 tweets, with 183 instances of offensive or antagonistic content (10.15% of the annotated sample). More details on the data collection and annotation have been presented in [8, 9, 19].

4.2 Experimental Setup and Results

The experiments were conducted by taking the four types of hate speech instances, respectively, from the four single-labelled data sets, to form a training set for evaluating the detection rate of the presence of each hate speech type, through 10-fold cross validation. All the non-hate speech instances were taken from the four data sets to form a holdout test set for evaluating the irrelevance rate on each hate speech type, using the classifiers built on the training set.

For non-DNN based learning methods, all the tweets were pre-processed by converting the words to their lower case, and removing stop words, numbers, punctuation and words that contain less than 3 characters. The pre-processed tweets were then sent for embedding training. Furthermore, embedding features were prepared through adopting distributed bag of words (DBOW). In particular, the learning rate was set to 0.025 with the context window size of 2. Following the embedding learning with the batch size of 10000 for 45 epochs, all the words (appearing at least twice in the corpus) were used for embedding learning to transform each tweet into a document vector with 100 dimensions.

The embedding features were then sent to the learning algorithms for classifiers training. In particular, DT classifiers were trained by using the C4.5 algorithm [28] without pruning. SVM classifiers were trained with using the linear kernel [10]. For GBT training, all the attributes were used and attribute selection for each node of a tree was done by using the same set of attributes. In the setting of the proposed fuzzy ensemble approach, we selected Min/Max norm [37], Product norm [11], Lukasiewicz norm [24] and Yager norm [36], respectively, alongside the border based shrink heuristic as the parameters, for training fuzzy classifiers. The trained fuzzy classifiers were then fused through the maximum rule (Eq. (7)). For defuzzification, a membership degree $\mu_{l_j}(x_i) > 0.5$ is used for identifying the presence of a type of hate speech.

For DNN methods, embedding features were prepared according to the settings of CNN and LSTM reported in [12] and [3], respectively. Based on the prepared embedding features, the classifiers were trained through 2 fully connected layers with 100 units in each layer. The rectified linear unit (ReLU) activation function and the mean squared error (MSE) loss function were used with the learning rate of 0.01, and Stochastic Gradient Descent was used for optimizing the parameters over 20 epochs with the batch size of 10.

The results (rounded to 2 decimal places) on detection rate and irrelevance rate are shown in Tables 1 and 2, respectively. In particular, Table 1 shows that the proposed fuzzy ensemble approach performs the best in terms of the overall detection rate and the rate on the detection of the religion hate speech, whereas it performs the same as or marginally worse than SVM on the detection of the other types of hate speech.

Table 1: Detection rate on four types of hate speech

Learning Method	Overall	Religion	Race	Disability	Sexual Orientation
DT	0.84	0.86	0.70	0.75	0.90
NB	0.63	0.57	0.43	0.73	0.75
SVM	0.92	0.92	**0.84**	**0.86**	0.97
GBT	0.90	0.93	0.80	0.82	0.92
CNN	0.35	0.00	0.00	0.00	**1.00**
LSTM	0.33	0.00	0.00	0.00	0.95
Fuzzy	**0.93**	**0.96**	0.81	**0.86**	0.95

Table 2: Irrelevance rate on four types of hate speech

Learning Method	Overall	Religion	Race	Disability	Sexual Orientation
DT	0.57	0.76	0.58	0.19	0.21
NB	**0.00**	**0.00**	**0.00**	**0.00**	**0.00**
SVM	0.37	0.25	0.29	0.20	0.53
GBT	0.54	0.13	0.77	0.12	0.26
CNN	1.00	**0.00**	**0.00**	**0.00**	1.00
LSTM	1.00	**0.00**	**0.00**	**0.00**	1.00
Fuzzy	0.13	0.15	0.00	0.00	0.02

On the other hand, Table 2 shows that the proposed fuzzy ensemble approach outperforms all the other probabilistic approaches, except for NB, in terms of the overall irrelevance rate. In particular, the fuzzy approach performs with an extremely low irrelevance rate on identification of the presence of the race, disability and sexual hate speech (note: 2 non-hate speech instances identified irrelevantly as the race type and 1 identified irrelevantly as the

disability type leading to the rounded irrelevance rate of 0 for both hate speech types) and a fairly low irrelevance rate on identification of religion hate speech (although the rate is considerably higher than the ones on the other types of hate speech).

Although the fuzzy ensemble approach shows a considerably higher overall irrelevance rate than NB, the detection rate obtained using the fuzzy approach is much better than the one obtained using NB. In general, a low detection rate alongside a low irrelevance rate would indicate that the classifier has a strong tendency of not outputting the target class label. In this situation, the irrelevance rate can be extremely low (even equal to 0), since the classifier rarely or even never outputs the target class label.

Table 3: Correlation analysis between different types of hate speech

Label	Religion	Race	Disability	Sexual orientation
Religion	1	-0.221	-0.168	-0.524
Race	-0.221	1	-0.165	-0.221
Disability	-0.168	-0.165	1	-0.237
Sexual Orientation	-0.524	-0.221	-0.237	1

On the basis of the above discussions, the overall performance of the proposed fuzzy ensemble approach is better than the ones of the other probabilistic approaches. In addition, the fuzzy approach can also be used for effectively identifying the label correlations, where the probabilistic approaches fall short [31, 39]. The results on correlation analysis between different labels are shown in Table 3, which indicates the correlation coefficient for each pair of class labels in terms of the membership degrees.

In general, there are three extreme cases, namely, 'mutually exclusive' (the most strongly negative correlation), 'independent' and 'identical' (the most strongly positive correlation), when the correlation coefficients are -1, 0 and +1, respectively. The results shown in Table 3 indicate that the four types of hate speech generally involve very weakly negative correlations. The results on correlation analysis between different types of hate speech show supporting evidence that it is much more necessary to formulate the problem as multi-label classification instead of single-label one. In order to show the correlation analysis in more depth, we conduct an extended study on topic detection using the Latent Dirichlet Allocation (LDA) algorithm. The results are shown in Table 4.

In general, the results show high diversity of hate speech instances, i.e. diverse topics involved in hate speech instances. Some common topics can be found from different hate speech data sets. For example, both religion and race hate speech data involve the topics on black and white people. Also, the topics on christian can be found from both religion and sexual orientation hate speech data. In addition, sports related topics are involved in both disability and sexual orientation hate speech data.

The results on topic detection generally indicate that hate speech instances are highly diverse, leading to a high likelihood that a single tweet could be related to more than one type of hate speech, although the class labels may not have strongly positive correlations. In this case, the proposed fuzzy approach is even more suitable for dealing with the diversity, since it is essentially an instance based approach of fuzzy rule learning. In other words, the generation of each fuzzy rule is triggered by an instance without direct discrimination between different classes.

Table 4: Topics detected from hate speech instances in four data sets using LDA

Dataset	Topic ID	Word Cluster
Religion	0	nigger, paki, black, guy, incident
	1	black, people, shot, killed, white
	2	black, edl, nigga, home, send
	3	niggers, nigga, shame, kill, fuck
	4	black, niggas, paki, nigger, islam
Race	0	nigga, niggas, america, shit, won
	1	black, voted, people, tweets, cuz
	2	white, black, romney, won, gotta
	3	niggas, yall, president, hate, nigga
	4	nigga, real, mitt, house, white
Disability	0	irony, leg, called, lickmynippless, mybad
	1	dont, swimmer, ill, understand, drunk
	2	han, labradors, cancelled, highjumps, blind
	3	moving, arsed, wish, falling, women
	4	wheelchair, team, day, events, frankieboyle
Sexual Orientation	0	gay, chris, broussard, http, dick
	1	gay, hes, nba, call, ball
	2	gay, aint, niggas, pretty, espn
	3	nba, faggot, hes, gay, coming
	4	media, tebow, tim, christian, yourself

5 CONCLUSIONS

In this paper, we have proposed a theoretical framework that involves fuzzy mutli-task learning for hate speech types detection. In particular, a novel formulation of the problem has been introduced in the setting of semi-supervised multi-label learning from single-labelled data. An experimental study has been reported to evaluate the performance of the proposed fuzzy ensemble approach using the two new metrics referred to as 'detection rate' and 'irrelevance rate', respectively. The experimental results show that the proposed fuzzy approach outperforms the state of the art probabilistic approaches such as SVM and DNNs on embedding features. Also, the proposed fuzzy approach provides an intensity score for the presence of each type of hate speech from a tweet and enables the analysis of correlation between different labels, while the probabilistic approaches fall short in this aspect.

In the future, we will collect more diverse types of hate speech instances to increase the number of labels, and investigate the impacts of the increased number of labels on the detection performance of each type of hate speech as well as the intersectionality between different types. Also, an extension of the currently proposed fuzzy approach to involve multiple iterations of semi-supervised multi-labelling would be another interesting further direction in the setting of self-labelling based semi-supervised learning [21], i.e. the original single-labelled data becomes multi-labelled for further training after the first iteration of training.

ABSTRACT

Chinese word segmentation (CWS) is very important for Chinese text processing. Existing methods for CWS usually rely on a large number of labeled sentences to train word segmentation models, which are expensive and time-consuming to annotate. Luckily, the unlabeled data is usually easy to collect and many high-quality Chinese lexicons are off-the-shelf, both of which can provide useful information for CWS. In this paper, we propose a neural approach for Chinese word segmentation which can exploit both lexicon and unlabeled data. Our approach is based on a variant of posterior regularization algorithm, and the unlabeled data and lexicon are incorporated into model training as indirect supervision by regularizing the prediction space of CWS models. Extensive experiments on multiple benchmark datasets in both in-domain and cross-domain scenarios validate the effectiveness of our approach.

1 INTRODUCTION

Chinese word segmentation (CWS) aims to segment Chinese sentence into words [7, 10, 22]. For example, "习近平常与特朗普通电话" is segmented into "习近平/常/与/特朗普/通/电话". Different from English texts where whitespace is used to separate words, there is no natural word delimiter in Chinese. Thus, CWS is very important for processing Chinese texts and is an essential step for many downstream tasks [3, 5, 15].

In recent years, neural network based methods have been widely used for CWS [1, 17, 23, 26]. Most of these methods model CWS as a sequence labeling problem [22, 30], and utilize neural networks to learn the hidden character features [2, 32]. For example, Chen et al. [2] used LSTM [8] to learn character features by capturing the global information of sentence. Peng and Dredze [18] proposed to use LSTM for character feature learning and CRF [9] for character label decoding. However, these methods usually rely on a large number of labeled sentences to train word segmentation models, which are expensive and time-consuming to annotate. Besides, these methods usually have difficulty in segmenting sentences with OOV (out of vocabulary) words or words that are rare in training data [27]. For example, if "习近平" and "特朗普" are OOV words in training data, then these methods will probably segment "习近平常与特朗普通电话" into "习近/平常/与/特朗/普通/电话".

Our work is motivated by following observations. First, the unlabeled Chinese sentences are usually easy to collect on a large scale and can provide useful information for Chinese word segmentation. For example, if the character sequences "习近平" and "特朗普" appear many times in unlabeled data with different contexts, then we can infer that they are probably Chinese words. Second, many high-quality Chinese lexicons have been built and can cover a large number of Chinese words. These lexicons can provide important information of whether a Chinese character sequence can be a valid Chinese word, which is useful for CWS. For example, if "习近平" and "特朗普" are included in a Chinese lexicon, then we can better segment aforementioned sentences. Thus, both unlabeled data and lexicons have the potential to improve the performance of CWS, especially on sentences with OOV and rare words.

In this paper, we propose a neural approach for Chinese word segmentation which can exploit the useful information in both Chinese lexicon and unlabeled data. More specifically, in our approach we propose a unified framework based on posterior regularization [6] to incorporate Chinese lexicon and unlabeled data as indirect supervision to regularize the prediction space of the neural CWS models. The neural CWS architecture used in our approach is CNN-CRF. The neural CWS model is trained based on both indirect supervision inferred from lexicon and unlabeled data and the direct supervision inferred from labeled sentences. Extensive experiments

are conducted on multiple benchmark datasets in both in-domain and cross-domain scenarios. The experimental results show that our approach can effectively improve the performance of Chinese word segmentation, especially when training data is insufficient.

2 RELATED WORK

In recent years, neural network based methods have been widely used for Chinese word segmentation. These methods usually regard CWS as a character-level sequence labeling task. For example, Chen et al. [2] proposed to apply LSTM to Chinese word segmentation. They used LSTM to learn hidden character features by capturing the global context information of sentences. They also used a character window to capture local contexts for building character features. Peng et al, [18] used LSTM to learn the contextual character features and used CRF to jointly decode the labels of characters. These neural methods for CWS usually rely on a large number of labeled sentences for model training. When the labeled data is insufficient, the performance usually declines heavily [21, 27, 28].

Incorporating the useful information in unlabeled sentences and lexicons into CWS has attracted increasing attentions [11, 20, 23]. For example, Li et al. [11] proposed to utilize unlabeled sentences for CWS by using punctuation marks as implicit annotations. However, punctuation marks are sparse in Chinese texts, and the annotations of most characters cannot be obtained in this way. Sun et al. [20] proposed to extract statistics-based character features such as mutual information and accessor variety from unlabeled data, and use these features to improve CWS. Designing these handcrafted features needs a large amount of domain knowledge. Zhang et al. [27] proposed to incorporate lexicon into a neural CWS method based on LSTM-CRF architecture. They designed several handcrafted feature templates to extract additional character features using lexicon, and used another LSTM to learn character representations from these lexicon based features. Liu et al. [12] proposed to utilize lexicon for neural CWS via multi-task learning. They designed an auxiliary task of word classification to exploit lexicon information. Then they jointly trained CWS and word classification models using a multi-task learning framework. However, these methods cannot exploit the useful information in unlabeled data.

There are a few methods which can incorporate both lexicon and unlabeled data into Chinese word segmentation. For example, Liu et al. [13] proposed to build partially annotated data using unlabeled data and lexicons via many handcrafted rules. Then they trained CWS models based on both labeled and partially annotated data using CRF. However, designing these rules requires a lot of domain knowledge. Zhao et al. [31] used a similar way to build partially labeled data for CWS by combining unlabeled data and Chinese lexicons. They trained neural CWS models on both labeled and partially labeled data using a variant of LSTM. However, in these methods the partially annotated data is built simply by word matching without considering the contexts of sentences. Thus, the partially annotated data may contain heavy noise and is not suitable to use directly as training data. Different from these methods, in our approach the lexicon and unlabeled data are incorporated to provide indirect supervision via posterior regularization.

Posterior regularization algorithm [6] can incorporate additional knowledge into model training as constraints over the posterior distributions of models. For instance, Zhang et al. [24] applied posterior regularization to integrate various kinds of knowledge such as bilingual dictionary, phrase table and coverage penalty into neural machine translation and gained huge performance improvements. Our approach is motivated by posterior regularization, and we apply it to incorporate the useful information in Chinese lexicon and unlabeled data into neural Chinese word segmentation.

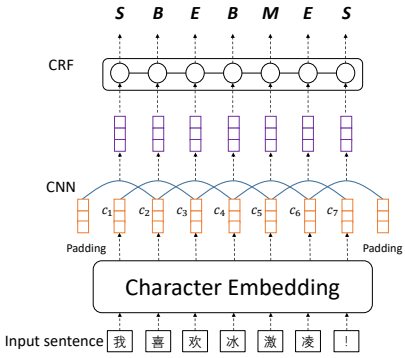

Figure 1: The CNN-CRF neural architecture for CWS.

3 OUR APPROACH

We first introduce the CNN-CRF neural architecture in our approach for Chinese word segmentation. Then we introduce our approach to incorporate lexicon and unlabeled data into neural CWS.

3.1 CNN-CRF Architecture

Following many previous works [14, 29], we model Chinese word segmentation as a character-level sequence labeling problem. For each character in a sentence, our model assigns a tag from a predefined tag set to it which indicates the position of this character in a word. The tag set used in our model is $\{B, M, E, S\}$, where B, M and E mean the beginning, middle and end position in a word respectively, and S means single character word.

We use CNN-CRF as the neural architecture for CWS which is illustrated in Fig. 1. The CNN-CRF architecture contains three layers. The first one is character embedding. Given a sentence $x = [c_1, c_2, ..., c_N]$, the character embedding layer will map each character to a low-dimensional dense vector. Here c_i is the i-th character in the sentence, and N is the sentence length. The output of this layer is $x = [\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_N]$, where $\mathbf{e}_i$ is the embedding of c_i.

The second layer is a CNN network. It is used to learn contextual representations of characters. The hidden feature of the i-th character learned by a convolutional kernel is:

$$h_i = f(\mathbf{w}^T \times \mathbf{e}_{i-\lceil \frac{k-1}{2} \rceil : i+\lfloor \frac{k-1}{2} \rfloor} + b), \quad (1)$$

where $\mathbf{w}$ and b are the parameters of the convolutional kernel, K is the kernel size, and $\mathbf{e}_{i-\lceil \frac{k-1}{2} \rceil : i+\lfloor \frac{k-1}{2} \rfloor}$ represents the concatenation of the embeddings from $i - \lceil \frac{k-1}{2} \rceil$-th character to $i + \lfloor \frac{k-1}{2} \rfloor$-th character. We use multiple kernels with different kernel sizes and concatenate the outputs of these convolutional kernels as the feature representation for each character. The output of CNN layer is

$[\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_N]$, where $\mathbf{h}_i \in \mathcal{R}^F$, and F is the number of kernels in the CNN network.

The third layer is CRF [9]. Given a sentence $\mathbf{x} = [c_1, c_2, ..., c_N]$ and a tag sequence $\mathbf{y} = [y_1, y_2, ..., y_N]$, the score of sentence $\mathbf{x}$ having tag sequence $\mathbf{y}$ is formulated as follows:

$$s(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{N} U_{i,y_i} + \sum_{i=1}^{N-1} A_{y_i, y_{i+1}}, \tag{2}$$

where U_{i,y_i} represents the unary score of assigning tag y_i to the i-th character, and $A_{y_i,y_{i+1}}$ represents the score of jumping from tag y_i to tag y_{i+1}. The unary score $\mathbf{U}_i \in \mathcal{R}^T$ is formulated as:

$$\mathbf{U}_i = \mathbf{W}_c \mathbf{h}_i + \mathbf{b}_c, \tag{3}$$

where $\mathbf{W}_c \in \mathcal{R}^{T \times F}$ and $\mathbf{b}_c \in \mathcal{R}^T$ are trainable parameters, and T is the size of the tag set. Then the likelihood probability of sentence $\mathbf{x}$ having tag sequence $\mathbf{y}$ is defined as:

$$p(\mathbf{y}|\mathbf{x}) = \frac{e^{\mathbf{s}(\mathbf{x},\mathbf{y})}}{\sum_{\mathbf{y}' \in \mathcal{Y}_\mathbf{x}} e^{\mathbf{s}(\mathbf{x},\mathbf{y}')}}, \tag{4}$$

where $\mathcal{Y}_\mathbf{x}$ represents the set of all possible tag sequences of sentence $\mathbf{x}$. And the loss function is formulated as follows:

$$\mathcal{L}(\boldsymbol{\theta}) = -\sum_{i=1}^{N_l} \log(p(\mathbf{y}_i|\mathbf{x}_i;\boldsymbol{\theta})), \tag{5}$$

where $\mathbf{x}_i$ is the i-th training sentence, $\mathbf{y}_i$ is its ground truth tag sequence, N_l is the number of labeled sentences in training set, and $\boldsymbol{\theta}$ represents all parameters of the neural CWS model.

3.2 Neural CWS with Lexicon and Unlabeled Data via Posterior Regularization

In this section we introduce our approach to exploit lexicon and unlabeled data to train a neural CWS model. Our approach is based on posterior regularization [6], and we propose a unified framework to incorporate the useful information in lexicon and unlabeled data as indirect supervision into model training by regularizing the prediction space of neural CWS model. In our approach the neural CWS model is trained in an iterative manner. Following [24], in iteration t, the loss function of the indirect supervision is:

$$\mathcal{L}^{PR}(\boldsymbol{\theta}) = \sum_{i=1}^{N_u} \mathrm{KL}(Q(\mathbf{y}|\mathbf{x}_i;\boldsymbol{D},\boldsymbol{\theta}^t)||p(\mathbf{y}|\mathbf{x}_i;\boldsymbol{\theta})), \tag{6}$$

where $\boldsymbol{\theta}$ is the parameter set of CNN-CRF model, $\boldsymbol{\theta}^t$ is the model learned in iteration $t-1$, $\boldsymbol{D}$ represents Chinese lexicon, and N_u is the number of unlabeled sentences. KL is the KL divergence function. $Q(\mathbf{y}|\mathbf{x};\boldsymbol{D},\boldsymbol{\theta}^t)$ is the probability distribution of tag sequence $\mathbf{y}$ for unlabeled sentence $\mathbf{x}$ given lexicon $\boldsymbol{D}$ and previous model $\boldsymbol{\theta}^t$:

$$Q(\mathbf{y}|\mathbf{x};\boldsymbol{D},\boldsymbol{\theta}^t) = \frac{\exp(\phi(\mathbf{y},\mathbf{x};\boldsymbol{D},\boldsymbol{\theta}^t))}{\sum_{\hat{\mathbf{y}} \in \mathcal{Y}(\mathbf{x})} \exp(\phi(\hat{\mathbf{y}},\mathbf{x};\boldsymbol{D},\boldsymbol{\theta}^t))}, \tag{7}$$

where $\phi(\mathbf{y},\mathbf{x};\mathbf{D},\boldsymbol{\theta}^t)$ is a score function of tag sequence $\mathbf{y}$ for sentence $\mathbf{x}$, and $\mathcal{Y}(\mathbf{x})$ is the set of all possible tag sequences of $\mathbf{x}$. $\phi(\mathbf{y};\mathbf{x},\mathbf{D},\boldsymbol{\theta}^t)$ is designed to encode both lexicon information and the predictions of previous CWS model towards this sentence:

$$\phi(\mathbf{y};\mathbf{x},\boldsymbol{D},\boldsymbol{\theta}^t) = \frac{n(\mathbf{x},\mathbf{y};\boldsymbol{D})}{n(\mathbf{x},\mathbf{y})} + \alpha \cdot s(\mathbf{x},\mathbf{y};\boldsymbol{\theta}^t), \tag{8}$$

where $n(\mathbf{x},\mathbf{y})$ is the number of words in the segmentation result, $n(\mathbf{x},\mathbf{y};\boldsymbol{D})$ is the number of words in segmentation result which are included in lexicon $\boldsymbol{D}$, $s(\mathbf{x},\mathbf{y};\boldsymbol{\theta}^t)$ is the segmentation score predicted by the CWS model $\boldsymbol{\theta}^t$ trained in previous iteration according to Eq. (2), and α is a positive coefficient. According to Eq. (8), if a tag sequence $\mathbf{y}$ for an unlabeled sentence $\mathbf{x}$ can lead to more lexicon-included words and has higher segmentation score according to existing CWS model, then it will have a higher probability in Eq. (7), and we regularize our neural CWS model so that it tends to generate this tag sequence in Eq. (6). In this way, the useful information in lexicon and unlabeled sentences can be incorporated into the learning of neural CWS model as indirect supervision.

Since a sentence usually has many possible tag sequences, following [24], KL function in Eq. (6) is approximated as:

$$\sum_{\mathbf{y} \in \mathcal{S}(\mathbf{x}_i)} \tilde{Q}(\mathbf{y}|\mathbf{x}_i;\boldsymbol{D},\boldsymbol{\theta}^t) \log(\frac{\tilde{Q}(\mathbf{y}|\mathbf{x}_i;\boldsymbol{D},\boldsymbol{\theta}^t)}{p(\mathbf{y}|\mathbf{x}_i;\boldsymbol{\theta})}), \tag{9}$$

where $\mathcal{S}(\mathbf{x}_i)$ is a subset of $\mathcal{Y}(\mathbf{x}_i)$ whose elements have the highest prediction scores according to existing CWS model $\boldsymbol{\theta}^t$. $\tilde{Q}$ is an approximation of Q on the subset $\mathcal{S}(\mathbf{x}_i)$ as follows:

$$\tilde{Q}(\mathbf{y}|\mathbf{x}_i;\boldsymbol{D},\boldsymbol{\theta}^t) = \frac{\exp(\phi(\mathbf{y},\mathbf{x}_i;\boldsymbol{D},\boldsymbol{\theta}^t))}{\sum_{\hat{\mathbf{y}} \in \mathcal{S}(\mathbf{x}_i)} \exp(\phi(\hat{\mathbf{y}},\mathbf{x}_i;\boldsymbol{D},\boldsymbol{\theta}^t))}. \tag{10}$$

In our approach, in each iteration the neural CWS model $\boldsymbol{\theta}$ is updated based on both labeled sentences and the indirect supervision from lexicon and unlabeled data. The objective function for model update at iteration t is formulated as follows:

$$\mathcal{J}(\boldsymbol{\theta}) = -\sum_{i=1}^{N_l} \log(p(\mathbf{y}_i|\mathbf{x}_i;\boldsymbol{\theta})) - \lambda \sum_{i=1}^{N_u} \sum_{\hat{\mathbf{y}} \in \mathcal{S}(\mathbf{x}_i)} \tilde{Q}(\hat{\mathbf{y}}|\mathbf{x}_i;\boldsymbol{D},\boldsymbol{\theta}^t) \log(p(\hat{\mathbf{y}}|\mathbf{x}_i;\boldsymbol{\theta})), \tag{11}$$

where λ is a positive coefficient to control the relative importance of indirect supervision in model training. In the first iteration, the initial neural CWS model $\boldsymbol{\theta}^1$ is trained on labeled sentences.

4 EXPERIMENT

4.1 Datasets and Experimental Settings

Two benchmark datasets released by the third international Chinese language processing bakeoff[1] [10] are used in our experiments. The first one is the *MSRA* dataset, which contains 46,364 labeled sentences for training and 4,365 labeled sentences for test. The second one is the *UPUC* dataset, which contains 18,804 and 5,117 labeled sentences for training and test.

The lexicon used in our experiments is the Sogou Chinese lexicon[2]. The size of character embeddings is 200. These character embeddings are pretrained on the Sogou news corpus[3] using the word2vec [16] tool. We use 400 convolutional kernels in the CNN network, and the sizes of these kernels vary from 2 to 5. λ in Eq. (11) and α in Eq. (8) are set to 0.5 and 1 respectively. We apply dropout technique to the embedding layer and the CNN layer, and the dropout rate is 0.3. RMSProp [4] algorithm is used for model training. The learning rate is 0.001 and the batch size is 64. These hyper-parameters are selected using validation data. Following [2],

[1] http://sighan.cs.uchicago.edu/bakeoff2006/download.html
[2] http://www.sogou.com/labs/resource/list_lan.php
[3] http://www.sogou.com/labs/resource/ca.php

we use the last 10% sentences in the training set as validation data, and the remaining labeled sentences for model training. In addition, we randomly sample 50% training data as unlabeled data. Each experiment is repeated 5 times and the average results are reported.

4.2 Performance Evaluation

In this section we evaluate the performance of our approach by comparing it with many baseline methods for Chinese word segmentation. These methods include: (1) LSTM-CRF, the most popular neural method for CWS based on the LSTM-CRF architecture [18]; (2) CNN-CRF, the neural CWS method based on the CNN-CRF architecture, which is the basic model in our approach; (3) Chen [2], a neural CWS method using LSTM to learn character features and also considering local contexts; (4) Zhang [27], an LSTM-CRF based CWS method which integrates lexicon into model training via feature templates; (5) Liu [12], a neural CWS method which incorporates lexicon into model training via multi-task learning; (6) Liu [13], a CRF based CWS method which utilizes lexicon and unlabeled data to build partially labeled data for model training; (7) Zhao [31], an LSTM based CWS method which incorporates lexicon and unlabeled data via building partially labeled data; (8) LUPR, our proposed neural CWS approach with both lexicon and unlabeled data via posterior regularization. We conducted experiments on different ratios of training data, and the experimental results of different methods are summarized in Tables 1 and 2.

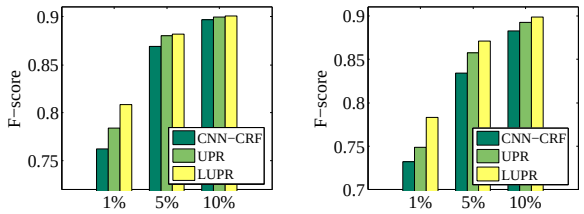

Table 1: The results on the *MSRA* dataset. P, R and F represent precision, recall and Fscore respectively.

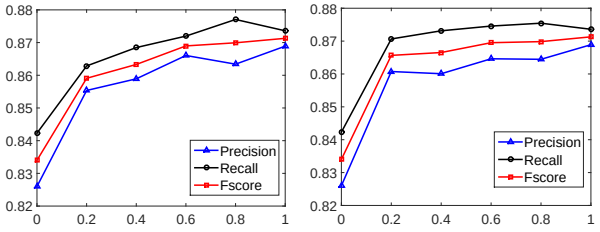
According to Tables 1 and 2, our approach can outperform many neural Chinese word segmentation methods such as CNN-CRF, LSTM-CRF and Chen [2]. In addition, the advantage of our approach over these baseline methods becomes bigger when the number of training samples decreases. This is because these methods rely on a large number of labeled sentences to train neural CWS models, and cannot exploit the useful information in lexicon and unlabeled data.

(a) *MSRA* dataset. (b) *UPUC* dataset.

Figure 2: The performance of the basic CNN-CRF model and our approach with only unlabeled data (UPR) and with both lexicon and unlabeled data (LUPR).

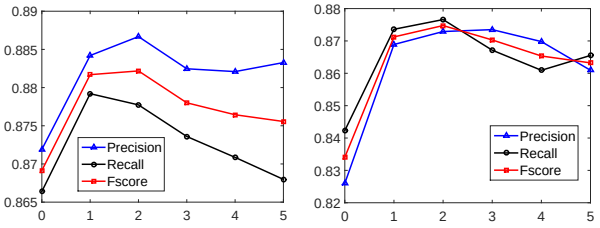
When training data is insufficient, it is very difficult for these methods to train accurate and robust CWS models. Since our approach can exploit the useful information in both lexicon and unlabeled data, it can reduce the dependence on labeled sentences and achieve better performance than these baseline methods.



Although the methods proposed in [27] and [12] can also incorporate lexicon information into neural CWS model training, our approach can consistently outperform them. In [27] the lexicon is utilized via handcrafted feature templates, which need a lot of domain knowledge to design and may not be optimal. In addition, an extra LSTM network is incorporated to learn hidden character representations from these lexicon based features, making the neural model more difficult to train when labeled data is scarce. In [12] the lexicon is utilized via an auxiliary word classification task which is jointly trained with CWS model. Although these methods can utilize the lexicon for neural CWS, the useful information in massive unlabeled data is not considered. Our approach can exploit both lexicon and unlabeled data for neural Chinese word segmentation. Thus, our approach can consistently outperform them.

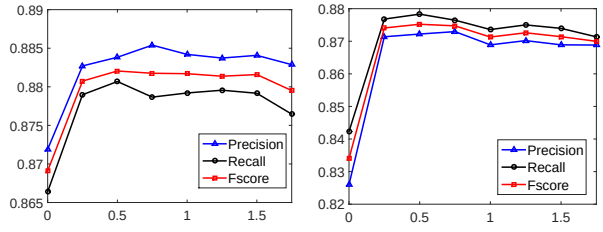
Although the methods in [13] and [31] can also exploit both lexicon and unlabeled data for CWS, our approach can still outperform them. In [13] and [31], the lexicon and unlabeled data are used to build partially annotated datasets. However, the partially annotated data constructed by word matching based on lexicons may contain heavy noise and the context information of sentences is not considered. In our approach, the lexicon and unlabeled data are used to provide indirect supervision for model training by regularizing the prediction space of the neural CWS model. The experimental results show that our approach is more effective in exploiting Chinese lexicon and unlabeled data for CWS than [13] and [31].

4.3 Effect of Lexicon and Unlabeled Data



In this section, we conducted experiments to explore the effectiveness of lexicon and unlabeled data for neural Chinese word segmentation. The experimental results are summarized in Fig. 2.

According to Fig. 2, incorporating unlabeled data can effectively improve the performance of CWS in our approach. This is because the massive unlabeled data contains rich useful information for word segmentation. For example, if the character sequence "特朗普" frequently appear in unlabeled sentences with different contexts, then we can infer that it is probably a unique Chinese word. The result in Fig. 2 shows that our approach is effective in exploiting



(a) Ratio of unlabeled data. (b) Ratio of words in lexicon.

Figure 5: Influence of λ in Eq. (11).

(a) *MSRA* dataset. (b) *UPUC* dataset.

Figure 6: Influence of iteration number.

the useful information in unlabeled data for CWS. In addition, according to Fig. 2 after incorporating lexicon the performance of our approach can be further improved. This is because the Chinese lexicon can provide important information of whether a character sequence can be a valid Chinese word, which is useful for the CWS task. The result in Fig. 2 validates that our approach can effectively exploit Chinese lexicon to improve the performance of neural CWS.

4.4 Size of Lexicon and Unlabeled Data

In this section, we conduct experiments to explore the influence of the sizes of unlabeled data and Chinese lexicon on the performance of our approach. The experiments were conducted on the *UPUC* dataset, and we randomly sampled 5% of the training data for model training. The experiments on the *MSRA* dataset show similar patterns. The experimental results of unlabeled data size are summarized in Fig. 3(a). We can see that as more unlabeled data is incorporated, the performance of our approach consistently improves. This result further validates that the unlabeled data contains a lot of useful information for Chinese word segmentation, and our approach is effective in exploiting unlabeled data for neural CWS methods. The experimental results of lexicon size are shown in Fig. 3(b). According to Fig. 3(b), as more Chinese words are included in the lexicon, the performance of our approach improves. This is because with more Chinese words in the lexicon, our approach can have better capacity in recognizing the boundaries of words which rarely or never appear in training data but are included in the Chinese lexicon.

4.5 Influence of Hyper-parameters

In this section, we conducted experiments to explore the influence of three important hyper-parameters, i.e., the size of set S in Eq. (9), λ in Eq. (11) and iteration number, on the performance of our approach. The experimental results of the size of set S in Eq. (9) are shown in Fig. 4. In these experiments, we randomly sampled 5% of the training data for model training. According to Fig. 4, when the size of S in Eq. (9) increases from 0 to 1, the performance of our approach significantly improves. This is because when the size of S is 0, the useful information in unlabeled data and lexicon is not incorporated. Thus, the performance is not optimal. When the size of S becomes too large, the performance of our approach slightly decreases. It indicates that the number of informative tag sequences of unlabeled sentences inferred from lexicon is usually limited, and incorporating too many of them may introduce some noisy information. A moderate size of S (e.g., 2) is most suitable for our approach.

The experimental results of λ are shown in Fig. 5. λ is used to control the relative importance of the indirect supervision from unlabeled data and lexicon in Eq. (11). According to Fig. 5, as λ increases, the performance of our approach first increases and then slightly decreases. This is because when λ is too small, the useful information in the lexicon and unlabeled data is not fully exploited. Thus, the performance is not optimal. However, when λ becomes too large, the indirect supervision inferred from lexicon and unlabeled data is over-emphasized and the labeled sentences are not fully respected. Thus, the performance starts to decline. A moderate value of λ is most appropriate for our approach.

The experimental results of iteration number are shown in Fig. 6. According to Fig. 6, as the iteration number grows, the performance of our approach first improves and then gradually becomes stable. This is because in each iteration the neural CWS model can be enhanced by incorporating the unlabeled data and lexicon, and the refined CWS model in turn can help improve the indirect supervision in the next iteration of our approach. This result validates the

effectiveness of our approach in iteratively training neural CWS model by exploiting both labeled sentences and the indirect supervision inferred from the unlabeled sentences and Chinese lexicons.

4.6 Domain Adaptation for CWS

In Chinese word segmentation field, several domains (e.g., news) have accumulated much labeled data, while in many other domains (e.g., medical records) labeled data for CWS is scarce and even nonexistent. Although annotating sufficient labeled data for these domains is time-consuming and expensive, the unlabeled sentences are usually easy to collect. In addition, in many target domains there are off-the-shelf lexicons or it is relatively easy to build one. Thus, an interesting application of our approach is domain adaptation for Chinese word segmentation, i.e., using labeled sentences in a source domain (e.g., news) and unlabeled sentences in a target domain (e.g., medical records) as well as the lexicon from the target domain to train a robust neural CWS model for target domain. In this section we conduct experiments to explore the performance of our approach in domain adaptation for word segmentation.

Two datasets are used in our experiments. The first one is the *Zhuxian* dataset[4] built by Zhang et al. [25] from a Chinese online novel. We used the same lexicon[5] as [31] for this domain. In addition, we used the same unlabeled data as [13] which contains about 16K sentences. The second dataset is the Weibo dataset[6] released by the Weibo word segmentation task of NLPCC2016 [19]. This dataset contains 20,135 sentences for training and 8,592 sentences for test. Since there is no off-the-shelf lexicon for Weibo word segmentation, we built one using the words extracted from the training data. In addition, we regarded the training sentences as unlabeled data. We used *Zhuxian* and *Weibo* datasets as two target domains, and used the *UPUC* dataset as source domain. The experimental results are summarized in Table 3. The settings of our approach and baseline methods are consistent with previous experiments.

Table 3: Experimental results of domain adaptation.

	Zhuxian			Weibo		
	P	*R*	*F*	*P*	*R*	*F*
CNN-CRF	87.95	87.68	87.81	86.11	88.23	87.16
LSTM-CRF	85.94	86.26	86.10	86.39	88.35	87.36
Chen [2]	85.24	87.57	86.39	86.87	89.28	88.06
Zhang [27]	88.70	87.89	88.29	88.94	**90.89**	89.90
Liu [12]	87.79	88.04	87.91	86.24	88.49	87.35
Liu [13]	89.86	89.04	89.44	**90.31**	89.89	90.10
Zhao [31]	88.50	**91.32**	89.90	89.83	85.07	87.39
LUPR	**90.53**	89.39	**89.95**	89.85	90.73	**90.29**

According to Table 3, the performance of neural models that are trained on labeled data of source domain such as CNN-CRF, LSTM-CRF and [2] is relatively low in target domains. This is because there is huge difference in word distribution between source and target domains. Many words in target domain may not or rarely appear in the labeled data of source domain, making it difficult for these CWS methods to segment the sentences in target domain. The methods proposed in [27] and [12] which incorporate lexicon can effectively improve the performance of CWS in target domains. Our approach can outperform these methods because beyond the lexicon information our approach can also incorporate massive unlabeled data into neural model training, which can provide useful information for CWS. Although [13] and [31] can incorporate both lexicon and unlabeled data for word segmentation, our approach can outperform them in the domain adaptation scenario. This result implies that incorporating the lexicon and unlabeled data as indirect supervision via posterior regularization is more suitable for domain adaptation of CWS than utilizing them to build partially labeled data through word matching, which may introduce heavy noise.

4.7 Case Study

In this section, we conducted several case studies to further explore why our approach can improve the performance of CWS. We studied several cases in the domain adaptation experiments, where the source domain is *UPUC* and the target domain is *Weibo*. Several examples are illustrated in Table 4.

Table 4: Several examples of Chinese word segmentation.

	Example 1	Example 2
Sentence	养老金调整三大焦点问题	穆勒操刀梅开二度
CNN-CRF	养/老金/调整/三/大/焦点/问题	穆勒/操刀/梅开/二/度
LUPR	养老金/调整/三/大/焦点/问题	穆勒/操刀/梅开二度

According to Table 4, our approach performs better than baseline methods in domain adaptation scenario, especially on the sentences with OOV and rare words of source domain. For example, in the first example “养老金" is a rare word in the training data of source domain, and in the second example “梅开二度" is an OOV word in source domain. The segmentation results of the basic CNN-CRF model on these words are not correct. Since “养老金" is a popular word in the unlabeled data of target domain and “梅开二度" is included in the target domain lexicon, our approach can correctly segment these sentences. Thus, our approach can improve the performance of Chinese word segmentation by exploiting the useful information in both lexicon and unlabeled data.

5 CONCLUSION

In this paper, we propose a neural approach for Chinese word segmentation which can exploit the useful information in both Chinese lexicon and unlabeled sentences for model training. Our approach is based on the posterior regularization algorithm, and we propose a unified framework to incorporate both unlabeled data and lexicon to provide indirect supervision for model training by regularizing the prediction space of the neural CWS models. Extensive experiments are conducted on multiple benchmark datasets in both in-domain and cross-domain scenarios. The experimental results validate that our approach can effectively improve the performance of neural Chinese word segmentation.

ABSTRACT

With the increasing popularity of micro-video sharing where people shoot short-videos effortlessly and share their daily stories on social media platforms, the micro-video recommendation has attracted extensive research efforts to provide users with micro-videos that interest them. In this paper, a hypothesis we explore is that, not only do users have multi-modal interest, but micro-videos have multi-modal targeted audience segments. As a result, we propose a novel framework User-Video Co-Attention Network (UVCAN), which can learn multi-modal information from both user and microvideo side using attention mechanism. In addition, UVCAN reasons about the attention in a stacked attention network fashion for both user and micro-video. Extensive experiments on two datasets collected from Toffee present superior results of our proposed UVCAN over the state-of-the-art recommendation methods, which demonstrate the effectiveness of the proposed framework.

1 INTRODUCTION

In the era of mobile Internet, people are now able to shoot micro-videos (or short-videos) effortlessly and share their daily stories on social media platforms, such as Musical.ly and TikTok. With the usage of social media platforms rapidly increasing, millions of micro-videos are being generated from users of different kinds. For example, Figure 1 gives an example of micro-video on Musical.ly. The ever-increasing volume of micro-videos makes it harder for users to find the micro-video that best interests them. This has increased the demand for recommender system more than ever before.

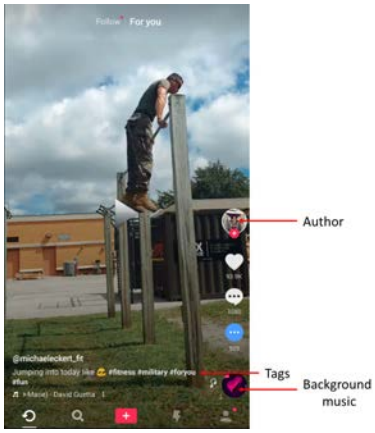

Figure 1: An example of micro-video on Musical.ly.

An offline recommender system predicts user preference and retrieves micro-video list which will be recommended to them by using users' features such as user ID or cookies, and personalizes the micro-videos for individual users [9]. However, traditional ID-based recommendation methods, such as collaborative filtering (CF) [27] and low-rank factorization [15], only consider the linear users' interaction with micro-videos without exploring non-linear and more complicated user-video interaction representation based on their features, which is important for users' hidden preferences learning. To solve this problem, recently Ma et al. [24] have proposed a genre aware neural network micro-video recommendation model on micro-video recommendation. Micro-video attention based model [5] has been explored for recommendation, where the attention mechanism learns a video representation highlighting micro-video frames relevant to user's preference. In this paper, we argue that, not only do users have multi-modal interest, but micro-videos have multi-modal targeted audience segments. In addition to visual feature, we also consider more micro-video side information that has effect on user's preference.

In this paper, we present a novel User-Video Co-Attention Network (UVCAN) framework for personalized micro-video recommendation which can learn multi-modal information from both user and micro-video side using attention mechanism. Unlike previous work, which connects these side information features as the user or micro-video embedding representation and only focuses on video attention, UVCAN proposes alternating co-attention to attend both user and video modalities. Through the user-video co-attention network, micro-video's and user's representations focus more on key features that demonstrate user's hidden preference. In addition, for each attention processing, we design stacked attention network to learn attention representation since only one layer of reasoning may be not enough to learn complex multi-modal features representation. Besides, we adopt a connection to associate the learned user representation, micro-video multi-modal representation, user ID embedding and micro-video ID embedding, hoping to combine collaborative filtering and attention mechanism learning for personalized micro-video recommendation.

The main contributions of this work are summarized as follows:

- A novel co-attention mechanism for personalized micro-video recommendation is proposed to jointly perform user-guided micro-video attention and video-guided user attention. Moreover, we explore this mechanism with multi-modal micro-video features and user profile.
- A stacked attention network is proposed for each attention processing to deal with complex multi-modal information, and attention learning on user attributes or micro-video multi-modal features is refined with the network step by step.
- Real-world micro-video datasets are constructed, which consist of user's attributes (user gender and location), micro-video's content information (micro-video author, background music and tags) and user-video interaction records. Extensive experiments on our collected micro-video datasets with about 336K interactions demonstrate that our proposed UVCAN outperforms current state-of-the-art methods that use hybrid approaches.

2 RELATED WORK

2.1 Video Recommendation

The existing approaches to deal with video recommendation fall into three categories: collaborative filtering [1, 11, 18], content-based filtering [9, 10] and hybrid approaches [3, 5]. Majority of the existing approaches deal with traditional videos (e.g., YouTube) while little research has been conducted for micro-videos. Because of the increasing popularity of micro-video sharing, researchers have paid more attention to micro-video data analytics. For example, Ma et al. [24] proposed a latent genre aware neural network micro-video recommendation model on micro-video recommendation. More recently, Chen et al. [7] proposed temporal attention network for user behavior modeling for micro-video recommendation. In this paper, we build new micro-video datasets involving more side information, such as user's attribute information as well as micro-video's background music and author, for studying personalized micro-video recommendation. Our proposed model using stacked co-attention deep network to sequentially model user and micro-video representations is also distinctive from the aforementioned work.

2.2 Recommendation with Neural Networks

Recently, deep neural networks are being used to extract refined latent features [14] from the user-item interaction data. The early work [26] proposes Restricted Boltzmann Machines (RBM) with an input layer and a hidden layer for collaborative filtering. Auto-Encoder has been applied to recommendation tasks, e.g., AutoRec [28], DAE [22] and CDAE [33]. Cheng et al. [8] propose Wide& Deep approach for app recommendation, where the deep component is a MLP on concatenated feature embedding vectors.

Attention mechanism has been applied to deal with a variety of problem including computer vision [34], neural language processing [23] and recommender systems [2, 4, 30, 31]. For example, Chen et al. [4] introduce a attention mechanism to explore the usefulness of reviews, and propose a neural attentional regression model with review-level explanations for recommendation. Wei et al. [36] propose a user-guided attention network to attend image's multi-modal information for image representation learning. However, Chen's and Wei's work [4, 36] only utilize user-guided attention on item to generate item representation, and do not attend user side attention. These methods are fundamentally different from our proposed approach that employs user-video co-attention network to jointly describe user and micro-video attention mechanism.

3 PRELIMINARIES

In this section, we first introduce the notation and define the problem. We then introduce the embedding of user's and micro-video's information to construct the input representation.

3.1 Problem Formulation and Notations

Table 1: Definitions of notations.

Notation	description
$\mathcal{U}, \mathcal{V}$	user set, micro-video set
S^u, S^v	multi-modal information embedding of u, v
u, v	a specific user, item
$\boldsymbol{h}^u, \boldsymbol{h}^v$	identity embedding vector of u, v. $h^u, h^v \in \mathbb{R}^K$
$\boldsymbol{s}^u, \boldsymbol{s}^v$	feature embedding vector of u, v. $s^u, s^v \in \mathbb{R}^K$
K	dimensionality of the embedding vector
$\boldsymbol{Y}$	user-video interaction matrix $\boldsymbol{Y} \in \mathbb{R}^{U \times I}$
$\delta(\cdot)$	the logistic sigmoid function

We are tackling the micro-video recommendation problem by jointly considering user and micro-video attention. We consider the task of recommending micro-videos denoted as $\mathcal{V} = \{v_1, v_2, ..., v_{|\mathcal{V}|}\}$ to users denoted as $\mathcal{U} = \{u_1, u_2, ..., u_{|\mathcal{U}|}\}$. Each user u is associated with some attribute features denoted as S^u (e.g., user gender, location): $S^u = (S^u_1, S^u_2, ..., S^u_{|S^u|})$. The micro-video content information is denoted as S^v (e.g., micro-video visual content, author, background music): $S^v = (S^v_1, S^v_2, ..., S^v_{|S^v|})$. We define a user-video interaction matrix as $\boldsymbol{Y} \in \mathbb{R}^{U \times I}$, where the entry y_{uv} is defined

from user's implicit feedback, $y_{uv} = 1$ indicates that the user u has given the micro-video v a thumbs-up and $y_{uv} = 0$ indicates that there is no observed data about the interaction (user u, micro-video v). Our goal is to predict the user's preference for micro-videos not exposed to them before, and recommend micro-videos accordingly. Some notation frequently used throughout this paper is introduced in Table 1. Matrices are denoted with bold symbols.

3.2 Construction of Input Representation

For side information of users and micro-videos, the original representation are strings (e.g., 'gender=F' for a user, 'tag=fun' for a micro-video). We convert these sparse categorical features to low-dimensional vectors, which are referred as embedding vectors and initialized randomly. Incorporating user's identity vector $\boldsymbol{h}^u$ and side information, the embedding vectors for user u is extended as $\{\boldsymbol{h}^u, \boldsymbol{s}^u_1, \boldsymbol{s}^u_2, ..., \boldsymbol{s}^u_{|s^u|}\}$. The side information for the user is user gender and location. The side information for micro-video is tags, author id and background music id.

For micro-video visual feature, we follow the work [21] by extracting visual feature from micro-videos using pre-trained model. In particular, we extract image features at 1-frame-per-second using an Inception-v3 network [29]. We fetch the Relu activation of the last hidden layer and apply PCA (and whitening) to reduce feature dimensions to 1024 for storage and computational reasons. These frame-level features are aggregated into video-level by average pooling. For convenience of calculation, we use a single layer perceptron to convert each visual vector into a new vector that has the same dimension K as other side information feature vector. Incorporating micro-video identity vector $\boldsymbol{h}^v$ and visual feature, the embedding vectors for micro-video v is extended as $\{\boldsymbol{h}^v, \boldsymbol{s}^v_1, \boldsymbol{s}^v_2, ..., \boldsymbol{s}^v_{|s^v|}\}$, where $\boldsymbol{s}^v$ is the multi-modal information embedding for micro-video.

4 USER-VIDEO CO-ATTENTION NETWORK (UVCAN)

In this section, we first present our User-Video Co-Attention Network (UVCAN) model in detail. We then go through the learning details of UVCAN. The overall architecture of the model is shown in Figure 2.

For the user's embedding column vectors, we concatenate them to form the whole user feature representation matrix: $\boldsymbol{q}^u = concat^{(1)}(\boldsymbol{h}^u, \boldsymbol{s}^u_1, \boldsymbol{s}^u_2, ..., \boldsymbol{s}^u_{|s^u|})$ where $\boldsymbol{q}^u \in \mathbb{R}^{K\times(|s^u|+1)}$. For the micro-video's embedding column vectors, we concatenate them to form the whole micro-video feature representation matrix: $\boldsymbol{q}^v = concat^{(1)}(\boldsymbol{h}^v, \boldsymbol{s}^v_1, \boldsymbol{s}^v_2, ..., \boldsymbol{s}^v_{|s^v|})$ where $\boldsymbol{q}^v \in \mathbb{R}^{K\times(|s^v|+1)}$. Because not only do users have multi-modal interest, but micro-video have multi-modal targeted audience segments, we propose a user-video co-attention network that learn multi-modal information from both user and micro-video side using attention mechanism.

We first define the attention operation $\hat{x} = \mathcal{A}(\boldsymbol{X}, \boldsymbol{g})$, which takes the micro-video (or user) features $\boldsymbol{X}$ and attention guidance $\boldsymbol{g}$ derived from user (or micro-video) as inputs, and outputs the attended micro-video (or user) vector x. The operation can be denoted in the following.

$$\begin{aligned} \boldsymbol{H} &= tanh(\boldsymbol{W}_x\boldsymbol{X} + (\boldsymbol{W}_g\boldsymbol{g})\boldsymbol{I}^T), \\ \boldsymbol{a}^x &= softmax(\boldsymbol{w}^T_{hx}\boldsymbol{H} + \boldsymbol{b}), \\ \hat{\boldsymbol{x}} &= \sum a^x_i \boldsymbol{x}_i, \end{aligned} \tag{1}$$

where $\boldsymbol{I}$ is a vector with all elements to be 1. $\boldsymbol{W}_x, \boldsymbol{W}_g \in \mathbb{R}^k$ are parameters. $\boldsymbol{a}^x$ is the attention weight of feature $\boldsymbol{X}$.

4.1 User-guided Micro-video Attention

In most cases, a user is attracted by some specific micro-video features. For example, the user may pay more attention to the micro-video's visual content and author, which will play vital importance role for micro-video representation that caters user's personal preference. Hence, instead of using a global vector connecting micro-video features, we use a user-guided attention layer to filter and find features that are relevant user's personalized preference.

Before the micro-video attention, we first take user's features $\boldsymbol{q}^u$ and attention guidance $\boldsymbol{g} = \boldsymbol{0}$ to summarize the user features into a single vector $\hat{\boldsymbol{q}}_0$. Next, we take micro-video features $\boldsymbol{q}^v$ as $\boldsymbol{X}$ and the guidance $\boldsymbol{g}$ is the intermediate attended user feature $\hat{\boldsymbol{q}}_0$. Based on the attention probability of each micro-video feature, the new representation of the micro-video is constructed as weighted sum of the micro-video vector. we then use the new micro-video representation $\hat{\boldsymbol{v}}_v$ to guide the user attention.

4.2 Video-guided User Attention

Compared to models that only use user identity to guide item attention, the co-attention network model develops a more informative representation by mutually attending micro-video and user. After the phrase of user-guided micro-video attention (see Figure 2), UVCAN further incorporates user attention guided by micro-video representation since user's preference on micro-video varies with different user attributes such as gender and location. In order to obtain the user attention distribution, we take the new representation $\hat{\boldsymbol{v}}^v$ of micro-video to query the original user feature matrix $\boldsymbol{q}^u$ according to Equation 1. We then generate a new representation $\hat{\boldsymbol{v}}^u$ for user.

4.3 Stacked Attention Networks

For each attention processing, we design stacked attention network to learn attention representation which can explore some subtle relationship among query and value by iteratively querying the original feature matrix in each $\mathcal{A}$. The formula can be summarized as follows: for the m-th attention layer (where m is greater than or equal to 2), we compute the distribution of video-guided (or user-guided) by user (or micro-video) query and generate a new representation for the micro-video (or user) based on the attention probability. The new query vector is formed by adding the new feature vector to previous query vector, the equation for micro-video attention guided by user vector is as follows:

$$q^u_m = \hat{v}^v_m + q^u_{m-1}, \tag{2}$$

where q^u_1 is initialized to be $\hat{q}_0$. The user attention is as same.

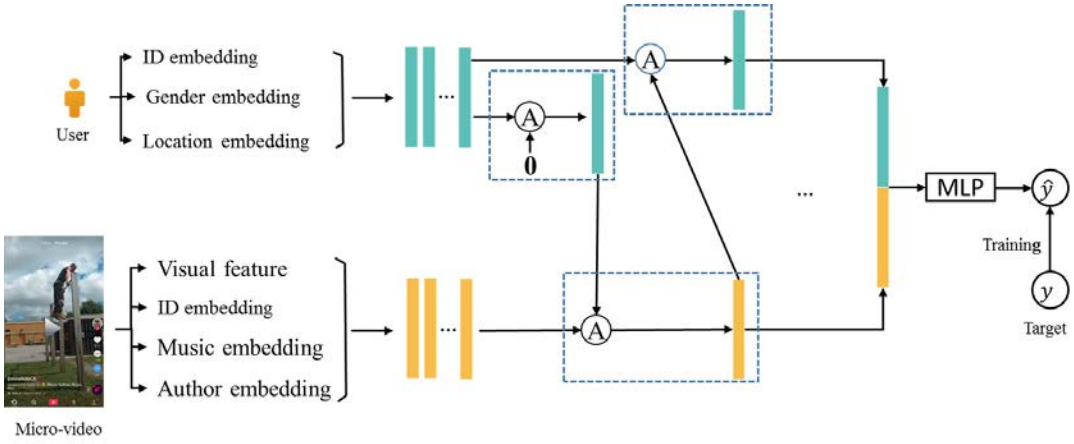

Figure 2: The illustration of Collaborative filtering stacked attentive network framework with three-step reasoning to explore user's attention to micro-video's features.

4.4 Learning for Recommendation

To test the effectiveness of learned user and micro-video representations via co-attention network on personalized micro-video recommendation, we connect these two learned multi-modal information representation vectors, user ID embedding vector and micro-video ID embedding vector to get the combination of collaborative filtering and attention mechanism. And we utilize a simple 3-layer feed-forward neural network to generate final preference rating, which dose not incur much modal complexity and ensures the capacity of nonlinear modeling for recommendation. Specifically, we define the computational formula as follows:

$$z = \begin{bmatrix} \hat{\boldsymbol{v}}^u \\ \hat{\boldsymbol{v}}^v \\ \boldsymbol{h}^u \\ \boldsymbol{h}^v \end{bmatrix}, \tag{3}$$

$$\hat{y}_{uv} = \text{MLP}(z), \tag{4}$$

where the final output layer is the estimated scores $\hat{y}_{uv}$ and training is carried out by minimizing the point wise loss function between estimated score $\hat{y}_{uv}$ and real value y_{uv}.

To learn the model parameters, UVCAN is trained as a binary classification problem. Considering the one-class nature of implicit feedback, we can view $y_{ui} = 1$ as a positive label that means user u likes the micro-video v otherwise it is a negative one. The UVCAN predicts the likelihood of user u favors micro-video v. With sigmoid $\delta(\cdot)$ as the activation function for the output layer, we can constrain the output $\hat{y}_{uv}$ in $[0, 1]$. Based on the above setting, we minimized the cross-entropy loss for true labels and sampled negative instances:

$$L(y_{uv}, \hat{y}_{uv}) = \sum_{(u,v)\in Y^+ \cup Y^-} -y_{uv}\log(p) - (1-y_{uv})\log(1-p), \tag{5}$$

where $p = \delta(\hat{y}_{uv}) = 1/(1 + exp(-\hat{y}_{uv}))$ represents the sigmoid function on the output $\hat{y}_{uv}$. Y^+ and Y^- denote the observed user-video pairs and unobserved user-video pairs, respectively. We uniformly sample negative instances Y^- from unobserved interaction according to the fixed sampling ratio 4:1 to the number of observed interactions in each iteration. An Adaptive Moment Estimation (Adam) [19] algorithm is adopted to optimize the loss function.

5 EXPERIMENTS

In this section, we conduct extensive experiments on the collected micro-video datasets from Toffee to compare UVCAN against other state-of-the-art recommendation methods. We first briefly depict the collected two real-world micro-video datasets, followed by experimental setting and evaluation scheme. Then we introduce the baseline algorithms and parameter settings. Finally, we present our experimental results and discussions, with comparison to different kinds of baseline methods.

5.1 Dataset

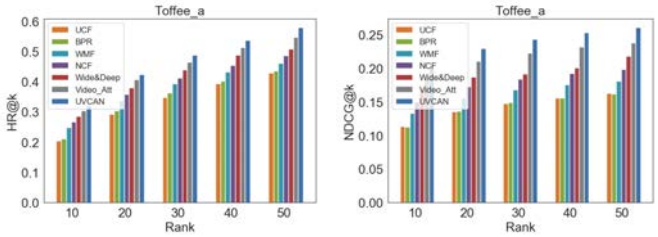

Table 2: Basic statistics of datasets.

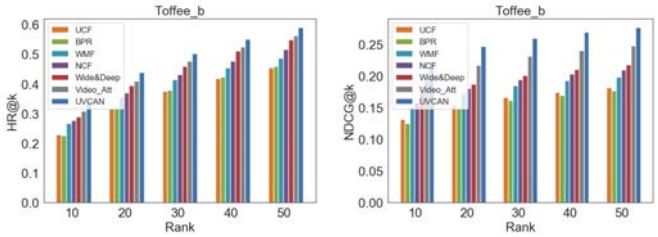
Dataset	#User	#Micro-video	#Interaction	Span
Toffee_a	780	73,015	233,144	2017.01-2017.06
Toffee_b	3,231	50,574	336,460	2017.07-2018.06

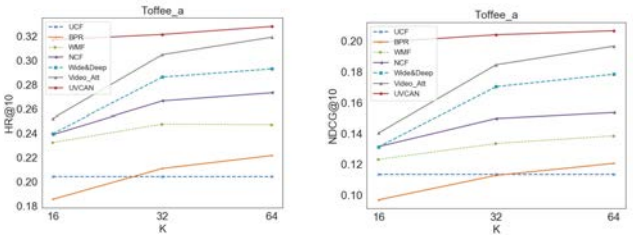


We construct our datasets using micro-videos collected from Toffee, one of China's popular micro-video social media platform. As far as we know, there is no publicly available micro-video social media dataset that contains users' metadata, content information of micro-videos, and the user-to-video connections simultaneously. In addition to establish connections (make new friends) between users, Toffee allows users to publish and share videos to others, and send thumbs-up to different videos. Toffee is a micro-video social media app which starts run from Jan 2017. To study the effect of different phrase of development on recommendation, we crawled micro-videos of Jan 2017 to Jun 2017 as the developing phrase and Jul 2017 to Jun 2018 as the plateau.

We constructed the two datasets from the Toffee in a user-centric method, which is also adopted by [6]. We first crawled one week of public timeline micro-videos and random sampled active users.

We defined active users who have at least interacted (send a thumb-up to the video to express liking) with 5 micro-videos. Then we expanded the seed users by crawling their followees, as the followees of active users were more likely to be active users relative to their followers. We performed three layers of crawling and further crawled users' ID and registering information, the ID list of their preferred micro-videos and the content information of these micro-video such as video file, tag, author ID and music ID. To test a scenario where user profile is known, we filtered out users without location or gender information. With this crawling method, we got the two datasets for different developing phrase: Toffee_a and Toffee_b. The detailed statistics of these datasets after preprocessing are shown in Table 2. The sparsity ($\#interaction/(\#user \times \#video)$) of the two datasets is 0.4094% for Toffee_a and 0.2059% for Toffee_b.

(a) Toffee_a — HR@k (b) Toffee_a — NDCG@k



(c) Toffee_b — HR@k (d) Toffee_b — NDCG@k

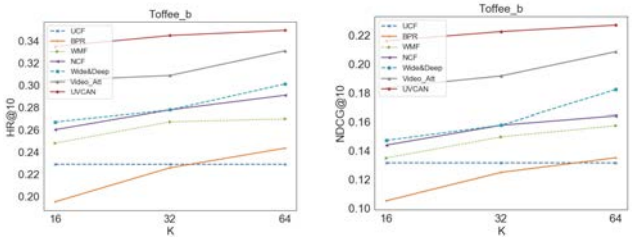


Figure 3: Performance of top-k recommendation where k range from 10 to 50 on Toffee_a.

5.2 Evaluation Scheme

For each dataset, we randomly hold 20% of micro-videos associated with each user to form the test set, and put the other micro-videos in the training set. The splitting methods is widely used in previous work on recommendation system [16, 32, 35]. In term of performance evaluation, for each (u, v) pair in the test set, we random select 1000 additional micro-video and predict scores by u for v and the other 1000 micro-videos. The evaluation criteria is to measure how well the method ranks the correct pair (u, v) against the other random micro-videos. This evaluation strategy is commonly used by [12, 13, 20]. We evaluate our method and other compared ones on micro-video recommendation by using two popular metrics, i.e., Hit Ratio (HR) and Normalized Discounted Cumulative Gain (NDCG), which regard liking as positive labels.

(a) Toffee_a — HR@10 (b) Toffee_a — NDCG@10

(c) Toffee_b — HR@10 (d) Toffee_b — NDCG@10

Figure 4: Performance of HR@10 and NDCG@10 w.r.t dimensionality of predictive factors on two datasets.

5.3 Baselines

We compare our proposed UVCAN with a series of state-of-the-art baseline algorithms as follows: **UCF** [37], **BPR** [25], **WMF** [17], **NCF** [14], **Wide&Deep** [8] and **Video-Att**. **Video-Att** is a variant of our proposed model, which only use user-guided micro-video attention. Similar work is done by [5], which proposes a linear model considering user-guided attention to item while **Video-Att** extends the implement to non-linear model.

5.4 Parameter Settings

We use a Gaussian distribution to randomly initialized the model parameters with a mean of 0 and standard deviation of 0.1 for our UVCAN model, and optimize the model through mini-batch Adaptive Moment Estimation (Adam). We tested the learning rate of [0.0001, 0.001, 0.01, 0.1], latent feature dimension of [16, 32, 64] and the regularizer of [0, 0.001, 0.01, 0.1]. The grid search method is used to determine hyper-parameters. If not specified, we employed three hidden layers for multi-Layer perceptron and show the results of $K = 32$ for all methods because of the consistent across the dimension of latent vector. Without special mention, we employ two attention layers for UVCAN.

5.5 Results and Analysis

5.5.1 Model Comparison. The performance of all competitors with HR@10 and NDCG@10 on micro-video recommendation is shown in Table 3. Figure 3 demonstrates the performance of Top-k recommendation list with ranking position starting from 10 to 50 on Toffee_a and Toffee_b dataset. From the table and figure, we have the following observations:

Table 3: Recommendation performance in terms of the HR@10 and NDCG@10.

Dataset		(a) UCF	(b) BPR	(c) WMF	(d) NCF	(e) Wide&Deep	(f) Video-Att	(g) UVCAN	Improvement (g) vs. (c)	(g) vs. (e)	(g) vs. Best
Toffee_a	HR10	0.2043	0.2110	0.2478	0.2666	0.2863	0.3049	**0.3217**	29.81%	12.36%	5.50%
	NDCG10	0.1135	0.1128	0.1335	0.1497	0.1705	0.1847	**0.2042**	52.92%	19.74%	10.53%
Toffee_b	HR10	0.2290	0.2259	0.2672	0.2780	0.2891	0.3089	**0.3448**	29.06%	19.28%	11.64%
	NDCG10	0.1317	0.1250	0.1497	0.1578	0.1765	0.1917	**0.2226**	48.72%	26.13%	16.13%

(a) On average, our proposed method outperforms the second-best method by 8.57% in terms of HR@10 and 13.33% in terms of NDCG@10 across the two datasets. We speculate that learning users' hidden preferences through combining micro-video and user mutual attention mechanism improves the performance of recommendation, which can be also seen from the superior performance of UVCAN than that of Video_Att.

(b) Using attention networks to explore a more powerful latent representation for user and micro-video improves the performance of recommendation. UVCAN and Video_Att outperform the model that concatenates identity embedding and side feature embedding of user and micro-video and feeds them directly in deep neural networks (namely, NCF and Wide&Deep).

(c) As can be seen from Figure 3, UVCAN shows consistent improvement compared with other methods in different ranking positions. While the Toffee_b dataset is more sparse than Toffee_a, the performance of all competitor on Toffee_b is much better. The possible reason may be that in Toffee_b dataset, which is from the developing plateau of the social media platform, the connection between users is constructed more densely, which also explain why the performance of UCF on Toffee_b is better than that of BPR.

5.5.2 Effects of the number of predictive factors. Figure 4 shows the performance of HR@10 and NDCG@10 with respect to different size of predictive factors on two datasets. When other factors remain the same, increasing the number of predictive factors introduces more information. As we can observe from Figure 4, compared to other competitor methods, the performance improvement of UVCAN also increases substantially. The possible reason is that the combination of collaborative filtering and attention mechanism requires larger embedding vector to incorporate the abundant information. For Toffee_b, even with a small predictive factor of 16, UVCAN performs substantially perform better than WMF and BPR with a large factor of 64. This shows the high effectiveness of UVCAN by learning users' hidden preferences.

5.5.3 Effects of the number of attention layers. We experiment with different number of attention layers to investigate the effect on the recommendation performance of UVCAN on Toffee_a and Toffee_b datasets, which is shown in Tables 4 and 5. We only show the results of NDCG, and the results of HR admit the same trend thus they are omitted. AL-2 indicates the micro-video attention and user attention both have two attention layers with other factors remaining the same. As can be seen, the performance improves at the beginning which also indicates the effectiveness of stacked attention layers. We owe this improvement to the multi-step reasoning of user-guided attention on micro-video's side information and video-guided attention on user's attribute information. When using more attention layers than two or three, the performance does not further improve significantly.

Table 4: NDCG@10 of UVCAN with different attention layers on Toffee_a.

factors	AL-1	AL-2	AL-3	AL-4
16	0.1947	**0.1993**	0.1948	0.1920
32	0.2022	**0.2042**	0.1927	0.1982
64	0.1947	0.1968	**0.2009**	0.2008

Table 5: NDCG@10 of UVCAN with different attention layers on Toffee_b.

factors	AL-1	AL-2	AL-3	AL-4
16	0.2045	**0.2161**	0.2123	0.2124
32	0.2161	**0.2226**	0.2116	0.2094
64	0.2105	0.2171	**0.2219**	0.2159

6 CONCLUSION

In this paper, we propose a User-Video Co-Attention Network (UVCAN) framework for personalized micro-video recommendation, based on the hypothesis that not only do users have multi-modal interest but micro-videos have multi-modal targeted audience segments. UVCAN achieves superior performance over state-of-the-art methosd by following advantages: 1) It uses embedding-based method to represent side information features and users' history interaction behavior with micro-videos; 2) It explores users' hidden preferences on side information of micro-videos, which views user's features as an input query and learn micro-video attention through multi-step reasoning with stacked attention network. 3) In addition, it explores user's diversity preference from different attribute, which views the learned micro-video representation as query and learn user attention through multi-step reasoning with stacked attention network. We conduct extensive experiments on two collected real-world micro-video datasets to compare UVCAN with state-of-the-art methods and demonstrate its effectiveness.

ABSTRACT

In modern recommender systems, both users and items are associated with rich side information, which can help understand users and items. Such information is typically heterogeneous and can be roughly categorized into flat and hierarchical side information. While side information has been proved to be valuable, the majority of existing systems have exploited either only flat side information or only hierarchical side information due to the challenges brought by the heterogeneity. In this paper, we investigate the problem of exploiting heterogeneous side information for recommendations. Specifically, we propose a novel framework jointly captures flat and hierarchical side information with mathematical coherence. We demonstrate the effectiveness of the proposed framework via extensive experiments on various real-world datasets. Empirical results show that our approach is able to lead a significant performance gain over the state-of-the-art methods.

1 INTRODUCTION

Recommender systems can mitigate the information overload problem by providing online users with the most relevant information [23, 25, 27]. A successful recommender system often requires accurate understanding of user preferences. Collaborative filtering, which models the interactions between users and items, is one of the most popular techniques to achieve this goal [9, 11, 25]. Traditional collaborative filtering based recommender systems have been proven to be suffered from the data sparsity and cold-start problems [1, 27]. On the other hand, in addition to interactions, users and items are often associated with side information, which has become increasingly available in real-world recommender systems [5, 21]. Such side information provides independent sources for recommendations, which can mitigate the data sparsity and cold start problems and have great potentials to boost the performance. As a consequence, a large body of research has been developed to exploit side information for recommendations [15, 23, 31, 32]. Side information is typically heterogeneous, which can be roughly categorized into flat and hierarchical side information [31]. Flat and hierarchical side information are referred to attributes associated with users and items presenting no hierarchical and hierarchical structures, respectively [31]. Take books for example, side information of one book can include the publish year, the book authors, the written language, and the genres it belongs to. Attributes such as year, author and language, presenting no hierarchical structures, are flat. The genres, however, contain *subtypeOf* relationship and can be organized in a hierarchical structure. Figure 1 gives a concrete example, which shows six attributes of the book *Animal Farm* with colored background. The flat information includes *George Orwell*, *1945* and *English* and are listed in the left part of figure. *Literature&Fiction*, *Historical Fiction*, and *Political* are the genres

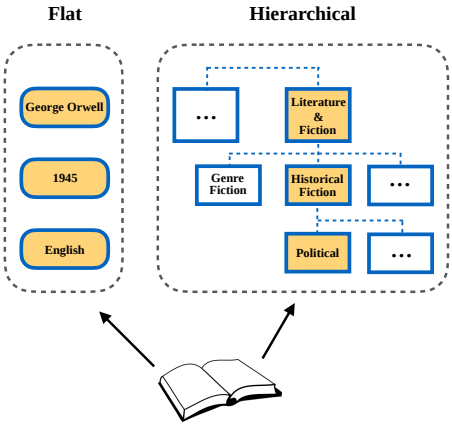

Figure 1: An illustration of flat and hierarchical side information.

Animal Farm belongs to according to Amazon Web Store. As shown in the figure, these genres are organized into a hierarchical structure as genre→subgenre→detailed-genre such that *Animal Farm* firstly belongs to the genre *Literature&Fiction*, under which there are sub-genres such as *Historical Fiction* and *Genre Fiction*. In this sub-genre level, *Animal Farm* belongs to *Historical Fiction*. It further falls into a more detailed-category *Political*. Likewise, users are also associated with both flat information such as age, gender, education level and hierarchical information such as communities they belong to and the places of their birth.

There are numerous works incorporating flat or hierarchical side information for recommendations [5, 15, 21, 23, 31, 32]. Most of these systems have been designed to exploit either only flat side information or only hierarchical side information. The major reason is that flat and structured side information are intrinsically different and it is challenging to jointly exploit them. One trivial solution is to flatten the hierarchy and treat it as flat information. However, such solution ignores the unique properties of hierarchical information, which have been proven beneficial by previous works [15, 19, 31]. In fact, both flat and hierarchical side information can provide valuable information for understanding user preferences and item characteristics. For instance, female are generally more interested in high heel shoes than male and items belonging to the same detailed-genre are likely to be more similar than those in the same sub-genre. Thus, it is desired to design frameworks incorporating the two types of side information simultaneously.

In this paper, we investigate the problem of exploiting both flat and hierarchical side information for recommendations. We propose a novel framework, which aims to address two challenges: (1) how to jointly capture heterogeneous side information and (2) how to mathematically use them for recommendations. The main contributions of our work can be summarized as follows:

- We provide a principled approach to simultaneously capture both flat and hierarchical information mathematically.
- We introduce a unified recommendation framework HIRE, which can model **H**eterogeneous side **I**nformation for **RE**commendation coherently.
- We conduct extensive experiments with various real-world datasets to validate the effectiveness of the proposed framework and understand the importance of flat and hierarchical side information for recommendations.

2 METHODOLOGY

In this section, we present the proposed recommendation framework that coherently captures flat and hierarchical information of both users and items. Specifically, we firstly introduce the notations that will be used in the rest of the paper and then describe a basic model which forms the basis of the framework. After that, we go into details of the framework components that model the flat and heterogeneous information, respectively, combining of which leads to an optimization problem. Finally, we propose an efficient algorithm to solve it.

Throughout this paper, regular letters are used to denote scalers. The vectors and matrices are represented by bold lower-case letters such as $\mathbf{h}$ and bold upper-case letters such as $\mathbf{W}$, respectively. In addition, for an arbitrary matrix $\mathbf{W}$, we use $\mathbf{W}(i,:)$ and $\mathbf{W}(:,j)$ to denote the i^{th} row and j^{th} column of it, respectively; and the $(i,j)^{th}$ entry of $\mathbf{W}$ is represented as $\mathbf{W}(i,j)$. The transpose and Frobenius norm of $\mathbf{W}$ is denoted as $\mathbf{W}^T$ and $\|\mathbf{W}\|_F^2$, respectively. Moreover, let $\mathcal{U} = \{u_1, u_2, \cdots, u_n\}$ to be the set of n users and $\mathcal{V} = \{v_1, v_2, \cdots, v_m\}$ be the set of m items. We assume there exists a user-item rating matrix $\mathbf{R} \in \mathbb{R}^{n\times m}$ and if a user u_i has rated item v_j, $\mathbf{R}(i,j) > 0$ denotes the rating score, otherwise, $\mathbf{R}(i,j) = 0$. In addition, let $\mathbf{X} \in \mathbb{R}^{d_x\times n}$ and $\mathbf{Y} \in \mathbb{R}^{d_y\times m}$ be the matrices that contain flat side information of users and items with d_x and d_y associated attributes, respectively. Next, we will describe a basic recommendation model, based on which we will build the whole framework.

2.1 The Basic Model

Weighted matrix factorization is an effective approach used in collaborative filtering based recommender systems to obtain users' and items' representations that contain information regarding users' preference and items' characteristics. Specifically, it decomposes the rating matrix and models the users and items in the same low-dimensional latent space. Mathematically, weighted matrix factorization solves the following optimization problem:

$$\min_{\mathbf{U},\mathbf{V}} \underbrace{\|\mathbf{M}\odot(\mathbf{R}-\mathbf{U}\mathbf{V})\|_F^2 + \lambda(\|\mathbf{U}\|_F^2 + \|\mathbf{V}\|_F^2)}_{f(\mathbf{U},\mathbf{V})}$$

where $\odot$ is the Hadamard operation denoting element-wise multiplication. $\mathbf{M} \in \mathbb{R}^{n\times m}$ is the indication matrix such that $\mathbf{M}(i,j) = 1$ if $\mathbf{R}(i,j) > 0$, otherwise, $\mathbf{M}(i,j) = 0$. The obtained matrices $\mathbf{U} \in \mathbb{R}^{n\times d}$ and $\mathbf{V} \in \mathbb{R}^{d\times m}$ are the corresponding representations of users and items in the latent space. Thus, the rating score given by u_i to v_j is approximated by the dot item of their latent representations, that are $\mathbf{U}(i,:)$ and $\mathbf{V}(:,j)$, respectively. λ is used to control the weight of regularization terms that are adopted to avoid overfitting. One of the most important strength of matrix factorization based model is that it allows to incorporate other information in addition to the ratings [11]. Next, we will base on the basic weighted matrix factorization model to build our framework.

2.2 Capturing The Flat Information

The side information of items or users are intrinsically heterogeneous, which can be flat and heterogeneous. For example, in Figure 1, a book can have both flat attributes such as author, year, and hierarchical attributes such as genres it belongs to. The difference between different types of side information requires special treatment for each individual. In this subsection, we describe the model component that aims to capture the flat side information. To simplify, we first focus on capturing side information of users and then generalize it to that of items.

In weighted matrix factorization, users' latent representation matrix $\mathbf{U}$ contains their preference indicated by the rating scores they give to items. The side information, however, provides another independent source from which users' preference could be inferred. For example, it is very likely that a programmer is more interested in a mechanical keyboard than a dancer, which suggests that users' occupation could provide an important indicator whether an item should be recommended or not. In addition, both hidden representation $\mathbf{U}(i,:)$ and side information $\mathbf{X}(:,i)$ describe the same user u_i.

Hence, in the same latent space, $\mathbf{U}(i,:)$ and $\mathbf{X}(:,i)$ should be similar. With this intuition, we extend the basic weight matrix factorization model to capture the flat side information contained in $\mathbf{X}$ as follows:

$$\min_{\mathbf{U},\mathbf{V}} f(\mathbf{U},\mathbf{V}) + \gamma \|\mathbf{S}^u\mathbf{U}^T - \mathbf{X}\|_F^2$$

where $\mathbf{S}^u \in \mathbb{R}^{d_x \times d}$ is the projection matrix that projects users' hidden representations $\mathbf{U}$ into the same latent space as $\mathbf{X}$. The Frobenius norm indicates the distance between the representations of users from two perspectives, which are forced to be close. In this way, the learned users representations $\mathbf{U}$ also capture flat side information contained in $\mathbf{X}$.

However, in practice, $\mathbf{X}$ is usually very sparse. For example, while a user profile could include various types of information, making $\mathbf{X}$ high-dimensional, many users may only provide a part of the profile, which renders $\mathbf{X}$ very sparse. To address this issue, we adopt autoencoders, which provide a way to obtain robust feature representations in an unsupervised manner [3] and have been successfully applied in various tasks such as speech enhancement [16], natural language generation [13] and face alignment [33]. In this work, we choose to incorporate marginalized denoising autoencoders (MDA) into the proposed model, as it is much more computationally efficient than others [4] and we leave incorporating other autoencoders as one future direction.

MDA firstly takes the side information $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n]$ as input and corrupts the features to obtain noising version $\tilde{\mathbf{x}}_i$ for each user u_i. The corruption process can be done in different ways. In this paper, we follow the practice in [4] and corrupt features by randomly setting each feature to be 0 with the probability $p \geq 0$. In contrast to traditional stacked denoising autoencoders that have the two-level encoder and decoder structures, in MDA, only one single mapping $\mathbf{W}^u : \mathbb{R}^{d_x} \rightarrow \mathbb{R}^{d_x}$ is used to reconstruct the original features and the reconstruction loss is defined as follows:

$$\mathcal{L}(\mathbf{W}^u) = \frac{1}{2n}\sum_{i=1}^{n} \|\mathbf{x}_i - \mathbf{W}^u\tilde{\mathbf{x}}_i\|^2 \tag{1}$$

The random corruption of the features may lead to the solution $\mathbf{W}^u$ of high variance. In order to avoid this, k-times corruption is performed and the overall reconstruction loss becomes:

$$\mathcal{L}(\mathbf{W}^u) = \frac{1}{2nk}\sum_{j=1}^{k}\sum_{i=1}^{n} \|\mathbf{x}_i - \mathbf{W}^u\tilde{\mathbf{x}}_{i,j}\|^2 \tag{2}$$

where $\tilde{\mathbf{x}}_{i,j}$ denotes the corrupted version of feature $\mathbf{x}_i$ at the j^{th}-time. Written in matrix form, the above loss function can be expressed as:

$$\mathcal{L}(\mathbf{W}^u) = \frac{1}{2nk}\|\bar{\mathbf{X}} - \mathbf{W}^u\tilde{\mathbf{X}}\|_F^2 \tag{3}$$

where $\bar{\mathbf{X}} = [\mathbf{X}, \mathbf{X}, \cdots, \mathbf{X}] \in \mathbb{R}^{d_x \times nk}$ and $\tilde{\mathbf{X}} = [\tilde{\mathbf{X}}_1, \tilde{\mathbf{X}}_2, \cdots, \tilde{\mathbf{X}}_k] \in \mathbb{R}^{d_x \times nk}$ with $\tilde{\mathbf{X}}_j$ denoting the j^{th} corrupted version of the original features $\mathbf{X}$. The solution of the minimization of the loss function defined in Eq (3) can be written in a closed form: $\mathbf{W}^u = \mathbf{K}\mathbf{J}^{-1}$, where $\mathbf{K} = \bar{\mathbf{X}}\tilde{\mathbf{X}}^T$ and $\mathbf{J} = \tilde{\mathbf{X}}\tilde{\mathbf{X}}^T$. Ideally, we would like to make infinitely corrupted versions of $\mathbf{X}$ to obtain the most stable mapping $\mathbf{W}^u$. This can be achieved by letting $k \rightarrow \infty$ and computing the expectations of $\mathbf{K}$ and $\mathbf{J}$ [4].

With the obtained mapping layer $\mathbf{W}^u$, robust features of users can be easily constructed from original feature matrix $\mathbf{X}$ by $\mathbf{W}^u\mathbf{X}$.

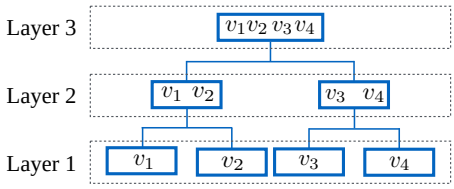

Figure 2: An illustrative example of hierarchical structure.

Hence, the framework that captures the flat side information of users with robust feature mapping becomes:

$$\min_{\mathbf{U},\mathbf{V},\mathbf{S}^u,\mathbf{W}^u} f(\mathbf{U},\mathbf{V}) + \gamma(\|\mathbf{S}^u\mathbf{U}^T - \mathbf{W}^u\mathbf{X}\|_F^2 + \|\bar{\mathbf{X}} - \mathbf{W}^u\tilde{\mathbf{X}}\|_F^2) \tag{4}$$

Similarly, the flat information of items can also be captured as follows:

$$\min_{\mathbf{U},\mathbf{V},\mathbf{S}^v,\mathbf{W}^v} f(\mathbf{U},\mathbf{V}) + \theta(\|\mathbf{S}^v\mathbf{V} - \mathbf{W}^v\mathbf{Y}\|_F^2 + \|\bar{\mathbf{Y}} - \mathbf{W}^v\tilde{\mathbf{Y}}\|_F^2) \tag{5}$$

where $\mathbf{S}^v \in \mathbb{R}^{d_y \times d}$ is the project matrix that projects $\mathbf{V}$ into the same space as $\mathbf{Y}$, $\mathbf{W}^v \in \mathbb{R}^{d_y \times d_y}$ is the mapping layer that obtains robust features from $\mathbf{Y}$, $\bar{\mathbf{Y}} = [\mathbf{Y}, \mathbf{Y}, \cdots, \mathbf{Y}] \in \mathbb{R}^{d_y \times mk}$ and $\tilde{\mathbf{Y}} = [\tilde{\mathbf{Y}}_1, \tilde{\mathbf{Y}}_2, \cdots, \tilde{\mathbf{Y}}_k] \in \mathbb{R}^{d_y \times mk}$ with $\tilde{\mathbf{Y}}_j$ representing the j^{th} corrupted version of $\mathbf{Y}$.

2.3 Incorporating The Hierarchical Information

Unlike flat information, features in hierarchical information are structured. For example, as shown in Figure 1, the genres of books can be organized into a hierarchical structure. It is very likely that books belong to the detailed genres are more similar than those in sub-genres. Thus, it should be desirable to recommend the book that is in the same detailed-genre with the one that has received high rating score from the user. As hierarchical information is intrinsically different with flat information, the approach introduced in the previous subsection is not suitable. Hence, in this subsection, we introduce how to incorporate hierarchical information by extending the basic matrix factorization model. Without the loss of generality, we firstly introduce the approach to incorporate hierarchical side information of items, which can be naturally applied to that of users. Typically, we can use a tree to represent a hierarchical structure. In a tree, each parent node can have different numbers of child nodes, which can also be the parents of the nodes in the next layer. Recall the example given by Figure 1, which shows the hierarchical structure of genres of a book. The genre *Literature & Fiction* is the parent node of several child nodes, such as *GenreFiction*, *Historical Fiction*, etc. The child node *HistoricalFiction* is also the parent of other nodes such as *Political*. The leaf nodes are those who have no child such as *Political*. From this example, it is easily observed that the hierarchical structure can naturally be characterized by the *parent-child* relation. With this intuition, next we introduce how to incorporate the structure information from *parent-child* perspective.

The item characteristic matrix $\mathbf{V} \in \mathbb{R}^{d \times m}$ shows the latent representations of items in a d-dimensional latent space. To incorporate the hierarchical structure, we can further decompose $\mathbf{V}$ into two

matrices $\mathbf{V}^1 \in \mathbb{R}^{m_1 \times m}$ and $\mathbf{V}^{2\prime} \in \mathbb{R}^{d \times m_1}$ such that $\mathbf{V} \approx \mathbf{V}^{2\prime}\mathbf{V}^1$, assuming there are m_1 nodes (or sub-categories) in the second layer. Hence, $\mathbf{V}^1$ indicates the *parent-child* relation between the m_1 categories in the second layer and m items in the first layer. Moreover, $\mathbf{V}^{2\prime}$ gives the latent representations of the m_1 categories. In this way, the latent representation of v_j can be expressed by the j^{th} item's parent categories and their latent representations as $\mathbf{V}^{2\prime}\mathbf{V}^1(:, j)$. If the structured information has more than two layers, we can further decompose $\mathbf{V}^{2\prime}$ such that $\mathbf{V}^{2\prime} \approx \mathbf{V}^{3\prime}\mathbf{V}^2$, where $\mathbf{V}^2 \in \mathbb{R}^{m_2 \times m_1}$ denotes the *parent-child* relation between categories in the third and second layers, respectively. Similarly, $\mathbf{V}^{3\prime} \in \mathbb{R}^{d \times m_3}$ denotes the representations of m_2 categories in the third layer. With this, j^{th} item's representation can be expressed by $\mathbf{V}^{3\prime}\mathbf{V}^2\mathbf{V}^1(:, j)$.

The above process can be repeated q-1 times to capture hierarchical structure of q layers as follows:

$$\mathbf{V} \approx \mathbf{V}^q \cdots \mathbf{V}^3\mathbf{V}^2\mathbf{V}^1 \tag{6}$$

where $\mathbf{V}^i \in \mathbb{R}^{m_i \times m_{i-1}} (1 \le i < q)$, $\mathbf{V}^q \in \mathbb{R}^{d \times m_{q-1}}$ and $m_0 = m$.

The *parent-child* relations indicated by Eq. (6) are implicit and they should be in conformity with explicit ones suggested by hierarchical side information. To achieve this, next we extend Eq. (6) to incorporate the structures in the side information. Let $\mathbf{T}^k \in \mathbb{R}^{m_{k-1} \times m_k}$ indicate the *parent-child* relation between categories in layer k and layer $k+1$ of the hierarchical structure of side information. Specifically, $\mathbf{T}^k(i, j) = 1$ denotes that the i^{th} category in layer k is the child of j^{th} category in layer $k+1$. Figure 2 gives an example, where $\mathbf{T}^2 \in \mathbb{R}^{2\times 1}$ and $\mathbf{T}^2(1, 1) = 1, \mathbf{T}^2(2, 1) = 1$. Thus, the hierarchical structure can be defined by the set $\mathcal{T} = \{\mathbf{T}^1, \mathbf{T}^2, \cdots, \mathbf{T}^q\}$, assuming there are q layers. Intuitively, the presentation of a parent category should be aggregated from those of all the child categories it contains. Thus, a natural way to capture the *parent-child* relations in $\mathcal{T}$ is to make parent representations denoted as $\mathbf{V}^q \cdots \mathbf{V}^i$ to be close to the aggregation of their children's representations denoted as $\mathbf{V}^q \cdots \mathbf{V}^{i-1}$.

In this work, we choose the mean function to be the aggregation function due to its computational efficiency and leave exploring other choices as one future work. Thus, the structure indicated by the item side information can be captured as follows:

$$\min \underbrace{\sum_{i=2}^{q} \|\mathbf{V}^q \cdots \mathbf{V}^i - \mathbf{V}^q \cdots \mathbf{V}^{i-1}\mathbf{Q}^{i-1}\|_F^2}_{f^v(\mathbf{V}^i, \mathbf{Q}^{i-1})}$$

where $\mathbf{Q}^k$ is the normalized version of $\mathbf{T}^k$ and $\mathbf{Q}^k(i, j) = \frac{\mathbf{T}^k(i,j)}{\sum_{i=1}^{m_{k-1}} \mathbf{T}^k(i,j)}$.

In a similar way, we can also incorporate hierarchical information of users as:

$$\min \underbrace{\sum_{i=2}^{p} \|\mathbf{U}^i \cdots \mathbf{U}^p - \mathbf{P}^{i-1}\mathbf{U}^{i-1} \cdots \mathbf{U}^p\|_F^2}_{f^u(\mathbf{U}^i, \mathbf{P}^{i-1})}$$

where $\mathbf{U}^i \in \mathbb{R}^{n_{i-1} \times n_i}$ and $\mathbf{P}^k(i, j) = \frac{\mathbf{C}^k(i,j)}{\sum_{i=1}^{n_{k-1}} \mathbf{C}^k(i,j)}$ is the normalized version of $\mathbf{C}^k \in \mathbb{R}^{n_{k-1} \times n_k}$, which indicates the *parent-child* relationship in hierarchical side information of users. p is number of layers of the hierarchy and $1 \le i < p$.

2.4 The Proposed Framework HIRE

Previous subsections introduce the model components that aim to capture both flat and hierarchical side information. Combining them, the framework HIRE is to solve the following optimization problem:

$$\begin{aligned} \min_{\substack{\mathbf{U}^1, \cdots, \mathbf{U}^p, \mathbf{S}^u, \mathbf{W}^u \\ \mathbf{V}^1, \cdots, \mathbf{V}^q, \mathbf{S}^v, \mathbf{W}^v}} & f(\mathbf{U}, \mathbf{V}) + \alpha f^u(\mathbf{U}^i, \mathbf{P}^{i-1}) + \beta f^v(\mathbf{V}^i, \mathbf{Q}^{i-1}) \\ & + \gamma(\|\mathbf{S}^u\mathbf{U}^T - \mathbf{W}^u\mathbf{X}\|_F^2 + \|\bar{\mathbf{X}} - \mathbf{W}^u\tilde{\mathbf{X}}\|_F^2) \\ & + \theta(\|\mathbf{S}^v\mathbf{V} - \mathbf{W}^v\mathbf{Y}\|_F^2 + \|\bar{\mathbf{Y}} - \mathbf{W}^v\tilde{\mathbf{Y}}\|_F^2) \end{aligned} \tag{7}$$

where $\mathbf{U} = \mathbf{U}^1\mathbf{U}^2 \cdots \mathbf{U}^p$ and $\mathbf{V} = \mathbf{V}^q \cdots \mathbf{V}^2\mathbf{V}^1$. γ and θ control the contribution of flat information, α and β decides the contribution of hierarchical information. Hence, the proposed framework simultaneously models both flat and hierarchical side information with mathematical coherence. Following the tradition [11], we will use the gradient descent method to optimize the formulation of the proposed framework. Next we will use $\mathbf{U}^i$ as one example to illustrate how to get the gradient of parameters due to the page limitation. Before calculating the gradient, we define $\mathbf{A}^i$, $\mathbf{H}^i$, $\mathbf{D}^i$, $\mathbf{G}_i^k$ and $\mathbf{B}_i^k$ that can be used to simplify the expressions:

$$\mathbf{A}^i = \begin{cases} \mathbf{U}^1\mathbf{U}^2 \ldots \mathbf{U}^{i-1}, & \text{if } i \neq 1 \\ \mathbf{I}, & \text{if } i = 1 \end{cases}$$

$$\mathbf{H}^i = \begin{cases} \mathbf{U}^{i+1} \ldots \mathbf{U}^p\mathbf{V}^q \ldots \mathbf{V}^1, & \text{if } i \neq p \\ \mathbf{V}^q \ldots \mathbf{V}^1, & \text{if } i = p \end{cases}$$

$$\mathbf{D}^i = \begin{cases} \mathbf{U}^{i+1}\mathbf{U}^{i+2} \ldots \mathbf{U}^p, & \text{if } i \neq p \\ \mathbf{I}, & \text{if } i = p \end{cases}$$

$$\mathbf{G}_i^k = \begin{cases} \mathbf{U}^{k+1} \cdots \mathbf{U}^{i-1}, & \text{if } k \neq i-1 \\ \mathbf{I}, & \text{if } k = i-1 \end{cases}$$

$$\mathbf{B}_i^k = \mathbf{P}^k\mathbf{U}^k\mathbf{G}_i^k$$

where $1 \le i \le p$ and $1 \le k < i-1$. By dropping irrelevant terms in Eq. (7), remaining terms related to $\mathbf{U}^i$ are as follows:

$$\begin{aligned} \mathcal{L}(\mathbf{U}^i) &= \|\mathbf{M} \odot (\mathbf{R} - \mathbf{A}^i\mathbf{U}^i\mathbf{H}^i)\|_F^2 + \lambda\|\mathbf{U}^i\|_F^2 + \alpha\|(\mathbf{I} - \mathbf{P}^i\mathbf{U}^i)\mathbf{D}^i\|_F^2 \\ &+ \alpha \sum_{k=1}^{i-1} \|(\mathbf{G}_i^k - \mathbf{B}_i^k)\mathbf{U}^i\mathbf{D}^i\|_F^2 + \gamma\|\mathbf{S}^u(\mathbf{A}^i\mathbf{U}^i\mathbf{D}^i)^T - \mathbf{W}^u\mathbf{X}\|_F^2 \end{aligned}$$

Now, we can obtain the gradient of $\mathbf{U}^i$ as:

$$\begin{aligned} \frac{\partial \mathcal{L}(\mathbf{U}^i)}{\partial \mathbf{U}^i} &= \mathbf{A}^{iT}[\mathbf{M} \odot (\mathbf{A}^i\mathbf{U}^i\mathbf{H}^i - \mathbf{R})]\mathbf{H}^{iT} + \lambda\mathbf{U}^i \\ &+ \alpha \sum_{k=1}^{i-1} (\mathbf{G}_i^k - \mathbf{B}_i^k)^T(\mathbf{G}_i^k - \mathbf{B}_i^k)\mathbf{U}^i\mathbf{D}^i\mathbf{D}^{iT} \\ &+ \alpha\mathbf{P}^{iT}(\mathbf{P}^i\mathbf{U}^i\mathbf{D}^i - \mathbf{D}^i)\mathbf{D}^{iT} + \gamma\mathbf{A}^{iT}(\mathbf{A}^i\mathbf{U}^i\mathbf{D}^i\mathbf{S}^{uT} - \mathbf{X}^T\mathbf{W}^u)\mathbf{S}^u\mathbf{D}^{iT} \end{aligned} \tag{8}$$

2.4.1 Time Complexity Analysis. The most expensive operations in the optimization process are updating $\mathbf{U}^i$ and $\mathbf{V}^i$, which in each iteration will cost $O\Big(nn_1n_{i-1} + (2n_in_{i+1} + mm_1)d + n_{i-1}^2(n_i + \sum_{k=1}^{i-1} n_k)\Big)$ and $O\Big(mm_1m_{i-1} + (2m_im_{i+1} + nn_1)d + m_{i-1}^2(m_i + \sum_{k=1}^{i-1} m_k)\Big)$, respectively. Thus, assume N iterations are needed in total, the overall time complexity of the optimization process is $O\Big(\sum_i^p \big(nn_1n_{i-1} +$

$(2n_i n_{i+1}+mm_1)d+n_{i-1}^2(n_i+\sum_{k=1}^{i-1} n_k)\big)+\sum_i^q \Big(mm_1 m_{i-1}+(2m_i m_{i+1}+nn_1)d + m_{i-1}^2(m_i + \sum_{k=1}^{i-1} m_k)\big)\Big)$.

3 EXPERIMENTS

In this section, we firstly introduce the experimental settings. Then, we compare the proposed framework HIRE with representative baselines to answer the first question. Finally, we analyze each model component, which gives answer to the section question. To encourage the reproducible results, we make our code publicly available at: https://github.com/tal-ai/Recommender-Systems-with-Heterogeneous-Side-Information.

3.1 Experimental Settings

We evaluate the proposed framework on three benchmark datasets MovieLens (100K), MovieLens (1M), and BookCrossing and all of them are publicly available [8, 34].

- MovieLens (100K) and MovieLens (1M) are collected from a movie review website[1] where users can give movie rating scores on a scale from 1-5. MovieLens (100k) contains 100,000 ratings from 1000 users on 1700 movies and MovieLens (1M) contains 1 million ratings from 6000 users on 4000 movies. For movies, we use genres as hierarchical information; for users, we use age and gender as flat information and occupation as the hierarchical information.
- BookCrossing is a book rating dataset collected from BookCrossing[2] community and the rating score is from 1 to 10. After basic data cleaning, we get 17028 ratings from 1009 users on 1816 books. For books, we use publish year and author as flat information and publisher as hierarchical information; for users, we use age and location as the flat and hierarchical information, respectively.

For each dataset, we split it into training and test sets such that training set contains $x\%$ of the data and test contains $1 - x\%$. We vary x as $\{40, 60, 80\}$. We choose the commonly used Root Mean Square Error (RMSE) as the measurement metrics of the recommendation performance and lower value of RMSE indicates better performance. In fact, a small improvement in RMSE means a significant improvement of recommender systems [10].

3.2 Recommendation Performance Comparison

In this subsection, we evaluate the recommendation performance of proposed framework by comparing it with following representative baselines:

- **SVD [6]:** It is a matrix factorization technique that factorizes a user-item rating matrix to obtain latent representations of customers and products via singular-value decomposition (SVD). In this method, only rating information is used;
- **NMF [7]:** Non-negative matrix factorization (NMF) is one of the most popular algorithms used in recommender systems. Unlike SVD, it adds non-negative constraints to the latent representations. This method also only uses rating information;
- **I-CF [25]:** This is a item-based collaborative filtering approach that recommends items to users based on the similarity computed from the rating matrix;
- **NeuMF [9]:** NeuMF replaces inner product by combining GMF and MLP neural architectures with sharing embedding layer and is able to significantly improves recommendation performance. In this method, only rating information is used.
- **mSDA-CF [14]:** This method integrates matrix factorization and deep feature learning and achieves state-of-the-art performance. It uses both rating and flat side information and ignores hierarchical one.
- **HSR [31]:** HSR is a state-of-the-art algorithm which is able to capture both rating and structured side information. However, flat information is ignored in this method.

Note that the parameters of all methods are selected through five-fold cross validation and the details of parameter selection of the proposed framework are discussed in the later subsections. we repeat each experiment five times and report the average performance in Table 1. The following observations can be made from the table:

- NeuMF is likely to outperform other traditional CF methods, which suggests the power of deep learning in recommendations. Currently our basic model is based on matrix factorization and it has great potential to choose NeuMF as the basic model to further improve the performance.
- Systems incorporating side information tend to obtain better performance compared to their corresponding systems without side information. This observation supports the importance of side information.
- The proposed framework HIRE achieves the best performance in most of the cases. We contribute the superior performance to its ability to capture both flat and structured side information. More details regarding the contribution of each component will be discussed in following subsection.

With the above observation, we are able to draw a conclusion to answer the first question: the proposed framework that incorporates heterogeneous side information significantly improves the recommendation performance over the state-of-the-art methods. In the next subsection, we will give a detailed analysis of the contribution from flat and hierarchical side information, respectively.

3.3 Component Analysis

In this subsection, we systematically examine the effect of key components by constructing following model variants:

- HIRE-FU: it eliminates the contribution of flat side information of users by setting $\gamma = 0$ in Eq. (7).
- HIRE-FV: it eliminates the contribution of flat side information of items by setting $\theta = 0$ in Eq. (7).
- HIRE-SU: it eliminates the contribution of hierarchical side information of users by setting $\alpha = 0$ in Eq. (7).
- HIRE-SV: it eliminates the contribution of hierarchical side information of items by setting $\beta = 0$ in Eq. (7).

The recommendation performance on MovieLens (100K) is shown in Figure 3. Since we observe similar results on other datasets, we only show that on MovieLens (100K) dataset to save space. From the

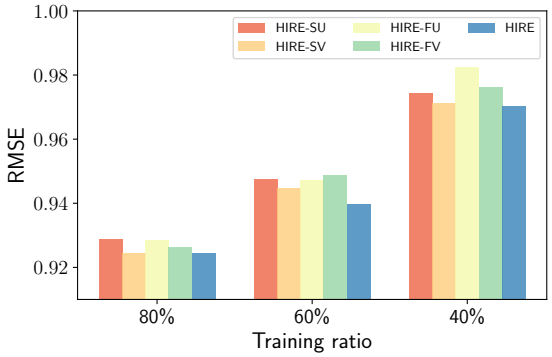
HIRE	0.9703	0.9398	0.9243	0.8957	0.8778	0.8607	2.3364	1.9193	1.8432



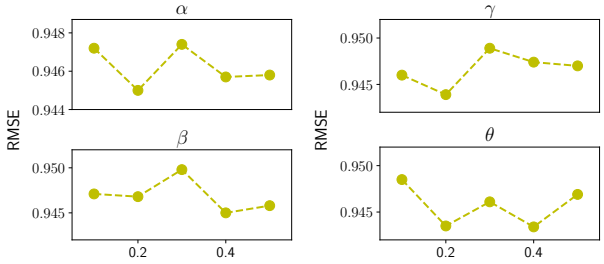


Figure 3: Performance analysis of HIRE with different components.

(a) Performance with α abd β (b) Performance with γ and θ

Figure 4: Parameter analysis with α, β, γ and θ

Figure 3, we can easily observe that HIRE obtains the least RMSE error among all its variants in all cases. This suggests that recommendation performance degrades when ignoring any type of side information. Thus, it is important to incorporate heterogeneous side information in recommender systems.

3.4 Parameter Analysis

In this subsection, we further analyze the sensitivity of the four key parameters γ, θ, α and β that control the contributions of flat side information of users, flat side information of items, hierarchical side information of users, and hierarchical information of items, respectively. In detail, for each of the four parameters, we conduct experiment with the proposed framework by varying the value of it while fixing the others. The performance is shown in Figure 4. Similarly, only performance on MovieLens (100K) is reported due to the space limitation. From both figures, we clearly see that the performance tends to first increase and then decrease, which further supports the importance of side information in recommendations.

4 RELATED WORK

In this section, we give a brief overview of the related recommender systems. A large body of research has been devoted to developing algorithms to improve the performance of recommender systems, which play a crucial role in the increasingly digitalized society. Among them, collaborative filtering based approaches have achieved great success. Roughly, collaborative filtering can be categorized into two type: (1) memory-based approaches [18, 22, 25, 30], which aim at exploring neighborhood information of users or items for recommendation; and (2) model-based methods [7, 11, 17], which try to model the underlying mechanism that governs user rating process. Generally, model-based methods show superior performance than the content-based ones. In particular, Matrix Factorization (MF) based collaborative filtering have gained great popularity due to their high performance and efficiency [11, 12, 20, 24, 26]. Despite of its success, collaborative filtering approaches are known to suffer from data sparsity issues, as the number of items or users is typically very large but the number of ratings is relatively small. One popular way to address this issue is to incorporate the increasingly available side information in the model [2, 5, 15, 28, 29, 31]. The majority of studies exploit either only flat side information [2, 5], or only hierarchical side information [15, 31] due to the challenges brought by the inherent difference between these two types of information. However, our work addresses these challenges and is able to incorporate the two types of information simultaneously.

5 CONCLUSION

In this paper, we investigate the problem of exploiting heterogeneous side information for recommendations. Specifically, we propose a novel recommendation framework HIRE that is able to capture both flat and hierarchical side information with mathematical coherence. Extensive experiments on three benchmark datasets verify the effectiveness of the framework and demonstrate the impact of both flat and hierarchical side information on recommendation performance.

ABSTRACT

In on-demand ridesharing, optimizing the quality of supply-demand matches and minimizing the number of unfulfilled trip requests is an important business problem. One approach is to match supply with demand based on greedy local heuristics, which is sub-optimal at the market level. Another approach is to find the globally optimal matching over the whole marketplace. However, because the computation has high latency, and usually requires aggregate supply and demand data over time, instead of only the supply and demand at the time of individual trip requests, it is unfeasible to perform the global optimization for every trip request in realtime. This paper proposes a solution that performs a global optimization offline periodically based on forecasted supply and demand data, and uses the offline results to guide realtime supply and demand matching. The solution is a novel two-stage robust optimization scheme for supply-demand matching in on-demand ridesharing. We implemented the proposed solution and evaluated it using simulated trips based on public industry data. It reduces the number of unfulfilled trips significantly compared to a state-of-the-art approach.

1 INTRODUCTION

A core value in the on-demand sharing economy is to effectively match supply and demand in realtime. Improving supply-demand matching can increase the utilization of suppliers and therefore reduce the service price. Through network effects, lower prices and higher utilization can help expand both supply and demand further in the market.

In this paper, we will focus on ridesharing, which has been used by hundreds of millions of people across the world. In this context, a supply unit stands for a driver, and a demand unit stands for a rider. How to match riders and drivers is at the core of a successful ridesharing platform's marketplace efficiency optimization.

The primary goal of supply-demand matching is to minimize the total unfulfilled demand. This calls for a non-trivial global optimization for trip-level supply-demand matching over all individual units of demand and supply in the whole geospace of a market (e.g. San Francisco Bay Area or Greater Los Angeles). However, in practice, a realtime trip request usually requires a matching decision to be made within only a few seconds. The global supply-demand matching optimization is often too complicated to finish in such a small amount of time.

As a result, one of the main limitations existing matching systems often have is the sacrifice of global optimality for quick suboptimal matching. They usually use local, greedy heuristics to perform supply-demand matching at individual trip request level, which often yield sub-optimal matching solutions, and cause high volumes of unfilled trip requests.

Another usual limitation of existing matching systems is the handling of future supply and demand. Existing matching methods often rely on point estimation, i.e., without considering the probability distribution of the predicted values. This is a main source of sub-optimal matching solutions.

To tackle the two challenges above, we propose a new approach, Globally-Optimized Realtime Matching (GORM). The algorithm has three main steps. First, we use historical time series data to predict the probabilistic distribution of supply and demand over the whole marketplace in the next 5 minutes. Second, we perform global optimization of supply-demand matching at an aggregated level over the whole market for the next 5 minutes using the forecasted data. To cope with the forecasting error, our global optimization will also find supplies to match the unpredicted extra true demands. Third, we use the pre-computed global optimization result to guide a local heuristic for realtime per-trip supply-demand matching.

In order to keep computational complexity low and maintain reasonable signal-to-noise ratios, we use hexagons (about 600 meters in diameter), as the smallest unit of geo area. For hexagonal geofences, we use Uber's open source library, H3 [3, 11].

The main contributions of this paper include:

(1) We present a new framework (GORM) for realtime efficient supply-demand matching for on-demand ridesharing. GORM combines periodical (offline) global optimization for market-wide aggregate supply-demand matching and realtime (online) local heuristics for per-trip supply-demand matching.
(2) We present a novel linear programming formulation for robust optimization that is resilient to the uncertainty in the underlying market data.
(3) We tested the proposed solution with simulated market dynamics based on real-world ridesharing data, and showed over 7-22% reduction on unfulfilled demand compared with a state-of-the-art supply-demand matching algorithm.

2 RELATED WORK

Because supply-demand matching is very important to the ridesharing business, there has been much related work on this topic.

One type of previous work focused on the realtime factor of the problem, and proposed to greedily find the nearest drivers for every incoming trip request [1, 4, 5, 8, 9]. Those approaches were likely to find suboptimal solution in terms of overall market efficiency.

Another type of previous work used more complex algorithms to find a globally more optimized matching of supplies and demands. The authors of the Didi Chuxing's Taxi order dispatch system [12] proposed a combinatorial optimization approach. They first predicted riders' destinations based on historical data, then estimated drivers' order acceptance rate based on the predictions, and finally searched for a globally optimized matching based on the above estimation. The main drawback of this approach was that it was hard to do such a large scale computation in realtime. Also, this approach did not put dispatch radius as a constraint, which could lead to long dispatch time and unsatisfactory rider experience. Another work [10] proposed an agent based model called NTuCab, where each agent processed N rider/driver pairs, and jointly minimized the rider waiting time. However, this approach did not try to minimize unfulfilled demands and could lead to suboptimmal market efficiency.

3 THE GORM FRAMEWORK

This section explains the globally-optimized realtime matching (GORM) framework for the global matching problem. The effectiveness of the GORM framework is related to the following aspects:

1) Forecasting the spatial and temporal distribution of demand and supply across the whole market's geo space over a short time period, e.g., 5 minutes in our case. The aggregate demand/supply forecast is always a probability distribution, not a point estimate. The GORM framework relies on the probabilistic estimation as the input to the global optimization problem.

2) Computing the globally-optimized matching solution into the future, based on the forecasts of demand and supply - their probability distribution. The global optimization needs to be resilient to the prediction error in the forecasts. GORM achieves this by optimizing the expected value of the cost function over the probabilistic demand/supply forecasts.

3) Performing the local trip-level matching, which is a heuristic guided by the forward-looking global-optimization result. There is a time constraint on the local matching decision. This way, each trip request can be matched to a supply in seconds, while the decision is aligned with the globally-optimized supply-demand matching at aggregate market level.

The GORM framework combines the forward-looking global matching optimization and the realtime local matching heuristic, by performing the 3 steps in Algo 1 for all the supply-demand matching decisions across the whole market over every 5-minute time window.

In the GORM framework, Step 1 can be performed with an existing time series forecasting algorithm, e.g., multivariate ARIMA. Since it is a relatively mature practice with off-the-shelf statistical tools, we will skip the explanation on it, and spend time on Steps 2 and 3 in the main body of the GORM framework.

ALGORITHM 1: Globally-Optimized Realtime Matching

input : the 5-minute time window to perform supply-demand matching over; all the hexagons in the whole marketplace

output : at the hexagon aggregate level,globally-optimized inter-hexagon supply relocating flow $x_{i,j}, \forall i, j \in \{hexagons\}$; at individual request level, a driver (if feasible) being matching to a trip request.

1 Step 1) Perform time series forecasting (with confidence intervals) for demand and supply in the next 5 minutes in the whole market, i.e., obtaining their confidence intervals ($\alpha = 0.05$): $\forall i \in \{hexagons\}, [T_i^l, T_i^u], [S_i^l, S_i^u]$ for the next 5 minutes;

2 Step 2) Perform optimization on the global matching problem, taking as the input the demand/supply forecasting across the whole market over the next 5-minute window, i.e., $\forall i \in \{hexagons\}, [T_i^l, T_i^u], [S_i^l, S_i^u]$. As a result, we solve the problem for $\forall i, j \in \{hexagons\}, x_{i,j}$ optimizing the whole market's efficiency over the next 5 minutes;

3 Step 3) Perform realtime supply-demand matching for each individual trip request, based on the globally optimized inter-hexagon supply flows from Step 2. Basically a demand in hexagon j is preferred to be matched to a supply from hexagon I with the highest supply-to-demand ratio among all corresponding candidate hexagons $\forall i$ where $x_{i,j} > 0$.;

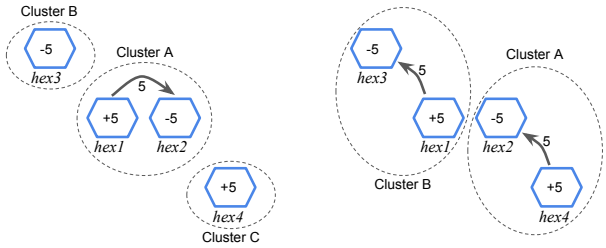

Figure 1: Supply-Demand Matching with Different Hexagon Clusters.

4 GLOBAL MATCHING

This section explains the global supply-demand matching, including its optimization goal, geospatial constraints, its implications for the ridesharing business, and our novel technique for handling the uncertainty in market forecasts, which are used as input to the global optimization problem.

An accurate yet compact representation of the spatial distribution of supply and demand requires dividing the whole market geospace into small basic geo units. Among all commonly-used shapes of the basic geo units, hexagons are our choice in solving this problem, because of their geometrical consistency, good coverage over the whole surface of the earth, and its roundness. Next we illustrate how global optimization can make a big difference in trying to achieve high market efficiency. In the following example, we consider two quite extreme ways of supply-demand matching:

1) matching individual demand to currently nearby supply by local greedy heuristics, without considering their interaction with other demand and supply further in the whole market; 2) matching all demand to all supply in the whole geo space of the marketplace across a certain time period, while minimizing the total unfulfilled demand globally.

In Fig. 1, we use a spatial cluster (i.e., Cluster A, B, or C in the example) to depict a group of one or more hexagons, between which supplies are matched to demands. There are a total of 4 hexagons in the whole marketplace, each of which is associated with the amount of supply units subtracting the amount of demand units. $hex2$ and $hex3$ both have 5 units of demand and no supply. $hex1$ and $hex4$ both have no demand and 5 units of supply. The spatial clusters on the left give an example of local greedy supply-demand matching. When demands in $hex2$ occur, we will match them with supplies from $hex1$ because the clusters are closest to each other. After that, when demand starts to surface in $hex3$, there are no supplies in Cluster B to match. Moreover, $hex1$ already run out of available supplies, and $hex4$ is too far away from $hex3$. Therefore, the system can only fulfill 5 out of 10 demand units. In contrast, the spatial clusters on the right side of the figure give an example of better globally optimized supply-demand matching in the same market scenario. In this case, we use $hex1$ to supply $hex3$, and $hex4$ to supply $hex2$. Therefore, all 10 demand units are fulfilled.

Now it is clear that the supply-demand matching problem needs a global optimization, we start to explain the problem and considerations around it. The input to our global matching optimization problem is a forecast of the demand and supply volumes across all individual hexagons in the whole market over a period of time (5 minutes in our case).

The primary goal of our matching problem is to minimize the total unfulfilled demand over all hexagons, i.e., minimize: $\sum_i \max(T_i - S_i, 0)$, where T_i denotes the volume of demand in hexagon i; and S_i denotes the total volume of supply in hexagon i, which is the summation of the supply originating from hexagon i and the supply relocated from other hexagons to hexagon i.

This goal is achieved by optimizing the supply movement flow between different pairs of hexagons. That is, the decision variable $x_{i,j}$ indicates the volume of supply that is relocated from hexagon i to hexagon j, in order to fulfill the demand in hexagon j. The supply movement from hexagon i to hexagon j effectively means dispatching the corresponding amount of supply in hexagon i to demand in hexagon j.

Because the forecast is subject to prediction error, our optimization problem formulation needs to take into account the uncertainty in the forecast. For the clarity of explanation, the rest of this section will describe our deterministic optimization formulation (without considering forecasting error) first, and then present the robust optimization formulation for coping with forecasting uncertainty.

4.1 The deterministic optimization

Before diving into the global optimization problem formulation, we explain a geospatial constraint on the supply movement. Supply can only move between two hexagons if they are within a dispatch radius to each other. This constraint is very important to a real-world on-demand ridesharing service: a unit of supply should be matched to a nearby unit of demand, to keep the estimated time to pickup (ETP) reasonably short for realtime trip requests.

The global matching optimization can be formulated into the following linear programming problem.

$$
\begin{aligned}
\text{Min: } & f(x) = \alpha \sum_i h_i \\
\text{S.t.: } & \forall i \in \mathbb{A}, h_i \geq T_i - s_i, h_i \geq 0 \\
& \forall i \in \mathbb{A}, s_i = S_i - \sum_j x_{i,j} + \sum_k x_{k,i} \\
& \forall i \in \mathbb{A}, \sum_j x_{i,j} \leq S_i \\
& \forall i,j \in \mathbb{A}, Dist_{i,j} \leq O, x_{i,j} \geq 0, x_{j,i} \geq 0
\end{aligned} \tag{1}
$$

where $\mathbb{A}$ denotes the set of all hexagons in the whole market; $x_{i,j}$ is a decision variable representing the supply volume flowing from hexagon i to hexagon j; h_i is an auxiliary variable representing the unfulfilled demand units in hexagon i; s_i is an auxiliary variable representing the total volume of supply in hexagon i (including those originated in hexagon i and those moved in-and-out from/to other hexagons); O denotes the maximum distance between two hexagons $Dist_{i,j}$ that allows the inter-hexagon supply flows.

4.2 The robust optimization

Because forecasts are inherently uncertain, the optimization process must be robust to actual supply and demand being different from what was forecasted. Furthermore, we must deal with prediction errors in a manner that is consistent with the overall optimization. This is similar to a 2-stage stochastic programming problem in general [2], which can be formulated as follows in our case.

$$
\begin{aligned}
\text{Min}_x\text{: } & g(x) = f(x) + E_\zeta[Q(x,\zeta)] \\
\text{S.t.: } & Q(x,\zeta) = \min_y \left(q(y,\zeta) = T(\zeta)x + W(\zeta)y \right)
\end{aligned} \tag{2}
$$

where ζ represents the vector of one possible combination of true supply and demand volumes over all hexagons in the marketplace; $Q(x,\zeta)$ denotes the optimal value of the second stage problem on a specific value of ζ; y indicates the recourse decision (matching on individual trip request level in our case) in the face of ζ; $E_\zeta[Q(x,\zeta)]$ is meant to capture the expected value of cost by all possible true volume values of demand and supply over all hexagons (there is a probability distribution over these possible values).

In our case, we create an uncertainty-resilient linear programming formulation for our matching problem. Basically, the robust optimization formulation wants to minimize the expected unfulfilled demand over the probability distribution of possible volume values given by the confidence interval of the market forecasting. We choose to use 95% confidence interval, corresponding to $\alpha = 0.05$, in the forecast of the market in the next 5 minutes.

In its essence, the robust optimization part of the formulation tries to approximate different probabilities of an amount of supply occurring in a hexagon in reality with different unit costs (they are set as problem parameters) of using the corresponding supply, i.e., matching the supply with some demand. Similarly, the unfulfilled demand's probabilistic unit costs are formed this way.

This is done by setting the unit cost of supply proportional to $1 - CDF$ (the reverse cumulative distribution function) at the volume range corresponding to the supply being charged. Let's use a simplified made-up example to see how this works. Assume our forecast with confidence interval says that S_i, the value of the supply volume originates in hexagon i, has 5% chance to randomly fall at somewhere between 1 and 10, while the chance for the value to take a random place between 11 and 15 is 95%. Now if we use supply within the [1,10] range, on average 97.5% of the time, we will be able to find the supply in the true market reality, because when S_i takes a value in [11,15] by 95% chance, we are warranted with obtaining supply from the first 10 of them. Therefore, we assign the unit cost of supply in [1,10] with $\beta(1-97.5\%)$. By similar reasoning, we can assign the unit cost of supply in [11,15] with $\beta(1-47.5\%)$.

This way, the linear relation between the cost and the probability of forecasted demand/supply approximates the expected value of the uncertain cost term $E_\zeta[Q(x,\zeta)]$, and our robust optimization formulation approximates the stochastic programming formulation given in Equ. 2.

In practice, without loss of generality, we simplify the forecast probability distribution to being piece-wise uniform, just like in the simplified example above. The approximation of more sophisticated forecast probability distribution can be done in similar manner.

$$
\begin{aligned}
\text{Min: } & g(x) = \alpha \sum_i h_i + \sum_i \beta_i \tilde{s_i} + \sum_i \gamma_i \tilde{h_i} \\
\text{S.t.: } & \forall i \in \mathbb{A}, h_i \geq T_i - s_i, h_i \geq 0 \\
& \forall i \in \mathbb{A}, s_i = S_i - \sum_j x_{i,j} + \sum_k x_{k,i} \\
& \forall i \in \mathbb{A}, \sum_j x_{i,j} \leq S_i \\
& \forall i,j \in \mathbb{A}, Dist_{i,j} \leq O, x_{i,j} \geq 0, x_{j,i} \geq 0 \\
& \forall i \in \mathbb{A}, h'_i \geq (T_i + T'_i) - (s_i + s'_i), h'_i \geq 0 \\
& \forall i \in \mathbb{A}, \tilde{h_i} \geq h'_i - h_i, \tilde{h_i} \geq 0 \\
& \forall i \in \mathbb{A}, s'_i = \tilde{s_i} + s_i \\
& \forall i \in \mathbb{A}, 0 \leq \tilde{s_i} \leq S'_i
\end{aligned} \tag{3}
$$

where $x_{i,j}$ and h_i remains their representation as in the deterministic optimization formulation Equ. 1; T_i and S_i are the lower bounds T_i^l, S_i^l of the confidence intervals of the predicted demand and supply, $[T_i^l, T_i^u]$, $[S_i^l, S_i^u]$, respectively. T'_i and S'_i are the spans of the confidence intervals of the predicted demand and supply, $T_i^u - T_i^l$ and $S_i^u - S_i^l$, respectively. As a result, $\tilde{t_i}$ and $\tilde{s_i}$ represent the usage of demand and supply in their corresponding confidence intervals, respectively.

5 REALTIME MATCHING

Realtime matching at the individual request level corresponds to the second stage decisions in a typical 2-stage stochastic programming. It is a simple, fast heuristic that uses the globally-optimized inter-hexagon supply flows (which are obtained from the global matching) to guide the realtime dispatch for individual demand. This way, our final matching on individual trip requests can leverage the globally-optimized uncertainty-resilient aggregate matches, while being very runtime efficient so as to comply to the realtime matching time limit.

More specifically, for each trip request, the heuristic consists of two main operations.

(1) *Request matching guided by global optimization result*: for each trip request in hexagon j, collect the candidate hexagon set that contains all hexagon i that either is hexagon j itself or having a positive supply flow to j, i.e., $x_{i,j} > 0$, according to the current value of the global optimization result $x_{i,j}$. Rank the candidate hexagons by their supply-to-demand ratio in the order from high to low, and go through the candidate list from top to bottom while trying to find the hexagon to dispatch a supply in it to the trip request.
(2) *Request matching updating the global optimization result*: with the selected hexagon i for the trip request, update the corresponding supply flow value by: $x_{i,j} = x_{i,j} - 1$.

6 EXPERIMENT

This section evaluates the effectiveness and efficiency of GORM's application on the globally-optimized realtime matching problem. We compare GORM against several existing matching heuristics and state-of-the-art matching optimization algorithms. Two publicly-available raw input data sources are used in generating the simulated demand/supply distribution data for the experiments: 1) Uber passenger pickup data in New York City [6], short named pickup data; 2) Google Maps street speed data in New York City [7], short named speed data.

The snapshots of the demand and supply distribution over the marketplace of NYC are generated in 4 parts based on the raw input data: 1) the matched demand in reality, 2) the matched supply in reality, 3) the unmatched demand estimated by simulation, and 4) the unmatched supply estimated by simulation. Parts 1 and 2 are obtained directly from the pickup data, except that the dispatch-time location of a matched supply is randomly assigned within the dispatch radius from the pickup location. Part 3 is estimated by simulation based on the street speed at the corresponding location. Basically, the slower the driving speed around the pickup location is, the heavier the traffic around the location is, and likely the more demand is around the location. Part 4 is estimated based on the volume of the unmatched demand. If there is unmatched demand, the surrounding area should have no unmatched supply; otherwise, the unmatched supply is randomly assigned to locations in proportion to the nearby pickups.

The experiments are performed over the simulated snapshots of demand and supply distribution in 5-minute windows over the marketplace of different sizes. Three sub-regions of NYC in different sizes - mimicking marketplace of different geo sizes - were used in the experiments: city-big with $80k$ hexagons, city-medium with $40k$ hexagons, and city-small with $20k$ hexagons, respectively.

The experiments are set up as follows: For each sub-region of the city, snapshots of 5-minute market dynamics are used as the test time windows. Inside each 5-minute window, individual units of demand and supply surface and expire in their respective time limits. For example, individual demand's expiration time, the realtime supply-demand matching time limit, is set to 10, 15, 20, 25 and 30 seconds in the experiments.

The simulated supply and demand data of each of the 5-minute windows are available to serve as the "historical" data for the market forecasting in the corresponding 5-minute window, should it be needed by an algorithm in the experiment. For simplicity, we assume the chosen matching algorithm will not significantly change supply and demand at the hexagon level over 5-minute windows. This allows us to use the simulated data without running a true experiment with interventions.

We experiment and observe how the matching solution quality responds to changes on the problem parameters, including the error in demand/supply forecasts, realtime matching time limit. On the other hand, some problem parameters are fixed for all experiments. For example, the maximum-allowed geospatial distance in dispatching a supply in a hexagon to another hexagon is 6 hexagons away.

6.1 The algorithms in the experiments

We test and compare our uncertainty-resilient globally-optimized realtime supply-demand match method, GORM, with three baseline algorithms. The three baseline algorithms represent greedy local matching heuristics, and global matching that needs more than a few seconds' runtime to come up with the solution, global matching without treatment to deal with the uncertainty in the market forecasts, respectively. They are briefly described as follows.

(1) Baseline algorithm 1 (LOC-GRD): Nearest neighbor dispatch with a preference of matching supply in hexagons having higher supply-to-demand ratio. This represents greedy, local matching heuristics. While missing global optimization, this method satisfies the realtime matching requirement with ease. It does not need market forecast, and thus it does not face the challenge of prediction uncertainty.
(2) Baseline algorithm 2 (GLO-HIL): A modified implementation of Didi Chuxing's hill-climbing optimization method, which is held against the realtime matching time constraints. Because this method does not depend on a forecast of the market, all the demand/supply considered and optimized by this method is limited to which have occurred in the corresponding matching time window. Thus, the maximum runtime of the optimization algorithm is the matching time limit, and the best solution obtained by the stopping point is used as the matching solution.
For example, if the realtime matching time limit is set to be 15 seconds, then the 5-minute experiment window is divided into 20 15-second sub-windows, during each of which the matching algorithm is performed among all demand and supply occurring in that sub-window, and the optimization has at most 15 seconds to run. This represents globally-optimized matching that usually makes pre-mature sub-optimal matching decision, due to its extensive runtime for matching every trip request with an open supply in a limited market scope. Note that because our supply-demand matching problem ensures a close-to-100% order acceptance rate by the supply, a prediction of driver acceptance rate is unnecessary. For the simplicity of demonstration, we enforce the supply acceptance in all of our supply-demand matching decisions.
(3) Baseline algorithm 3 (GLO-DET): Globally-optimized realtime matching without robust optimization, i.e., global deterministic optimization. This method represents global optimization driven realtime matching, which depends on a market forecast in point estimation style, but does not consider or optimize over prediction error.
(4) Our algorithm (GLO-OUR): Globally-optimized uncertainty-resilient realtime matching. This represents our algorithm that depends on a market forecast with a 95% confidence interval.

6.2 Solution quality evaluation

The solution quality is primarily measured by the total volume of unfulfilled demand (**UFD**), defined as $UFD = \sum_i \max(T_i - S_i, 0)$.

To calculate the theoretical minimum total unfulfilled demand (UFD) for the matching solution, we run the global optimization formulated as Equ. 1 over the true market demand and supply dynamics that is given by the simulation in the corresponding 5-minute window in the market. Summing up the unfulfilled demand over all hexagons in the optimization result gives us the theoretical minimum value of the total unfulfilled demand (UFD), which is the lowest possible UFD for the matching problem.

The effectiveness of a matching algorithm can be better measured in UFD relative to the theoretical minimum UFD. The relative UFD (rUFD) is simply the difference between the UFD yielded by an algorithm and the theoretical minimum UFD. In other words, rUFD is the UFD gap between an algorithm's solution and the ideal best solution.

Next, we review how the 4 algorithms in our experiments perform with their matching solutions. Change problem parameters: demand/supply perturbation, different city sub-regions, and realtime decision time constraint - algorithm runtime limit.

In the following result review, we will use the short names for the 4 algorithms in our experiments. All metric values in the following tables is the percentage of the measurement over the total volume of demand in the whole market. The UFD values from all 4 algorithms are measured as the average over the same 5 snapshots of 5-minute market. Note that the lower the UFD and rUFD values are, the better; the higher the Fulfillment values are, the better.

The columns labeled with "abs" and "relative" indicate the measurement itself and the percentage of its delta relative to the same measurement of the first baseline algorithm (LOC-GRD), respectively. The column named as "Min UFD" indicates the theoretically lowest UFD possible.

Overall, the improvements on rUFD achieved by GORM over the base algorithms range from 24% to 60%. Given the usual unfulfilled demand percentage shown in the experiments, this rUFD improvement by our method translates into roughly $3-7\%$ increase on the total fulfilled trips. More detailed solution-quality experiment result on the 3 sub-regions can be found in Tables 1, 2, and 3.

Now we observe how different algorithms respond to the change of problem parameters, namely the uncertainty in demand/supply prediction (perturbed by $0.5\sigma, 1.0\sigma, 3.0\sigma$) and the realtime matching time limit (10, 15, 20, 25, or 30 seconds).

Figure 2 shows our algorithm GLO-OUR and GLO-DET's reaction to forecast uncertainty change in city-medium. GORM's

Table 1: UFD: 5-minute matching in city-small

	Min UFD	UFD		rUFD		Fulfillment	
		abs	relative	abs	relative	abs	relative
LOC-GRD	3.51%	15.07%	↓ 0%	11.56 %	↓ 0%	84.93%	↑ 0%
GLO-HIL	3.51%	13.66%	↓ 9.36%	10.15%	↓ 12.19%	86.34%	↑ 1.7%
GLO-DET	3.51%	11.09%	↓ 26.41%	7.58%	↓ 34.43%	88.91%	↑ 4.7%
GLO-OUR	3.51%	8.64%	↓ 42.67%	5.13%	↓ 55.62%	91.36%	↑ 7.6%

Table 2: UFD: 5-minute matching in city-medium

	Min UFD	UFD		rUFD		Fulfillment	
		abs	relative	abs	relative	abs	relative
LOC-GRD	5.83%	22.52%	↓ 0%	16.69%	↓ 0%	77.48%	↑ 0%
GLO-HIL	5.83%	21.69%	↓ 3.69%	15.86%	↓ 4.97%	78.31%	↑ 1.07%
GLO-DET	5.83%	19.89%	↓ 11.68%	14.06%	↓ 15.76%	80.11%	↑ 3.39%
GLO-OUR	5.83%	18.51%	↓ 17.81%	12.68%	↓ 24.03%	81.49%	↑ 5.18%

Table 3: UFD: 5-minute matching in city-big

	Min UFD	UFD		rUFD		Fulfillment	
		abs	relative	abs	relative	abs	relative
LOC-GRD	6.88%	11.93%	↓ 0%	5.05%	↓ 0%	88.07%	↑ 0%
GLO-HIL	6.88%	11.63%	↓ 22.10%	4.75%	↓ 5.94%	88.37%	↑ 0.34%
GLO-DET	6.88%	10.34%	↓ 30.74%	3.46%	↓ 31.49%	89.66%	↑ 1.81%
GLO-OUR	6.88%	8.91%	↓ 49.03%	2.03%	↓ 59.80%	91.09%	↑ 3.43%

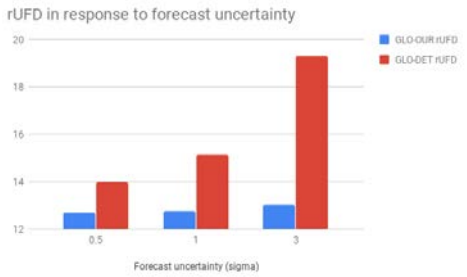

Figure 2: rUFD in response to forecast uncertainty

uncertainty resiliency keeps its solution from significant degradation, like what GLO-DET faces. GORM's fundamental advantage of being resilient to uncertainty usually expands as the uncertainty in the demand/supply forecasting increases.

Figure 3 shows our algorithm GLO-OUR and GLO-HIL's reaction to matching time limit change in city-medium. GLO-HIL's temporally local view of the market cannot improve the solution all the way to GLO-OUR's level, despite the extended optimization runtime. GORM's advantage over baseline algorithms usually expands when the time limit on realtime decision is lower (or equivalently when the trip expiration time is lower).

6.3 Algorithm Runtime

Algorithms in the experiment ran on a single 16-core Xeon machine. The runtime evaluation of all the algorithms is done in two runtime components: 1) offline market forecasting and optimization happening once every 5 minutes, if applicable to a specific algorithm. 2) online supply-demand matching at trip request level happening at realtime upon individual trip requests.

In all experiments, our algorithm - GLO-OUR - always finishes the offline forecasting and optimization under 2 minutes, while

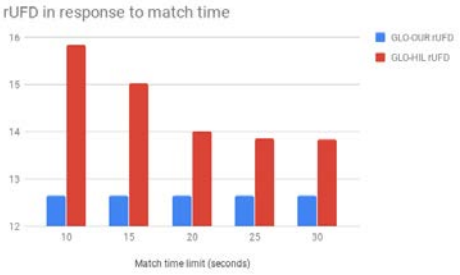

Figure 3: rUFD in response to matching time limit

takes less than a second to perform the realtime matching. Our algorithm performs both parts with less than 2 GB of memory.

More details of the runtime of all 4 algorithms can be found at Table 4. All the runtime measurements are in seconds.

Note that the runtime of the offline component cannot exceed 5 minutes; the runtime of the online component cannot exceed the matching time limit, which is set to 10 seconds in the solution quality experiments.

Notice that GLO-HIL's online component runtime is always 10 seconds, because it needs more than 10 seconds to complete a fully-optimized solution, but has to be cut off at the realtime matching time limit - 10 seconds.

Table 4: Algorithm runtime in seconds

	small city		medium city		big city	
	offline	online	offline	online	offline	online
LOC-GRD	0	<1	0	<1	0	<1
GLO-HIL	0	10	0	10	0	10
GLO-DET	52	<1	63	<1	79	<1
GLO-OUR	61	<1	76	<1	86	<1

7 FUTURE WORK

There are a range of algorithm/model improvements that can be considered in the GORM framework. Some examples include:

(1) Time-series optimization with minute-by-minute forecast.
(2) Global optimization on sliding time windows.

8 CONCLUSION

This paper presents the Globally-Optimized Realtime Matching framework (GORM) for supply-demand matching in ridesharing market. By applying GORM to a real world ridesharing matching problem, we showed significant improvements on market efficiencies - minimizing unfulfilled trip requests. Compared to several representative existing methods in the field, our method has the advantages of realtime matching runtime performance, globally-optimized supply-demand matching, and uncertainty-resilient robust optimization for forward-looking market optimization.

ABSTRACT

Relation classification is a basic yet important task in natural language processing. Existing relation classification approaches mainly rely on distant supervision, which assumes that a bag of sentences mentioning a pair of entities and extracted from a given corpus should express the same relation type of this entity pair. The training of these models needs a lot of high-quality bag-level data. However, in some specific domains, such as medical domain, it is difficult to obtain sufficient and high-quality sentences in a text corpus that mention two entities with a certain medical relation between them. In such a case, it is hard for existing discriminative models to capture the representative features (i.e., common patterns) from diversely expressed entity pairs with a given relation. Thus, the classification performance cannot be guaranteed when limited features are obtained from the corpus. To address this challenge, in this paper, we propose to employ a generative model, called conditional variational autoencoder (CVAE), to handle the pattern sparsity. We define that each relation has an individually learned latent distribution from all possible sentences expressing this relation. As these distributions are learned based on the purpose of input reconstruction, the model's classification ability may not be strong enough and should be improved. By distinguishing the differences among different relation distributions, a margin-based regularizer is designed, which leads to a margin-based CVAE (MCVAE) that can significantly enhance the classification ability. Besides, MCVAE can automatically generate semantically meaningful patterns that describe the given relations. Experiments on two real-world datasets validate the effectiveness of the proposed MCVAE on the tasks of relation classification and relation-specific pattern generation.

1 INTRODUCTION

Relation classification is a core task in natural language processing (NLP), which aims to identify semantic relations between a pair of entities in the given sentence. Relation classification can be widely used for multiple NLP tasks, such as knowledge graph completion and question answering. Traditional relation classification models [13, 27, 39] usually require high-quality annotated data, which makes them impossible to be applied to large-scale datasets.

Recently, distant supervision approach [26] has been proposed, which assumes that if a pair of entities has a relation in a knowledge base, then all the sentences that contain the two entities express this relation. This approach makes it easy to collect multiple sentences for different entity pairs and their relations, but it is hard to control the quality of the collected data. To remove the effect of "noisy" sentences, many approaches are proposed [8, 14, 15, 23, 31, 32, 37, 40]. All these studies are discriminative models, which aim to extract the accurate feature representations of relations to improve the prediction performance. However, if the quality of the input data is not very high, then they may not correctly capture the characteristics of the target, which will lead to unsatisfactory performance.

The quality of the collect data mainly depends on both the diversity of relation expressions and the quantity of sentences mentioning each entity pair. For a relation, it may be related to multiple entity pairs in the knowledge base. The extracted sentences mentioning those pairs may use different expressions to describe the semantic meanings of the relation. *If only a small part of commonly used expressions appear in the training data, it is hard for existing discriminative models to recognize the other possible expressions in the testing procedure.* This issue stems from the drawback of discriminative models, i.e., they are not designed to facilitate the **generalization ability**.

On the other hand, discriminative models focus on capturing those expressions with high occurrences among different sentences, i.e., recognizing relation patterns. In common domains, there may exist enough sentences with mentioned entity pairs on the same relation that can be used for the discovery of clear patterns. However, in specific domains, such as medical domain, given a pair of medical entities extracted from a medical knowledge base, to recognize the relation between the two entities, we need to extract sentences

from a given corpus. Unfortunately, the text corpus used for medical sentence extraction is usually not big. Though we can extract sentences for multiple entity pairs, the number of clean patterns among these sentences is limited, which leads to the *sparsity* of relation patterns and further decreases the quality of the dataset. Therefore, how to design a model that can handle the **diversity of relation expressions and sparsity of relation patterns** in the training dataset is a challenge for relation classification.

To tackle this challenge, instead of using discriminative models to capture the representative features of relations, we design a *generative* model, named MCVAE, which employs a Margin-based Conditional Variational AutoEncoder. The benefit of applying a generative model to solve a classification problem is that the generalization ability of generative models is significantly better than that of discriminative ones. Furthermore, such an ability helps generative models to handle the issue of pattern sparsity. Particularly, the proposed MCVAE consists of four modules: An **encoder** is used to learn the embeddings of input sentences. By concatenating the embeddings with the given relation, the encoder outputs the mean vector and the diagonal vector of covariance matrix for constructing the latent space of the given relation. A **decoder** aims to reconstruct the input sentence using a sample drawn from the constructed latent space. Motived by [22], a margin-based **regularizer** is designed to model the differences among different constructed latent spaces of relations and further increase the ability of classification. Finally, a **generator** is adopted to generate sentences and patterns for the given relation type based on the trained model. Experimental results on two datasets show that the proposed MCVAE outperforms existing relation classification models and produces meaningful patterns which describe the given relations. Here, we highlight our contributions as follows:

- To the best of our knowledge, this is the first work to design a generative model for solving the problems of expression diversity and pattern sparsity in the relation classification task.
- The proposed model not only accurately identifies the relation types of the input sentences with the designed margin-based regularizer, but also generates meaningful sentences and patterns for the given relations using the conditional variational autoencoder.
- Experiments on two real world datasets demonstrate the effectiveness of the proposed MCVAE for both relation classification and relation-specific sentence generation.

2 RELATED WORK

In this section, we review existing work from two aspects: relation classification and deep generative models.

Relation Extraction or Classification [1, 3, 10, 20, 21, 28, 29, 33, 34, 42] is an important sub-task of Information Extraction (IE). IE can be done in unsupervised [2, 7, 9] or semi-supervised domain [4, 36], and even in the form of OpenIE [16], where facts are extracted from the data along with the relation phrases, i.e., without predefined ontology or relation classes. Supervised relation classification aims to identify the relation between two entities with the given text. Many models are developed to solve this problem, such as deep learning based models with distant supervision technique [8, 14, 15, 23, 31, 32, 37, 40]. Distant supervision is proposed in [26] to collect large-scale datasets for training, but inevitably there is noise in the collected data. To reduce the effect of the noise in the data, many studies cast the problem of relation classification as a multiple instance learning problem [14, 32, 40]. Recently, sentence-level attention mechanism over multiple instances are proposed to assign lower weights to those noisy sentences [15, 23, 24]. Moreover, reinforcement learning-based sentence selection approaches [8, 31] are introduced to further improve the performance.

Deep generative models, such as generative adversarial networks (GAN) [11], have attracted much attention recently. Different from GAN, which generates data based on the arbitrary noise, variational autoencoder (VAE) tries to model the underlying probability distribution of data by constructing the latent variables, which makes it possible to generate new samples from the learned distributions. Actually, there are many VAE-based models [18, 38] that can be used to generate different kinds of data, such as images [12, 30], natural languages [5, 25] and structured medical entity pairs [41].

The aforementioned models either only focus on classification or generation. Different from them, the proposed model can handle both classification and generation simultaneously. The generative ability is obtained by the designed conditional variational autoencoder, while the ability of classification is achieved by the designed margin-based regularizer.

3 THE PROPOSED MODEL: MCVAE

In this paper, we introduce a novel margin-based conditional variational autoencoder (MCVAE) for distant supervised relation classification task. It is a fact that the relation between a pair of entities can be expressed by many ways (i.e., expression diversity). Thus, using a continuous vector to model a relation with multiple expressions is not enough. Moreover, the number of sentences used for relation classification may be small, which results in the problem of pattern sparsity. To solve these challenges, we propose to use a *generative model* for modeling the diverse expressions of relations. The benefits of the proposed MCVAE model are three-fold: (1) The relations are embedded into distributions, instead of vectors, which directly increases the ability of generalization; (2) given a relation, the proposed model is able to generate sentences on this relation, which may contain the frequently used patterns for this relation; and (3) the model can guarantee the prediction performance by modeling the differences among relation distributions. Next, we will introduce the details of the proposed MCVAE architecture.

3.1 Model Overview

Figure 1 shows the architecture of the proposed MCVAE. It consists of four modules: *encoder*, *decoder*, *regularizer*, and *generator*. The **encoder** module takes a relation r and a sentence $\mathbf{x} = \{w_i\}$ as input data, where $\{w_i\}$ represents a set of ordered words. For each word w_i, an embedding layer is employed to map the discrete word to a continuous vector representation. An RNN is then used to encode the whole sentence (i.e., a set of word embeddings) to a hidden vector. Combining the hidden vector with the input relation r, we can construct a latent space represented by the means and the diagonal vectors of covariances. The latent variable $\mathbf{z}$ can be

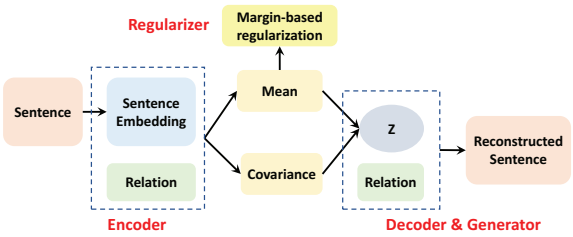

Figure 1: The Proposed MCVAE Model.

drawn from the learned latent space, which is one of the inputs of the decoder, and the other input is the label of the relation r.

The **decoder** tries its best to reconstruct the original input $\mathbf{x}$ based on another RNN. Through training the reconstruction loss and the KL-divergence as described in CVAE, we can learn all the parameters. However, a drawback of the naive model is that the constructed latent spaces for different relations are indistinguishable. In other words, the model does not have the ability for classifying the input data. To gain such an ability, we design a novel margin-based **regularizer**. The intuition behind the regularizer is that we want to increase the margins among latent spaces of different relations.

By training the proposed model MCVAE, we can generate sentences based on the given the relation types with the generator. The **generator** has the same structure with the decoder. However, instead of reconstructing the original inputs, it directly generates samples from the learned latent spaces of relations. The details of different modules are introduced in the following sections.

3.2 Encoder

Traditional relation classification models embeds a "bag" of sentences, which contains the same entity pair, into a common vector representation for the given entity pair. Different from existing models, we consider the sentence-level embeddings. We believe that each extracted sentence with distant supervision more or less expresses the relation between two entities.

For each word $w_i \in \mathbf{x}$, a word embedding layer is used to map it to a continuous vector $\mathbf{v}_i = f_{\text{EMB}}(w_i) \in \mathbb{R}^d$, where d is the size of the word embeddings, and $\mathbf{v}_i$ is the input of the encoder RNN. In particular, we employ the Gated Recurrent Unit (GRU) [6] as the encoder network in the proposed model. The output of the encoder is a hidden vector $\mathbf{h} \in \mathbb{R}^g$ produced by the GRU, which is defined as follows:

$$\mathbf{h} = f_{\text{ENC}}(\mathbf{x}) = \text{GRU}_{\text{ENC}}(\mathbf{V}; \varphi), \tag{1}$$

where g is the dimensionality, $\mathbf{V} \in \mathbb{R}^{s \times d}$ is the matrix of all the word embeddings, s is the length of the input $\mathbf{x}$, and φ is the parameter set of the GRU.

Based on the latent representation of the input $\mathbf{x}$ and its relation r, we can construct the latent space $Q_\phi(\mathbf{z}|\mathbf{x}, r)$ of the given relation r, which is represented by the mean μ and σ, and $\mathbf{z}$ is a sample drawn from the latent space. Towards this goal, we first concatenate the hidden vector $\mathbf{h}$ and the one-hot vector $\mathbf{r} \in \mathbb{R}^n$, and then use two separate linear functions to learn μ and σ as follows:

$$\mu = [\mathbf{h}; \mathbf{r}] \cdot \mathbf{W}_\mu + \mathbf{b}_\mu, \tag{2}$$

$$\sigma = [\mathbf{h}; \mathbf{r}] \cdot \mathbf{W}_\sigma + \mathbf{b}_\sigma, \tag{3}$$

where n denotes the number of relations, $\mathbf{W}_\mu$, $\mathbf{W}_\sigma \in \mathbb{R}^{(g+n)\times m}$ and $\mathbf{b}_\mu$, $\mathbf{b}_\sigma \in \mathbb{R}^m$ are the parameters to be learned, and m is the number of dimensions. With the learned μ and σ, we can obtained the latent space of the given relation r. Next, we will introduce how to reconstruct the input sentence x with the learned μ and σ.

3.3 Decoder

Given μ and σ, we can directly sample a latent variable $\mathbf{z} \in \mathbb{R}^m$ from the constructed relation space $\mathcal{N}(\mu, \sigma)$. However, the direct sampling dose not make the whole model differentiable, which leads to the failure of existing optimization approaches to compute the gradients. To address this problem, we follow the method in [19] and apply the reparameterization trick. It works as follows: Instead of directly sampling from $\mathcal{N}(\mu, \sigma)$, we first sample from a standard normal distribution $\epsilon \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$, and then obtain a reparameteried $\mathbf{z} = \mu + \sigma \odot \epsilon$, where $\odot$ represents the element-wise multiplication. Since sampling from ϵ dose not depend on the network, it makes the proposed model differentiable again.

The decoder aims to reconstruct the input x with a recurrent neural network, which means that the input and output must be sequences. To decode the input sentence x, we need to add two special symbols: $\langle sos \rangle$ (the start of the sequence) and $\langle eos \rangle$ (the end of the sequence). The input of the decoder is $\langle sos \rangle + \mathbf{x}$, and the target is $\mathbf{x} + \langle eos \rangle$.

Since reconstructing relation-specific sentences is the goal of the designed decoder, the relation information should be considered in the decoding procedure, and the decoder can be denoted as $P_\theta(\mathbf{x}+\langle eos \rangle|\mathbf{z}, r)$. To this end, we first concatenate the latent variable $\mathbf{z}$ and the one-hot relation vector $\mathbf{r}$, and then convert it to a new vector $\mathbf{h}' \in \mathbb{R}^g$ with a linear function. The mapped vector $\mathbf{h}'$ is considered as the initial hidden state of the decoder RNN. Similar to the encoder, we need to embed the input words into continuous vector representations. Here, we use dropout technique [35] to remove the irrelevant information on the word embeddings of the decoder input, and then these embeddings $\mathbf{V}' \in \mathbb{R}^{(s+1)\times d}$ are treated as the inputs of the decoder RNN. Mathematically, we use the following formulation to represent the decoder RNN:

$$\mathbf{C} = f_{\text{DEC}}(\langle sos \rangle + \mathbf{x}) = \text{GRU}_{\text{DEC}}(\mathbf{V}', \mathbf{h}'; \varphi'), \tag{4}$$

where $\mathbf{C} \in \mathbb{R}^{(s+1)\times g}$, and φ' is the parameter set of the decoder RNN. To generate discrete words, we need to obtain the probability of each word using a softmax layer after a linear mapping as follows:

$$\mathbf{O} = \text{softmax}(\mathbf{C}\mathbf{W}_o + \mathbf{b}_o), \tag{5}$$

where $\mathbf{O} \in \mathbb{R}^{(s+1)\times|V|}$ is the probability matrix, $\mathbf{W}_o \in \mathbb{R}^{g\times|V|}$ and $\mathbf{b}_o \in \mathbb{R}^{|V|}$ are parameters to be learned, and $|V|$ is the vocabulary size. Cross entropy between the probability matrix $\mathbf{O}$ and the target $\mathbf{x} + \langle eos \rangle$ can be used to optimize the objective. To simplify the notations, we remove the special symbols (i.e., $\langle sos \rangle$ and $\langle eos \rangle$) in the following sections. We use $\mathbf{x}$ to represent the input and output of the decoder.

3.4 Training with Large-Margin Regularizer

Given the encoder and decoder, and following the loss of CVAE, we can define the reconstruction loss to minimize the variational

lower bound:

$$\mathcal{L}_{\text{ENC+DEC}}(\mathbf{x}, r; \theta, \phi) = \\ -\text{KL}(Q_\phi(\mathbf{z}|\mathbf{x}, r)\|P_\theta(\mathbf{z}|r)) + \mathbb{E}[\log P_\theta(\mathbf{x}|\mathbf{z}, r)]. \tag{6}$$

The first term is in charge of measuring the difference between the prior distribution $P_\theta(\mathbf{z}|r)$ and a sample distribution $Q_\phi(\mathbf{z}|\mathbf{x}, r)$ with KL-divergence loss. Actually, the unknown true distribution can be simplified by a prior distribution $P_\theta(\mathbf{z}|r)$. The second term is the reconstruction loss from the decoder. Let $P_\theta(\mathbf{z}|r) \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ be the prior distribution, and then the KL-divergence can be rewritten as follows:

$$\begin{aligned} &-\text{KL}(Q_\phi(\mathbf{z}|r)\|P_\theta(\mathbf{z}|r)) = -\text{KL}(\mathcal{N}(\mu, \sigma)\|\mathcal{N}(\mathbf{0}, \mathbf{I})) \\ &= -\frac{1}{2}\sum_{i=1}^{m}(-\log(\sigma_i) + \sigma_i + \mu_i^2 - 1). \end{aligned} \tag{7}$$

Since the exponential term is more stable than the log term, in the experiments, we use $\log(\sigma)$ to model σ, i.e,

$$-\text{KL}(Q_\phi(\mathbf{z}|r)\|P_\theta(\mathbf{z}|r)) = -\frac{1}{2}\sum_{i=1}^{m}(-\sigma_i + \exp(\sigma_i) + \mu_i^2 - 1). \tag{8}$$

As discussed in the decoder, the cross entropy loss can be used, i.e.,

$$\mathbb{E}[\log P_\theta(\mathbf{x}|\mathbf{z}, r)] = -\sum_{j=1}^{s+1}\left(\mathbf{y}_j^\top \log(\mathbf{O}_j) + (\mathbf{1} - \mathbf{y}_j)^\top \log(\mathbf{1} - \mathbf{O}_j)\right), \tag{9}$$

where $\mathbf{y}_j$ is the one-hot representation of the j-th word in $\mathbf{x} + \langle eos \rangle$, and $\mathbf{O}_j$ is the estimated probability of the j-th word. Using both Eq. (8) and Eq. (9), we can optimize the model with the gradient-based optimizer, such as Adam [17]. However, this basic model does not have the ability of classification. The reason is that all the relation distributions are close to the prior distribution $\mathcal{N}(\mathbf{0}, \mathbf{I})$, which means that different relation spaces are mixed together. Thus, for a given sentence, it is hard for the basic model to assign the correct category label.

To gain the ability of distinguishing different relation types, the proposed model requires to learn the differences among relation spaces. In the proposed MCVAE, we add a large-margin regularizer into the objective of $\mathcal{L}_{\text{ENC+DEC}}$. There are n relation types, and for each sentence, it has a relation type r. In the encoder, we can obtain the mean vector $\mu_r \in \mathbb{R}^m$ of the relation distribution r. To ensure the classification ability of the proposed model, μ_r should be far away from the mean vectors of other relation distributions. Meanwhile, $\mathcal{N}(\mu_r, \sigma_r)$ should be closer to the prior distribution $\mathcal{N}(\mathbf{0}, \mathbf{I})$. Following these motivations, we design a margin-based regularizer, which is defined as follows:

$$\mathcal{L}_{\text{REG}} = \max(\alpha + f_{\text{D}}(\mu_r) - \beta, 0), \tag{10}$$

where $\alpha > 0$ is the predefined margin, $f_{\text{D}}()$ is the distance function (i.e., $f_{\text{D}}(\mu_r) = \sum_{i=1}^{m}\mu_{ri}^2$) to calculate the distance between the mean vector μ_r and the mean of the prior vector $\mathbf{0} \in \mathbb{R}^m$. β is defined as follows:

$$\beta = \min(f_{\text{D}}(\mu_1), \cdots, f_{\text{D}}(\mu_{r-1}), f_{\text{D}}(\mu_{r+1}), \cdots, f_{\text{D}}(\mu_n)). \tag{11}$$

From the designed regularizer (Eq. (10)), we can observe that if $f_{\text{D}}(\mu_r) > \beta - \alpha$, then $\mathcal{L}_{\text{REG}} > 0$. In this case, the proposed model should penalize the loss of $\mathcal{L}_{\text{REG}}$, which indicates that the difference value between $f_{\text{D}}(\mu_r)$ and β is at least α. The final loss function of the proposed MCVAE used in the training procedure is formulated as follows:

$$\mathcal{L}_{\text{MCVAE}} = \mathcal{L}_{\text{ENC+DEC}} + \mathcal{L}_{\text{REG}}. \tag{12}$$

In the testing procedure, assume that there is a bag of sentences $\{\mathbf{x}_1, \cdots, \mathbf{x}_t\}$ which mentions a pair of entities. For each sentence x_i, we first use the encoder to obtain the mean vector according to Eq. (2) for each relation r, and then calculate the distance using $f_{\text{D}}(\mu_r)$. Since we have n relations, for each sentence, n distances can be obtained and are denoted as $\mathbf{d}_i = [f_{\text{D}}(\mu_1), \cdots, f_{\text{D}}(\mu_n)]$. As there are t sentences in the bag, we aggregate all the distance vectors $\mathbf{d}_1, \cdots, \mathbf{d}_t$ to obtain an average vector $\mathbf{d}_{avg} \in \mathbb{R}^n$. Finally, we use the index corresponding to the minimum value in $\mathbf{d}_{avg}$ as the predicted label $\hat{r}$.

3.5 Generator

Based on the trained model, we can generate sentences which are related to a specific relation. Here, we use a density-based sampling approach for the generator to sample $\hat{\mathbf{z}}$ directly from the distribution of relations' latent spaces as [41]. The intuition of using density-based sampling approach is that the dense area (i.e., the area around the mean vector) contains "patterns" to express the relation r. A pattern means that a phrase or a set of words frequently appears in the sentences that express the relation r. Therefore, using the patterns in the dense area of the latent space, the generator can generate multiple meaningful sentences. The benefit of applying the density-based sampling method is that we do not need to cast a sentence with its relation into the encoder for learning μ and σ for the generator.

Particularly, given a relation type r, its one-hot vector representation can be obtained, which is denoted as $\mathbf{r} \in \mathbb{R}^n$. The following step is to sample a latent variable $\hat{\mathbf{z}}$ from the latent space $P_\theta(\hat{\mathbf{z}}|r)$. If the model is well-trained, then the latent variable $\hat{\mathbf{z}}$ will be drawn from $P_\theta(\hat{\mathbf{z}}|r) \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$. The concatenation of $\hat{\mathbf{z}}$ and $\mathbf{r}$ and the embedding of $\langle sos \rangle$ are the inputs of the generator RNN, which has the same architecture with the decoder RNN, to generate the first word. The output of the generator RNN and the embedding of the first generated word are used to produce the second word. By repeating this procedure, the generator will generate the whole sentence.

4 EXPERIMENTS

In this section, we conduct experiments to show the effectiveness of the proposed model MCVAE.

4.1 Experimental Setting

In this subsection, we introduce the datasets, baselines, parameter settings and evaluation measures.

• **Datasets**. In our experiments, we adopt two datasets. The first one is a widely used public available dataset, called NYT[1], generated by [32]. For this dataset, we remove the sentences in the NA relation. For each entity pair, at most 500 sentences are kept. Finally, there are 136,844 sentences and 19,539 entity pairs (bags) in the training dataset. In the testing dataset, we have 6,437 sentences and 1,755 entity pairs. The total number of relation types is 54, which are extracted from Freebase.

[1] http://iesl.cs.umass.edu/riedel/ecml/

The other dataset, named MedBook, is generated from medical books with Tencent medical knowledge graph. In the training dataset, there are 8,509 sentences and 2,213 entity pairs. The testing dataset contains 592 entity pairs with 740 sentences, and there are 14 relations in the MedBook dataset.

• **Baselines**. Since the proposed MCVAE is a generative model, and there is no existing work for relation classification task using generative models. Thus, we use the variant of the proposed model as a baseline method, which is CVAE. CVAE removes the proposed large-margin regularizer from the proposed MCVAE. The proposed model can be used for not only sentence generation but also relation classification. Therefore, we compare MCVAE with discriminative models for relation classification: PRNN+AVG and PRNN+ATT. PRNN+ATT uses attention mechanism over sentences in a bag as the way in [23]. The only difference is that we use RNN instead of CNN. The reason is that the proposed model is based on RNN, and designing a CNN-based generative model is our future work. PRNN+AVG learns the embeddings of entity pairs by averaging representations of all the sentences in the same bag.

• **Parameter Settings**. For the NYT dataset, we use a pretrained word embeddings[2]. The parameters are set as follows: For each sentence, the max length s is 70; the size of word embeddings d is 50; the hidden size of RNN g is 256; the size of the latent spaces of relations m is 16; and the margin $\alpha = 5$. The learning rate for Adam is 0.001, and the dropout rate for the decoder inputs is 0.5. The batch size is 256 on the NYT dataset and 32 on the MedBook dataset. The number of epochs is set as 50 for both datasets.

• **Evaluation Measures**. To fairly evaluate the proposed MCVAE, we utilize two measures: accuracy and weighted F1 score. The number of entity pairs for different relations in the testing dataset is significantly different, so the weighted F1 score is introduced, which considers the number of instances when calculating the score. The higher the measures, the better the performance.

4.2 Performance of Relation Classification

Table 1 shows the results for relation classification task on the two datasets. We can observe that the overall performance of the proposed MCVAE is better than that of the baselines.

Table 1: Performance of Different Methods.

Method	NYT		MedBook	
	Accuracy	Weighted F1	Accuracy	Weighted F1
PRNN+AVG	0.4650	0.2951	0.2010	0.0775
PRNN+ATT	0.5031	**0.5019**	0.1537	0.0975
CVAE	0.0501	0.0537	0.2010	0.2180
MCVAE	**0.5288**	0.4875	**0.3108**	**0.2821**

On the NYT dataset, the variant of the proposed MCVAE, i.e., CVAE, has the worst performance. Both the accuracy and weighted F1 value are largely lower than those of other approaches. The reasons are two-fold: (1) When CVAE is well trained, all the latent spaces of different relations are close to the prior distribution $\mathcal{N}(\mathbf{0}, \mathbf{I})$. It means that CVAE only focuses on how to generate new sentences based on the given relations, instead of paying attention to classification. Thus, the latent spaces of different relations may be mixed together. In such a case, using the learned μ's for classifying different relations is impossible. (2) There are a lot of shared common words to describe multiple relations on this dataset. For example, the relations, */people/person/nationality*, */people/person/place_of_birth* and */people/person/place_lived*, may share many context words, which leads to the failure of CVAE on the relation classification task. However, by adding the proposed large-margin regularizer with CVAE, the proposed MCVAE can significantly improve the performance. This demonstrates that when using generative models to do the classification tasks, it is essential for them to consider the differences among different classes.

Compared with the discriminative models, the performance of the proposed MCVAE is better than that of PRNN+AVG, and is comparable with PRNN+ATT. Since the number of sentences for each entity pair is large on the NYT dataset, the attention mechanism can effectively assign greater weights to those sentences semantically expressing the given relations. Moreover, the classifier can correctly capture the characteristics of different relations. Thus, PRNN+ATT can achieve better performance compared with PRNN+AVG. Different from the learning procedure of discriminative models, the proposed MCVAE tries to enhance the ability of generalization. It means that MCVAE aims to use latent distributions to model different expressions of relations. MCVAE intends to put all the words or patterns describing the same relation together, but designs a margin-based regularizer to distinguish the differences among different distributions.

On the MedBook dataset, since the number of sentences in each bag (i.e., entity pair) is small, which leads to the bad performance of using attention mechanism. Thus, PRNN+AVG performs better than PRNN+ATT. However, both the proposed MCVAE and its variant CVAE achieve better performance than PRNN+AVG and PRNN+ATT. It is because on this dataset, for the same relation, there are many different expressions, and the occurrence of those expressions is much lower than that on the NYT dataset. Without the generalization ability being facilitated, discriminative models are less likely to capture features that are generalizable for classification during the test phase. However, for the generative models, they can collect all the related features to construct the relation distributions. Since the dataset is not big, even for CVAE, the learned relation distributions are still distinguishable. Therefore, the generative models outperform existing discriminative models. It shows the advantage of employing the designed margin-based regularizer for relation classification task.

4.3 Case Study

The benefit of the proposed MCVAE is that it not only guarantees the performance for relation classification, but also generates sentences that express the semantics of the given relations. To validate this claim, we conduct a case study on the NYT dataset. Given a relation type, the proposed MCVAE can produce sentences with the designed generator. In this case study, we show the sentences generated from the following four relations: */people/person/nationality*, */people/person/place_lived*, */business/company/founders*, and */location/us_state/capital*. The generated sentences are shown in Table 2.

[2]https://github.com/thunlp/NRE

Table 2: Case Study on the NYT Dataset.

Relation	Generated Sentences
/people/person/nationality	(1) he was born in <unk> , germany , and raised in 1958 , england , and received a bachelor (2) president hamid_karzai of afghanistan said he believed that he had been <unk> by the taliban and passport (3) president bush <unk> prime minister , ariel_sharon , said that he had spoken that the united states would not be
/people/person/place_lived	(1) <unk> , the former senator from north_carolina , said he was <unk> by the (2) a former senator from nebraska , said he was <unk> by the senate speaker (3) the former governor of massachusetts , who was elected to represent the senate seat <unk>
/business/company/founders	(1) but <unk> , the founder of microsoft , has been (2) the news_corporation <unk> chairman , rupert_murdoch , objected to the news_corporation (3) but larry_page , google <unk> chief executive , said that
/location/us_state/capital	(1) showdown in ethiopia <unk> capital of addis_ababa , ethiopia (2) new_york wants to endorse the state of albany , the state of new_york , which has been broadcast in albany (3) <unk> <unk> , born in columbus , ohio , on august 10 , 2005 .

From Table 2, we can observe that the proposed MCVAE indeed generates some meaningful patterns on the given relations. Although there are some noisy cases, such as the third sentence in relation */people/person/nationality* and the first sentence in relation */location/us_state/capital*, most generated sentences are reasonable. For the relation */people/person/place_lived*, there is a clear pattern extracted by the proposed MCVAE, i.e., "the former [title] of [location name]". This observation can also be found in the relation */business/company/founders*. When expressing the relation between company and founders, the proposed MCVAE can recognize the key phases: "the founder of [company name]", "chairman", "[company name] chief executive", and so on. Even for the noisy cases, we can observe the ability of generalization of the proposed MCVAE. For example, the first sentence in relation */location/us_state/capital* is obviously wrong. Since the target relation is about the states in USA and their capitals, the country is not "ethiopia". Though the relation of the generated sentence is different from the target one, the relation between "addis_ababa" and "ethiopia" is indeed related to capitals.

4.4 Relation Pattern Generation

It is obvious that the generated sentences shown in Table 2 contain noisy information, and it may be hard for us to discover clear patterns that describe the given relations from the noisy generated sentences. To further enhance the understandability and readability of the discovered patterns, we conduct another experiment on the NYT dataset. In this experiment, for each entity, we first extract its types from Freebase and manually assign a type to it according to the semantic meaning of the relation. Next, we replace the entities in the sentences with their types. Finally, we run the proposed MCVAE on the new typed NYT dataset with the same parameter settings.

The accuracy on the typed NYT dataset is **0.7761**, and the weighted F1 value is **0.7358**, which are much greater than those on the original NYT dataset. The reason is that after mapping the entities into their types, the proposed MCVAE can effectively recognize the patterns of different relations, and the margin-based regularizer can successfully distinguish these latent distributions of relations. Similar to the case study conducted on the original NYT dataset, we list some patterns extracted by the proposed MCVAE on the new typed NYT dataset shown in Table 3. From Table 3, we can observe that the generated patterns are highly related to the semantic expressions of all the four listed relations. Based on the results in this experiment, we can safely conclude that the proposed MCVAE is able to generate meaningful and distinguishable patterns for different relation categories.

Table 3: Generated Patterns on the Typed NYT Dataset.

Relation	Generated Patterns
/people/person/nationality	(1) the deputy president of $LOCATION , $PEOPLE (2) president $PEOPLE of $LOCATION (3) the former prime minister of $LOCATION , $PEOPLE
/people/person/place_lived	(1) senator $PEOPLE of $LOCATION (2) representative $PEOPLE of $LOCATION (3) $PEOPLE , the $LOCATION borough president
/business/company/founders	(1) $PEOPLE , the founder of $BUSINESS (2) $PEOPLE , the chief executive of $BUSINESS (3) the company owned by $PEOPLE , $BUSINESS
/location/us_state/capital	(1) located in $LOCATION , $LOCATION (2) who was born in $LOCATION , $LOCATION (3) who lives in $LOCATION , $LOCATION

5 CONCLUSIONS

In this paper, we propose a novel generative model for relation classification task, which can handle the problems of both expression diversity and pattern sparsity. The proposed MCVAE not only guarantees the classification performance, but also generates useful patterns which describe the semantic meanings of relations. MCVAE consists of four modules: encoder, decoder, regularizer and generator. The encoder embeds each input sentence into a vector representation, which is further adopted for constructing the latent space of the given relation. The decoder is in charge of reconstructing the input sentences with a designed decoder RNN. The designed regularizer is the core module of the proposed MCVAE, which equips MCVAE with the ability of distinguishing

different relation distributions. The generator is employed to generate sentences based on the given relations. Experiments on two real datasets demonstrate the effectiveness of the proposed MCVAE and the strong ability of generation.

ABSTRACT

Rumors can cause devastating consequences to individual and/or society. Analysis shows that widespread of rumors typically results from deliberately promoted information campaigns which aim to shape collective opinions on the concerned news events. In this paper, we attempt to fight such chaos with itself to make automatic rumor detection more robust and effective. Our idea is inspired by adversarial learning method originated from Generative Adversarial Networks (GAN). We propose a GAN-style approach, where a generator is designed to produce uncertain or conflicting voices, complicating the original conversational threads in order to pressurize the discriminator to learn stronger rumor indicative representations from the augmented, more challenging examples. Different from traditional data-driven approach to rumor detection, our method can capture low-frequency but stronger non-trivial patterns via such adversarial training. Extensive experiments on two Twitter benchmark datasets demonstrate that our rumor detection method achieves much better results than state-of-the-art methods.

1 INTRODUCTION

The proliferation of rumors is a rampant phenomenon on social media. Rumor producers can cause devastating effects by manipulating public events. Information campaigns are frequently carried out by rumor makers via social networks to promote controversial memes, fake news, etc. with high volume of misinformation that competes with genuine ones for dragging people's attention to bogus claims. For example, during the US 2016 presidential election, Russia reportedly had coordinated thousands of "social bots" like covert human agents and automated programs to spread false information by corroborating each other[1]. The widespread of rumors has triggered huge debates and has already unprecedentedly influenced US politics.

Social psychology literature defines a rumor as a story or a statement whose truth value is unverified or deliberately false [1]. Fact-checking websites such as snopes.com and politifact.com rely on manual effort to track and debunk rumors, which have obvious limitation on efficiency and coverage. Existing automated methods typically resort to supervised classifiers trained on a wide range of hand-crafted features based on message contents, user profiles and diffusion patterns [3, 8–10, 13]. To avoid feature engineering effort, data-driven models were exploited more recently and demonstrated state-of-the-art detection performances. For example, Ma et al. [12] employed recurrent neural networks (RNNs), specifically LSTM and GRU, to learn hidden features from text content of relevant posts regarding given claims for detecting rumors. Yu et al. [20] used convolutional neural networks (CNNs) for obtaining local-global features from the relevant posts.

Nevertheless, existing data-driven approaches typically rely on finding indicative responses such as skeptical and disagreeing opinions for detection. Rumor producers can take advantage of promoted campaigns to entangle public opinions or influence collective stances to get it widely disseminated and amplified. This poses a major technical challenge to data-driven methods as text patterns and other explicit features become hardly discriminative. Various conflicting and uncertain voices that co-exist can seriously disturb the learning (or extraction) of useful features. Figure 1 illustrates a case of promoted campaign for the rumor about "Saudi Arabia beheads first female robot citizen", which shows how the popular indicative patterns expressing skepticism and disagreement such as "fake news", "not sure", "no truth" are inundated by the promoted posts. Therefore, developing a more robust feature learner for rumor detection is urgently desirable.

In this paper, we propose a radically new rumor detection method by leveraging the mechanism of information campaign and promoting it in a controlled manner in order to achieve more robust and effective detection. Our seemingly counter-intuitive idea is inspired by the Generative Adversarial Networks or dubbed as GAN [6, 7], where a discriminative classifier learns to distinguish whether an instance is from real world, and a generative model is trained to confuse the discriminator by generating proximately realistic examples. The harder are the generated examples to be distinguished from real-world ones, the stronger is the discriminator that can be

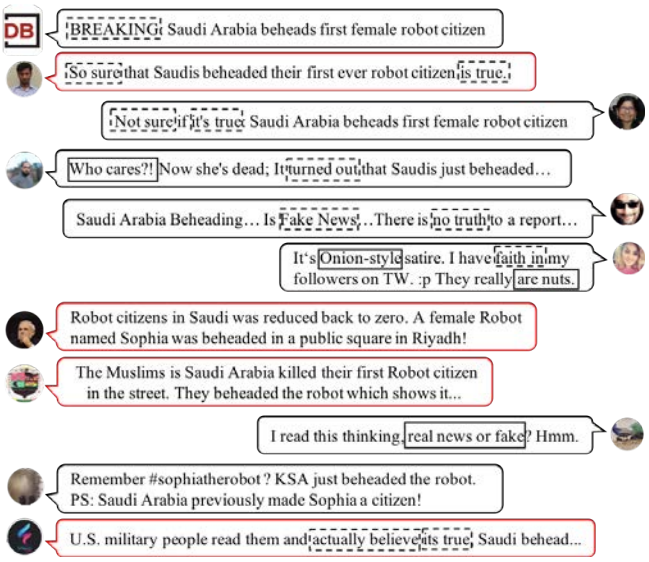

Figure 1: Sample responses to a rumor claim about "Saudi Arabia beheads its first female robot citizen" in a promoted campaign. Social bots activities are marked as red box. The supportive responses are listed at left side and denial (or uncertain) responses at right side. Patterns captured by existing methods are marked by dashed rectangles, and patterns that can be missing are marked by solid rectangles.

learned. We train our generator to output challenging examples by mimicking campaign promotions including misled grassroots conversations with uncertain and conflicting voices, so as to push our discriminator to strengthen feature learning from such difficult examples for capturing more discriminative patterns. Unlike typical GAN-style models such as in computer vision [6], which aim to learn a strong (image) generator, our goal however is to force our (rumor) *discriminator* to be more discriminative.

Intuitively, why can such a GAN-style method do better in feature learning? As shown in Figure 1, various users engagements can easily break the past data-driven methods that typically resort to repetitive patterns in responding posts. Due to the effect of generated campaign, high-frequency patterns such as "fake news" or "no truth" commonly occurring in the responses of rumors and "be true/sure" in those of non-rumors become less discriminative. As a result, the discriminator is adjusted adaptively to focus on capturing the relatively low-frequency patterns, such as "onion-style" and "be nuts", which are expected non-trivial as high-frequency ones while used to be ignored in existing feature learning methods. To retain the discriminative power of the original high-frequency patterns, we train the discriminator on an augmented training data with both generated campaign-like examples and the original examples.

The main contributions of our paper are four-fold:

- To the best of our knowledge, this is the first generative approach for rumor detection using a text-based GAN-style framework, where we make the text generator and discriminator adversarially strengthen each other for enhancing representation learning of rumor-indicative patterns.
- We model rumor dissemination as generative information campaigns for generating confusing training examples to challenge the discriminator of its detection capacity.
- Under the GAN-style framework, we reinforce our discriminator, which is trained on a set of more challenging examples replenished by the generator, to be focused on learning low-frequency yet discriminative patterns.
- We experimentally demonstrate that our model is more robust and effective than state-of-the-art baselines based on two public benchmark datasets for the tasks of rumor detection on Twitter.

2 PROBLEM STATEMENT

In general, rumor detection task can be defined as a binary classification problem, which aims to learn a classifier from training claims labeled as **rumor** or **non-rumor** for predicting the label of a test claim. A claim is a factual (rather than opinionated) assertion or statement that something is true, such as the example statement "Saudi Arabia beheads its first female robot citizen" in Figure 1.

Typically, a claim is short which contains very limited context. For reliable feature extraction, in Twitter rumor detection task, a claim is commonly represented by a set of posts (i.e., tweets) relevant to the claim which can be collected via Twitter's search function. Specifically, we represent a rumor dataset as $\{X\}$, where each $X = (y,\ x_1 x_2 \dots x_T)$ is a tuple representing a given claim: X consists of the ground-truth label $y \in \{N, R\}$ of the claim (i.e., Non-rumor or Rumor) and a sequence of relevant posts $x_1 x_2 \dots x_T$, where each x_t can represent a post or more generally a batch of posts in a time interval, and is indexed with a time step t. Thus, a claim can be considered as a time sequence of relevant posts. For clarity, we write an instance (claim) X as X_y, that is, X_R denotes a rumor and X_N a non-rumor.

3 GENERATIVE ADVERSARIAL LEARNING FOR RUMOR DETECTION

Information campaigns pose challenges to existing rumor detection models since frequent patterns indicative of veracity become distorted and misleading. Our basic idea is to strengthen representation learning of rumor indicative features, inspired by the mechanism of generative adversarial learning [7]. We propose a GAN-style model where a generator attempts to promote campaigns by generating hard examples and a discriminator aims to identify robust features to overcome the difficulty posed by the generator. Unlike the recent event adversarial model [18] for multi-modal fake news detection and the neural user response generator [16] for early detection, our idea and the adopted mechanisms are significantly different.

3.1 Controversial Example Generation

Our generative model aims to produce uncertain or conflicting voices regarding a given claim, making the differentiation of rumor and non-rumor harder which used to rely on repetitive patterns.

A straightforward way is to twist or complicate the opinions expressed in the original data examples via a handful of rule templates. For instance, we can 1) incorporate enquiry expressions such as "really?", "is it true?", "not sure", etc. into responding posts; 2) negate its stance of a post by adding a "not" after a "be" verb; and/or 3) apply antonym replacement at certain parts of the keywords, e.g.,

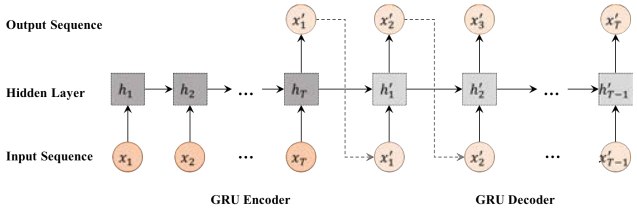

Figure 2: Framework of our generator with a neural sequence-to-sequence model. x'_t is the transformation of x_t, assuming that the length of output sequence equals to that of the input.

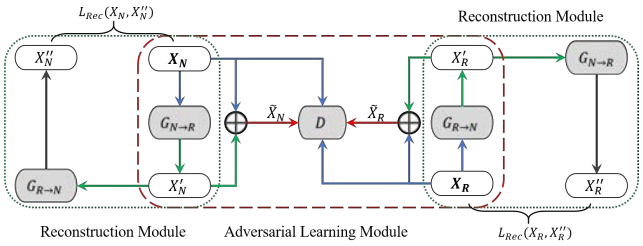

Figure 3: Overview of our GAN-style rumor detection model. $G_{N\to R}$ (or $G_{R\to N}$) is a generator. D denotes the discriminator.

by replacing "fake" with "true", "right" with "wrong", etc. However, it is difficult to generalize these rules for formally producing any kind of controversial voices. A general approach would be to cast our generator as trainable model that can cover a wide range of variations of expressions.

To this end, we design two generators, one for distorting non-rumor to make it look like a rumor, and the other for "whitewashing" rumor so that it looks like a non-rumor: 1) $G_{N\to R}$ generates skeptical or opposing voices against non-rumor claim; and 2) $G_{R\to N}$ generates supportive voices towards rumor claims. We define a function f_g to formulate our generative model:

$$X'_y = f_g(X_y) = \begin{cases} G_{N\to R}(X_y) & \text{if } y = N; \\ G_{R\to N}(X_y) & \text{if } y = R \end{cases} \tag{1}$$

where X_y is an original instance from training set which is either a rumor or non-rumor, and X'_y is the transformed instance with the generator while the label remains intact.

Considering the time sequence structure of posts in each instance, we use a sequence-to-sequence model [11, 17] for the generative transformation, which is illustrated in Figure 2. We encode an input sequence X_y into a hidden vector via an RNN encoder, and then generate the transformed sequence X'_y from it via an RNN decoder.

GRU-RNN Encoder: We batch relevant posts into time intervals and treat each batch as a single unit in the time sequence, following the similar time segmentation described in [12]. Using RNN, we map each input unit $x_t \in X_y$ into a hidden vector h_t, for which we use GRU [4] to store hidden representation:

$$h_t = \text{GRU}(x_t, h_{t-1}; \theta_g) \tag{2}$$

where GRU$(\cdot)$ denote standard GRU transition equations, x_t is the input unit represented as a vector of tf*idf values of vocabulary words computed from the posts falling into the t-th time step, h_{t-1} refers to the previous hidden state, and θ_g represent all the parameters of GRU.

The output of the last time step h_T from the GRU-RNN encoder will be the hidden representation of X_y. Note that the sequence length T is not fixed which can vary with different instances.

GRU-RNN Decoder: We now describe the GRU-RNN decoder that transforms h_T into the generated sequence $X'_y = x'_1 x'_2 \dots x'_T$. Specifically, each unit is sequentially generated using GRU followed by a softmax output function. In each step t, a softmax output layer maps the hidden states h'_t which is obtained via GRU into the target representation x'_{t+1} of a batch of posts by computing a distribution over vocabulary words:

$$\begin{aligned} h'_t &= \text{GRU}(x'_t, h'_{t-1}; \theta'_g) \\ x'_{t+1} &= \text{softmax}(V_g h'_t + b_g) \end{aligned} \tag{3}$$

where h'_{t-1} is the previous hidden state of GRU decoder and θ'_g represents all the parameters inside the GRU[2], V_g and b_g are trainable parameters of the output layer.

3.2 GAN-Style Adversarial Learning Model

In this encoder-decoder framework, $f_g(X_y)$ defines the policy that generates the representation of controversial posts which are used to confuse the discriminator based on the input X_y. A crucial issue is how to control the generator to generate the needed. To this end, we use the performance of discriminator as a reward to guide the generator. Before we present the discriminator, let us introduce the architecture and control mechanism of our GAN-style model as shown in Figure 3, which consists of an adversarial learning module and two reconstruction modules (one for rumor and the other for non-rumor).

Adversarial learning module: In our model, the generators are encouraged to produce campaign-like instances to fool the discriminator so that discriminator can be focused on learning more discriminative features. Such a goal suggests a training objective resembling adversarial learning [7]. We formulate adversarial loss as the *negative* of discriminator loss based on the generator-augmented training data:

$$L_{Adv} = -L_D(\bar{y}, \hat{y}) \tag{4}$$

where $L_D(\cdot)$ is the loss between the ground-truth class probability distribution $\bar{y}$ and the class distribution $\hat{y}$ predicted by discriminator given an input instance (see Eq. 11 for the specific form of L_D).

We combine the generated examples and original ones to augment the training set by taking the union of them, i.e., $\{\{X_y\} \cup \{\tilde{X}_y\}\}$, where $\tilde{X}_y = X_y \oplus X'_y$ is the elementwise addition of the original and generated examples. Note that the elementwise addition has the effect to cancel out influential high-frequency patterns and promote the chance of important less frequent patterns for being selected. Meanwhile, we do not want to seriously weaken those useful features in the original example. Thus, the original example X_y is combined with $\tilde{X}_y$ for training as shown in Figure 3.

[2]Note that each generator ($G_{R\to N}$ or $G_{N\to R}$) corresponds to a unique sequence-to-sequence model. The encoding and decoding GRUs have similar yet different set of parameters: θ_g and θ'_g.

Reconstruction module: It is likely that the generator could distort the original example towards unexpected direction by changing some essential aspects of a story. For example, the theme of "Saudi beheads robot citizen" might get distorted as "Saudi digs canal for Qatar" which is irrelevant and not helpful. To avoid that, we introduce a reconstruction mechanism to make the generative process reversible. The idea is that the opinionated voices will be reversible through two generators of opposite direction so as to minimize the loss of fidelity of information. We define the reconstruction function as follows:

$$X''_y = f_r(X_y) = \begin{cases} G_{R\to N}(G_{N\to R}(X_y)) & \text{if } y = N; \\ G_{N\to R}(G_{R\to N}(X_y)) & \text{if } y = R \end{cases} \tag{5}$$

where X''_y is the reconstructed instance from an original instance X_y via two opposite generators. We formulate the difference between X''_y and X_y as a reconstruction loss:

$$L_{Rec} = \frac{1}{T}\sum_{t=1}^{T} ||x_t - x''_t||_2 \tag{6}$$

where x_t and x''_t are the t-th unit in the original and reconstructed sequences, respectively, T is the sequence length, and $||\cdot||_2$ is the L2-norm of a vector.

Objective of optimization: The overall loss function of our GAN-style adversarial learning is defined as linear interpolation of L_{Adv} and L_{Rec}:

$$L = \alpha L_{Adv} + (1-\alpha)L_{Rec} \tag{7}$$

where α is the trade-off coefficient between adversarial and reconstruction losses. And the objective of adversarial learning takes a min-max form:

$$\max_{\Theta_D}\left(\min_{\Theta_G} L\right) \tag{8}$$

where $\Theta_G = \{\theta_g, \theta'_g, V_g, b_g\}$ are generators' parameters, and Θ_D are discriminator's parameters which will be detailed in the next section. In the min-max process, we first optimize Θ_G by minimizing adversarial loss L_{Adv} (i.e., maximizing discriminator loss L_D) and reconstruction loss L_{Rec} to generate confusing but reversible examples; we then optimize discriminator parameters Θ_D for classification by maximizing adversarial loss L_{Adv} (i.e., minimizing discriminator loss L_D), and note that L_{Rec} is independent of Θ_D.

3.3 Rumor Discriminator

With the training data augmented with the generative processing, the discriminator learns to capture more discriminative features, especially from low-frequency non-trivial patterns.

We build the discriminator based on a RNN rumor detection model [12]. Given an instance (either original or generated), the RNN model first maps relevant posts x_t at the t-th step into a hidden vector s_t using GRU:

$$s_t = \text{GRU}(x_t, s_{t-1}; \theta_d) \tag{9}$$

where s_{t-1} is the previous hidden vector and θ_d denotes all the GRU parameters in discriminator.

Following [12], we feed the hidden vector s_T at the last time step as the representation into a 2-class softmax function for classifying the instance:

$$\hat{y} = \text{softmax}(V_d s_T + b_d) \tag{10}$$

Algorithm 1: Generative adversarial training procedure.

Input : A set of training claims $\{X\}$, learning rate ϵ

1 Initialize Θ_G, and Θ_D with random weight values;
2 **for** *epoch from 1 to maxIter* **do**
3 **for** *each mini-batch* $\{\{X_N\},\{X_R\}\}$ **do**
4 Generate $\{\tilde{X}_N\}$: $\{X_N \oplus G_{N\to R}(X_N)\} \to \{\tilde{X}_N\}$;
5 Generate $\{\tilde{X}_R\}$: $\{X_R \oplus G_{R\to N}(X_R)\} \to \{\tilde{X}_R\}$;
6 Augment training set: $\big\{\{X_N\}\cup\{\tilde{X}_N\}, \{X_R\}\cup\{\tilde{X}_R\}\big\}$;
7 Compute loss L using Eq. 7;
  `/* Minimize L w.r.t. Θ_G */`
8 Compute gradient $\nabla(\Theta_G)$;
9 Update generators: $\Theta_G \leftarrow \Theta_G - \epsilon\nabla(\Theta_G)$;
  `/* Maximize L w.r.t. Θ_D */`
10 Compute gradient $\nabla'(\Theta_D)$;
11 Update discriminator: $\Theta_D \leftarrow \Theta_D - \epsilon\nabla'(\Theta_D)$;
12 **end for**
13 **end for**

where $\hat{y}$ is the vector of predicted probabilities over the two classes, V_d is the weight matrix of output layer and b_d is the trainable bias.

The loss of discriminator is defined as the square error between distributions of the predicted class and the ground-truth class:

$$L_D(\bar{y}, \hat{y}) = ||\bar{y} - \hat{y}||_2^2 + \lambda||\Theta_D||_2^2 \tag{11}$$

where $\bar{y}$ and $\hat{y}$ are respectively the ground-truth and predicted class probability distributions, $\Theta_D = \{\theta_d, V_d, b_d\}$ are discriminator parameters, and λ is the trade-off coefficient.

3.4 Generative Adversarial Training Algorithm

Algorithm 1 presents the iterative training process of the generators and discriminator in our GAN-style framework. Unlike original GAN [7] for obtaining better generators, our goal is to reinforce the discriminator to be more discriminative and generalizable.

The generators and discriminator are alternately trained using stochastic gradient decent with mini-batches [2]. In each epoch, controversial examples are generated and augmented into the original training data. We optimize the generator and discriminator against the augmented training examples with Eq. 8 that enforces a min-max game through steps 8-11 in Algorithm 1.

In training, we initialize model parameters with uniform distribution and update them by employing the derivative of the loss through back-propagation [5]; we iterate training until the maximum epoch number is met, which is set as 200; we fix the vocabulary size as 5,000, the size of hidden vector as 100, and tune the hyper parameters α, λ and ϵ using held-out dataset; post sequences take variable length dependent of specific instances by following [12].

4 EXPERIMENTS AND RESULTS

4.1 Datasets

We resort to two public datasets TWITTER [12] and PHEME [22] for experimental evaluation[3] The two datasets were used for binary classification of rumor and non-rumor with respect to a claim via

[3]https://figshare.com/articles/PHEME_dataset_of_rumours_and_non-rumours/4010619.

Table 1: Statistics of the datasets

Statistic	TWITTER	PHEME
Users #	491,229	29,387
claims #	992	2,246
Non-Rumors #	498	1,123
Rumors #	494	1,123
Avg. time length / claim	1,582.6 Hours	19.9 Hours
Avg. # of posts / claim	1,111	26
Max # of posts / claim	62,827	289
Min # of posts / claim	10	12

its relevant tweets. In particular, PHEME were collected based on 5 breaking news, thus its claims overlap more than TWITTER which was collected based on the claims reported on snopes.com. Moreover, we filtered out claims with less than 10 tweets and balanced the number of instances of the two classes. Statistics of the resulting datasets are given in Table 1.

4.2 Experimental Setup

We made comparisons among the following models:

DT-Rank: A Decision-Tree-based Ranking method that identifies trending rumors [21] through searching for disputed claims.

DTC: A Decision Tree Classifier for modeling Twitter information credibility [3] using various handcrafted features.

SVM-TS: A linear SVM classification model that uses time series to model the chronological variation of social context features [13].

BOW: A naive baseline representing the texts using bag-of-words and building the rumor classifier with linear SVM.

GRU: A RNN-based rumor detection model [12] with GRU for representation learning of relevant posts over time.

CNN: A CNN-based model for misinformation identification [20] for learning rumor representations by framing the relevant posts as fixed-length sequence.

GAN-GRU, **GAN-CNN** and **GAN-BOW**: Our GAN-style learning models where the discriminator adopts the data-driven models **GRU**, **CNN** and **BOW** above, respectively. Since replacing GRU with CNN or BOW as discriminator is straightforward, we omit describing the structures of **GAN-CNN** and **GAN-BOW**.

We hold out 10% of the claims in each dataset for tuning the hyper parameters, and for the rest of the claims, we conduct 5-fold cross-validation and use accuracy, precision, recall and F-measure as evaluation metrics. We implemented these models under comparison and will release our source codes publicly[4].

4.3 Result and Analysis

Table 2–3 demonstrate the performance of all the compared models based on the two datasets. The results indicate that our **GAN-GRU** model outperforms all the baselines, which confirms the advantage of generative adversarial learning for rumor detection task.

It is observed that the 3 baselines based on hand-crafted features perform clearly worse than all the 6 purely data-driven models. **SVM-TS** is relatively better because it incorporate additional temporal information into the conventional models. The results of

DT-Rank are poor due to the low coverage of the patterns using the regular expressions it defined.

BOW performs surprisingly well which is comparable to or even outperforms using hand-crafted features which confirms the advantage of using the simplest data-driven approach. **GRU** performs the best among all the baselines, which is not surprising since it takes advantage of deep neural nets to capture complex hidden features indicative of rumors beyond explicit and shallow patterns.

We conjectured that **CNN** should be comparable to **GRU** because both can learn deep latent features from data. This turned out to be incorrect on PHEME where CNN performs much worse. The reason is that RNN can inherently deal with variable-length sequence while CNN is essentially not a sequential model. The relevant posts per

(a) TWITTER dataset (b) PHEME dataset

Figure 4: Results of rumor early detection

claim in PHEME is significantly fewer than TWITTER, rendering lots of zero-valued input units to CNN that can worsen convolution operations, but RNN can easily get rid of zero input units by shortening sequence length. This also explains the overall better performance of all models on TWITTER.

Clearly, our three generative adversarial models outperform their counterparts in baselines that are not generative adversarial. The improvements of our models over these baselines range from 2.6% to 5.3% on the two datasets, indicating the adversarial learning with the generative-discriminative process is generally helpful and effective. However, two reasons may prevent further improvements on the two datasets: 1) The post content associated with PHEME claims overlap heavily since they come from only 5 breaking news, rendering high-frequency patterns more sensitive to topical categories than veracity categories. The claims in TWITTER dataset are however easier to classify as per veracity since each of them is an independent news topic, making high-frequency patterns well correlated to veracity rather than topic[5]. The potential of GAN-style learning by promoting the chance of low-frequency patterns is thus somewhat limited on TWITTER. This can be implied by the relatively lower improvement obtained on TWITTER than PHEME. 2) In addition to overlapping topics, PHEME is harder to classify also because there are only 26 posts per claim in average, thus useful information available is relatively limited.

Furthermore, rumor detection task emphasizes the identification performance on the rumor category. GAN-GRU achieves the highest recall on rumor category, indicating that more rumors can be found. From a balanced view of precision and recall, we also observe that the F1 scores of rumor category achieved by GAN-GRU are higher than non-rumor category.

4.4 Early Rumor Detection

Early alerts of rumors can prevent further spreading of rumorous content. By setting a detection delay time, only tweets posted no later than the delay can be used for evaluating early detection performance. We compare the accuracies of different baselines and our models as shown in Figure 4.

The accuracies of all methods increase with elapsed time, and our models demonstrate clear advantages at early stage. Particularly, **GAN-GRU** using less than 12-hour data, has already outperformed **GRU** (the best baseline) using all time data, indicating the superior early detection performance of our model. This is due to the generation component that can enrich training data at early stage when the volume of actual posts is generally low.

[5]This can be confirmed by the relatively higher performance of all models on TWITTER.

Table 4: Examples of original and generated posts

claim	**[Non-rumor:] Augusta County School Close over Arabic Assignment**
Real Posts	Believe that is scary ? Augusta County schools closed Friday ... Schools are shut down for a homework assignment on Arabic Augusta County schools closed Friday... Oh, the stupid -it burns. $G_{N \to R}$	The assignment in school not well with great wrong , I disagree ... Why close school? seriously? I not believe . not sure but wrong :d I think the assignment will be a mess , do harm to... so disappointed . Those teacher have fault, that was crazy, not a truth , totally a rumor I am confused of not enough report about us. Will be a joke
claim	**[Rumor:] Dearborn Implement Sharia Law**
Real Posts	A satire website produces fake news for entertainment. An oninion-style ... No movement implement Sharia Law Dearborn just sustain Shawarma Law Link me your source, even better, public voting record doesn't exist I can assure you that no one is trying to implement Sharia Law. Is this true? the city council of Dearborn, Michigan became the first
$G_{R \to N}$	A Claim that Law probably offense and out of control :p #Wakeupamerica, A Claim expose that is well great via fully report Omg, a claim earn simultaneously smile and pleasant , Seriously? Report that breaking for nyc, I mean it Awesome! no rumor just fact I discover it a total fact , but claim is illegal, will appear to be wrong .

We also conduct experiments to explain why the generator can boost the discriminator in an adversarial manner. We sample a rumor and a non-rumor claim from TWITTER, and list some generated contents in Table 4. We observe that 1) the generations although seemed non-grammatical are relevant to the input claim; 2) the generations can distort the real-world posts by using conflicting or uncertain expressions; 3) incorporating the generations counterbalances the discriminative power of high-frequency patterns (in yellow), implying a higher chance of lower-frequency features (in blue) being captured by the discriminator.

Given the limited number of claims in the datasets, our models perform reasonably well. This is because there are a good number of relevant tweets per claim, where many indicative patterns exist, such as those highlighted keywords and phrases in Table 4. Therefore, the feature space is not sparse, which is generally advantageous for generators to generate diverse campaign-style texts and for the discriminator to capture discriminative features.

5 CONCLUSION AND FUTURE WORK

We propose a novel GAN-style model that can generate and exploit the effect of information campaigns for better rumor detection. Our neural-network-based generators create training examples to confuse rumor discriminator so that the discriminator are forced to learn more powerful features from the augmented training data. Experimental results confirm that our method is effective and robust based on two public benchmark datasets for rumor detection on Twitter. In our future work, we plan to use GAN to generate structured data such as rumor propagation trees to boost rumor detection performance and compare with structured models [14, 15, 19].

Parametric Models for Intransitivity in Pairwise Rankings

ABSTRACT

There is a growing need for discrete choice models that account for the complex nature of human choices, escaping traditional behavioral assumptions such as the transitivity of pairwise preferences. Recently, several parametric models of intransitive comparisons have been proposed, but in all cases the model log-likelihood is non-concave, making inference difficult. In this work we generalize this trend, showing that there cannot exist an parametric model that both (i) has a log-likelihood function that is concave in item-level parameters and (ii) can exhibit intransitive preferences. Given this observation, we also contribute a new simple model for analyzing intransitivity in pairwise comparisons, taking inspiration from the Condorcet method (majority vote) in social choice theory. The *majority vote model* we analyze is defined as a voting process over independent Random Utility Models (RUMs). We infer a multidimensional embedding of each object or player, in contrast to the traditional one-dimensional embedding used by models such as the Thurstone or Bradley-Terry-Luce (BTL) models. We show that a three-dimensional majority vote model is capable of modeling arbitrarily strong and long intransitive cycles, and can also represent arbitrary pairwise comparison probabilities on any triplet. We provide experimental results that substantiate our claims regarding the effectiveness of our model in capturing intransitivity for various pairwise choice tasks such as predicting choices in recommendation systems, winners in online video games, and elections.

1 INTRODUCTION

Modeling discrete choice is a key challenge at the heart of many ranking problems, with applications to recommendation systems [8], information retrieval [12], and predicting the outcomes of diverse pairwise competitions [13]. The "choice" being modeled is sometimes a choice made by an individual over alternative options, or sometimes a matter of a competition or game "choosing" a player to win that competition. Prominent examples of ranking systems based on discrete choice models are the the Elo system for Chess ranking and the TrueSkill system [9] for matching players in online games. Meanwhile pairwise comparisons are used in recommendation systems to infer global quality measures from pairwise preferences of users [20], an idea that builds on Thurstone's original observation from the 1920's that comparative judgments are often easier than absolute judgments in many contexts [21].

Two of the most widely used models of ranking from pairwise comparisons are the Thurstone [21] and the Bradley-Terry-Luce (BTL) [3] models. These two models both belong to a broader class of Random Utility Models (RUMs) [1, 14], which assume that each alternative i is completely described by a random utility U_i with a innate quality λ_i, also known as the nominal utility, and a zero-mean noise term ϵ_i such that $U_i = \lambda_i + \epsilon_i$. For a random utility model with n items and utilities $U_1, \ldots, U_n$, it is assumed that the probability that an item is chosen can be written as:

$$P(a \text{ chosen from } S) = Pr(U_a \geq U_c, \forall c \in S),$$

for all possible alternatives $a \in S$ and choice sets S. For pairwise choices, this structure reduces to assuming that choices

$$P_{AB} := \Pr[A \text{ chosen from } \{A, B\}] = \Pr[U_A - U_B > 0].$$

The Thurstone model assumes that each ϵ_i is i.i.d. Normal while the BTL model assumes that each ϵ_i is i.i.d. Gumbel (sometimes also called double-exponential). A model is an *independent* RUM if the random variables ϵ_i are all independent. Thurstone's model and the BTL model are therefore both independent RUMs. For the Thurstone and BTL models, the difference of two utilities $U_A - U_B$ obeys a Normal distribution and Logistic distribution, respectively.

An important general feature of RUMs with i.i.d. noise is that they implicitly assume stochastic transitivity. Informally, if A beats B more often than not and B beats C more often than not, then any such model will assume that A beats C more often than not. The stochastic transitivity of these RUMs follows very specifically from the requirement that the noise be both independent *and* identically distributed. A famous examples of stochastic *intransitivity* is that of *non-transitive dice* [16], which can be formulated as a RUM with independent but non-identical noise distributions. Thus, independent RUMs need not exhibit stochastically transitive choices.

Non-transitive dice raise an intriguing question, namely whether it is possible to efficiently learn the parameters of an independent RUM that models intransitive pairwise comparisons using distributions defined by a small set of parameters (such the moments of the noise distributions). Several models of intransitive comparisons have recently been proposed, notably the 2-dimensional BTL model [4] and the Blade-Chest model [6]. But these and other models suffer from non-concave log-likelihood functions, meaning that maximum likelihood estimation is challenging. In this work we therefore formally ask: is there some overlooked model with a tractable concave log-likelihood that can support intransitive pairwise preferences? Our main result answers this question with a general "no."

Given this result, we investigate interpretable models of intransitivity, drawing inspiration from social choice theory. Under the

Condorcet method of voting, individual rankings may be transitive but overall the collective social decision procedures are not. While the log-likelihood of this model is still non-concave, we find that standard routines for non-convex optimization work well. Furthermore, the relatively well-understood structure of majority vote allows us to derive a collection of expressivity results regarding what sorts of intransitivity this model can and can't represent.

2 MODELLING INTRANSITIVITY

There are three basic mathematical definitions of stochastic transitivity - weak, strong, and antitransitivity. *Weak stochastic intransitivity* is defined as the existence of three alternatives A, B, C in a set of alternatives such that:

$$P_{AB} > 0.5, \;\; P_{BC} > 0.5, \;\; P_{CA} > 0.5,$$

and we are specifically focused on weak stochastic intransitivity in this work. As we will now show, any RUM with i.i.d. uncertainties, including the Thurstone and BTL models, exhibit weak stochastic transitivity.

Proposition 2.1. *For any Random Utility Model with random utilities $U_i = \lambda_i + \epsilon_i$ with i.i.d. ϵ_i and $\lambda_i \neq \lambda_j, \forall i, j$, weak transitivity holds.*

Proof. For any three alternatives A, B, and C, we have that ϵ_A, ϵ_B, and ϵ_C are i.i.d., implying that $\epsilon_A - \epsilon_B$, $\epsilon_B - \epsilon_C$, and $\epsilon_A - \epsilon_C$ are all identically distributed and also symmetric. We see then that $\Pr[U_i - U_j] > 0.5$ iff $\lambda_i > \lambda_j$, and thus the three alternatives are totally ordered by their means. □

There are three traditional approaches to introducing pairwise intransitivity into choice models: RUMs with possibly dependent distributions, RUMs with non-identical distributions, or departures from the RUM framework. Our work here falls in the last category. The study of dependent RUMs has led to an expansive modeling literature, but inference in these settings is generally quite difficult [23]. For intransitivity from independent but non-identical RUMs, we refer the reader to the literature on non-transitive dice [16], which is bounded in the intransitivity it can achieve, a matter that we elaborate on in Section 5.1. It is also possible to look at non-parametric models where each pairwise probability is its own "parameter" p_{ij}, which can be estimated using maximum likelihood [10]. Chatterjee [5] introduced the *non-parametric Bradley-Terry model* with a strong stochastic transitivity assumption that $p_{ik} \geq p_{jk}$ for $k \neq i, j$ whenever i beats j. This assumption facilitates an efficient consistent estimator. Without this transitivity assumption, a simple empirical estimator would be consistent but not very efficient. This motivates the need for parametric models where the p_{ij} can be expressed as a function of item-level parameters for i and j that may be efficiently estimated.

2.1 Prior work on multidimensional models

The use of higher dimensional scores to model pairwise intransitivity is an idea with a notable history [4, 15] and also recent advancements [6, 7, 17]. A two-dimensional extension of BTL is due to Causeur and Husson [4], parameterized by two-dimensional scores $\lambda_i \in \mathbb{R}^2$, $i = 1, \ldots, n$, as well as a binary matrix $\Sigma \in \{-1, +1\}^{n \times n}$ of pairwise dominances. During estimation, each $\sigma_{ij} \in \Sigma$ is determined from the data, taking the value $+1$ if player i wins the majority of the matches between player i and j, and -1 otherwise. From these parameters, $P_{ij} = S(\sigma_{ij}||\lambda_i - \lambda_j||_2)$, where $S(x) = 1/(1 + \exp(-x))$. Although the Casseur–Husson model can exhibit intransitivity, it is highly sensitive to changes in the empirical data since the dominance parameters Σ depend directly on the pairwise counts, and very little has been established regarding the transitive vs. intransitive properties of this model.

The Casseur–Husson model can be easily extended to obtain a d-dimensional BTL model where the score of each player $\lambda_i \in \mathbb{R}^d$. Note that such extensions require more constraints to impose uniqueness. As an example, for a 3-dimensional BTL of n players, the following constraints are sufficient for identifiability: $\sum_{i=1}^{3} \lambda_i = 0$ and $\lambda_i \cdot \lambda_j = 0 \; \forall i, j \in \{1, 2, 3\}, i \neq j$. The number of parameters for this *3D BTL model* are $3n - 6$ for λ (minus the six constraints) and $\binom{n}{2}$ for Σ. It is straight-forward to verify that the negative log-likelihood function of these extended BTL models are non-convex in general.

A recent model similarly based on a higher-dimensional embedding of alternatives is the blade-chest (BC) model [6, 7]. In this model, every player a is represented by two d-dimensional vectors, a "blade" vector $\mathbf{a}_{\text{blade}}$ and a "chest" vector $\mathbf{a}_{\text{chest}}$. There are two variations of the model, "BC distance" and "BC inner." In both models the probability of player a beating player b in the match is given by $S(Q(a, b))$ where $S(x) = 1/(1 + \exp(-x))$ is again the logistic function and $Q(a, b)$ is a choice of a so-called *match-up function* between players a and b. The match-up functions for the distance and inner variations of the Blade-Chest model are:

$$Q_{\text{dist}}(a, b) = |\mathbf{b}_{\text{blade}} - \mathbf{a}_{\text{chest}}|_2^2 - |\mathbf{b}_{\text{chest}} - \mathbf{a}_{\text{blade}}|_2^2 + \gamma_a - \gamma_b,$$
$$Q_{\text{inner}}(a, b) = \mathbf{b}_{\text{blade}} \cdot \mathbf{a}_{\text{chest}} - \mathbf{b}_{\text{chest}} \cdot \mathbf{a}_{\text{blade}} + \gamma_a - \gamma_b.$$

Here the γ parameters are additional parameters that assure that the BTL model is captured as a clean special case (when all blade and chest vectors are zero vectors). There are $2(d + 1)n$ parameters in such Blade-Chest models. BC models perform well when the dimension is large, specifically $O(n)$, leading to a total of $O(n^2)$ parameters. Performance improvements over BTL are modest when only a few dimensions are employed. High-dimensional BC models are computationally difficult to learn due to the necessary minimization of a non-convex non-separable negative log-likelihood function. These challenges of optimizing and interpreting high-dimensional models motivate the development of our low-dimensional model.

3 NON-CONCAVITY OF INTRANSITIVITY

We now give our main theoretical result, that intransitivity necessarily implies non-concavity for the log-likelihood of any item-parametric choice model. The extended BTL model and both Blade-Chest models are merely different choices of nonlinear pairwise probability functions that fall into this more general analysis. We begin with a useful definition.

Definition 3.1. A *pairwise probability function* $f : \mathbb{R}^d \times \mathbb{R}^d \to [0, 1]$ is a function mapping the d-dimensional parametric representations of two alternatives to a choice probability such that $f(i, j) + f(j, i) = 1, \forall i, j$.

For the BTL and Thurstone models, $f(a,b) = S(a-b)$ and $f(a,b) = \Phi(a-b)$, respectively, for scalars a and b and where S is the logit function and Φ is the cumulative distribution function of the standard Normal. For the extended BTL model we have that $f(i,j) = S(\sigma_{ij}||\lambda_i - \lambda_j||_2)$. For the Blade-Chest model we have e.g. $f_{\text{BC-dist}}(i,j) = S(Q_{\text{dist}}(i,j))$. For the Blade-Chest models we note that the dimension d of the score representation is different from the dimension D of the embedding: $d = 2(D+1)n$.

While high-dimensional BTL and Blade-Chest models are capable of exhibiting intransitivity, their negative log-likelihood functions are in general not convex in the parameters of the alternatives, which typically makes global minimization challenging. This difficulty raises a natural question: are there models of intransitive pairwise choice where the log-likelihood function is concave? Notice that for a generic pairwise probability function $f(i,j)$, the log-likelihood objective of the model given data becomes:

$$\ell(\lambda; \{n_{ij}\}) = \sum_{i=1}^{n} \sum_{j=1, j\neq i}^{n} n_{ij} \log(f(i,j)),$$

where n_{ij} denotes the number of times i is chosen over j.

In order to furnish a concave log-likehood function, we therefore seek pairwise probability functions $f(a,b)$ that are log-concave in the score parameters. Can any such f exhibit intransitivity? We obtain the following negative result.

Theorem 3.2. *For any pairwise probability function $f(\lambda_i, \lambda_j)$ with $\lambda_i, \lambda_j \in \mathbb{R}^d$, f can exhibit an intransitive cycle only if f is not log-concave.*

Proof. Let A, B and C be three objects with score parameters $\lambda_i \in \mathbb{R}^d$ and let them form an intransitive cycle, meaning that

$$\begin{aligned} P_{AB} &= f(\lambda_A, \lambda_B) > 0.5, \\ P_{BC} &= f(\lambda_B, \lambda_C) > 0.5, \\ P_{CA} &= f(\lambda_C, \lambda_A) > 0.5. \end{aligned} \tag{1}$$

Further assume that f is log-concave. We will show that this implies a contradiction.

Notice first that the function f is bounded, $0 \leq f(i,j) \leq 1$, $\forall i, j$. As f is log-concave we also have the following two log-concavity properties for pairs $f(p,q)$ and $f(x,y)$ and $0 \leq \alpha \leq 1$:

$$f(\alpha p + (1-\alpha)x, \alpha q + (1-\alpha)y) \geq \min\{f(p,q), f(x,y)\},$$

$$f(\alpha p + (1-\alpha)x, \alpha q + (1-\alpha)y) \geq f(p,q)^{\alpha} f(x,y)^{1-\alpha}.$$

Using this second log-concavity property for $\alpha = 1/2$ we have

$$f((\lambda_A + \lambda_B)/2, (\lambda_B + \lambda_C)/2) \geq \sqrt{f(\lambda_A, \lambda_B) f(\lambda_B, \lambda_C)}.$$

Further employing $f(\lambda_A, \lambda_B) > 0.5$ and $f(\lambda_B, \lambda_C) > 0.5$, from Equation (1) and the log-concavity, we have

$$f((\lambda_A + \lambda_B)/2, (\lambda_B + \lambda_C)/2) > 0.5. \tag{2}$$

Clearly $f(-\frac{\lambda_B}{2}, -\frac{\lambda_B}{2}) = 0.5$ because it is a pairwise probability function. By convexity between $f(-\frac{\lambda_B}{2}, -\frac{\lambda_B}{2})$ and Equation (2) with $\alpha = 1/2$, we obtain $f(\frac{\lambda_A}{4}, \frac{\lambda_C}{4}) > 0.5$ and hence $f(\frac{\lambda_C}{4}, \frac{\lambda_A}{4}) < 0.5$.

To obtain the contradiction we simply employ log-concavity for the pairs $\{\lambda_C, \lambda_A\}$ and $\{0,0\}$ to obtain $f(\frac{\lambda_C}{4}, \frac{\lambda_A}{4}) > 0.5$, contradicting the earlier conclusion. □

Among the many possible choices of intransitive pairwise probability functions f, the very general family of functions that define a model, we might have suspected that there were some function with favorable inferential properties, i.e. one that yielded an overall log-likelihood function that was concave. The above result tells us that no such function exists, at least for item-level parameterizations. We note that this result covers independent RUMs (non-transitive dice) where one might think it possible to achieve intransitivity using multiple "score parameters" to separately represent the location, variance, and/or skewness of the random utilities. Such a model does have the capacity to model intransitive choice, but the above result applies even to such models, meaning they can not have a concave log-likelihood function.

In the absence of a convexity-based optimization argument for one pairwise probability function over another—motivating one choice of model over another—we now turn to a particularly intuitive and low-dimensional pairwise probability function based on the majority vote model from social choice theory.

4 MAJORITY VOTE MODEL

In this section we present and investigate a model of pairwise comparisons based on the basic concept of majority vote. In the majority vote model, each object (player) has an attribute representation $\mu \in \mathbb{R}^k$, $k \geq 1$ odd, and the pairwise probabilities of choosing an object (player) is modeled as a simple dimension-wise majority vote function over the different attribute dimensions.

Consider a contest where there are n players competing and each player i has a vector of attributes μ_i. A game between players i and j is won by player i if $\mu_i - \mu_j + \xi$ is positive in $(k+1)/2$ or more coordinates, and player j otherwise. Here ξ is a noise vector defined in terms of a difference distribution, a definition due to Yellott [25].

Definition 4.1. If f and F are the probability density function (p.d.f.) and cumulative distribution function (c.d.f.) of two i.i.d. random variables X_1 and X_2, then the *difference density function* and *difference distribution function* d_f and D_f are the p.d.f. and c.d.f. of $X_1 - X_2$ respectively.

The noise vector ξ in the majority vote model is drawn independently for each match-up from a multivariate distribution G with independence between the dimensions such that $G = \prod_{i=1}^{k} g_i$, where g_i is a distribution function such that the difference distribution function of two g_i's is continuous and strictly increasing over $\mathbb{R}$. Two useful examples of g_i are the Normal distribution and the Gumbel distribution, leading to d_{g_i} being Normal and Logistic, respectively. We refer to the model with Gaussian noise as the Gaussian majority vote model. The Gaussian majority vote model reduces to the Thurstone model if the "voting" is conducting using only one dimension.

Although this majority vote model can be extended to arbitrarily large dimensions, we focus our analysis on the simple case of $k = 3$ dimensions and furnish a complete derivation of the maximum likelihood estimate of the parameter representations in this case. This choice of k limits the number of parameters to $3n$, where n is

the number of alternatives (players). We show in Section 5 of this work that three dimensions is sufficient to (1) model strong and long intransitive cycles and (2) completely express the pairwise choice probabilities of any triplet. Based on these arguments we argue that three dimensions are sufficient for many applications. That said, it is straight-forward to generalize the MLE derivation below to arbitrarily large dimensions.

4.1 MLE derivation for three dimensions

For the three-dimensional model we let $M \in \mathbb{R}^{3n}$ denote the matrix of attributes μ of all the n players. The i^{th} row of matrix M is then $\mu_i = (\mu_i^1, \mu_i^2, \mu_i^3)$, the attributes of the i^{th} player. Let $p_1(i,j), p_2(i,j)$, and $p_3(i,j)$ be the probabilities that $\mu_i - \mu_j + \xi$ are positive in the first, second, and third dimensions, respectively. We write $p_k(i,j)$ as p_k for notational simplicity. Hence

$$p_k = D_g(\mu_i^k - \mu_j^k), \quad \forall k = 1,2,3.$$

For additional notational simplicity we define the win probability w_{ij} to be the pairwise probability function f evaluated for two players i and j, were $x \geq y$ indicates that x is greater than y in at least two coordinates:

$$\begin{aligned} w_{ij} &= \Pr[\mu_i - \mu_j + \xi \geq 0] \\ &= p_1p_2p_3 + (1-p_1)p_2p_3 + p_1(1-p_2)p_3 + p_1p_2(1-p_3). \end{aligned}$$

The log-likelihood $\ell(M;N)$ is, dropping additive constants and focusing on only pairs $i < j$:

$$\ell(M;N) = \sum_{i,j:i<j} n_{ij}\log(w_{ij}) + n_{ji}\log(w_{ji}).$$

Here N denotes the pairwise comparison matrix and n_{ij} be the number of times i has been chosen over j. The gradients for the majority vote model can be calculated easily for gradient-based optimization methods [2]. As an example, for the Gaussian majority vote model we obtain the following gradient for parameter μ_{i1}:

$$\frac{\partial \ell}{\partial \mu_{i1}} = \sum_{i<j}\left[\left(\frac{n_{ij}}{w_{ij}} - \frac{n_{ji}}{1-w_{ij}}\right)\phi(\mu_{i1}-\mu_{j1})\Big(p_2 + p_3 - 2p_2p_3\Big)\right].$$

5 CHARACTERISTICS OF THE MAJORITY VOTE MODEL

A possibly desirable property of a model capturing intransitivity is the ability to represent all pairwise win probabilities between players, but the ability to represent any $n \times n$ matrix of pairwise probabilities would clearly require $\binom{n}{2}$ parameters. In this work we are interested in models with few parameters, at most $O(n)$ and specifically $3n$ for our 3D majority vote model, and seek focused results that establish the expressiveness of the majority vote model despite only having $3n$ parameters. Specifically, we show that it is capable of representing arbitrarily long intransitive cycles and that it is capable of representing any submatrix of probabilities between a triplet of players (though this is not the same as simultaneously being able to represent any submatrix on all triplets).

5.1 Cycle expressivity

The random utility model (RUM) framework is an important framework for the characterization of various ranking models [1, 14]. Random Utility Models in general do not necessarily assume stochastic transitivity, not even for independent RUMs: consider the example of non-transitive Efron dice [16] discussed in the introduction. There are, however, limits on how "strong" the intransitivity for independent RUMs can be: Trybula provides conditions for existence of independent random variables $X_1, X_2, ..., X_n$ such that $\min\{P(X_1 > X_2), P(X_2 > X_3), ..., P(X_n > X_1)\}$ is bounded by a constant $c_n < 1$ for all n [24]. The sequence c_n is increasing and converges to 3/4. It is easy to determine that $c_3 = (\sqrt{5}-1)/2$ and $c_4 = 2/3$. In this subsection we show that majority vote models exhibit no such bound on the strength of intransitivity.

Our majority vote model can be understood as an aggregation of independent RUM models. There is no statistical dependence between the random variables used to represent players, yet we will show that the 3D majority vote model exceeds Trybula's bounds. Specifically, we will prove that the intransitivity of the majority vote model is not bounded away from 1 by any constant. As a result we are able to conclude that our model, despite not relying on any dependence between individuals or heterogeneous noise distributions, is qualitatively different from any univariate independent RUM.

Theorem 5.1. *Given $\epsilon > 0$ and n i.i.d. random variables with distribution g whose pairwise difference follow the difference distribution function D_g which is continuous, strictly increasing on $\mathbb{R}$ with finite variance c, there exists an attribute matrix M for n players such that*

$$\min\{P(X_1 > X_2), P(X_2 > X_3), ..., P(X_n > X_1)\} \geq 1 - \epsilon.$$

Proof. The proof is by construction. Let X_i and X_{i+1} denote cyclically consecutive players, where X_n is cyclically adjacent to X_1. For all i we have that:

$$\Pr(X_i > X_{i+1}) = p_2p_3 + p_1p_3 + p_1p_2 - 2p_1p_2p_3.$$

As before, we write $p_k(i,j)$ as p_k when the intended (i,j) pair is unambiguous. As defined before $p_k = D_g(\mu_i^k - \mu_{i+1}^k)$ where $k \in \{1,2,3\}$.

For our construction an appropriate μ is selected for the first three players, where we choose μ_1, μ_2, and μ_3 to be

$$\mu_1 = (a, 3a, -a), \quad \mu_2 = (-a, a, 3a), \quad \mu_3 = (3a, -a, a),$$

where $a \in \mathbb{R}^+$ is a constant to be determined. As D_g is a continuous cumulative distribution function there exists a constant $a_g \in \mathbb{R}^+$ s.t. $\forall a \geq a_g$ for the random variables X_1 and X_2 , $p_1 \geq 1 - \frac{\epsilon}{2}, p_2 \geq 1 - \frac{\epsilon}{2}$. As $p_3 \geq 0$ and $p_1 + p_2 - 2p_1p_2 \geq 0$, we observe that

$$\Pr(X_1 > X_2) \geq p_1p_2,$$

and hence $\Pr(X_1 > X_2) \geq 1 - \epsilon$. A similar argument holds for the pair $\{X_2, X_3\}$.

For players $i \geq 4$ the μ values are defined recursively:

$$\mu_i = (\mu_{i-1} + \mu_1)/2, \text{ for } i = 4, \ldots, n.$$

We aim to show the inequality $\Pr(X_i > X_{i+1}) \geq 1 - \epsilon$ for $i = 3$ and onward. As $p_2 \geq 0$ and $p_1 + p_3 - 2p_1p_3 \geq 0$, we observe that

$$\Pr(X_i > X_{i+1}) \geq p_1p_3.$$

By the given construction of the μ parameters, $\mu_i - \mu_{i+1}$ is decreasing in dimensions one and three for $i = 3, ..., n$. Hence the product p_1p_3 is decreasing for players X_i and X_{i+1} as i is increasing

since g is a strictly increasing function.

Define $h(i,j) = p_1(i,j)p_3(i,j)$ for players i and j. By construction we automatically have $h(3,4) > h(4,5) > \ldots > h(n-1,n) = h(n,1)$. The last equality follows from the fact $\mu_{n-1} - \mu_n = \mu_n - \mu_1$. Hence we only need to prove the inequality $p_1(i,j)p_3(i,j) \geq 1-\epsilon$ for players $i = n, j = 1$. For players X_n and X_1 we then have:

$$\Pr(X_n > X_1) \geq p_1 p_3, \text{ where } p_1 = p_3 = D_g\left(\frac{2a}{2^{n-3}}\right).$$

Now recall Chebyshev's inequality,

$$P(Z \geq z) \leq \frac{Var(Z)}{z^2}.$$

We apply the inequality with Z set to the first and the third dimensions of $X_n - X_1$. As the variance is bounded, $\mathrm{Var}(Z) \leq c$ where c is a positive constant and $\Pr(Z \geq z) = 1 - \Phi(z)$, we have that $D_g(z) \geq 1 - \frac{c}{z^2}$. Using this property with $z = \frac{2a}{2^{n-3}}$, we have

$$\begin{aligned}\Pr(X_n > X_1) &\geq p_1 p_3 \geq \left(1 - \frac{c}{z^2}\right)^2 \geq \left(1 - \frac{2^{2n-8}c}{a^2}\right)^2 \\ &\geq 1 - \frac{2^{2n-7}c}{a^2},\end{aligned}$$

where for the last part we employ the fact that $(1-x)^2 \geq 1-2x$ when $x > 0$. We conclude that $1 - \frac{2^{2n-7}c}{a^2} \geq 1-\epsilon$ when $\epsilon \geq \frac{2^{2n-7}c}{a^2}$. Combining this analysis with the earlier basic analysis for the initial $i = 1, 2, 3$, we can choose a such that $a \geq \max\{a_g, \frac{2^{n-3.5}\sqrt{c}}{\sqrt{\epsilon}}\}$ to complete the proof. □

The above theorem has two important implications. First, large intransitive cycles can be created using the majority vote model in merely three dimensions. Second, we can conclude that the majority vote model for a broad class of difference densities d_g is not equivalent to any independent RUM model.

5.2 Triplet expressivity

The lemma below shows how the three-dimensional majority vote model can represent all the pairwise win probability relations for a set of any three players.

Lemma 5.2. *Given $\epsilon > 0$ and a matrix W of pairwise win probabilities for any three players, there exists an attribute matrix M which can be used to construct a matrix $\tilde{W}$ of pairwise win probabilities from a Majority Vote model such that $\max_{i,j} |W_{ij} - \tilde{W}_{ij}| \leq \epsilon$.*

Proof. The proof is by construction. We are given a pairwise probability matrix W with elements w_{ij}. Let $c_1 = D_g^{-1}(w_{23})$. Define c_2 and c_3 similarly. Let $\alpha_1 = \frac{1-w_{12}}{w_{12}}$. Define α_2 and α_3 similarly in terms of w_{23} and w_{31} respectively. For the three players we can construct M as defined above to be

$$\begin{bmatrix} c_3 & 0 & 0 \\ 0 & -C + c_1 & C \\ C & -C & c_2 \end{bmatrix},$$

where D_g is continuous and strictly increasing and C is a positive constant such that $D_g(-C) \leq \frac{\epsilon}{2}$ and $D_g(C - c_i) \geq 1 - \alpha_i \epsilon$ for $i = 1, 2, 3$. The existence of C is guaranteed by the continuity of D_g.

Table 1: Pairwise comparison datasets.

Dataset	Players	Match-ups	Intransitive triplets
Election A5	16	44298	5
Election A9	12	95888	3
Election A17	13	21037	18
Election A48	10	25848	0
Election A81	11	20803	3
Jester	100	333956	90
Street Fighter (SF)	35	25000	476

We need to prove $|w_{i,j} - \tilde{w}_{i,j}| \leq \epsilon$ for $1 \leq i \neq j \leq 3$. Consider $i = 1$ and $j = 2$. We have $\tilde{w}_{12} = p_1 p_2 + p_2 p_3 + p_3 p_1 - 2p_1 p_2 p_3$. With $p_1 = w_{12}$, $p_3 \leq \frac{\epsilon}{2}$, and $1 - \frac{\alpha_1 \epsilon}{2} \leq p_2 \leq 1$ we have

$$\tilde{w}_{12} \leq w_{12} + (\epsilon/2) + (\epsilon/2)w_{12} \leq w_{12} + \epsilon.$$

Next we need to prove the bound in the other direction. Since

$$\tilde{w}_{12} \geq p_1 p_2 - 2p_1 p_2 p_3,$$

we have $\tilde{w}_{12} \geq w_{12} - \epsilon$. An identical argument can be applied to the other two pairs within the triplet, yielding the requisite bound on the maximum over pairs (i,j), as desired. □

It is not hard to verify that a three-dimensional Majority Vote model is not fully expressive for larger subsets of players (five players or more), but we consider the two expressivity results, for cycles and triplets, to be sufficiently flexible to model realistic competition data. Most significantly, we note that neither of these results can be achieved by any independent RUM.

6 EXPERIMENTAL RESULTS

We now study the predictive performance of the different parametric models of intransitive pairwise choice we have discussed: higher dimensional BTL models, the Blade Chest model, and our Gaussian Majority Vote model where each model is furnished with roughly the same number of free parameters ($\approx 3n$) for comparison. For the 3D BTL model, we do not count the elements of Σ as parameters for this comparison. We test the models on three datasets: a commonly studied set of election datasets (A5, A9, A17, A48) [22], the Jester joke rating dataset (underlying a recommendation system) [11], and the *Super Street Fighter IV* dataset (SF) (pairwise match-ups from competitive play between different video game characters) [6]. The election and Jester datasets are ranking datasets which were converted to pairwise comparisons datasets. Dataset details are given in Table 1, where the intransitive triplets count when the empirical pairwise probabilities violate weak stochastic transitivity.

Each pairwise comparison dataset was randomly split into training and test sets using 5-fold cross-validation, splitting at the matchup level[1]. The main evaluation metric used are root mean square error (RMSE) between the predicted probabilities $\tilde{p}$ from the model and the empirical probabilities $\hat{p}$ from the test data scaled by the number

[1]For datasets derived from rankings, ideally the splitting should be done based on rankings, but original rankings were not always available. We compared the splitting based on rankings vs matches for the Jester dataset, where rankings were available, and did not observe any significant difference in the results or the inference

of players:

$$\text{RMSE} = \frac{1}{n}\sqrt{\sum_{i,j\in n, j\neq i}(\hat{p}(i,j) - \tilde{p}(i,j))^2}.$$

We also consider the log-likelihood of each dataset under the models. The Thurstone and 3D Majority Vote models are nested, allowing us to apply a likelihood ratio test between the model estimates.

The non-concave likelihoods of all models were maximized using the Nelder–Mead simplex algorithm. The optimization was repeated multiple times to help escape possible poor local optima.

The RMSE results are provided in Table 2. We see that across the election datasets there is relatively little difference between the intransitive models. For the Jester dataset our model reports an RMSE that is 32% lower than the best Blade-Chest model. For the Blade-Chest models we again use the best results between "inner" and "dist" versions. That said, we still see significant improvements over a one-dimensional Thurstone model with all our models of intransitivity. And of all the models, we see that our 3D Majority Vote model generally has the lowest RMSE and highest likelihood. This empirical performance is particularly impressive given the simplicity of the model. Meanwhile Table 3 provides a comparison for the average cross-validated log-likelihood for the same datasets. We also perform a chi-square test for the nested models, 3D Gaussian MV and 1D Thurstone [18]. The p-values suggest that the unrestricted model (3D Gaussian MV) better fit the datasets specifically when large number of intransitive triplets are present.

6.1 Spectral analysis of dimension

In order to understand the role of higher dimensions in modeling skill, we perform an analysis of the singular values of the attribute matrix $\hat{M}$ learned from data for our 3D Gaussian Majority Vote model. In general if the dimensions of $\hat{M}$ are uncorrelated then this indicates the presence of multiple uncorrelated skills. If the variance of $\hat{M}$ is concentrated on just one dimension, the competition data can be viewed as mostly transitive. We use the explained variance of the vectors of the singular value decomposition of $\hat{M}$ as measures of how correlated the skill dimensions are in the learned representation. In Table 4 we observe that most, but not all, of the variance is explained by the first singular vector of $\hat{M}$ in all the data sets we examine. The model that is "the least one-dimensional" is the model of the Street Fighter data, in the sense that the leading singular vector explains the last percentage of the variance. If of interest, the leading dimension across which the maximum variance is spread could be used as a method for producing ranked orderings of all the alternatives/players.

To complement the empirical analysis, we also simulate data which is inherently one, two, and three dimensional, respectively. This is done by simulating a 3D Majority Vote model with a μ vector that is drawn from a uniform distribution for each player which is 1, 2, or 3-dimensional. For the 3-dimensional μ, the Gaussian Majority Vote model is then simulated. For the 1-dimensional and 2-dimensional μ, a version of the Gaussian Majority Vote model is then simulated where the excess dimensions are unbiased coin-flips. We use this process to produce a pairwise comparison matrices for 50 players with 10,000 games for each pair. We train the majority vote model based on the the simulated data, repeating the training five times, and calculate the fraction of variance explained by each singular vector of the learned $\hat{\mu}$. We see that even when the data is truly three-dimensional, there is still a "dominant" vector that explains most of the variation. When the data is two or one dimensional, the majority of the variation can be explained by fewer singular vectors, as expected.

7 CONCLUSIONS

We establish that intransitivity implies non-convexity in the log-likelihood objective of item-parametric choice models. This is a broad statement about many models of choice, though we note that convexity is possible for parameterizations that are not item-level [19]. We then introduce the Majority Vote model that can

represent intransitive relations richer than what are possible with independent RUM models. The model exhibits empirical performance that is comparable to earlier multidimensional models, with the added benefit of simplicity and interpretability. Another significant benefit is the ability to interpret the set of three- (or more) dimensional representations as a point cloud in a latent space, and we give a straight-forward spectral approach to measuring the "dimensionality" of intransitive data using singular values.

ABSTRACT

Smartphone sensors can be leveraged by malicious apps for a plethora of different attacks, which can also be deployed by malicious websites through the HTML5 WebAPI. In this paper we provide a comprehensive evaluation of the multifaceted threat that mobile web browsing poses to users, by conducting a large-scale study of mobile-specific HTML5 WebAPI calls used in the wild. We build a novel testing infrastructure consisting of actual smartphones on top of a dynamic Android app analysis framework, allowing us to conduct an end-to-end exploration. Our study reveals the extent to which websites are actively leveraging the WebAPI for collecting sensor data, with 2.89% of websites accessing at least one mobile sensor. To provide a comprehensive assessment of the potential risks of this emerging practice, we create a taxonomy of sensor-based attacks from prior studies, and present an in-depth analysis by framing our collected data within that taxonomy. We find that 1.63% of websites could carry out at least one of those attacks. Our findings emphasize the need for a standardized policy across browsers and the ability for users to control what sensor data each website can access.

1 INTRODUCTION

Smartphones have become almost ubiquitous, with the volume of Internet traffic from mobile devices surpassing that of desktop computers worldwide [35], while 56% of the traffic to top-sites in the US was from mobile devices [65]. Apart from the obvious usability benefits smartphones offer, they have also introduced a plethora of risks. Users are becoming increasingly aware of privacy issues including online tracking and internet surveillance, and employ private browsing among other techniques to remain anonymous online [70, 71]. However, adversaries can still track users through fingerprints [53], making it possible to identify which device is navigating a given webpage [42]. Prior work has also shown that imperfections in sensors' hardware render them fingerprintable [25]. Websites can access such mobile sensor data through the widely supported HTML5 WebAPI. Thus, a plethora of attacks that were previously limited to mobile apps can "migrate" to the mobile web, as modern browsers provide access to a device's sensors.

In this paper we present a *quantitative* and *qualitative* large-scale study of mobile-specific WebAPI calls made by websites in the wild. We build a unique crawling infrastructure that uses Android devices and perform an end-to-end analysis of WebAPI requests. Using our crawling infrastructure, we measure the prevalence of mobile-specific WebAPI calls across 183,571 of the most popular websites during March-November 2018. Our experiments capture the true scale of this phenomenon, as we detect 5,313 unique domains accessing at least one mobile WebAPI call; 35.89% of those also result in sensors being accessed by third-party scripts. To better understand the implications we survey prior literature on attacks from malicious apps that leverage data from mobile sensors. Based on this diverse yet representative selection of papers we create a taxonomy of attacks that could be potentially carried out by modern websites and conduct an in-depth analysis of our dataset. We argue that with browsers enforcing different access policies, as do the plethora of apps that support WebView, there is dire need for a standardized, fine-grained universal mechanism that allows users to control access to *all* types of mobile sensor data.

Overall, this paper makes the following contributions:

- We build a novel crawling infrastructure and conduct a high-fidelity, large-scale end-to-end study of websites targeting mobile-specific sensors.
- We provide a taxonomy of previously reported sensor-based attacks and reframe them within the modern mobile ecosystem. Guided by our taxonomy we conduct a qualitative analysis of our collected data and a provide a comprehensive assessment of the threat posed by the mobile WebAPI.
- We publicly release our data: https://www.cs.uic.edu/~webapi.

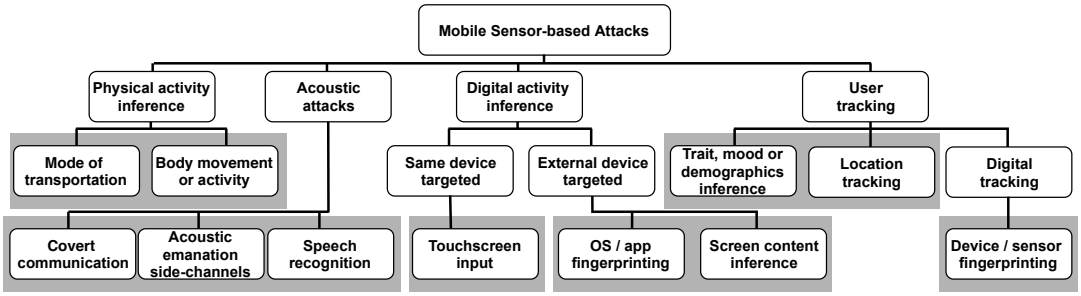

Figure 1: Taxonomy of attacks demonstrated in prior studies that leverage data from mobile sensors.

2 BACKGROUND

Attack Taxonomy. A plethora of research papers have demonstrated mobile-based attacks that employ sensor data. While a considerable number of attacks present similar characteristics, e.g., demonstrating different techniques for inferring a user's touchscreen input or fingerprinting the user's device, a wide range of different attacks have been proposed. Here we introduce a taxonomy of attacks compiled from the literature that captures the vast potential of how mobile sensor data can be misused by adversaries. Typically these attacks assume that attackers are able to obtain sensor data through a malicious app installed on the device. However, in practice, modern browsers can mediate data exchange between websites and sensor data through the HTML5 WebAPI. This leads to a different threat model and an increased attack surface, as it removes the constraint of users having to install a malicious app.

In Figure 1 we present our taxonomy which aims to highlight the variety of attacks enabled by sensor-data, while simultaneously obscuring the type of sensor used for each attack. We do not include explicit sensor information in our taxonomy, as prior attacks often obtain the same objective while using different combinations of sensors (as can be seen in Table 1). At the same time we opt for a relatively fine-grained first level, and specifically consider acoustic attacks as a separate class due to their unique and diverse nature, instead of including them as sub-classes of physical and digital activity inference attacks. Next we describe the 4 main classes from our taxonomy's first level and refer to some of the presented attacks.

Physical activity inference. Numerous studies [27, 36, 38, 46, 52, 58] have demonstrated that mobile sensors can be used to infer information about personal everyday activities. For example it is possible to infer whether the user is walking, running or their mode of transportation, by leveraging the Motion and GPS sensors [58].

Acoustic attacks. [11, 24, 32, 33, 44, 45, 47, 62] showed that access to Motion, Orientation or the Vibration API can be used to infer users' credit card numbers by listening for specific frequencies [62] or what a user is typing on the keyboard [45], and bypassing dynamic analysis and antivirus through covert channel attacks [44].

Digital activity inference. This class includes a wide range of attacks, with prior work [14, 16, 17, 30, 37, 46, 56, 64, 72] showing that sensor information (including the Accelerometer and Gyroscope) can be used to predict what the user is typing on the smartphone's touchscreen(e.g., [46, 56]). This is possible because typing leads to changes in the position of the screen, its orientation and the device's motion. In a different study, the Light sensor was used to identify the content of an external display and even classify users' digital activities into different categories with an 85% accuracy [17].

User tracking. User tracking has garnered much attention [9, 10, 15, 20–23, 25, 30, 36, 39, 40, 47, 52, 58, 59, 73, 74], and can be conducted in different ways – from coarse-grained location tracking that does not require any user-permission (using the Accelerometer or Gyroscope) [36, 52], to fine-grained device fingerprinting using rich and high-resolution data from smartphone sensors(e.g., [10, 25]). In this category we also include alternative attacks that could track users by inferring demographic information (e.g., age [23], gender [47] and fingerprints [30]), physical traits such as their gait [40, 59], or information about their mental state or mood [74].

Deconstructing sensor attacks. Table 1 lists the attacks described in the studies that guided our taxonomy. We classify previous attack papers based on the taxonomy introduced in Figure 1. Subsequently, we break down all the attacks presented in those papers based on the type of sensor data needed to carry out the attacks. For example [58] infers the body movement or activity of a user by accessing the motion and GPS sensors. On the other hand, [52] only requires the orientation sensor, but using the Motion or Magnetometer sensor can further improve the attack.

3 METHODOLOGY AND SYSTEM DESIGN

In this section we present our system design and experimental methodology. We give an overview of our system's architecture, and provide implementation details about the in-line hooking methods.

System architecture. Our system employs a proxy server that intercepts network traffic by using `mitmproxy` [18]. We configured all the Android devices used in our experiments with `mitm`'s certificate in order to intercept both HTTP and HTTPS traffic. The proxy server injects a JavaScript component that hooks and monitors JavaScript calls to mobile-specific WebAPIs. However, our aim is to obtain an in-depth view of sensor data access. In general, browsers are responsible for mediating access between high-level JavaScript function calls and low-level Android API calls. Understanding how this mechanism works for every browser would be time consuming and in many cases infeasible due to proprietary code. As such, we have opted for a generic and browser-agnostic approach, where we intercept Android system calls using a custom Xposed [60] module that (i) detects and hooks requests to sensor-specific Android API calls and (ii) identifies which of these API calls are permission-protected. By intercepting these low-level function calls we are able

Table 1: Sensor based side-channel attacks.

Sensors marked with (●) are sufficient for performing the specific attack. When a combination of multiple sensors is required to perform the attack, they are marked with (◖). We denote optional sensors that enhances the accuracy of the attack with (○). Grey columns denote sensor data that should require explicit user permission according to the W3C.

to validate that the JavaScript interception was successful and calls requesting sensor data were correctly logged.

Mobile HTML5 Functions. We identified the functions that retrieve mobile-specific data through the official mobile HTML5 WebAPI [31].We consider as *mobile-specific* any calls that obtain information originating from an integrated sensor of a mobile device. The HTML5 WebAPI calls interact with the webpage using either a direct one-time communication (i.e., Vibration and Media capture)

or through an event listener, since some sensors (i.e., Motion, Orientation, Proximity, and Ambient Light) continuously fire events in order to provide up-to-date readings in real time. For Geolocation one call exists for each category.

JavaScript Calls Interception. We build our component for hooking JavaScript methods upon the `javascript-hooker` Node.js module [13]. In our experiments we do not overwrite the original function but only need to identify whether a function is called. Thus, whenever a WebAPI is called the JavaScript modules creates a log entry for further analysis and executes the original function. Since `javascript-hooker` also takes the arguments of the original function, we can also intercept the arguments of the `addEventListener` and check for events of interest. Our code is injected in the `head` of the document (if there is one) or the page `body` otherwise.

In order to listen to events and associate a function to a specific target we need to intercept the `setter` property. Even though this is possible using `Object.defineProperty()` the original value will be lost and the webpage may not function as expected. Therefore, we follow the approach employed by Chameleon [34] and overwrite the `getter` property of each event prototype. As such, every time the property is read, our custom function is called. While certain sensor data may normally remain the same during navigation (e.g., properties related to display characteristics), remaining constant might be considered "suspicious" for other sensors. For instance, when an actual human uses the device, small changes in the gyroscope readings would be expected. As such, to make our crawling more realistic, our system intercepts the values returned by certain sensors and slightly modifies their value. In general, data retrieved through events, is handled in two different ways: listening to `addEventListener` on the target object while checking if the argument matches the desired event and defining new `getters` for the properties of the event's prototype.

Identifying the JavaScript source. Apart from logging WebAPI calls we also want to identify the origin of the JavaScript files being executed. This information is important in order to identify if the script belongs to a first-party domain or a third-party domain. We register the source of the URL by utilizing the `stack` property of the `Error` object. Our hooking script implements a mechanism that creates an `Error` object and reads its `stack` property.

Android API call interception. Each mobile HTML5 WebAPI is associated with a low-level Android API call. In order to validate the results of the JavaScript interception and to identify which ones require a permission, we use the PermissionHarvester [26] module that hooks every Android permission protected API call. Since access to some of the sensors does not require an Android permission, we also manually identified and hooked the functions that give access to non-permission-protected sensor data. Android apps (including the browser) cannot directly read the current value of a sensor and are required to register a listener in order to consequently read the captured events. Each sensor can be obtained by declaring a listener and specifying its name with the `getDefaultSensor()` function. Then, the listener is registered using the `registerListener()` method. Our module intercepts both of these function calls.

Experimental setup. In our experiments we use Mozilla Firefox (v.59.0.1) as our browser on three Android Google Nexus 5X and a OnePlus One device, all running AOSP 7.1.2. We controlled the devices using the Android Debug Bridge. We first evaluated the effectiveness of our methodology by creating a dummy website that executes all possible mobile HTML5 WebAPIs. Since browsers require a valid certificate in order to call certain APIs we used a self-signed certificate and confirmed that our approach can successfully intercept and monitor access to the devices' sensors. Our system also simulates brief user interaction through random gestures which are issued for approximately 30 seconds on average for each website, while an extra module monitors for potential redirections to different domains which are rolled back so the original website can continue to be processed.

Table 2: Number of domains using mobile WebAPIs calls.

WebAPI	#Domains	WebAPI	#Domains
Device orientation	2,199	Ambient light sensor	152
Geolocation	1,688	Proximity sensor	142
Device motion	1,360	Vibration	84
Screen orientation change	645	Media capture	12
Total 6,282			

4 DATA COLLECTION AND ANALYSIS

Our crawling list included the 200K most popular websites according to Alexa, as returned on 03/24/2018. Our system was unable to access or complete the crawling process for 16,199 (8%) of the domains in our list (e.g., 503-timeout, 502-Bad Gateway, or DNS errors), and omitted 230 domains flagged as malicious by the Google SafeBrowsing API. Our crawling experiments took place between 03/24/2018-09/03/2018 and 11/11/2018-11/22/2018, from US-based IP addresses.

In Table 2 we can see the prevalence of the mobile-specific WebAPI calls logged by our system among the 183,571 domains processed by our crawling infrastructure. We logged 5,313 (2.89%) websites using at least one of the targeted APIs, while 807 request access to sensor data using more than one of the API calls. The most prevalently accessed data is from the acceleration and orientation sensors which do not require the user's permission, as well as geolocation data which requires permission in major browsers. While the Geolocation API can also return information for desktop computers (using "information about nearby wireless access points and the IP address" [4]), we consider it mobile-specific due to smartphones' integrated GPS receivers which provide real-time location information. While geolocating users based on landline IP addresses is considerably accurate [68], that is not the case for mobile IP addresses [12, 66]. It is important to note that the Media capture and Geolocation APIs should explicitly request permissions from the user; while this is enforced in major browsers, it is not always the case with other browsers (e.g., for Geolocation [41]). For the remaining WebAPI calls, users will be unaware that such information is being retrieved by the website even for major browsers.

As Figure 2 shows the use of mobile-specific WebAPI calls is not uniform across our dataset. The highest concentration is found in the top 5K websites with 250 domains. We observe that domains also access more *permission-free* WebAPIs (gray bars) independently of their rank, indicating the importance of this sensor data. This type of information can be used for a plethora of attacks, and users should have the ability to explicitly grant permission for them.

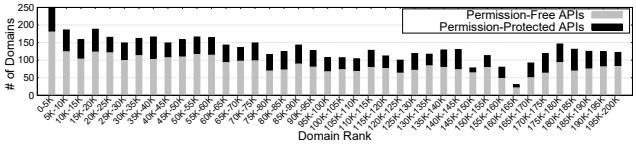

Figure 2: Number of domains using mobile WebAPI calls.

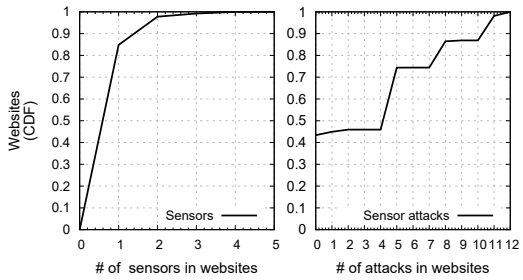

Figure 3: CDF of websites requesting access to sensors (left) and the number of feasible attacks (right).

Table 3: Breakdown of sensor based attacks and the number of domains capable of deploying them.

ID	Mobile Sensor-based Attack	#Domains
1	Mode of transportation	2,861
2	Body movement or activity	720
3	Location tracking	2,861
4	Acoustic emanation side-channels	1,372
5	Speech recognition	2,199
6	Touchscreen input	1,425
7	Screen content inference	152
8	Inferring user's age	1,360
9	Inferring user's sex	2,199
10	Inferring user's fingerprints	12
11	Inferring user's gait	1,360
12	Inferring user's mood	1,360
13	Device/sensor fingerprinting	2,873
14	Covert channels	96

As Figure 3 (left) shows the majority of websites issue request access to a single sensor through the WebAPI, while 15.1% of the domains we processed target at least two different types of sensor data. As shown in Table 1, only accessing the Motion sensor can lead to six different attacks, while a combination of two sensors (Motion and Orientation) leads to eight attacks. Furthermore, as can be seen in Figure 3 (right) 56.6% of the domains that issue mobile-specific WebAPI calls are able to perform at least one attack.

Sensor-based attacks. We continue our analysis by framing our dataset within our taxonomy based on representative prior work. It is important to note that in our analysis we do not take into account or argue for (or against) the *plausibility* of the attacks presented in previous studies. Instead, our goal is to measure the potential risk that mobile users face due to web browsing by identifying websites that request access to specific sensor data and could *potentially* misuse them in an invasive or malicious manner.

Table 3 breaks down the number of domains for each attack. We observe that the most common attacks across websites that access WebAPIs are device/sensor fingerprinting and trait, mood or demographic inference (54.07%), location tracking and mode of transportation (53.84%), speech recognition (41.38%) and touchscreen input (26.82%). We argue that any information gained from sensors poses a risk for users and an access control policy should be enforced, either through some form of run-time permissions [5] or using a mechanism similar to GDPR [3].

Banking sites. While fingerprinting allows third parties to track users across the Web [53], fingerprints can be used as an additional factor for authentication [8]. As such, banking websites are well-suited for deploying such a security mechanism [54] due to the significant implications of compromised accounts. As details of such practices are not typically disclosed, we further explore the prevalence of sensor-based information access across e-banking domains. We compiled a list of bank domains using [1, 6] and cross-referenced it with our dataset. We identified 65 banking domains that request access to at least one mobile sensor. Banking domains request access for 1.38 sensors on average, which is higher than the average of 1.17 in other domains, indicating that they are more likely to leverage the HTML5 WebAPI for accessing sensor data. We find that 24 of the domains obtain access to the sensor data necessary to conduct at least one of the attacks included in our taxonomy. Interestingly, all of those banks collect the sensor data leveraged in prior work for device fingerprinting, while 40 banks request access to the user's geolocation which can also be used for enhancing the authentication process [8]. We find that efirstbank.com actually requests access to more sensors than any other domain in our entire dataset. Overall, while accessing sensor data could be motivated by enhancing the authentication process, this practice raises privacy concerns as argued by privacy advocates [48].

Request origin. Next we explore the origin of WebAPI requests (first or third party) and whether it was included in an iframe. Different browsers implement different policies regarding which sensors can be accessed for these three different types of origin. We present statistics for all the websites that requested access, even if those requests were blocked by Firefox during our experiments.

Iframes. Our system collects all the calls executed by every element of a website, including iframes. In every log we record the source domain name of the element that is accessing sensor information. By comparing the URL of the address bar and the URL in the logfiles, we can identify whether WebAPIs are accessed by the DOM or by an iframe. Our analysis shows that 991 websites out of 5,313 contain iframes that use WebAPIs to access mobile specific information. We analyzed all iframes from our experiments and found that specific iframes are found in different websites. The two most frequent domains injected inside iframes exist in 389 webpages (or 39.3% of pages with iframes collecting data) and are related to online media players.

External sources. Among the websites that issue API calls for mobile specific information we found 40 scripts from external domains (either as a third-party scripts or inside an iframe) that collect data from 2461 websites 46.3%. We manually analyzed these scripts and found that they offer services for media-players and advertisements and they collect information about the orientation and motion of the device. In Table 4 we list the domains that appear in more than 50 websites and collect data from sensors. The first column is the origin of the script being executed. The second and third column show how many websites and iframes host this script. Given that

these third-party domains are used in 35.89% of websites that access sensor data, we classified them based on the type of service they provide using *Cyren*. The last two columns show which sensors the script accessed and their corresponding attacks. We observe that most of these domains call the motion and orientation WebAPIs which enable a plethora of attacks. Moreover, domains classified as search engines and ad-networks gain access to characteristics that can track users across the web.

From Table 4 we can see that the domain *api.b2c.com* enables 12 different attacks. After investigating this domain through VirusTotal [7] we found that scripts served from this domain and Android apps that communicate with it are classified as intrusive adware and even malware by some antivirus vendors. Another domain, *c.adsco.re*, is flagged as malware by Cyren, even though it is not considered malicious by the Google SafeBrowsing API. We manually analyzed the content of the script that retrieves the data and found that apart from retrieving information about the Motion and the Orientation sensors it also exhibits behavior which is a strong indicator of device fingerprinting, such as creating and manipulating canvas elements [50] and reading different Navigator, Screen, Storage and Window properties. Interestingly the *adsco.re* domain states that it is used for traffic validation by Adscore, a bot detection service. In total, these two domains which are considered malicious by certain security lists, were found on 5.4% of all the sensor-accessing domains logged by our system, which again raises concerns regarding browser policies that allow third party domains to access sensor data without explicit user permission.

Android internals. Our crawling system allows an end-to-end analysis of sensor data access. Apart from providing high call-detection fidelity, since we can match requests logged by our injected JavaScript to actions at the operating system level, it also revealed sub-optimal browser behavior. We found that while Firefox prevents iframes from accessing sensor data, in practice Firefox simply "omits" returning the sensor data instead of blocking (i.e., ignoring) the actual request. Specifically, Firefox allows iframes to create event listeners, which then trigger the necessary WebAPI calls which then trigger the corresponding Android-level processing and permission checks for obtaining the sensor data; the data is then returned to the browser but not provided to the iframe.

Malicious domains. Even though our system checked Google's SafeBrowsing API before visiting a domain, it is possible that visited domains could be flagged as malicious later on, or by different blacklists. As such, we submitted all the domains that issued WebAPI requests to VirusTotal. Figure 4 presents the websites flagged as malicious (sorted by their rank), the number of accessed sensors per website and feasible attacks. Out of those, 149 domains were flagged by one AV engine and 17 domains were flagged by two. We can see that higher ranking malicious domains are more likely to access more sensors which results in a higher number of feasible attacks. We found 11 websites being flagged by at least 3 AV engines. Finally, we found two websites, namely *goggle.com* and *yotube.com*, that are flagged by eight AV engines as malicious. Apart from likely examples of typosquatting [49, 69], these websites requested access to sensor data that could be used to perform one and eleven different attacks respectively.

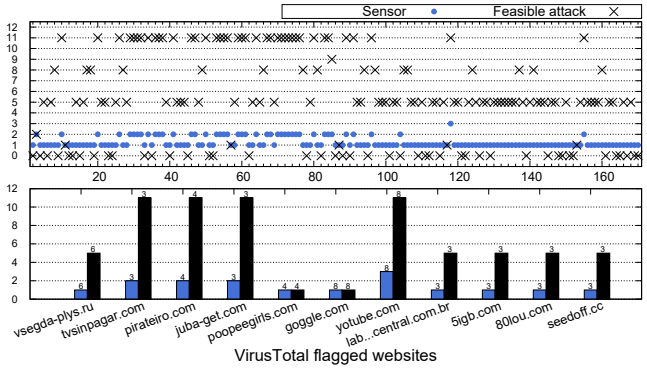

Figure 4: Number of accessed sensors and feasible attacks for websites flagged as malicious (top). Websites that were flagged by at least three AV engines (bottom) – the number on the bars shows how many AV engines flagged the domain.

Table 4: Third-party scripts accessing WebAPI calls.

Script origin	#Sites	iframes	Sensors	AttackID

M: motion, G: geolocation, P: proximity, O: orientation, L: light, OC: orientation_change

WebView usage is extremely widespread [51], so we tested three popular WebView-based browsers, namely Dolphin, UC, and WebView (info.android1.webview), along with Facebook and Messenger, and found that they all allow iframes to obtain motion and orientation data. As such, even if users use Firefox or Chrome for browsing, which currently block iframes from accessing sensor data, clicking a link within such popular apps can expose them to attacks.

Transience of web measurements. Scheitle et al. [61] found significant fluctuation in the websites contained in ranking lists used by academic studies, with Alexa being the most volatile list. As a result, similar measurement experiments that use an Alexa list from a different date could result in a significantly different view of the web ecosystem. To quantify and frame this effect within the dataset we have collected, we compare to the recently released dataset by Das et al. [19] which was part of their concurrent study on mobile sensor fingerprinting. While their collection set up was different (they used a modified version of OpenWPM as opposed to actual mobile devices) they also logged mobile sensor APIs used by popular websites. When comparing the domains that accessed mobile-specific WebAPI calls during our experiments to those in their dataset, we find only 403 overlapping domains – 7.9% of our detected websites. However, our system detected WebAPI calls in 2,252 domains that are in their two US-based datasets but with no calls logged during their experiments. Given that both of our experiments were conducted at similar times, including some overlap in May 2018, and used Alexa's list (our version is from 03/24/2018 while their version is from 05/12/2018), this is a surprising result.

Another important dimension that needs to be considered is that the modern web is highly dynamic and websites often introduce new functionality or may even remove existing functionality. To further explore how a view of the web can change through time, we compare the actual WebAPI calls reported for those 403 overlapping domains. While we find that for the vast majority (91.8%) of domains both datasets report the same calls across the two datasets, there are differences for 33 websites. In more detail, for those domains our system logged a total of 74 WebAPI calls, while the datasets from [19] contain 62 calls. This difference is partially due to that study targeting a *subset* of the calls that our study explores. However, there are other domains [2] where the two datasets report different sensor data being requested, which correspond to ~ 3.47% of the domains detected by both systems. While that number is not very large, it is non-negligible and highlights the dynamic and ever-evolving nature of the web.

5 RELATED WORK

The WebAPI has standardized many features providing greater support for developers and improving the user experience [57]. Snyder et al. [63] presented a cost-benefit analysis of the WebAPI using a small set of websites (10K) and focusing on desktop browsing.

In an independent and concurrent recent study Das et al. [19] presented a study on web scripts accessing mobile sensors. While their study also targets WebAPI calls for mobile sensors, our work presents significant differences. In regards to the actual datasets, our study is on a considerably larger set of domains while also having little overlap due to the fluctuation of the Alexa list [61]. Moreover, their system detects a subset of the mobile-specific WebAPI calls handled by our system, and their study focuses on sensor-based fingerprinting thus offering a limited examination of the risks that users face; we frame our findings within our attack taxonomy and provide a more comprehensive evaluation of the feasibility of a wide range of sensor-based attacks. Furthermore, our crawling infrastructure uses actual mobile devices and provides a unique end-to-end view of data requests and access, while their crawlers rely on a modified version of OpenWPM running on desktop machines which could be detected by evasive websites [43].

Browser fingerprinting has gathered a lot of attention and the research community has extensively studied the techniques that make it possible [28, 29]. With the growing usage of smartphones, traditional desktop fingerprinting techniques [67] are becoming less effective as some information is being standardized in many mobile browsers [39]. On the other hand, the development of new mobile-specific HTML5 WebAPIs offered new avenues for trackers to exploit other types of data that were not present in desktops. As previous work [9, 10, 15, 20–23, 25, 30, 36, 39, 40, 47, 52, 55, 58, 59, 73, 74] has shown, the huge amount of input collected by smartphones sensors resulted in new opportunities for device fingerprinting.

6 CONCLUSION

We presented a comprehensive evaluation of the threats that mobile users face when browsing the Web, due to capabilities offered by modern browsers, by conducting the largest and most extensive study to date on the use of mobile-specific WebAPI calls in the wild. Our study was conducted using a novel crawling infrastructure built on top of actual smartphones. Our findings demonstrate that WebAPI capabilities are actively being used by websites for accessing mobile sensors. To provide the appropriate context that highlights the true threat posed by this practice, we created a taxonomy of sensor-based attacks compiled from a wide range of attacks demonstrated in prior work. Our subsequent in-depth analysis correlated the sensor data currently being accessed by websites and the data-requirements of prior attacks, leading to several alarming findings. We argue that our findings support the need for more stringent policies for websites attempting to access sensor data.

ABSTRACT

A common approach when setting up a website is to utilize third party Web hosting and content delivery networks. Without taking this trend into account, any measurement study inspecting the deployment and operation of websites can be heavily skewed. Unfortunately, the research community lacks generalizable tools that can be used to identify *how* and *where* a given website is hosted. Instead, a number of ad hoc techniques have emerged, e.g., using Autonomous System databases, domain prefixes for CNAME records. In this work we propose PYTHIA, a novel lightweight approach for identifying Web content hosted on third-party infrastructures, including both traditional Web hosts and content delivery networks. Our framework identifies the organization to which a given Web page belongs, and it detects which Web servers are self-hosted and which ones leverage third-party services to provide contents. To test our framework we run it on 40,000 URLs and evaluate its accuracy, both by comparing the results with similar services and with a manually validated groundtruth. Our tool achieves an accuracy of 90% and detects that under 11% of popular domains are self-hosted. We publicly release our tool to allow other researchers to reproduce our findings, and to apply it to their own studies.

CCS CONCEPTS

1 INTRODUCTION

When deploying a website, companies have the choice to either host it on their own servers, or to offload the content to third-parties, e.g., Web hosts or Content Delivery Networks (CDNs). Choosing a third party can have multiple advantages, including cost savings, reliability, and the ability to sustain larger amounts of traffic (even during distributed denial of service attacks). We argue that understanding the Web hosting landscape is important for a number of reasons. These range from allowing us to assess how critical certain hosting infrastructures are and to estimate the impact that a network attack could have on the Web [8, 17, 24], to being able to determine who is responsible when incidents (e.g., malware hosting) occur [26]. Despite the importance of the problem, the research community lacks scalable methods to map the hosting landscape. Instead, multiple studies tend to take an ad hoc approach, relying on various assumptions, which differ between papers. Although there are third party services that offer this functionality [18, 30], they do not disclose their methodology, creating concerns for both reproducibility, as well as accuracy of their results.

To fill this gap, this paper *presents an open source tool to the community,*[1] *which can determine whether the webpage of an organization is self-hosted or it uses a third-party hosting provider.* Our tool, PYTHIA, leverages the HTML code of the webpage, domain information, and the network ownership obtained from RDAP records, to determine if the content is hosted on a third-party infrastructure. This is done by computing the ownership of both the webpage *and* the hosting provider, such that the two can be compared. PYTHIA is built with a modular design and it is capable of obtaining information of the landing webpage even in the presence of complex HTML structures which use redirects.

To evaluate the efficacy of PYTHIA, we run it on 40,000 URLs generated from the Alexa top-10k domains [2]. Our validation process shows that our framework outperforms similar applications available on the Web, and it achieves an accuracy of 90% in detecting when a webpage is hosted by a third party. Furthermore, our measurement reports that over 89% of the popular domains that we inspected, take advantage of third parties for their hosting needs.

PYTHIA is open source and allows the research community to reproduce our findings. We intend this to become a shared community effort, allowing third party researchers to avoid the complexity involved in devising and building their own independent methodologies for this commonly encountered task.

2 BACKGROUND

Understanding and measuring the Web hosting ecosystem is a complex endeavor. To complete this task, we need both information about the ownership of domains and the ownership of the IP addresses where webpages are hosted. In this section we introduce the concepts on which our approach is based, and the type of data that we retrieve to determine whether webpages are self-hosted or not.

2.1 Third-Party Hosting

Content Delivery Networks (CDNs) and Hosting Services are two popular mechanisms for delivering content to end users on behalf of other organizations. By offloading the task of serving the content of a website to third parties, these solutions are designed to provide better availability, scalability, faster content loads, redundancy, and enhanced security. These technologies have become so widespread that according to recent statistics, more than 60% of the most visited websites use CDNs to serve content to their users [4]. In this work we study the deployment of any kind of solution that delivers Web content for third parties, and for this reason we use the term *hosting* to refer to the *network where Web servers offering a service are based.*

There are countless papers that have explored the hosting patterns of websites, each taking a slightly different approach. A common approach is to launch large-scale distributed measurements [1, 9, 25], which perform DNS queries around the world to retrieve and classify DNS responses. This, unfortunately, is extremely complex and costly; furthermore, it cannot alone confirm if the infrastructure is third-party operated without further inspection. Calder et al. [6] utilized the EDNS-0 Client Subnet extension to simulate distributed queries towards Google's CDN. Although it revealed a large number of servers, all were operated by Google rather than third-parties. These techniques also do not work well for Anycast CDNs [7], which do not necessarily return DNS responses containing redirects. Another strategy employed is to utilize domain prefix lists, which map CNAME responses to their respective CDNs [21]. These, however, are limited to CDNs that exclusively rely on CNAME redirects (e.g., this excludes Bing). Furthermore, the list requires constant maintenance to remain up-to-date. Lastly, some studies utilize IP address to Autonomous System (AS) mappings [14] or metadata encoded into DNS records [3]; these, however are vulnerable to misattributing ownership, e.g, when a CDN places a cache in a third-party network. Such techniques have also been complimented with manually curated AS annotations, which stipulate the type of AS [19]. Again, these suffer from both manual annotation errors and require substantial upkeep. We argue that these diverse ad hoc techniques are driven by the lack of a standardized tool within the community, which can provide metadata on website hosting patterns.

2.2 The RDAP Protocol

To acquire information about a domain's ownership we use the Registration Data Access Protocol (RDAP) [22]. This protocol was designed to replace the WHOIS [16] protocol as the authoritative source for registering information about IP addresses, ASes and domain names. While its predecessor retrieved free text content, RDAP leverages a RESTful interface to deliver the data in a machine-readable JSON format. This simplifies the parsing process and allows us to easily extract information (e.g., the type of entity to which a range of IP addresses has been assigned, or the description of an AS). In this paper, we use the RDAP protocol to retrieve information about the ownership of an IP address to which a domain resolved.

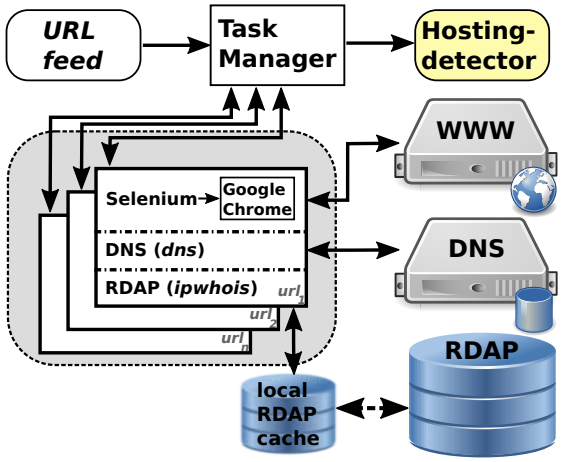

Figure 1: An overview of PYTHIA. The task manager processes URLs from a queue and instantiates a *crawler* task for each URL. The crawler collects information about a webpage and the environment from which the page was retrieved. The output of the crawler is stored in a dedicated data structure, which is later analyzed with the module that checks if content was served from a self-hosted network environment.

3 OVERVIEW OF PYTHIA

PYTHIA is entirely written in Python, and Figure 1 provides an overview of its system components. In a pipeline, PYTHIA performs the following two steps, (*i*) *Data Collection:* it takes a URL feed, and renders the list of websites, recording detailed information on all resources loaded, before complementing the data with RDAP records for the IP address hosting the website; and (*ii*) *Hosting Detector:* it then passes this information through a hosting detector, which decides if the owner of the webpage is the same as the owner of the hosting infrastructure where the server is located. The outcome is a structured JSON file that details if the website is self-hosted or operated by a third-party. In addition to this, PYTHIA also provides information on the ownership of both the webpage and the hosting service.

3.1 Data Collection

We first present the methods we use to collect the necessary data to infer ownership. This includes Web data, DNS information and, finally, RDAP records for all domains loaded.

Web Data Collection. Upon receiving a list of URLs, the crawler obtains Web content through Selenium,[2] a popular framework used for testing Web applications. We instrument Selenium to take a URL and to render it within a fully fledged instance of the Google Chrome browser. After the page has been loaded and rendered, our module outputs the retrieved HTML, in addition to a list of all the HTTP requests/responses (URLs) that were generated during the process. Each request/response is accompanied by metadata including the HTTP status code, and HTTP headers (e.g., server, content-type).

An important part of the crawling process is to determine when a webpage has finished loading. Since we do not know how long this process will take, we use an adaptive mechanism that leverages the information logged by the Web browser. We continuously monitor the browser logs and we consider the page loaded once all the requests to external resources have received their corresponding response. At the same time, we also set a hard timeout, after which we will close the browser session independently if the loading succeeded or not.

As part of the process, we also follow all the redirects that occur while loading an URL. This includes not just CNAME or HTTP redirects, but also those triggered by the refresh meta tag or a script. However, being primarily a tool for developers who need to check their own webpages, Selenium does not provide access to the browser internals. Hence, PYTHIA extracts information about the redirection chain from the browser log. After filtering out all the request to external resources, we identify the landing page and URLs on which the browser terminated the navigation.

Domain Resolution. Since Web browser logs do not contain information about domain resolution, PYTHIA launches DNS queries for all domains encountered (at a modest cost of only around 3.2% additional overhead per webpage). An advantage of this systems is that we can to use our own DNS server and we do not need to rely on the built-in mechanisms of proprietary resolvers, which might be hardcoded in the browser.

IP Ownership. Using the DNS results, we then determine the "owner" of the IP space where the content is hosted. PYTHIA uses the RDAP protocol to find the network prefix to which an IP address belongs to, and to identify the owner of that range. Our framework uses a local RDAP cache to overcome rate-limiting issues of RDAP servers and to avoid querying ranges for which we already have fresh information. After successfully completing the RDAP resolutions, all the data generated by the above steps is stored in a JSON data structure.

[2] https://www.seleniumhq.org/

3.2 Detecting Hosting Infrastructures

The next step is to use the above information to detect if a website is self-hosted, or whether it uses on a third-party infrastructure. Our tool identifies the organization/company behind a domain name and a webpage, and searches for evidence that the page owner is the same as the owner of the network prefix or the AS hosting the Web server. We do not differentiate among various types of hosting services (i.e., VPS, CDN, or generic web hosting) and we do not use any precompiled list of popular or known hosting services. Instead we extract our information from the URL and the HTML retrieved from the landing page, and we match this data with the RDAP response of the IP address that is hosting the web server. This process allows us to detect the third-party network infrastructures even in the presence of CDN caches located at ISPs: even if we did not identify correctly the provider, our algorithm will detect a mismatch in the ownership of the webpage and the IP range.

To identify the organization that owns a webpage we use both the information from the URL and the HTML code. In particular, from the URL component we extract the Effective Second Level Domain (ESLD), and from the HTML we use the content of the <title> tag. Before retrieving any ownership information for a RDAP response, we first filter unnecessary details from the data such as "comments" or the "symbolic name of the network", which can contain references to the owner of the webpage even when the IP range is assigned to a completely different organization. After this step, each string contained in the *HTML title* or the *RDAP fields* has its leading space delimiters removed, is cleaned from punctuation characters and stop words, converted into lower case, and finally is split into tokens on space delimiters. The DNS system does not allow domain names to contain space delimiters and it is common have domains, such as "bankofamerica.com", where the ESLD is a combination of multiple words. To overcome this issue, the ESLD string follows the same cleaning process of the title and the RDAP, with the only difference in the tokenization, which is performed following the technique described in [23].

This process results in a series of string tokens that represent ownership features of both the webpage and the domain/IP address hosting it. The next step is to compare these tokens to see if they correspond. Our algorithm does six checks: four with the strings contained in the title/ESLD/RDAP, and an additional two with the tokenized versions of those strings. First, the algorithm verifies if the HTML title or the ESLD appears as a sub-string in any of the RDAP fields. Subsequently it repeats the same procedure with each string in the RDAP fields by comparing it both with the HTML title and the ESLD. The output of this process is binary and if the algorithm finds a match, it concludes that the owner of the webpage is also the owner of the network. As a final step, the algorithm checks for the presence of common tokens among the lists of tokens obtained from the HTML title/ESLD and the RDAP information. In this case a single match is not enough to conclude that the same

organization owns both the webpage and the network, and we require that the common tokens represent at least 50% of the overall number of tokens in the shortest list.

4 VALIDATION AND EVALUATION

Pythia is intended to be both accurate and straightforward to use for the community. To validate its capabilities we next run it over multiple datasets.

4.1 Validating the Data Collection

Our first goal is to test the efficacy of our crawler in collecting the necessary data to perform the hosting classification. Hence, we run Pythia over a series of URL lists. A first dataset includes 10,000 unique domain names obtained from a snapshot of the "Alexa top 10,000 websites" (top-10k) on 1st of May 2018. A second dataset (top-20k-www) is an extended version of the previous one, where domains are extended with the "www." prefix. Finally, a third dataset (top-40k-URLs) includes all the entries from top-20k-www expanded with "http://" and "https://" prefixes.

Data Collection. We run Pythia over the top-40k-URLs to collect information about their home pages. We split our dataset into chunks of 350 elements and we process each chunk separately. Each element of the chunk is a unique domain name, which is crawled both with and without the "www." prefix and with the two protocols that Pythia supports (HTTP and HTTPS). This means that when we successfully crawl an entire chunk, we obtain information for 1400 unique URLs. We refer to the initial URL from which we begin our crawling, and that we load in the browser, as "starting URL"; similarly, the URL on which the crawl terminates is called "landing URL". Once a chunk is processed, Pythia waits for 120 seconds before switching to the next one. Each chunk is analyzed using 20 parallel instances of our Crawler module, which uses a maximum timeout of 60 seconds while waiting for a webpage to finish loading. Note that when collecting IP Ownership information from RDAP, we randomize waiting timeouts, with of a maximum of 90 seconds, before retrying a query that triggered an exception; after 3 consecutive exceptions, the module marks an IP as "no info available" before switching to the next one. The entire data collection process took place from a single machine, although we note it is possible to split the dataset and run parallel instances of Pythia on different machines.

Data Collection Performance. The overall process of downloading the HTML, resolving DNS names and collecting RDAP data, took 35 hours to complete for the top-40k-URLs. Figure 2 presents the Cumulative Distribution Function (CDF) of the increase of number successful crawls across time. To be able to use fresh entries from our local RDAP cache, we crawled the 4 starting URLs linked to each domain at the same time. Due to this choice, the CDFs of each "URL format" have very similar shapes. Hence *four* distributions in Figure 2 are almost stacked on the top of each other, and the red line connecting the values is the average across

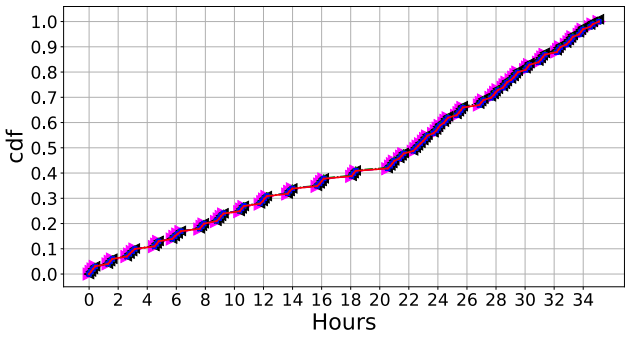

Figure 2: Cumulative distribution functions of the successful crawls with different URL formats.

those distributions. After 24 hours, we had crawled only 50% of the URLs, and in the last 1/3 of the time, we obtained the information for the remaining half of the dataset. The dataset contained shuffled entries, which did not follow any ranking depending on the "popularity of a domain" and the likelihood to have an "unreachable URL" at the beginning or at the end the crawl is the same. We explain the spike in the increase of the number of downloads after the 24th hour with the presence of our RDAP cache. As we will later show, the majority of URLs/domains use a third-party hosting provider and as times passes we observe an increase of the number of RDAP queries which can be resolved with our local cache. Those local resolutions increase our crawling speed allowing us to allow us to gather information for the same amount of elements, in half of the time.

In Table 1 we summarize the results of the data collection process using Pythia. The first thing to notice is that 85% of the starting URLs are successfully reached. Overall, our crawler visited 1,736,929 external URLs, which were retrieved from 54,410 different domains. This suggests an average factor of 42 URLs per "starting URL". It is therefore clear that each HTML page contains a considerable number of external resources, although it should be noted that this not only includes links to script and images, but also *redirects* from a starting to a landing webpage. Independently of the protocol and the presence of the "www." prefix, the 6th column in the Table shows that redirects are extremely popular. On average we pass via 2.4 intermediate URLs before reaching a landing page. For this estimate we *only* use redirects that happen when loading a "starting URL" in our browser, and we excluded any redirects triggered by the external resources embedded in the HTML of the landing webpage. In general, redirects seem to be more popular for the HTTP protocol, but the average difference with HTTPS is minimal.

Related to the redirect phenomenon, we also notice that more than 60% of the crawls observed a "change of the domain" name among the "starting URL" and the "landing URL". This happens with only 1/3 of that frequency value if we crawl domains without the "www." prefix. The reason is that often the redirection happens from one domain to the same domain expanded with the "www." prefix. A similar

	URLs (Domains)									IPs

Table 1: Results of running PYTHIA on the top-40k-URLs dataset. The values in the brackets indicates the unique number of elements for each entry.

trend is observable for the "change of the protocol", when crawling URLs with HTTP (which get upgraded to HTTPS).

The overall number of unique IPs of the landing pages is slightly less than 10,000, and it reflects the fact that crawling the same domain with the four different formats, most of the time will lead to the same landing URL/domain. On average there are 1.22 domain per each landing IP (comparison of columns 7 and 12 in Table 1). This is explained by the presence of large hosting providers with many different customers. The same argument explains why we observe a similar relationship of 1.43 domains per each IP, when considering the dataset of all URLs. Finally, the results of PYTHIA indicate that 89% of the landing URLs are served from a third-party hosting infrastructure which does not belong to the owner of the webpage. In the following section we illustrate how we tested the accuracy of our classification, by using a manually validated groundtruth and by comparing with similar applications.

4.2 Classification Validation

We next validate the efficacy of our tool by compiling a groundtruth classification, and comparing it against PYTHIA.

Compiling a Comparative Dataset. To the best of our knowledge, no groundtruth dataset exists regarding Web hosting. To build this, we randomly select 324 domain names to manually annotate. These are taken from the TOP-10K dataset, crawled with the HTTP protocol. For each of these domains, we load the landing webpage in a browser and use search engines to check if the owner of the IP prefix is an organization offering Web hosting or CDN services to its customers.

We note that 324 domains are not enough to evaluate our tool. Thus, we also collect equivalent data from a variety of public tools that allow users to "*discover who is hosting a website*". This allows us to compare our results against their outputs. Example of those services include HOSTINGCOMPASS.COM which can detect who is hosting an ESLD, or HOSTINGDETECTOR.COM and WHAT'S MY CDN? which allow more fine grained queries including "www." as prefix to the ESLD [11, 12, 31]. We choose to use those three application because they are free Web-based services that do not require any registration. We query those services with the URLs from our TOP-10K and TOP-20K-WWW datasets,

	Self-hosting		3rd-party hosting		
Tool/Service	TP	FN	TP	FN	F1-score
PYTHIA	26	3	279	16	0.73
hostingcompass	27	2	102	193	0.21
hostingdetector	12	17	239	56	0.25
whatsmycdn	27	2	127	168	0.24
cdnfinder	28	1	65	230	0.2

Table 2: Performance comparison of PYTHIA and other applications on our manually validated groundtruth.

depending on the service. As the services mentioned above do not provide any detail about the methodology they use to detect hosting providers, in addition to those Web applications, we also use CDNFINDER, an open-source project which aims to detect the usage of CDNs within websites. The tool uses PHANTOMJS and a hard-coded list of hostnames to load a webpage and detect the presence of external resources which are hosted on a CDN [20, 28]. Analogously to the Web services, we downloaded the tool and run it on our TOP-40K-URLs dataset. In total, this results in 5 datasets to compare PYTHIA against.

Comparison with Manual Annotations. Table 2 contains the results of comparing PYTHIA against the above online services, using the manual annotations as the groundtruth. Our algorithm was specifically designed for detecting the presence of "self-hosting" environments. Consequently, a domain will be flagged as "hosted on third-parties" in any situation where the webpage owner differs from the owner of the network prefix (e.g., a private Web server run at at home, where the broadband ISP is the owner of the network prefix). Despite this limitation, in the binary classification problem where a website is either self-hosted or hosted on a third-party service, PYTHIA still outperforms all the other services that we tested, achieving an F1-score which is almost three times larger than the average for the other services. Indeed, on our manual groundtruth we observe an accuracy of over 95%, even when, instead of verifying self-hosting, we focus on the complementary problem of detecting the presence of third-party hosting providers. CDNFINDER performs well in detecting self hosting, but has a very high false positive rate when classifying domains as third-party hosting. Similarly, HOSTINGDETECTOR achieves the highest accuracy in detecting external hosting

SERVICE	DOMAIN	WWW. + DOMAIN	HTTP + DOMAIN	HTTPS + DOMAIN	HTTP + WWW. + DOMAIN	HTTPS + WWW. + DOMAIN
HOSTINGCOMPASS	3,481 (3,283)	-	-	-	-	-
HOSTINGDETECTOR	3,229 (2,879)	5,607 (4,973)	-	-	-	-
WHATSMYCDN	978 (963)	3,268 (3,202)	-	-	-	-
CDNFINDER	-	-	59 (55)	403 (395)	149 (144)	1,849 (1,700)

Table 3: Comparison of PYTHIA with similar services/applications when evaluated on all of our datasets. The values in the brackets indicates results obtained by PYTHIA.

services, at a cost of an extremely high false negative rate (59%), when a single organization is in control of both the webpage and the network prefix.

Comparison with Similar Services. To further test the accuracy of our framework, we compare our results with the four tools/services mentioned earlier. The results of this comparison are shown in Table 3. The goal of this is to show that PYTHIA achieves similar results to other applications. To this end, we narrow our goal to identify all domains which are hosted on third-party network infrastructures. As mentioned in the previous sections, PYTHIA follows any kind of redirect. Hence, Table 1 only presents the classification using the "landing URLs/domains". Since we do not know what are the exact capabilities of the four services that we tested, and how they handle redirects, we decided to back-propagate the results of our classification from the "landing URL" to the corresponding "starting URL", and "starting domain", from where the navigation started. In this way we are able to compare our results with each one of those services and verify that our framework has a detection rate close to those of the other services.

For almost all of the domains inspected, PYTHIA achieves an accuracy of around 90%, and it identifies a third-party-hoster every time one of the other four services detects its presence. Since the highest number of misclassified services originate from the sets of domains analyzed with HOSTINGDETECTOR, we sampled 20 domains without the "www." prefix and another 20 with the "www." prefix. We then manually verify if they are actually hosted on a third-party infrastructure. For 27 out of 40 cases, HOSTINGDETECTOR failed to identify self-hosted domains and PYTHIA correctly labeled those as "self-hosting". Ten of those cases were domains of large universities with their own network prefixes. For another 7 cases, the landing page is the home page of large hosting services such as "Google", "Salesforce" or "1and1". PYTHIA correctly labeled these as self-hosted. For four domains our PYTHIA did not succeed in downloading the RDAP information, and PYTHIA could not classify those domains. The remaining 9 domains were hosted on a third-party infrastructure, but we did not detect them. According to those results, we conclude that the accuracy of PYTHIA is inline with similar services we compared to.

5 RELATED WORK

A significant amount of research has been done in the field of Content Delivery Networks and cloud computing. Krishnamurthy et al. [15] were the first to analyze the rise of CDNs and the benefits that they provide to end-users. After them several studies investigated this trend [1, 7, 13, 25]. Similar work has tried to uncover cloud usage patterns and which Web services are running on a cloud-associated IP address [10, 29].

Our techniques relies on a mix of methodologies, particularly exploiting RDAP data. There have been a small set of past papers that rely on similar data. For example, Cai et al. proposed to combine WHOIS information with the ASN in order to generate a comprehensive AS-to-organization mapping [5]. Tajalizadehkhoob et al. were the first ones to explore the identification of hosting provides by combining passive DNS with WHOIS information [27]. Unfortunately their approach leverages a classification of 2,000 ASes to filter out organization such as ISPs, education and government. This list has limited size and is manually generated, and this raises concerns about its reliability across time. Contrary to previous studies, our work does not use any precomplied list of organization names and it focuses on identifying self-hosting environments. PYTHIA allows other researchers to reproduce our results and it does not require any manual analysis or a priori knowledge of network prefixes or the ASes in charge for routing the network traffic.

6 CONCLUSION

In this work we presented PYTHIA, a tool for collecting information about a webpage and the environment where the page is hosted. Our framework extracts information from the retrieved HTML, the DNS and the ownership information associated to a network prefix. PYTHIA then exploits this data to infer if the website is self-hosted, or is reliant on a third party operator, e.g., a Content Delivery Network. We tested PYTHIA on 40,000 URLs and compared the results with similar applications that detect the presence of known hosting providers. Our framework is accurate and outperforms all other applications, when tested on a manually validated groundtruth. PYTHIA is released as open source and is built in a modular way, which gives the possibility to integrate it with new capabilities and extensions.

ABSTRACT

Classical event encoding and extraction methods rely on fixed dictionaries of keywords and templates or require ground truth labels for phrase/sentences. This hinders widespread application of information encoding approaches to large-scale free form (unstructured) text available on the web. Event encoding can be viewed as a hierarchical task where the coarser level task is event detection, i.e., identification of documents containing a specific event, and where the fine-grained task is one of event encoding, i.e., identifying key phrases, key sentences. Hierarchical models with attention seem like a natural choice for this problem, given their ability to differentially attend to more or less important features when constructing document representations. In this work we present a novel factorized bilinear multi-aspect attention mechanism (FBMA) that attends to different aspects of text while constructing its representation. We find that our approach outperforms state-of-the-art baselines for detecting civil unrest, military action, and non-state actor events from corpora in two different languages.

1 INTRODUCTION

Given the large volumes of text available on the web in the form of news, social media, blogs and discussion forums, it is crucial to identify and extract meaningful nuggets of information. A wide range of applications from question answering [24], knowledge base construction [21] and named entity recognition [19] to informing critical decisions in domains ranging from national security to cyber security [22] rely on the event extraction and encoding process. Event analysis refers to the extraction of specific information about certain events from text. It can be categorized as a hierarchical task where the coarser level task is event detection, i.e., identification of documents containing a specific event and the fine-grained task is one of event encoding, i.e., identifying key phrases and sentences describing event related information such as the type of the event, type of people involved in the event, and relationships between these aspects. The sheer diversity of applicable event domains and types combined with the multitude of data sources, and scarcity of fine-level labels make both these tasks challenging.

Prior work in event encoding has focused on extracting entities, detecting trigger terms, and matching slots on predefined templates [3, 16, 26]. However there are a few shortcomings of these approaches. The first drawback is that they rely on fine-grained labeled training data which is hard to obtain for a variety of domains and different types of events. On the other hand, labels at the document level are easier to obtain. Second, they use of sentence-level embedding [16] removes contextual information resulting in false negatives because event occurrences do not neatly partition into unique sentences. Multiple instance learning (MIL) approaches have been proposed [9, 23] as a solution to partly alleviate these problems. MIL approaches view documents as bags of sentences, make predictions at the sentence level, aggregate sentence level probabilities for a select few sentences to obtain document-level predictions. In this work we model the tasks of event detection and key sentence identification from a news article in a unified framework without explicit labels at the sentence level by leveraging the implicit hierarchy in textual corpora. Hierarchical attention based networks seem like a natural choice for this problem, given their ability to differentially attend to more or less important words and sentences when constructing document representations [25].

We use a recurrent neural network (RNN) based hierarchical model (with attention mechanisms at both levels in the hierarchy) that constructs sentence and document representations. The sentence representation is constructed by attending to all words in the sentence, whereas the document representation is constructed by attending to all sentences. To capture the fact that a sentence might capture multiple aspects related to an event (e.g., cause, location, population) we adapt hierarchical attention network models [25] by using a novel multi-aspect attention mechanism that allows for multiple attention distributions over words for a single sentence where each distribution can be thought of as attending to a different aspect of a sentence.

We evaluate the proposed hierarchical attention models for the task of event detection on civil unrest (CU) and military action/non-state actor (MANSA) datasets.
Our contributions in this work can be succinctly summarized as follows:

- We present a novel factorized bilinear multi-aspect attention mechanism (FBMA) that constructs a sentence representation using multiple attention distributions and that when used with hierarchical models improves performance for event detection.
- Our FBMA approach achieves state-of-the-art results for event detection on three event datasets from two different domains in two different languages.

2 RELATED WORK

2.1 Event Extraction

In event extraction supervised approaches usually rely on manually labeled training datasets and handcrafted ontologies. Li et al. [10] utilize annotated arguments and specific keyword triggers in text to develop an extractor. Supervised approaches have also been studied using dependency parsing by analyzing the event-argument relations and discourse of event interactions [14]. These approaches are usually limited by the availability of fine-grained labeled data and require elaborately designed features. In contrast to these approaches our method uses attention mechanisms to implicitly weigh words and sentences and is able to extract event extents and trigger words with labels provided only at the document level. This formulation is suitable because labels at document level are easier to obtain than at the per-sentence level or at the word level. This makes the task of event extraction also amenable to multiple instance learning (MIL) [5] solutions. In MIL 'bags' are groups of 'instances' which are to be classified. In a standard MIL formulation individual instance level labels are not available and labels are provided only at the group/bag level. Each bag is labeled positive if it contained at least one positive instance and negative otherwise. Kotzias et al. [9] focus on instance-level predictions from group level labels and allow for the application of general aggregation functions for sentiment classification. Wang et al. [23] use a similar idea and hold the previous state-of-the-art results on one of the datasets we evaluate on. Contrary to these approaches our method is hierarchical and computes the feature representation for the next level in the hierarchy using a weighted average of feature representations in the current layer.

2.2 Attention for Structured Representations

Models have been proposed that compute multiple attention distributions over a single sequence of words. The multi-view networks proposed by Guo et al. [6] use a different set of parameters for each view which leads to a large increase in the number of parameters with increasing number of views. Lin et al. [12] alleviate this problem by producing a matrix embedding from a single set of parameters. Both these methods use a special case of additive attention proposed by Bahdanau et al. [1] in the context of neural machine translation. Luong et al. [13] simplify additive attention operations by introducing the notion of multiplicative attention which is faster to compute. In multiplicative attention, the score between two feature vectors is learned using a bilinear projection matrix. Dot product attention [13] is a special case of multiplicative attention where the score between two features vectors is computed by a simple dot product between them. Yang et al. [25] use dot product attention to compute the similarity of word hidden representation to a word-level context vector which is learned with the rest of the model. In our work we compute the score between the context vector and the word hidden representation using a bilinear projection matrix and then we use an approach inspired by multi-modal low rank bilinear pooling proposed by Kim et al. [8] to factorize the matrix into two low rank matrices to compute multiple attention distributions over words. Contrary to Guo et al. [6] we use matrix factorization to alleviate the problem of increasing parameters with increasing views and our approach uses fewer parameters than Lin et al. to compute multiple attention calculations and performs superior to their approach. We refer to this as multi-aspect attention as it attends to different aspects or parts of a sentence for constructing a sentence embedding.

3 PROPOSED MODEL

The event detection problem can be defined as follows: Given a corpus containing N news articles $\{x_1, x_2, ..., x_N\}$, each article is associated with an event label $y \in \{0, 1\}$, with 1 corresponding to articles containing an event. For each news article we aim to predict its label, indicating if it contains an event or not.

3.1 Sequence Encoder

Consider a news article containing n sentences with each sentence containing T words. A sentence consists of word tokens w_{it}, $t \in [0, T]$ where every word is converted to a real valued word vector $\mathbf{x}_{it}$ using the pre-trained embedding matrix $\mathbf{W}_e = R^{dx|V|}$, $\mathbf{x}_{it} = \mathbf{W}_e\mathbf{w}_{it}$, $t \in [1, T]$ where d is the embedding dimension and V is the vocabulary. We encode the sentence using a bi-directional Gated Recurrent Unit [4](bi-GRU) RNN that summarizes information in both directions along the sentence to get a contextual annotation of a word. In a bi-GRU the hidden state at time step t is represented as a concatenation of hidden states in the forward and backward direction. The forward GRU denoted by $\overrightarrow{GRU}$ processes the sentence from w_{i1} to w_{iT} whereas the backward GRU denoted by $\overleftarrow{GRU}$ processes it from w_{iT} to w_{i1}.

$$\mathbf{x}_{it} = \mathbf{W}_e\mathbf{w}_{it} \tag{1}$$

$$\overrightarrow{\mathbf{h}_{it}} = \overrightarrow{GRU}(\mathbf{x}_{it}, \mathbf{h}_{i(t-1)}, \boldsymbol{\theta}) \tag{2a}$$

$$\overleftarrow{\mathbf{h}_{it}} = \overleftarrow{GRU}(\mathbf{x}_{it}, \mathbf{h}_{i(t+1)}, \boldsymbol{\theta}) \tag{2b}$$

Here the word annotation $\mathbf{h}_{it}$ is obtained by concatenating the forward hidden state $\overrightarrow{\mathbf{h}_{it}}$ and the backward hidden state $\overleftarrow{\mathbf{h}_{it}}$.

3.2 Word-Level Attention

For event extraction the presence of certain words increases the probability of a sentence containing the event. Such words should be given higher weight than other words while computing a sentence representation. Since an event related trigger word can occur

anywhere in a sentence we choose the global attention mechanism [13] in which the sentence representation is computed by attending to all words in the sentence.

3.2.1 Bilinear Attention. Let $\mathbf{h}_{it}$ be the annotation corresponding to the word $\mathbf{x}_{it}$. First we transform $\mathbf{h}_{it}$ using a one layer Multi-Layer Perceptron (MLP) to obtain its hidden representation $\mathbf{u}_{it}$.

$$\mathbf{u}_{it} = tanh(\mathbf{W}_w \mathbf{h}_{it} + \mathbf{b}_w) \tag{3}$$

We measure the importance of word by computing an alignment score of $\mathbf{u}_{it}$ to a word level context vector $\mathbf{u}_w$ using a bilinear model:

$$f_{it} = \mathbf{u}_w^T \mathbf{W}_i \mathbf{u}_{it} \tag{4}$$

Here, $\mathbf{W}_i$ is a bilinear projection matrix, $\mathbf{u}_w$ is randomly initialized and jointly learned with other parameters during training. Similar to [25], $\mathbf{u}_w$ can be seen as a high dimensional representation of the fixed query 'What is the informative word'. $\mathbf{u}_w \in \mathbb{R}^l$, $\mathbf{u}_{it} \in \mathbb{R}^{2h}$ and $\mathbf{W}_i \in \mathbb{R}^{2hx2h}$. The attention weight for the word $\mathbf{x}_{it}$ can be computed through a softmax function.

$$\alpha_{it} = \frac{exp(f_{it})}{\sum_{t'} exp(f_{it'})} \tag{5}$$

3.2.2 Factorized Bilinear Multi-Aspect Attention. The attention distribution above usually focuses on a specific component of the sentence, like a special set of trigger words or phrases. So it is expected to reflect an aspect, or component of the semantics in a sentence. However there can be multiple aspects that describe an event like who were involved in the event, what were the causes of the event or where did the event occur. For this we introduce the novel factorized bilinear multi-aspect attention (FBMA) mechanism. Suppose m aspects are to be extracted from a sentence, we need m alignment scores between each word hidden representation $\mathbf{u}_{it}$ and the context vector $\mathbf{u}_w$. To obtain an m dimensional output $\mathbf{f}_{it}$, we need to learn $\mathbf{W} = [\mathbf{W}_1, ..., \mathbf{W}_m] \in \mathbf{R}^{lx2hxm}$ as demonstrated in previous works. Although bilinear model might be effective in capturing pairwise interaction it introduces a huge number of parameters that may lead to a high computational cost. Inspired by multi-modal low rank bilinear pooling approach proposed by Kim et. al [8] and the matrix factorization approaches proposed in [11, 18] the bilinear projection matrix $\mathbf{W}_i$ can be factorized into two rank 1 matrices $\mathbf{P}$ & $\mathbf{Q}$. Eq.4 can be written as:

$$\mathbf{f}_{it} = \mathbf{u}_w^T \mathbf{W}_i \mathbf{u}_{it} = \mathbf{P}^T \mathbf{u}_w \circ \mathbf{Q}^T \mathbf{u}_{it} = \tilde{\mathbf{u}}_w \circ \tilde{\mathbf{u}}_{it} \tag{6}$$

Here $\mathbf{P} \in \mathbb{R}^{lxm}$ and $\mathbf{Q} \in \mathbb{R}^{2hxm}$ are two rank 1 matrices, m is the number of aspects to extract and $\circ$ is the Hadamard product or elementwise multiplication. This brings the two feature vectors $\mathbf{u}_{it} \in \mathbf{R}^{2h}$, the word hidden representation and $\mathbf{u}_w \in \mathbf{R}^l$, the word level context vector in the common space and are given by $\tilde{\mathbf{u}}_{it}$ and $\tilde{\mathbf{u}}_w$ respectively. $\mathbf{f}_{it} \in \mathbb{R}^m$ now is a multi-aspect alignment vector for the word $\mathbf{x}_{it}$. The multi-aspect attention vector $\boldsymbol{\alpha}_{it} \in \mathbb{R}^m$ is obtained by computing a softmax function along the sentence length:

$$\boldsymbol{\alpha}_{it} = \frac{exp(\mathbf{f}_{it})}{\sum_{t'} exp(\mathbf{f}_{it'})} \tag{7}$$

Before computing softmax, similar to [8] we apply an additional tanh nonlinearlity to $\mathbf{f}_{it}$. Since elementwise multiplication is introduced the values of neurons may vary a lot so we apply an l_2 normalization layer across the m dimension, ($\mathbf{f}_{it} \leftarrow \frac{\mathbf{f}_{it}}{||\mathbf{f}_{it}||}$) after the Hadamard product.

3.2.3 Sentence Representation. Let $\mathbf{H}_i = (\mathbf{h}_{i1}, \mathbf{h}_{i2}, ...\mathbf{h}_{iT})$ be a matrix of all word annotations in a sentence; $\mathbf{H}_i \in \mathbb{R}^{Tx2h}$. Let $\mathbf{A}_i = (\boldsymbol{\alpha}_{i1}, \boldsymbol{\alpha}_{i2}, ...\boldsymbol{\alpha}_{iT})$ be the multi-aspect attention matrix for the sentence; $\mathbf{A}_i \in \mathbb{R}^{mxT}$. The sentence representation for an aspect j given by $\boldsymbol{\alpha}_{ij} = \{\alpha_{j1}, \alpha_{j2}, ..\alpha_{jT}\}$ can be computed by taking a weighted sum of all word annotations.

$$\mathbf{s}_{ij} = \sum_{k=1}^{T} \mathbf{h}_{ik} * \alpha_{jk} \tag{8}$$

Similarly, sentence representation can be computed for all aspects and is given in a compact form by:

$$\mathbf{S}_i = \mathbf{A}_i \mathbf{H}_i \tag{9}$$

Here $\mathbf{S}_i \in \mathbb{R}^{mx2h}$ is a matrix sentence embedding and contains as many rows as the number of aspects. Each row contains an attention distribution for a new aspect. It can be flattened by concatenating all rows for further processing.

3.3 Sentence-Level Attention

News articles consist of many sentences with a few of them describing the event and the rest describing the supporting facts. The ones containing event related information should be assigned higher weights. Instead of hard selecting top K sentences and aggregating their probabilities as in prior MIL approaches such as [23] we use the global attention mechanism over the sentence annotations to get the document representation. Specifically, given a document containing sentence embeddings $\{\mathbf{s}_1, ..., \mathbf{s}_i, ..., \mathbf{s}_n\}$ where each $\mathbf{s}_i$ is a flattened representation of the matrix sentence representation $\mathbf{S}_i$ as given by eq. 9 we get the document vector as follows.

$$\overrightarrow{\mathbf{h}_i} = \overrightarrow{GRU}(\mathbf{s}_i, \mathbf{h}_{i-1}, \boldsymbol{\theta}) \tag{10a}$$

$$\overleftarrow{\mathbf{h}_i} = \overleftarrow{GRU}(\mathbf{s}_i, \mathbf{h}_{i+1}, \boldsymbol{\theta}) \tag{10b}$$

$$\mathbf{h}_i = \{\overrightarrow{\mathbf{h}_i}, \overleftarrow{\mathbf{h}_i}\} \tag{10c}$$

The sentence annotation $\mathbf{h}_i$ is obtained by concatenating the forward and backward hidden representations of the bi-GRU. Document representation is obtained by attention over sentences.

$$\mathbf{u}_i = tanh(\mathbf{W}_s \mathbf{h}_i + \mathbf{b}_s), \tag{11a}$$

$$\alpha_i = \frac{exp(\mathbf{u}_i^T \mathbf{u}_s)}{\sum_{t'}' exp(\mathbf{u}_{t'}^T \mathbf{u}_s)} \tag{11b}$$

$$\mathbf{d} = \sum_i \alpha_i \mathbf{h}_i \tag{11c}$$

Here $\mathbf{u}_s$, the sentence level context vector, is randomly initialized and learned along with other model parameters while training and $\mathbf{d}$ is the document representation that summarizes all the information

Table 1: First row indicates population classes participating in a protest in the CU dataset. Second row indicates the causes of protest.

Event Population	General Population, Business,Legal, Labor, Agricultural, Education, Medical, Media
Event Type	Government Policies, Employment and Wages, Energy and Resources, Economic Policies, Housing

in the article. Given the document representation, we use a two hidden layer MLP with dropout to get the class scores.

$$\hat{y} = \mathbf{W}_c\mathbf{d} + \mathbf{b}_c. \tag{12}$$

Loss for the document is computed using the standard cross entropy.

$$l = -(y \log(\hat{y}) + (1-y)\log(1-\hat{y})) \tag{13}$$

The sentence embedding given by eq. 9 can suffer from redundancy issues if the attention mechanism always provides similar weights for all the m aspects. To attend to a small set of trigger words in each aspect and to encourage diversity in different aspects we use penalization as described by Lin et al. [12] that is added to the loss:

$$P = \frac{\sum_i \left\|\mathbf{A}_i\mathbf{A}_i^T - \mathbf{I}\right\|_F^2}{n} \tag{14}$$

Where $\|\bullet\|_F$ stands for the Frobenius norm of a matrix and the summation is taken over all sentences in the document. The final training loss is given by:

$$L = \sum_d l + \lambda P \tag{15}$$

The summation is taken over all the documents in the batch and λ is a hyperparameter. We use the mini-batch stochastic gradient descent algorithm [7] with momentum and weight decay for optimizing the loss function and the backpropogation algorithm is used to compute the gradients.

3.3.1 Hyperparameters. We use a word embedding size of 100. The embedding matrix $\mathbf{W}_e$ is pretrained on the corpus using the gensim [1] implementation of the widely used distributed representations model word2vec [15]. All words appearing less than 5 times are discarded. The GRU hidden state is set to $h = 50$. In FBMA the dimension of $\mathbf{u}_{it}$ is given by the dimension of the GRU hidden state, but the dimension of $\mathbf{u}_w$ can be tuned. Empirically we find that setting the dimension of $\mathbf{u}_w$ to 32 gives us the best results. We set the classifier MLP hidden state to 512 and apply a 0.4 dropout to the hidden layer. We use a batch size of 64 for training and an initial learning rate of 0.05. For early stopping we use $patience = 5$.

4 EXPERIMENTS

4.1 Datasets

To evaluate our approach we use three event datasets - (i) the Civil Unrest Gold Standard Report labeled manually by analysts from MITRE corporation [17]. It contains encodings of civil unrest events from 10 Latin American countries in Argentina, Brazil, Chile, Colombia, Ecuador, El Salvador, Mexico, Paraguay, Uruguay, and Venezuela. The encodings are obtained from major national newspapers as identified by 4imn.com. It contains a total of 24,110 news articles out of which 18% mention a protest event while the rest are non-protest articles. All the articles are in Spanish and we refer to this dataset as CU (Spanish) in this paper. (ii) The AutoGSR dataset – This dataset comes from the EMBERS AutoGSR system [20] which is a web based system that generates validated civil unrest events extracted from news articles. It contains a total of 32,019 news articles out of which 18% describe protest events (protest articles) and the rest do not describe any protest events (non-protest articles). We refer to this dataset as CU (English) in the paper. For each protest article, the CU English & Spanish datasets contain the population type and protest event type. The population type indicates which class of population are involved in the protest and the event type indicates the main reason behind the protest. These are listed in table 1.

Finally, we evaluate on iii) the Military Action and Non-State Actor (MANSA) GSR dataset which is in English and Arabic. This contains event encodings from gulf countries namely, Bahrain, Egpyt, Iraq, Jordan, Lebanon, Qatar, Saudi Arabia and Syria. The event types include 'Military Actions' (MA) which are actions by military, police, or security organization and 'Non-State Actor'(NSA) which are actions initiated by non-governmental groups or individuals to further political, social, religious or ideological objectives. These events are encoded from news articles collected from the web and print media. Event collection techniques include Google Advanced Search (limited to the newspaper website), Nexis queries, and IHS Janes. Google Advanced Search is used to collect events in online media. Nexis and IHS Janes are used to collect events in print media. About 34% articles describe an event and rest are non-event articles. We refer to this dataset as MANSA dataset in the paper. MA & NSA events are further divided into subtypes. In this work we combine NSA & MA events together for detection. Please refer to table 2 for the overview of our datasets.

Table 2: Dataset statistics. Total number of news articles, average number of sentences per article and average number of words per article in the datasets.

Datset	# articles	# sents	# words
MANSA	105858	6.3	250.3

(a) English (b) Spanish (c) MANSA

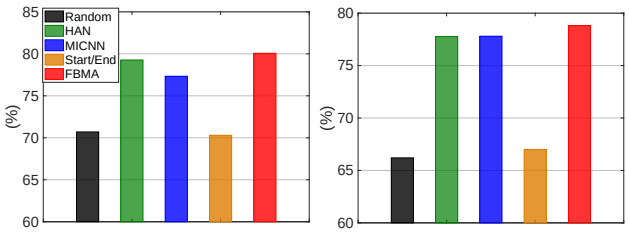

Figure 1: Comparison of event probabilities assigned by FBMA, MICNN and HAN on the CU English, Spanish and MANSA datasets. We can clearly see that mean probability is greater for FBMA in all the datasets for the event class. This depicts that FBMA is usually more confident than other methods in classifying the event articles. We also observe MANSA dataset contains some outliers (shown in red dots at the bottom).

variants as our baselines. The MI-CNN approach first constructs a sentence vector by applying convolution in the temporal dimension followed by $k-$ *maxpooling*. A document vector is formed from sentence vectors in a similar way. Instance representation for each sentence is constructed by concatenating sentence and document representations. Finally probabilities at instance level are aggregated to compute the document level probability. In our first baseline we replace the convolutional sentence encoder by a GRU sentence encoder followed by a simple attention mechanism that attends to words while constructing a sentence representation. We refer to this model as MI-GCNN and it extracts both trigger words and key sentences.

Since, the proposed model is a multi-aspect attention mechanism, we compare it with another multi-aspect attention mechanism proposed by Lin et al. [12]. We refer to as Hierarchical Self Attention (HSA) where we replace the word-level attention mechanism by the Self-Attentive mechanism proposed by them.

We also evaluated the Hierarchical Attention Network (HAN) model proposed by Yang et. al. [25], which attends to both trigger words and keys sentences while constructing sentence and document representations respectively but it only consists of a single aspect attention mechanism at both levels.

Finally, we replace the word level attention in the HAN model with the bilinear attention mechanism given by eq. 4 which has shown promising results in question answering tasks [2, 8].We refer to

(a) Population (b) Event

Figure 2: Event Extraction accuracy for event type detection and population class detection from key sentences extracted by different models. FBMA outperforms all the methods.

this model as Bilinear Single Aspect Attention model (BSA). We compare the performance of these models with the proposed FBMA model. In all the datasets, the event class is a rare class and hence we report the precision, recall and F1 score of that class for the test set. For each dataset we trained our model using 5-fold cross-validation with an 80/20 train/test split and employed early stopping. Models took less than an hour on a single Tesla P100 GPU to train.

5 RESULTS

5.1 Event Detection

Table 4 reports the performance of our models compared to the baseline approaches. On average, the FBMA model outperforms the MIL-based MICNN and MIGCNN models by 14.2 % & 12.9% on MANSA, 32.2 % & 3.5 % on CU Spanish and 6.6% & 3.9% on CU English datasets respectively. The FBMA model also outperforms HAN across the three datasets. Moreover, unlike HAN our model attends to different aspects while constructing a sequence representation, which results in an increased model size due to added parameters. One key aspect of our model is the ability to tune the dimensionality of the word level context vector $\mathbf{u}_w$. We find that models with $l \leq 2h$ where l is the dimension of $\mathbf{u}_w$ and $2h$ is the dimension of the word hidden representation tend to outperform models with $l > 2h$. The FBMA model is forced to learn a more compact representation of the word-level context vector and thus, retains only the most relevant information.

FBMA also beats HSA on CU English, CU Spanish & MANSA datasets by 5.1 %, 6.1 % and 1.5% respectively. Moreover our attention mechanism uses fewer parameters than the Self-Attentive model proposed by Lin et al. [12].

We also observe that the simple bilinear attention models outperform the dot product based attention models in HAN. For the CU English dataset, the BSA approach outperforms HAN & MIL-based baselines by 1.2% and 6.4% & 3.9% respectively. For the CU English and CU Spanish datasets we set $l = 2h$, whereas for MANSA dataset we set $l = 64$. These values were empirically found to perform best on the corresponding datasets.

5.2 Event Probabilities

For event encoding it is important that models have a high precision otherwise it may lead to false-positives and incorrect representations. This is also an issue with traditional detection approaches that detect events based on occurrence of certain set of trigger words from a pre-curated list, without taking into account the sentence context or relationship between different entities. Hence, it is important for the models to assign a high confidence to positive articles and a low confidence to negative articles. We present a distribution of event probabilities assigned to the positive articles by the FBMA, HAN and MICNN models for the test sets for all the three event datasets in Figure 1. We observe that generally the average probability assigned by FBMA is higher than MICNN and HAN confirming our hypothesis that having multi-aspect attention for each sentence increases the model confidence for a positive article.

6 CONCLUSION

In this paper we presented a framework for event detection. We used hierarchical attention based models for the task because of their ability to attend to words and sentences while constructing sentence and document representations respectively. With the hierarchical models we used our proposed FBMA mechanism which computes multiple attention distributions over words which leads to contextual sentence and document representations. Our results showed that this mechanism performed better than several other approaches and especially single-aspect mechanisms that miss out on the context because there is only one attention distribution. The proposed attention mechanism could easily be used for other tasks where document context is important. Moreover, it uses less number of parameters than other similar approaches, and hence can be scaled for larger datasets. An important open question to investigate in the future is that if the attention weights in each aspect can be constrained using certain rules to capture co-occurrence patterns of event arguments. This will lead to a wider distinction between different aspects captured and more precise event extraction.

ABSTRACT

Stack Overflow, a Q&A site on programming, awards reputation points and badges (game elements) to users on performing various actions. Situating our work in Digital Signaling Theory, we investigate the role of these game elements in characterizing social qualities (specifically, popularity and impact) of its users. We operationalize these attributes using common metrics and apply statistical modeling to empirically quantify and validate the strength of these signals. Our results are based on a rich dataset of 3,831,147 users and their activities spanning nearly a decade since the site's inception in 2008. We present evidence that certain non-trivial badges, reputation scores and age of the user on the site positively correlate with popularity and impact. Further, we find that the presence of costly to earn and hard to observe signals qualitatively differentiates highly impactful users from highly popular users.

1 INTRODUCTION

Stack Overflow has evolved from a simple Q&A site to a massive social community where knowledge seekers and knowledge providers of all levels of expertise interact with each other to solve programming difficulties [2]. It has significantly impacted the way programmers learn, communicate and collaboratively build content repositories for future reference [6, 31, 34]. Due to its widespread use, it has become an integral part of the software development ecosystem and developers increasingly rely on it for their daily programming needs. Moreover, users on other platforms such as mailing lists, Github, etc. actively encourage their participants to refer back to posts on Stack Overflow for solutions [38].

This rise in the site's importance stems from four factors: (i) users can find multiple high quality answers for questions on nearly every programming language, tool, framework and software [28], (ii) if what is needed is not available, they can create a post themselves and receive answers extremely quickly [24], (iii) virtual rewards (reputation points and badges) incentivize users to contribute [14], and (iv) the rich interface enables them to display their expertise to potential recruiters [9]. These factors facilitate the transparent nature of the site. Each user has their own dedicated profile page that aggregates their contributions and achievements on the site. As a result, other users and recruiters can form impressions about their expertise of topics, their programming abilities, skills and experience [13]. In such a highly competitive environment, users that stand out are those that successfully acquire visible traces to attract attention [12]. One such significant way for users to stand out is by acquiring a large number of reputation points and badges.

Social status and reward system design. Virtual rewards act as symbols of social status, despite having no explicit value of their own. Some badges require users to expend costly effort and are therefore earned by few. These confer a higher status value since they distinguish members within the community. Others are easier to earn and act as motivations, and sources of learning. Badges serve various socio-psychological functions on crowdsourced platforms [4]. A prominent theme in literature has focused on the roles of badges in incentive structures [10, 19, 22, 27, 29]. Immorlica, et al. [21] show that the optimal design employs threshold badges where only users above a pre-defined number of contributions receive badges. Easley, et al. [16] take a game-theoretic approach to analyze the effectiveness of systems of such threshold badges.

Effects of virtual rewards. A separate line of research has analyzed the qualitative and quantitative effects of virtual rewards in diverse settings such as open-source software [29, 37] and knowledge repositories [38, 39]. Anderson, et al. [3] define a formal model that predicts how badges steer user behaviour. Mutter, et al. [26] provide empirical evidence that as users' proximity to goals defined by badges increases, so does the level of the users' contributions (goal-gradient hypothesis). First-time badges, awarded after a user takes a specific action for the first time, causally affect user behaviour and

Table 1: General statistics of users' activities in our dataset.

Total number of active users	3,831,147
Total number of questions	15,711,957
Total number of answers	24,492,236
Mean reputation of active users	111
Mean number of badges earned by active users	22
Mean year when users joined the site	2015

also improve the functioning of the site itself [23]. The reputation points of users on Stack Overflow along with community activity dynamics are good predictors of the long-term value of questions and answers [2]. But, what attributes these virtual rewards can signal about users themselves is not yet well understood.

Research Questions. In this paper, we focus on finding important markers of user attributes since they are known to relate to dynamics of identity, crowdlearning, social benefits and societal acceptance [5, 36]. Specifically, we ask:

RQ1: According to Stack Overflow users, what social qualities (if any) do reputation scores and badges intend to signal?

RQ2: To what extent do these game elements actually signal or indicate the qualities that users expect them to?

The paper most closely related to ours is that of Trockman, et al [35]. They analyze various categories of badges such as Quality Assurance, Dependency Management, etc., in the `npm` ecosystem on Github as signals of *repository properties* such as dependency freshness, test suite quality and popularity. Some of these signals are subjective. Also, maintainers of the repositories can choose which badges they wish to display and which they do not. We consider Stack Overflow with a completely different and more complex system of reputation points and badges that it awards *to users* and is based on objective, pre-defined metrics [3].

We summarize our contributions below.

- We conduct a survey of Stack Overflow users and draw preliminary insights about how they view reputation points and badges as indicators of various social qualities.
- We perform empirical investigations on a large dataset of 3,831,147 users and the complete time-stamped history of their actions on Stack Overflow spanning a decade.
- Employing nonlinear regression models, we find that the presence of certain non-trivial badges correlates with higher popularity and impact. We also provide evidence that badges add more explanatory power compared to reputation scores.
- Statistical analyses of user activity show distinct differences in patterns of engagement between popular and impactful users.

Through these findings, we shed new light onto the role of virtual rewards in studying user qualities on crowdlearning platforms.

2 THEORETICAL FRAMEWORK

The widespread adoption of game elements on Stack Overflow invites a deeper examination of their effects on its users. Reputation scores are received for taking various positive actions whereas badges are awarded for "being especially helpful". We argue that given the variety of actions rewarded through reputation scores and badges, they are important signals of underlying qualities of users. We thus investigate their value from a signaling perspective.

Adverse Selection. Users on Stack Overflow possess different levels of information about various topics as well as other users on the platform. Users have a better understanding of their own expertise and limitations. They thus choose to participate selectively in order to maximize their benefits. Users however, tend to be uncertain about the preferences of heterogeneous audiences in terms of how they will respond to their actions. At the same time, the audience's qualitative assessment of users' abilities is based on limited information. Such a state where neither party has complete knowledge about the other is called information asymmetry [32]. This causes adverse selection, i.e. bias towards only particular kinds of actions [30]. For instance, most individuals prefer high returns and so they differentially choose low-hanging fruits, and broadly useful actions, while a few others may prefer more niche and challenging questions. As a result, participation is severely affected.

Digital Signaling. Signaling is a well-studied and popular solution to the problem of adverse selection [20, 32]. Signals are images, symbols and signs that allow users to communicate information and meaning with appropriate context. Signals that are costly to generate for the signaler and cognitively easy to process for the observer tend to be very reliable [11]. The design of sets of such assessment signals can specifically combat the inefficiencies arising due to information asymmetry [15]. The audience on Stack Overflow upvotes or downvotes posts to indicate that they approve or disapprove of them. This is a basic signal that is cheap to produce. Conversely, reputation scores and badges can help highlight deep technical qualities of a user since they require significant effort to achieve. This allows the user to potentially make better decisions in the future and the audience to gain more knowledge about him/her.

Gamification. Gamification is the use of game design elements in non-game contexts [14]. Badges on Stack Overflow are automatically earned by users based on their performance, unlike Github, where they are voluntarily displayed [7]. A single badge can holistically combine multiple qualitative actions whereas reputation points can be earned for every positive unit of action. This involves users in a social environment thereby motivating increased participation. In this paper, we consider game elements such as reputation scores and badges to be *digital signals* and investigate whether they are indicative of the performance and qualities of users.

3 DATA DESCRIPTION

Our experiments are conducted on a publicly available dataset containing all individual time-stamped actions of Stack Overflow users from the site's inception on July 31, 2008 to June 5, 2018 [33]. Table 1 describes a summary of the general statistics of our data.

Reputation. Reputation[1] scores are officially considered a "rough measurement of how much the community trusts you". Reputation is earned (or lost) when a user's question or answer is upvoted (or downvoted), when an answer is marked accepted by the user who originally asked the question, when bounties are received (or spent), or when suggested edits are accepted.

Badges. Badges are awarded in addition to reputation scores when the corresponding pre-defined set of actions and/or reactions are performed. They can be classified in two primary ways.

[1] https://stackoverflow.com/help/whats-reputation

– *Class-wise:* Bronze class badges are the easiest to obtain, Silver class badges require additional effort and Gold class badges are the hardest to earn. For instance, *Popular Question* is a bronze badge awarded to users when they ask a question that receives at least 1,000 views. *Notable Question* (silver) and *Famous Question* (gold) badges are awarded when the question receives at least 2,500 and 10,000 views respectively.
– *Category-wise:* Categories include Question, Answer, Participation, Moderation, Documentation, Tag and Other. Each category incentivizes users to conduct different kinds of actions. A user can earn multiple category badges as long as the requirements are fulfilled each time. For instance, a user obtains a new Nice Question badge for every question with a score of 10 or more.

Currently, there are 91 different badges[2] available on the site.

Active Users. We define active users as those who have asked at least one question, or have written at least one answer. We only consider these participants for our experiments to reduce the noise introduced by non-active users. Some users create throwaway accounts to ask a question. Our results hold when considering users who created up to 10 posts (questions and answers combined).
We also use other information available such as the time-stamps when users joined the site, number of questions, answers and comments they made, etc. The complete list of fields in the dataset along with detailed descriptions is available here.

4 USER SURVEY

We conducted an online survey of Stack Overflow users to gauge their views about the game elements and the platform in general.

Survey Design. We extracted email addresses of 2,740 users who had voluntarily shared this information in the About Me section of their profile pages on Stack Overflow. We divided these users into three groups based on their reputation scores (low, medium and high). Then, we randomly selected 500 users from each group and sent personalized invitations to participate in the survey. We received a total of 56 responses. Our respondents have a mean of 10 years of experience with coding/programming.
The survey[3] focused on two themes namely, (a) inferences regarding what reputation scores and badges can say about users, and (b) perceived effects of these game elements on the community. We also requested participants to indicate names of specific badges they considered important along with free-text boxes for longer comments, if any. The survey was piloted first.

Survey Results. The general consensus is that Stack Overflow is a good site to get multiple high-quality answers to programming questions. Across the three groups combined, 87% of the respondents either Strongly Agree or Agree with the statement *"Stack Overflow, in general, is more trusted than other communities for programmers."* Respondents felt that reputation scores tend to convey engagement, experience, contributions, helpfulness and knowledge. They consider badges like Good Answer, Popular Question, Pundit, Necromancer and Populist to be important. However, some answers mentioned that they did not consider reputation scores and badges to be important at all. Sixty five percent of respondents agreed with the statement that reputation scores are indicative of helpfulness but only 51% somewhat agreed that they indicate knowledge.

Survey Insights. Users interpret the importance of badges differently, yet badges and reputation scores have a subconscious impact on their future actions [23]. Our survey responses support these results. But they also point towards the question of what user attributes they can signal and to what extent. We focus on the following two attributes:

– *Popularity:* Respondents with low reputation consider reputation scores to be better indicators of user popularity than badges; yet majority of respondents with high reputation only somewhat agree with this statement.
– *Impact:* Fifty one percent of respondents feel that badges are a good measurement of how helpful and knowledgeable a user is (while another 30% somewhat feel the same). A larger majority, 67%, find reputation scores to be good indicators of expertise.

Note, we do not conclude our survey respondents' views to be representative of the entire community. Rather, we use these insights to design hypotheses which we then test empirically on the massive dataset described in Section 3.

5 CHARACTERIZING EFFECTS OF SIGNALS

Our goal is to identify important signals of popularity and impact of users based on their behaviour and actions on Stack Overflow.

Hypotheses. Based on survey insights, we test the following:

H1: Reputation scores and Badges are positively correlated with popularity as well as impact of users.
H2: Reputation scores are better indicators of popularity as well as impact compared to Badges.

Operationalization. To operationalize the two attributes in question, we adopt measures proposed by users, moderators and administrators on Meta Stack Exchange (a sister site for discussions on the workings and policies of Stack Overflow).

– *Popularity Score:* A user's place in the social landscape of Stack Overflow is the result of how they are perceived and how well they are known. We define the perceived popularity of a user to be the total number of distinct views on their profile page.
– *Impact Score:* A user's reach on the site is the number of people who have benefited from the user's actions. We consider the impact score of a user, as defined on Meta Stack Exchange[4], as the sum total views on questions, and answers with non-zero scores that have either been accepted, or are in the top 3 answers, or have a score of at least 5, or have at least 20% of the vote count.

Data Preparation. We preprocess our data as follows; (1) Since the distributions of both popularity and impact scores are heavy-tailed, we z-score transform them to capture the relative variation across users. (2) We create three sets of features namely, control, reputation, and number of badges. The Control Model (CM) consists of features such as number of days since the user joined the site, number of questions asked, number of answers given, etc. The Reputation Model (RM) consists of all the control features and one additional feature, i.e. the reputation score of the user. And the Badges Model (BM) similarly consists of all the control features plus

Table 2: Summary of importances of the exogenous variables for the Control, Reputation and Badges models. Table 2a and Table 2b show the results for predicting the popularity and impact of users, respectively. In each case, we present scores of the five most important badges. The importance values are relative to other exogenous variables within the specific model only.

Features	Control Model	Reputation Model	Badges Model
Age on the site	**0.319**	0.225	**0.191**
Number of questions	0.055	0.074	0.008
Number of answers	0.250	0.047	0.075
Number of upvotes	0.122	0.123	0.021
Number of downvotes	0.115	0.092	0.048
Reputation score		**0.313**	
Nice Answer Badges			0.062
Populist Badges			0.052
Enlightened Badges			0.029
Necromancer Badges			0.039
Good Answer Badges			0.031
	R^2 = 0.911	R^2 = 0.939	R^2 = 0.957

(a) Regression models for predicting Popularity of users.

Features	Control Model	Reputation Model	Badges Model
Age on the site	**0.321**	0.225	0.065
Number of questions	0.129	0.129	0.015
Number of answers	0.250	0.094	0.119
Number of upvotes	0.085	0.067	0.013
Number of downvotes	0.033	0.049	0.006
Reputation score		**0.394**	
Great Answer Badges			0.069
Revival Badges			0.055
Enlightened Badges			0.071
Necromancer Badges			**0.188**
Good Answer Badges			0.043
	R^2 = 0.685	R^2 = 0.767	R^2 = 0.858

(b) Regression models for predicting Impact of users.

one additional feature per badge, i.e. number of each such badges earned by the user (for all 91 badges on the site). We conduct an ablation study to compare their performances.

Model Fitting. We propose a Gradient Tree Boosting Regression model[5] to analyze the fit of the endogenous variable (popularity or impact score) from the exogenous variables (feature sets). We set the maximum tree depth as 3, learning rate as 0.1 and the number of boosted trees to fit as 100. We divide the data into training and testing sets and average the results over 50 runs of the experiment. We validate the model using the R^2 metric. Since it denotes how well the model fits the data points, higher values are better.
We also compute the relative importance scores of the features in each model. This score estimates the improvement in the squared error risk due to each feature compared to that for a constant fit [18]. Specifically, it is the average total decrease in impurity of a node across all trees in the ensemble. Decrease in impurity is the number of times a feature is used to split a node divided by the number of samples that it splits. It thus indicates how useful the feature was in the construction of the boosted decision tree model.

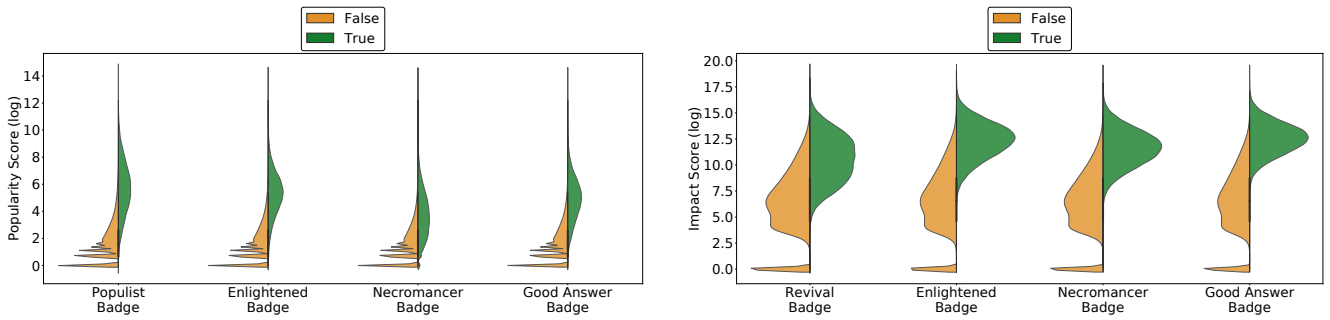
5.1 Signals of Popularity

Results. Table 2a presents the relative feature importances for fitting popularity scores within CM, RM and BM. For brevity, we report only the top five badges ordered according to their importance scores. BM explains 95.7% of the variance, while RM and CM explain 93.9% and 91.1% of the variance respectively.

Analysis. We observe RM provides more explanatory power compared to CM with a small, but significant increase in R^2 scores. This improvement in the model fit is due to the reputation points feature which also has the highest importance score. This indicates that it is a good predictor of popularity. That is, users with high reputation points tend to attract other users to their profile pages.

Notably, BM outperforms with RM and CM in terms of goodness-of-fit. This happens because badges aggregate various sets of actions thereby providing more information than just the reputation score. For instance, the most important badge feature is the number of Nice Answer badges. This badge is earned every time a user provides an answer that receives a score of 10 or more. More generally, we find that the five most important badges are all Answer Badges.

5.2 Signals of Impact



Results. Table 2b similarly presents the performances of the three models in fitting impact scores. CM, RM and BM models achieve R^2 scores of 68.5%, 76.7% and 85.8% respectively. Here too, we find that BM significantly outperforms the other two models.

Analysis. Once again, we find that reputation points are good predictors of impact. Yet, BM improves upon RM and CM because badges capture a more nuanced summary of the user's contribution. Reputation points increase not only due to upvotes on posts, but also on performing other actions such as useful edits, winning bounties, etc. This combines all positive actions into a single score thereby diluting it's effect. Contrasted with BM, consider the number of Necromancer badges earned by the user. A Necromancer[6] badge is awarded on posting an answer to a question at least 60 days after it has been asked and which receives a score of 5 or more. Two answers with the same score, but one written on the same day (say) and another written 60 days after the question was posted represent different value to the community. This is captured by the badge and not the reputation score. It is interesting to note, that once again each of the 5 most important badges are Answer badges.

As we can see in Table 2b, the importance score of the best feature is almost twice that of the next best feature in RM and BM both. But these two models exhibit largely different performance characteristics. Due to the smaller number of features, RM is extremely

[5]The code is available on Github at this url.

[6]https://stackoverflow.com/help/badges/17/necromancer

(a) **Popularity** (b) **Impact**

Figure 1: Distribution of popularity and impact scores of users (in log-scale) in the presence/absence of badges.

fast. BM is slower because it has more features and, in the context of Stack Overflow, they suffer from multi-collinearity. However, BM is more accurate because the ensemble of decision trees is able to separate users that have made helpful contributions on a variety of different metrics of helpfulness.

5.3 Discussion

Hypotheses. Our empirical results on the active Stack Overflow community mostly support our hypotheses and reveal interesting observations. High reputation corresponds with higher popularity and impact. Not all badges are good predictors; Documentation and Other badges show no correlation at all. However, certain Answer badges (such as, Necromancer, Enlightened and Good Answer) tend to be reliable signals. Figure 1 compares the distribution of users along their popularity and impact scores in the presence and absence of badges. This shows that users having these specific answer badges tend to be more popular and impactful than users that do not. The time since the user joined the site is an important signal of impact. And lastly, contrary to the impressions of users in our survey and the subsequent hypothesis (**H2**), badges are better predictors of popularity and impact compared to reputation.

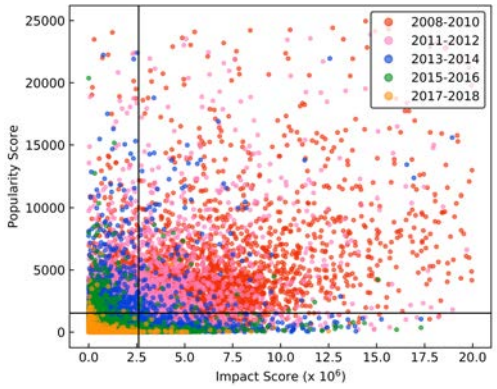
Implications. Broadly useful and important questions can be asked by experienced and novice users alike. But writing impactful answers sometimes requires domain expertise. Different answers to the same question can be helpful to different users or to the same user at different times. Our results indicate that reputation scores seemingly fail to capture such nuances, whereas Answer badges appear adept at doing so. One potential explanation is that answers to some relatively easier questions with long-term value may have been posted during the initial years of the site [2]. Such answers yield a substantially high return on reputation to the original poster. Moreover, there exists evidence to suggest that reputation scores are easier to "farm" than badges through strategies such as writing answers in niche communities, or during off-peak hours [8].

Threats to Validity. We identify three primary threats to the validity of our approach. First, our metrics for computing popularity and impact scores are reductive. They are biased towards estimates of the number of views on profile pages and user posts obtained via internal site analytics. Second, we focus specifically on reward-based features and do not incorporate content-based features. Future work could examine linguistic attributes of posts that affect performance. Third, past evidence [17, 25] has shown that women have faced significant barriers to participating on the site. This suggests that game elements may be biased against some users. Thus, we advise caution in inferring broader interpretations of our results since we do not guarantee whether the positive links between badges and user attributes are causal or not.

6 DIFFERENTIATING POPULAR AND IMPACTFUL USERS

We now ask whether these game elements act as *differentiating signals* between popular and impactful users, and if so, why.

Thematic Representation of Users. Figure 2 depicts user distribution along two axes, popularity and impact. Time since the user joined the site is strongly associated with their standing in the community. As expected, a large concentration of users have low popularity and impact. Most new users along with a large fraction of the older users belong to this category. On the other hand, most highly popular and impactful users joined during the early years.



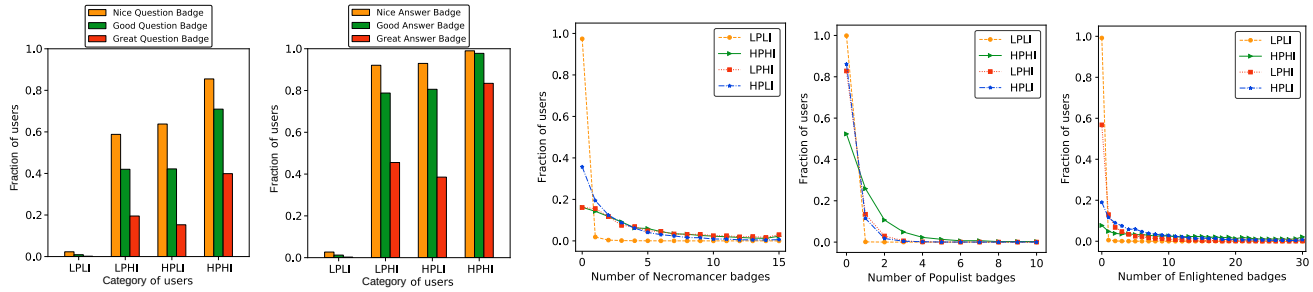


Figure 2: Distribution of users across popularity and impact scores based on the year in which they joined Stack Overflow. The horizontal and vertical black lines segment the population into the top 0.1%.

We segment users into four groups based on whether or not they belong to the top 0.1% of the community along the two social attributes: (a) high popularity, high impact (HPHI), (b) high popularity,

(a) **Fraction of users with badges for high scoring questions** (b) **Fraction of users with badges for high scoring answers** (c) **Distribution of number of Necromancer badges earned** (d) **Distribution of number of Populist badges earned** (e) **Distribution of number of Enlightened badges earned**

Figure 3: Relationship of LPLI, HPLI, LPHI and HPHI users to badges earned. Figures 3a and 3b study the presence of good quality question and answer badges among the different groups. Figures 3c, 3d and 3e depict the fraction of users in different communities that have earned multiple Necromancer, Populist and Enlightened badges.

low impact (HPLI), (c) low popularity, high impact (LPHI), (d) low popularity, low impact (LPLI). This segmentation is represented by the horizontal and vertical black lines in Figure 2. HPHI have mean popularity and impacts scores of 13,134 and 11,972,950 respectively, whereas LPLI have mean scores of 23 and 35,081 respectively. This shows the vast gulf between the two groups.

Figures 3a and 3b show the fraction of users belonging to each of the four categories HPHI, HPLI, LPHI and LPLI that have the particular badge. Interestingly, more LPHI, HPLI and HPHI users have badges for well-received answers (such as Nice Answer Badge) than they do for well-received questions (such as Nice Question Badge). Figures 3c, 3d and 3e display the distribution of the number of Necromancer, Populist and Enlightened badges earned by the four groups of users respectively. Consider the case of the Enlightened badge. We see that nearly 60% of LPHI users have zero Enlightened badges whereas only about 20% of HPLI users do not have that badge. We argue that there must be meaningful explanations that can be learned by comparing between these two groups.

Table 3: Differentiating between HPLI and LPHI users. ** = p < 0.01, *** = p < 0.001 represents statistical significance of Welch's t-statistic after Bonferroni correction ($p/14$).

Feature	HPLI	LPHI	t-statistic	Sig
Questions	54.65	42.02	-6.23	***
Answers	452.63	137.89	-39.97	***
Question Scores	233.15	286.61	4.38	**
Answer Scores	1190.07	679.83	-24.09	***
Reputation	16304.64	8672.31	-30.20	***
Necromancer Badges	2.47	6.32	29.6	***
Populist Badges	0.174	0.218	4.041	**
Great Answer Badges	0.682	0.887	7.84	***

We therefore examine HPLI and LPHI users and expect there to be differences in the way they contribute as well as reception to their contributions. Using Welch's t-test, we study the differences present between these two groups and present the features with the most significant differences between them in Table 3. We find that the number of questions and answers posted are significantly higher among HPLI, reflecting that they are more active. Conversely, the number of Necromancer, Populist and Great Answer Badges are higher for LPHI users. These badges appear to be signals that are costly to earn but not easily observable. Site design dictates that upvotes on answers return double the reputation points compared to upvotes on questions. Our findings show that LPHI users have a proportionally higher number of question and answer posts/scores. This implies that answers drive popularity, but it is questions that offer more influence. Further, some users link their SO accounts with other platforms such as LinkedIn, Github, etc. that may explain why they may be better known [1]. This is another potential source of divergence between high popularity and high impact.

7 CONCLUSION

The diverse range of actions and users, and massive quantity of content on Stack Overflow obfuscates the quality of information and efficiency of deliverables. It increases the transaction costs of participation. Game elements such as badges and reputation scores aim to provide incentives to balance these costs. But the design of these incentive structures has led to problems of adverse selection. In this paper, we present evidence that some of these game elements also act as reliable digital signals of social qualities such as popularity and impact. Our experiments reveal that certain non-trivial answer badges, high reputation scores and age of the user on the site indicate significant correlations. We also find differentiating characteristics that distinguish communities of popular and impactful users. We believe these insights offer guidance on combating inefficiencies arising out of bias towards specific actions. Our results encourage further exploration of the role of game elements as symbols of social status in socio-technical systems.

8 ACKNOWLEDGEMENTS

We thank Indira Sen, Shubham Singh, Shwetanshu Singh, and Srishti Aggarwal for useful discussions and the anonymous reviewers for detailed, helpful comments. We thank Language Technologies Research Centre (LTRC, IIIT-H) and Precog (IIIT-D) for their support. We are grateful to the respondents of our survey and to Stack Overflow for releasing their data publicly.

ABSTRACT

Knowledge Graphs (KGs) have been proven to be incredibly useful for enriching semantic Web search results and allowing queries with a well-defined result set. In recent years much attention has been given to the task of inferring missing facts based on existing facts in a KG. Approaches have also been proposed for inferring types of entities, however these are successful in common types such as 'Person', 'Movie', or 'Actor'. There is still a large gap, however, in the inference of fine-grained types which are highly important for exploring specific lists and collections within web search. Generally there are also relatively fewer observed instances of fine-grained types present to train in KGs, and this poses challenges for the development of effective approaches. In order to address the issue, this paper proposes a new approach to the fine-grained type inference problem. This new approach is explicitly modeled for leveraging domain knowledge and utilizing additional data outside KG, that improves performance in fine-grained type inference. Further improvements in efficiency are achieved by extending the model to probabilistic inference based on entity similarity and typed class classification. We conduct extensive experiments on type triple classification and entity prediction tasks on Freebase FB15K benchmark dataset. The experiment results show that the proposed model outperforms the state-of-the-art approaches for type inference in KG, and achieves high performance results in many-to-one relation in predicting tail for KG completion task.

1 INTRODUCTION

Knowledge Graphs (KGs) mainly describe real-world objects and their interrelations in various topical domains by organized in graphs. KGs are web-scale probabilistic knowledge bases that store billions of facts about people, places, and things that are often represented in the form of a triplet (head entity, relation, tail entity). The way KGs are enriching information about the real worlds objects and connections by combine extractions from web contents (obtained via analysis of text, tabular data, page structure, and human annotations) with prior knowledge derived from existing knowledge repositories [42] [47]. Examples of prominent large-scale KGs are Yago [54] [28] [11], Freebase [16] [3], DBpedia [14] [37] [1], NELL [20] [5], Google's Knowledge Graph, Microsoft's Satori, Probase [7] , and Google Knowledge Vault [27]. These KGs have become powerful assets for improving Web search by providing richer data for Entity Pane, Carousel, and Facts Across Segments in the search panel. Additionally, KGs are becoming important resources for different Artificial Intelligence (AI) and Natural Language Processing (NLP) applications. Despite their seemingly large size, these knowledge graphs are still incomplete with missing information, such as type, properties, and relations [42] [47] [23] [57] [63] [50].

Types in KG are used to express the concept of classes. According to KG idiomatic usage, a KG object "has X, Y, Z types" is equivalent to an object "is a member of the X, Y, Z classes". In the case of U.S. President Barack Obama, the KG object for Obama would have the types *person* and *US president* to indicate that the object is a member of the Persons and U.S. Presidents. Fine-grained types are sub-classes of type classes in KG. For example, a type class *'Actor'* may has *American Actor, Film Actor, TV Actor, Hollywood Actor, Female Actor, Voice Actor* or *Comedy Actor* sub classes. The Actor typed entities in KG are therefore can be further defined with these fine-grained types.

Defining fine-grained types of entities in KG allows Web search queries with a well-defined result set. When someone doing a search on the web, the search engines need to understand the words what they refer to real-world things, and by this, search engines can do a better search with just the contents when someone looks up on the web. The types of entities in KG provide the meaning of

the words, such as building is a building object and animal are animal objects; they are not just a random string of characters. Fine-grained typed entities and entities with complete set of types in KG, make possible to explore lists and collections with web searching by 'Knowledge Graph Carousel' in popular search engines. For example, you can explore, how many woman won the Noble prize? or list of Renaissance painters.

Type inference is concerned with inferring the existence (or probability of existence) of missing types for instances (objects or entities) in KGs. In a KG, not every entity may come with proper type information. Untyped entities and entities with incomplete set of types are a common problem in Semantic Web KGs [42] [47]. In recent years much attention has been observed in KG completion task that automatically infer missing facts based on existing facts in a KG [23] [57]. Approaches have also been proposed for inferring types of entities, however these are successful in common types such as 'Person', 'Movie', or 'Actor'. There is still a large gap, however, in the inference of fine-grained types which are highly important for exploring specific lists and collections within web search. Generally, very limited numbers of observed fine-grained types data (RDF-triples with fine-grained type information) present in KGs, and this poses a high challenge in developing approaches for inferring entities of the fine-grained types.

This paper proposes a new approach based on a tensor model for fine-grained type inference. This new approach is explicitly modeled for leveraging domain knowledge and utilizing additional data outside KG, that allows a ranked representation for type inference and result in richer data for tensor factorization. Further improvements in efficiency are achieved by extending the model to *probabilistic inference* based on entity similarity and typed class classification. We evaluate our approach with two standard evaluation tasks *type triple classification* and *entity prediction* on benchmark dataset Freebase FB15K dataset [4] and FB15K-237 Knowledge Base Completion Dataset [2]. The experiment results show the proposed model outperforms the state-of-the-art approaches for type inference in KG (10% to 19% on different fine-grained types compare to Rescal [43]), and achieve high results in many-to-one relation in predicting tail for KG completion task.

2 RELATED WORK

Given the importance of missing type assertions task, there are some approaches based on *Reasoning*, *Probabilistic Method* [49], *Hierarchical Classification Approach* [40] [41] [60], *Association Rule Mining* [32] [46], *Topic Modelling* [52], *Support Vector Machine (SVM)* [51], *k-nearest neighbors classifier (KNN)* [45], and *Tensor Factorization* [44] have been proposed and applied on different in KGs are summarized in Table 1. All approaches have merits and demerits in performance for missing type assertions task in KG.

In [52],the use of *Topic Modeling* for type prediction is proposed. Entities in a KG are represented as documents, on which *Latent Dirichlet Allocation (LDA)* [15] is applied for finding topics. In [45], [51] authors exploit interlinks between the KGs, and Wikipedia predict types in a KG. In [46], exploit such association rules to predict missing types in DBpedia based on redundancies different type systems of KGs. As topics, the interlinks and the type redundancies between KGs can only be covered limited associated top level types, these approaches are not capable for fine-grained type inference.

Some approaches have been proposed for type inference in KG such as SDType [49] a heuristic approach, SNCN [41], a hierarchical classification approach. Since SDType is based on statistical method and there are not enough facts exits in KG for fine-grained types [48], [49], this approach is not capable to produce meaningful results in predicting fine-grained types. Fine-grained types basically are not systematically structured with a type hierarchy in KGs and SNCN relay on the hierarchical type structure in KG, this approach is therefore not efficient in fine-grained type inference. Besides, some KGs (such as Freebase) are not systematically structured with a type hierarchy, in this case, this approach is not useful for this task. Though, SDType, and SNCN algorithm is successful in predicting higher-level classes (Actor), while predicting fine-grained classes (such as VoiceActor or AmericanActor) is much more difficult. None of these methods are able to capture the interactions of latent features that obtain probabilistic likelihoods of type-relations existing between entities (objects) in KG. Tensor modeling, a well-known approach to represent and analyze latent relationships inherent in multi-dimensional data [35].

RESCAL [43] [44] is the state-of-the-art method for link prediction and type inference in KGs that has been used for type inference on YAGO [11] entire KG [44]. Though, RESCAL has been achieved good performance among the state-of-the-art approaches for type inference in KG, the performance of type inference (fine-grained types) are significantly lower than the performance of top level (common) types in KG. Furthermore, this method and other existing methods for type inference in KG are not able to utilize the domain knowledge in KG and the additional sources of information outside of KG. However, for type inference in KG, it has not been explored that the utilization of additional sources of information by combining knowledge base and text. Our approach is based on tensor factorization method which is specially designed for fine-grained type inference in KG. This approach is able to capture interactions of entities outside of KG and to learn type-domain knowledge in KG. Furthermore, this model is designed to learn type hierarchy structure and similarities of entities for type; and utilize these information to improve fine-grained type inference results in KG.

3 UTILIZING ADDITIONAL DATA

Semantic Web KGs are represented in the form of the Resource Description Framework (RDF) [8] triples <*subject, predicate, object*>, where the subject and object are entities and the predicate is the relation type, (e.g. <*Steve Jobs, founderOf, Apple*>). Uniform Resource Identifier (URI) uniquely identifying each entity in Semantic Web KGs. For instance, entity *Donald Trump* can be found as *http://dbpedia.org/page/Donald_Trump* in DBpedia, and as *https://en.wikipedia.org/wiki/Donald_Trump* in Wikipedia. Every entity in Semantic Web KGs (e.g. DBpedia or Freebase) has anchor link to Wikipedia page, where a document of information is available for an associated entity.

Each entity in Freebase is uniquely identified by a MID (Machine ID). For instance, */m/0cqt90* as MID is used for *Donald Trump* entity. Using MID and the predicate *http://www.w3.org/2002/07/owl#sameAs*

for each entity in Freebase, we can issue a SPARQL query to retrieve the corresponding DBpedia, or Wikipedia URIs. For example, Donald Trump, the current President of USA, is mapped via the triple by SPARQL query. The texts (information) available for an associated entity can be represented as full lexicalized dependency paths. For instance, the entity in KG such as *Donald Trump*, or *United States* has textual information in Wikipedia page, or other online news repositories (e.g. New York Times or ClueWeb), as illustrated in Fig 1.

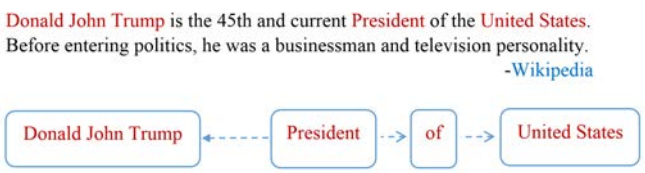

Figure 1: A full lexicalized dependency path from textual data.

Figure 1 shows the lexicalized dependency path between two entities that occur together in a sentence. An instance of textual relation of type "<nsubj> president <prep> of <obj> United States", corresponding to the sentence is added as additional data based on this occurrence. These full lexicalized dependency path from textual data are used as relations between Freebase entities by mapping with MID. For instance, the entity */m/0cqt90* (Donald Trump) in RDF triple relationship in Freebase as: (*/m/0cqt90, <President_of>, /m/01kw0b*). In addition to KG some other relations can be obtained from other sources by mapping MID. Relations connected to entity */m/0cqt90* (MID) from additional data sources (see in Fig 2). Relations come from additional data sources (outside from KG) may be useful information about entities in KG. From modelling perspective, tensor representations are appealing to RDF KGs because they provide an elegant way to represent multiple RDF triples.

We propose the *weighted-tensor* interpretation scheme to effectively model KG and text-based data for constructing the tensor. Without applying weight in tensor construction, the objective function would place equal importance on fitting both observed and unobserved values. As KGs are typically very large scale, and constructed tensors are therefore often very sparse, this will result in fitting a large number of unobserved data and uncertainty in the observations. The weighting tensor prevents this from happening by emphasizing only the observed (or certain) entries. Each RDF triples in KG expresses facts (complete meaningful information) about real world object, and whereas each text based triples provides less important facts (auxiliary information) about the real world object. The observed data for factorization is therefore obtained from combination of KG and other dataset which contains textual relations. The interpretation of RDF KG can be interpreted as a tensor, where first mode of a tensor therefore models the occurrences of all entities as a subject, the second mode models the occurrences of all entities as an object, and the third mode models the different relations. The incorporation of additional data for type inference in KG becomes possible via a tensor factorization model where KG and additional data consisting of e entities and r different relations can then be represented in form of a tensor $X \in R^{e \times e \times r}$ with entities

$$X_{i,j,k} = \begin{cases} 2, & \text{if the relationship } r_k(e_i; e_j) \text{ exists in KG.} \\ 1, & \text{if the relationship } r_k(e_i; e_j) \text{ exists in additional data.} \\ 0, & \text{otherwise.} \end{cases} \tag{1}$$

The values ('2' and '1') and ('0') of X_{ijk} come from tensor model are regarded as observed and un-observed data respectively for tensor factorization. Weighting the tensor by this scheme allows a ranked representation for type inference and result in richer data for tensor factorization, that leads to an improvement in efficiency for fine-grained type inference.

4 LEVERAGING DOMAIN KNOWLEDGE

Most KGs store facts about real-world objects covering only numbers of specific domains (e.g. *"Movie"*, *"Book"*, or *"Place"*). For instance, types in KG such as *actor, film, director,* or *producer* and fine-grained types such as *filmActor, TVActor, regularActor, guestActor, executiveDirector, AssistantProducer* are in *"film"* domain. Given the importance the fine-grained inference task in KG, typed entities (objects) for given fine-grained types in one domain (such as *"film"* domain) are less likely to be entities in other domains (such as *"book"*, or *"place"*). For instance, inferring entities for fine-grained types (such as regularActor, guestActor) would be a typed in Actor, those entities generally are in same domain in KG.

The collaborative activities between the entities in *"film"* domain are therefore higher importance for fine-grained type inference in this domain. However, interactions among entities with different relation types can be among different domains as well, as types of entities in KG may be come from different domains. Domain information can be obtained from KG, such as in Freebase each relation start with domain e.g. */film/film/starring/film/performance/actor*, and */tv/tv_program/regular_cast/tv/regular_tv_appearance/actor*; in DBPedia domain information can be found in the property of a relation by SPARQL [9] query with *http://www.w3.org/1999/02/22-rdf-syntax-ns#Property*. For example, a set of actor typed entities can be a set of author typed where these entities are involved with different domains. Ignoring these information (inter-domains collaboration activities of entities) may effect on latent features learning by factorization. Modelling domain knowledge (the interactions of entities in the domain, and inter-domins) is therefore prevents this happening and leverages the domain information in factorization for an improvement in fine-grained type inference.

We propose the *domain-relevance weighted tensor (DrWT)* method for fine-grained type inference, that explicitly model a mapping from the domain-based representation to the observed tensor in factorization. Given the KG and additional data along with list of labelled domain, *DrTW* classifies the entries correspondence to the domains in KG and additional dataset.

DrWT Algorithm:

Input: *Knowledge Graph* $G = (D, E, R)$*; where set* D *is a set of domains in KG,* $D = \{d_1, ..., d_{|d|}\}$*; set* E *is a set of entities (objects),* $E = \{e_1, ..., e_{|e|}\}$*, and* E_s *as subject set of entities which occur as subject in relation links, where* $E_s \in E$*; and and* E_o *as object set of entities which occur as object in relation links where* $\{E_o \in E\}$ *and, the set* R *is a set of relations (Predicates) between entities,* $R = \{r_1, ..., r_{|r|}\}$.

Output: set ∇T_d is a list of triples $<< (E_s)_i, (R)_i, (E_o)_i >>$ for each $d_i \in D$ (Domains)
Start
01: **function** DomainRelevance (D, E, R)
02: $d \leftarrow domain$
03: **for each** $r_i \in R$ **do**
04: **for each** $r_i \in d$ **do**
05: $source\ (e_s) : R \rightarrow E_s$ ▷ return source(e)
06: $target\ (e_o) : R \rightarrow E_o$ ▷ return target(e)
07: $e_d \leftarrow (e_s \cup e_o)$
08: **while** $e_i \in e_d$ OR $r_i \in d$ **do**
09: $T_d \leftarrow$ SELECT-TRIPLES $\{(e_s)_i, (r)_i, (e_o)_i\}$
10: **end while**
11: $\nabla T_d \leftarrow T_d$
12: **end for**
13: **end for**
14: **end function**

Applying *DrWT* the populated tensor is then represented the collaborative activities of the type domain can be modelled subject, object, predicate and domain in 4th-order tensor presentation. Once the 4th-order tensor representations are constructed applying DrWTF method, the next steps is latent factors generation via tensor factorization, where tensor factorization technique is applied to learn effectively the latent factors for fine-grained type inference.

5 FINE-GRAINED TYPE INFERENCE WITH TENSOR MODEL

We use CP [21] [30] based *4th-order Tensor Factorization* for deriving the latent relationships between dimensions of the tensor model. After latent factors generation via tensor factorization, we therefore follow *tensor reconstruction* process to reveal new entries that are inferred from the latent factors. the *4th-order Tensor Factorization* model, CP factorizes each forth-order domain-relevance weighted tensor $\mathcal{X} \in \mathbb{R}^{S \times O \times P \times D}$, can be formulated as

$$f(\mathbf{E}, \mathbf{F}, \mathbf{G}, \mathbf{H}) = \|\mathcal{X} - \mathbf{E}, \mathbf{F}, \mathbf{G}, \mathbf{H}\|^2 \tag{2}$$

where $\mathcal{X}$ is factorized using a CP model on each mode-n matricization and results in four latent factors matrices, $\mathbf{E} \in \mathbb{R}^{S \times R}$, $\mathbf{F} \in \mathbb{R}^{O \times R}$, $\mathbf{G} \in \mathbb{R}^{P \times R}$ and $\mathbf{H} \in \mathbb{R}^{D \times R}$ corresponding to the each dimensions of tensor $\mathcal{X}$. R is the column size of the corresponding latent factor matrices; S, O, P and D are denoted as *Subject, Object, Predicate* and *Domain* of entries to tensor. The diagonal core tensor $\hat{\mathcal{C}} \in \mathbb{R}^{R \times R \times R \times R}$, that defines the interaction between the *Subject, Object, Predicate* and *Domain* can be calculated by multiplying all the latent factors. Afterwords, the reconstructed tensor $\hat{\mathcal{X}}$ is derived multiplying the core tensor by all latent factor matrices:

$$\hat{\mathcal{X}} := \hat{\mathcal{C}} \times_s \hat{\mathbf{E}} \times_p \hat{\mathbf{F}} \times_o \hat{\mathbf{G}} \times_d \hat{\mathbf{H}} \tag{3}$$

Where the core tensor $\hat{\mathcal{C}}$ and the feature matrices $\hat{\mathbf{E}}$, $\hat{\mathbf{F}}$, $\hat{\mathbf{G}}$ and $\hat{\mathbf{H}}$ are the model parameters that have to be learned and $\mathcal{X}$ is the tensor product to multiply a matrix on dimension x with a tensor.

The task of fine-grained type inference in KG is to infer which subject entities (s) of a type relation (p) is missing to object entity (o). That means that the model has to infer from the values of $\hat{x}_{s,p,o,d}$ of the domain tensor $\hat{\mathcal{X}}$ (from equation no. 5). Instead of inferring single element (subject entities) from $\hat{\mathcal{X}}$, this model provides a list of best possible (ranked) elements (subject entities) of a fine-grained type relation. Given a reconstructed tensor $\hat{\mathcal{X}}$ the list of top of the N highest scoring entities for a given fine-grained type relation (p) and an object entity (o)

$$Top(N, p, o, d) := argmax^N_{t \in T}\{\hat{x}_{s,p,o,d}\} \tag{4}$$

To infer entities for fine-grained type inference, we define appropriate thresholds for each of fine-grained type relations. These thresholds are therefore used as metric in the inference model so that the missing entries can be regarded as either "relevant" (score higher than the threshold) or "irrelevant" (score lower than the threshold) entries from the revealed new entries that are inferred from the latent factors. In order to further improve the performance of inference to the missing entities for fine-grained types, the inference model is extended to *probabilistic inference* approach with multilabel classification of type classes.

5.1 Probabilistic Inference with Collective Multilevel Type Classification and Typed Entity Similarity

The probabilistic inference in an alternative approach to define the probability of one set typed entities to be other fine-grained typed by observing data from classification of type classes, and the latent similarity of entities in KG. In this case, the list of fine-grained types is ranked and generated based on the probability score of an entity to select candidate entities, in which the entity typed classes, and entity similarity to the fine-grained type classes are taken into account. The underlying idea of probabilistic ranking is that collective multilabel classification of entities where entities are allowed to have more than one class types and related entities often share identical classes in RDF KG. For instance, en entity of *Actor* typed is also typed of *Artist, Person,* and *Thing* classes (see in Fig. 2). Fine-grained type inference further can be cast as a multilabel

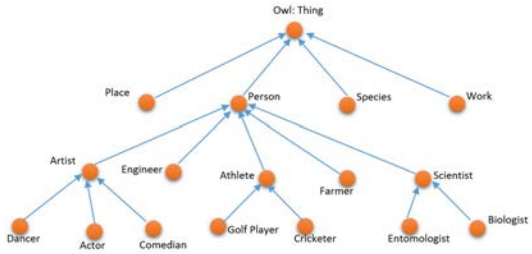

Figure 2: A part of DBPedia type hierarchy.

classification problem, by introducing type classes as entities to the data, and inferring the probability of relationships *rdf-type*.

As RDF KG is multi-relational data, the similarity of entities is therefore determined by the similarity of their relationships, following the intuition that "if two objects are in the same relation to the same object, this is evidence that they may be the same object" The collaborative activities of entities as subjects $\mathbf{A_s} \in \mathbb{R}^{S \times P}$ and objects $\mathbf{A_o} \in \mathbb{R}^{O \times P}$ in relations in a domain can be modelled by the entity matrix $\hat{\mathbf{A}}$, where $\hat{\mathbf{A}}$, is QR matrix factorization [22] [29] of $\sum(A_s + A_o)$. For each domain the the latent space $\hat{\mathbf{A}}$ therefore

reflects the similarity of entities in the relational domain. The type or fine-grained type classes set $C_e = \{t_1, t_2, t_3, ...t_n\}$ where C_e is a set of Types in one KG. A list of type or fine-grained type classes that are considered for given fine-grained type. For each fine-grained type in C_e the candidate entities set, $\hat{E}_t = \{\hat{e}_1, \hat{e}_2, \hat{e}_3, ...\hat{e}_n\}$ where E_t is a set of typed entities in one KG.

We use the Bayes' theorem [26] [61] for predicting the class candidate entity E_t that have the highest posterior probability given C_e, $p(C_e|E_t)$. The posterior probability is utilized to calculate the preference probability of an entity e to be fine-grained typed t in C_e type classes by observing current type classes of entity e, and latent similarity of entity e to fine-grained typed entity. The conditional probability can be formulated as:

$$p(C_e|E_t) = \frac{p(E_t|C_e)p(C_e)}{p(E_t)} \tag{5}$$

where *prior probability* $p(C_e)$ is the prior distributions of parameter set C_e in a single domain before E_t is observed, that is relative frequency with which observations from that class occur in a population. Generally, prior probability for fine-grained type classes are lower compared to top level type classes in KG. $p(C_e|E_t)$ is the joint probability of observing type class preference set C_e given E_t, and entity similarity preference given fine-grained type t. Using the assumption of multinomial event model distribution for the Naive Bayes classifier, the posterior probability p_{e_n,t_r} for fine-grained type t_e with fine-grained type class C_e for candidate entity e_n, an instance of E_t, is obtained by multiplying the *prior probability* of t_e, $P(C_e = t_e)$, with the probability of preference candidate entity e_n, an instance of E_t, given t_e, $P(e_n|C_e = t_e)$:

$$p_{e_n,t_e} = p(t_e|C_e) = \sum_{t=1}^{|C_e|} P(e_n|C_e = t_e) \prod_{\hat{e}=1}^{|\hat{E}_e|} P(\hat{E}_e|C_e) \tag{6}$$

where, $P(\hat{E}_e|C_e)$ is probability of likelihood for t_e in C_e, is derived from the entities set, $\hat{E}_t = \{\hat{e}_1, \hat{e}_2, \hat{e}_3, ...\hat{e}_n\}$ where values from reconstructed tensor $\hat{X}$, and entity similarity values from $\hat{A}$ are used.

Algorithm: Probabilistic Inference

Input: *Initial tensor* $\mathbf{X} \in \mathbb{R}^{S \times O \times P \times D}$, *reconstructed tensor* $\hat{X}$, *the type or fine-grained type classes set* $C_e = \{t_1, t_2, t_3, ...t_n\}$, *and number N rank list for top candidate entities.*

Output: *A list of top entities set* $\nabla\hat{E}_t$ *for each fine-grained type* t_i.

Start:

01: Get the candidate entities set $\hat{E}_t = \{\hat{e}_1, \hat{e}_2, \hat{e}_3, ...\hat{e}_n\}$:

$\hat{E}_t \leftarrow \{\hat{X} \,|(t_i \in \hat{X}$ AND $t_i \in C_e)$ AND $(\hat{X} \leftarrow \hat{x}_{s,p,o,d})\}$

02: Get the similarity of entities set $\hat{A}_{e(t)} = \{\hat{a}_1, \hat{a}_2, \hat{a}_3, ...\hat{a}_n\}$:

$\hat{A}_{e(t)} \leftarrow \{\hat{A} \,|(e(t)_i \in \hat{A}$ AND $e(t)_i \in \hat{X})\}$

03: ***function*** CalculatePosteriorProbability $(\hat{X}, \hat{E}_t, \hat{A}_{e(t)}, N)$

04: ***while*** $e_i \in \hat{E}_t$ ***do***

05: $p_{e_n,t_e} \leftarrow p(t_e|C_e)$ ▷ *from Equation no.* (9) *where,* $P(\hat{E}_e|C_e)$ *is probability of likelihood for* t_e *in* C_e

06: ***end while***

07: ***for*** $n \leftarrow 1toN$ ***do***

08: $\hat{E}_t \leftarrow argmax^N_{e_i \in \hat{E}_t} \{p_{e_n,t_e}\}$

09: ***if*** $n \leftarrow 1toN$ ***do***

10: ***end for***

11: $\nabla\hat{E}_t \leftarrow \hat{E}_t$

14: ***end function***

Further accuracy improvements are therefore achieved by extending the inference model by probabilistic inference with collective multilevel type classification and typed entity similarity.

6 EMPIRICAL EVALUATION

We evaluate our approach on Freebase FB15K dataset [4] and FB15K-237 Knowledge Base Completion Dataset [2] (see Table 1). Freebase [16] [3] is a large collaborative knowledge base consists of a large number of the world facts, such as triplets (*Donald Trump, PresidentOf, United States*) and (*Johnny Depp, profession, actor*). The FB15K (Bordes et al. 2013), is a subset of Freebase which has been commonly used to evaluate various KG completion models [18] [58] [39] [39] [33] [38] [31] [59]. In the FB15K-237 Knowledge Base Completion Dataset, the triples (entity- textual-entity) are derived from 200 million sentences from the ClueWeb12 corpus coupled with Freebase entity. There are around 3.9 million text descriptions corresponding to the relation types in Freebase. The FB15K-237 dataset has been used in [56] [55] [62] for embedding representations for textual relations with Freebase entity mention annotations.

Table 1: Datesets used in the experiments.

Datasets	# Entities	# Relations	# Triples
FB15K	14,951	1,345	486,641
FB15K-327	14,951	2,766,477	3,977,677

For implementation, we use *tensor-toolbox* [10] and *poblano-toolbox* [6] in Matlab. We apply *weighted tensor scheme* in constructing tensor where the tensor size (14951 x 14951 x 2,767,822) with 486541 entries from KG (FB15K); and 4460819 entries from textual dataset (FB15K-237). We then apply *domain-relevance weighted tensor (DrWT)* to construct 4th order tensor with domain entries, where the tensor size (14951 x 14951 x 2,767,822 x 52) . We use CP [21] [30] based *4th-order Tensor Factorization* for the latent factor generation, and use CP-ALS algorithm [24] [34] [25] for computing tensor factorization. Since domain information is not depended in one other dimension of the tensor, we use 4th order tensor factorization instead of using *Coupled Matrix Tensor Factorization (CMTF)* [12] [13]. We also apply *non-negativity constrain* [36] for effectively interpreting factor components from tensor factorization.

Two standard tasks, *Entity Prediction* and *Type Triple Classification* as are proposed to evaluate our approach for fine-grained type inference. The triple classification task e.g. type triple classification for fine-grained type which was first introduced by by Socher et al in [53]. The link prediction task which is standard task for KG completion evaluation e.g entity inference for fine-grained type, was first introduced by Bordes et al. in [18]. Since then these standard tasks have been used to evaluate various KG completion models, such as Rescal [43], TransE [18], TransH [58], TransR [39], CTransR [39], TransD [33], PTransE [38], and KG2E [31].

6.1 Type Triple Classification Task

We evaluate our approach with *Type Triple Classification* aims to judge whether a given triplet (h, r, t) with fine-grained type relation

is correct or not, which is a binary classification task. In FB15K, types of a person entity can be obtained from a triples by both (/people/person/profession) relation and by (/people/profession/people_with_his_profession) relation. Fig. 10 shows some different type triplets distributions with both relations in *Film, Television,* and *Music* domains in FB15K.

We evaluate our approach by type triple classification task on FB15K with six general types and eight fine-grained types in three different domains: *'Film'*, *'TV'* and *'Music'* with the relevant state-of-the-art method RESCAL [43] [44]. As we have mentioned previous section, RESCAL has been achieved good performance among the state-of-the-art approaches for type inference in KG [44]. As SDType [49] and SNCN [41] are not latent factor model, we can not directly compare our model with them.

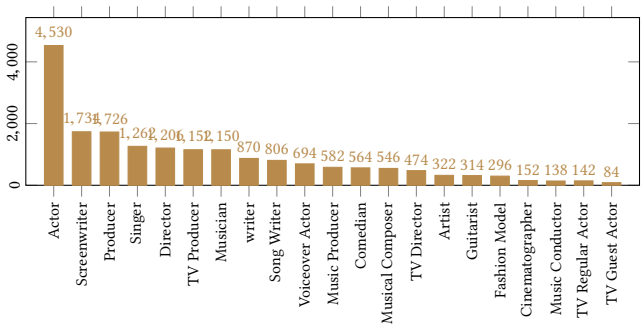

Figure 3: Different Type Triplets Distributions in FB15K.

Evaluation protocol. We follow the same protocol introduced by Socher et al in NTN [53]. Evaluation of classification needs negative labels. As FB15k has not released negative triples in previous works, we construct negative triples by corrupting the corresponding positive (observed) triples. This is followed with the same procedure used in [53]. Dissimilarity between triple and typed triple classifications is that, we only consider to corrupt observed triples that convey types or fine-grained types of entities as shown in Fig. 3. Corrupting observed triples for all relations is not required experiment for evaluation to our approach, as it is out of the scope of this work. The decision rule for classification is simple: for each type triple (h; r; t), if the similarity score (obtained by the models) is below a relation-specific threshold T, then the triple will be classified as positive. Otherwise, it will be classified as negative.

Discussion. From Table 2, we can see that our approach outperforms RESCAL significantly in all the reported top level types and fine-grained types. Some observations are as follows:

(a) From top class types, we can see that both RESCAL and our approach have achieved very high performance results for inferring *actor* type on FB15K. This is because high number of observed triples with actor type object (see Fig. 10), and therefore associated other relationships to actor type object present in FB15K, that positively impact both models for correctly scoring positive and negative triples.

(b) However, from fine-grained class types, we can see that our approach improves results for *Film Actor* and *TV Actor* significantly (11%) and (16%) respectively. Since *Film Actor* and *TV Actor* are in different domains (Film and TV), these domain entries for corresponding triples to the tensor model is defined by DrWT method. This prevents bias scoring positive and negative triples for *Film Actor* to *TV Actor* and vice-versa. Similar effect by DrWT method on results for *TV Director* and *TV Producer* fine-grained type inference.

(c) From fine-grained class types, we can see that our approach our approach significantly outperforms Rescal for *Regular TV Actor* and *Guest TV Actor* where very less number of observed triples with these fine-grained types object present in FB15K (see Fig. 10).

Table 2: Types Inference Comparison with RESCAL

Top Class Types		
	RESCAL	**Our Approach**
Actor	98.0	99.0
Director	90.0	96.0
Producer	89.0	93.0
Musician	78.0	89.0
Singer	74.0	81.0
Writer	70.0	76.0
Fine-grained Types		
	RESCAL	**Our Approach**
TV Director	82.0	91.0
Voiceover Actor	60.0	79.0
Song Writer	79.0	88.0
TV Producer	81.0	90.0
Film Actor	87.0	98.0
TV Actor	77.0	93.0
Regular TV Actor	58.0	78.0
Guest TV Actor	49.0	68.0

6.2 Entity Prediction Task

Entity prediction aims to predict the missing head (h) or tail (t) entity given relation type (r) and other entity, i.e. predicting h given (?; r; t) or predicting t given (h; r; ?) where ? denotes the missing element. In this task, for each position of missing entity, the system emphasizes more on ranking a set of candidate entities from the KG, instead of only giving one best result. In testing phase, for each test triple (h; r; t), we replace the head/tail entity by all entities in the KG, and rank these entities in descending order of similarity scores calculated by the models.

In FB15K, relations can be categorized according to the cardinalities of their head and tail arguments into four classes: one-to-one, one-to-many, many-to-one, and many-to-many. A given relationship is one-to-one if a head can appear with at most one tail, one-to-many if a head can appear with many tails, many-to-one if many heads can appear with the same tail, or many-to-many if multiple heads can appear with multiple tails (see in Table 3).
Evaluation protocol. We follow the same protocol in TransE [18]: For each testing triplet (h; r; t), we replace the tail t by every entity e (14951 in FB15K) in the KG and calculate a similarity score obtained by the model on the corrupted triple (h; r; e). Ranking the scores in ascending order, we then get the rank of the original correct triplet. Aggregated over all the testing triplets, the proportion of

Table 3: Examples of four types of relations in FB15K

Types of Relation	Relations in FB15K
one-to-one	/location/country/capital
one-to-many	/people/profession/people_with_his_profession /film/production_company/films /music/genre/artists /film/director/film
many-to-one	/people/person/place_of_birth /film/film/production_companies /people/person/profession /film/film/directed_by
many-to-many	/film/film/starring/film/performance/actor /film/actor/film/film/performance/film /film/actor/film

ranks not larger than 10 (denoted as Hits@10) metric is reported for evaluation. For this metric a higher Hits@10 is better.

Since the dataset is same, we directly report the experimental results of several baselines from the literature, (see Table no. 4). Instead of taking overall link prediction task results, we take link prediction reported results for predicting heads and prediction tails based on all types of relations: *one-to-one (1-1), one-to-many (1-N), many-to-one (N-1)* and *many-to-many (N-N)*) separately.

Discussion. For the comparison of Hits@10 of different kinds of relations, Table 4 shows the detailed results (entity prediction for heads and tails in triples) by mapping properties of relations on sparse dataset, FB15k. In predicting tail, we can see that our approach outperforms baseline approaches, e.g. TransE, TransH, TransR, CTransR significantly in *many-to-one relation*. In predicting head, we can see that our approach produces good results in *one-to-many relation*. KG2E outperforms other approaches in one-to-one relations, and PTransE has achieved highest results in one-to-many and many-to-many relations in predicting tail on FB15K. Compared with other types of relations, our approach does not outperform previous methods for one-to-one, one-to-many and many-to-many relations in predicting tail. This is because, our approach explicitly considers many-to-one relation for predicting tail, as this type of relationship between entities can only convey types or fine-grained types of entities in KG. For example, in the KGs, such as Freebase, DBPedia types of entities e.g. *Johnny Depp* can form in a KG triple as (Johnny Depp <subject entity> , type <relation> , actor <object entity>). In Freebase in DBPedia, type relation expresses as <http://www.w3.org/1999/02/22-rdf-syntax-ns#type>. Fine-grained type inference is therefore ideologically comparable by many-to-one relation for predicting tail in KG.

7 CONCLUSION

This paper proposes a new approach based on a tensor model for fine-grained type inference in KG. This approach is explicitly modelled for leveraging domain knowledge in KG, and for utilizing the additional large amount of interactions among multiple entities and text descriptions. We further develop probabilistic inference based on collective multilevel type classification and latent similarity of typed entities. Experiment results show that utilizing additional data outside of KG, leveraging domain knowledge with tensor modelling; and developing 'probabilistic inference' by observing data from classification of type classes, and the latent similarity of entities significantly improves performance for inferring fine-grained types of entities in KG. Results in type triple classification and entity prediction tasks show the proposed model outperforms the state-of-the-art approaches for type inference in KG (10% to 19% on different fine-grained types compare to the state-of-the-art approach Rescal), and achieves high results in many-to-one relation in predicting tail for KG completion task.

ABSTRACT

Computer-aided education systems are now seeking to provide each student with personalized materials based on a student's individual knowledge. To provide suitable learning materials, tracing each student's knowledge over a period of time is important. However, predicting each student's knowledge is difficult because students tend to forget. The forgetting behavior is mainly because of two reasons: the lag time from the previous interaction, and the number of past trials on a question. Although there are a few studies that consider forgetting while modeling a student's knowledge, some models consider only partial information about forgetting, whereas others consider multiple features about forgetting, ignoring a student's learning sequence. In this paper, we focus on modeling and predicting a student's knowledge by considering their forgetting behavior. We extend the deep knowledge tracing model [17], which is a state-of-the-art sequential model for knowledge tracing, to consider forgetting by incorporating multiple types of information related to forgetting. Experiments on knowledge tracing datasets show that our proposed model improves the predictive performance as compared to baselines. Moreover, we also examine that the combination of multiple types of information that affect the behavior of forgetting results in performance improvement.

1 INTRODUCTION

Computer-aided education (CAE) systems are widespread. Because a huge amount of learning logs can be collected from CAE systems, they can provide personalized materials to students based on their individual knowledge. This helps to reinforce knowledge by repeating materials that are difficult for a student and reducing learning costs by skipping materials that a student already knows.

To recommend suitable learning materials to each student, we should understand each student's knowledge accurately. The knowledge tracing task, which consists of: (1) modeling a student's knowledge through their interactions with the learning system contents and (2) predicting how a student will perform on future interactions, is a well-established and challenging problem in the field of CAE. The more precise the knowledge tracing is, the more satisfactory and suitable the contents provided by the system are [4]. On the contrary, a user study has shown that providing contents and questions to students at an inappropriate level of difficulty causes a decrease in their engagement [1]. Therefore, it is important to model and predict a student's knowledge precisely. This, in turn, is directly related to how efficiently a student can learn and how satisfied a student is with the CAE system.

For knowledge tracing, Bayesian knowledge tracing (BKT) [3] and performance factors analysis (PFA) [14] have been explored widely and applied to intelligent tutoring systems [10, 19, 20]. Recently, as deep learning models are outperforming the conventional models in a range of domains such as pattern recognition and natural language processing, the deep knowledge tracing (DKT) model [17], based on deep learning, can model a student's knowledge more precisely as compared to the conventional models mentioned above. The DKT model represents a student's knowledge state using the hidden variable of a recurrent neural network (RNN), which is a low-dimensional and dense vector. The BKT model represents a student's knowledge state as a binary variable for each skill. A skill is a class of related material, such as by grammar, and is identified with a question tag or ID. Hence, the DKT model can represent a student's knowledge more richly than the BKT model, which leads to improvements in knowledge tracing performance.

Predicting a student's knowledge precisely is a difficult task because students do forget. The recall rate five minutes after the previous learning may be different as compared to that after five days. Besides, the number of times students learn a target skill changes the behavior of forgetting: the more number of times they

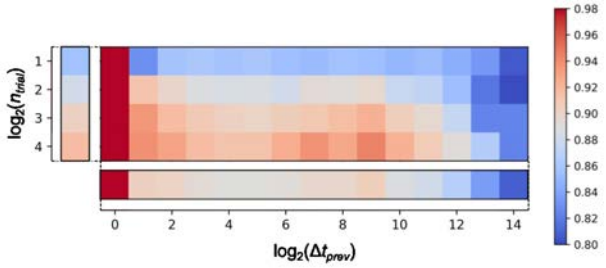

Figure 1: The quantized distribution map of the probability of a student correctly answering a question against the lag time from the previous interaction with the same skill id, Δt_{prev} and the number of past trials, n_{trial}. The distribution averaged over either the lag time or the number of trials are on the left and bottom of the distribution map, respectively. Note that single feature consideration does not capture the complex behavior of forgetting.

learn, the less they are likely to forget. To confirm the complexity of human forgetting, we analyzed the slepemapy.cz dataset, which is real-world learning logs acquired from an online learning platform. Figure 1 shows how the probability of answering correctly depends on both the lag time from the previous interaction with the same skill id and the number of past trials of that skill id. We aggregated interactions that students answered the previous question correctly. The marginal (averaged) distribution over the number of trials and the lag time are shown at the bottom and to the left of the distribution map, respectively. The forgetting behavior for a given lag time differs among the number of trials: as the number of trials increases, the student is less likely to forget. Such complex forgetting behavior cannot be captured if only lag time information is considered. Hence, this comprehensive context related to forgetting should be incorporated to achieve an accurate knowledge modeling.

There are only a few studies that have addressed forgetting in the field of knowledge tracing [11, 15, 18, 21], which either simplify the forgetting behavior or are independent of past sequences. Extensions of BKT only consider a fragment of the information related to forgetting: either the number of past trials [11], or the lag time from the previous interaction with the same skill. [18]. Regression models for knowledge tracing incorporate both the number of trials and the lag time from the previous interaction with the same skill. However, these regression models use features obtained from the interactions with the same skill [15, 21]. Considering a student's whole sequence makes it possible to modify the student's knowledge state on a skill with the student's interactions on other related skills. Otherwise, a model does not acquire any benefits from interactions on other skills.

In this study, we focus on modeling and predicting a student's knowledge considering the forgetting behavior from large amounts of learning logs to support providing adaptive learning materials in CAE systems. We propose an extension of the DKT model which can incorporate the information related to forgetting in the model. We have conducted experiments to examine the predictive performance of our model using two knowledge tracing datasets: Assistments 2012 dataset [7] and slepemapy.cz dataset [13]. In addition, we have investigated the properties of our model by analyzing the output of the model.

The contributions of the paper are summarized as follows.

- We propose a knowledge tracing model that extends the DKT model to consider both a learning sequence and the forgetting behavior by explicitly modeling the forgetting behavior using multiple features.
- We have conducted experiments showing that our proposed model outperforms conventional methods in terms of the predictive performance on the knowledge tracing datasets.
- We have also examined how the combination of multiple types of forgetting information influences the performance.

2 RELATED WORK

2.1 Knowledge tracing

Conventional knowledge tracing models such as BKT [3] and PFA [14] have been explored widely and applied to actual intelligent tutoring systems [10, 19, 20]. The BKT models a student's knowledge using a hidden Markov model (HMM). Each student's knowledge is represented as a set of binary latent variables, and the value of each variable corresponds to whether the student has mastered a skill or not. The PFA is a logistic regression model that predicts the probability of answering correctly based on the number of previous successes and failures. Although the PFA can easily incorporate several features, it basically cannot consider the whole sequence of interactions; instead, it considers the interactions only from the same skill.

As deep learning models are outperforming the conventional models in a range of domains such as pattern recognition and natural language processing, the DKT model [17] has shown that deep learning can model a student's knowledge more precisely as compared to the conventional models mentioned above. The DKT models a student's knowledge by an RNN which is often used for sequential processing. Although the DKT model is a sequence model as well as the BKT model, the DKT model represents a student's knowledge state using the hidden variable of a RNN, which is a low-dimensional and dense vector; the BKT model represents a student's knowledge state as a binary variable for each skill. In doing so, the DKT model can represent a student's knowledge more richly than the BKT model, which leads to an improvement of the predictive accuracy for the student's future performance. Following the DKT model, there are increasing amounts of research on deep learning-based knowledge tracing models [2, 12, 23, 24]. Zhang et al. improved DKT by incorporating additional features into it [24]. Although their approach has similarity to ours in terms of incorporating additional features to the DKT model, they neither focused on modeling forgetting and modeling across time, nor used time-based features such as lag time from the previous interaction.

2.2 Considering forgetting for student's knowledge tracing

There are several research branches that focus on improving knowledge tracing tasks [16]. Considering the forgetting behavior is one of the directions to better understand a student's knowledge. One of the early studies about forgetting [5] revealed that the retention

Table 1: Comparison between our proposed approach and previous work. Sequence indicates the method used to model the sequence of interactions. Time-based forgetting information is the lag time between interactions, and the count-based forgetting information is the number of trials in the past.

Method	Sequence	Forgetting info.	
		Time-based	Count-based
BKT [3]	HMM	-	-
PFA [14]	-	-	-
DKT [17]	RNN	-	-
Qiu et al. [18]	HMM	✓	-
Khajah et al. [11]	HMM	-	✓
Pelánek [15]	-	✓	✓
Settles and Meeder [21]	-	✓	✓
Ours	RNN	✓	✓

rate decreases exponentially as time passes by, and also, increasing the number of repetitions helps a user avoid forgetting. Without considering forgetting behavior in a knowledge tracing model, a student's knowledge state cannot be changed as time passes by. This assumption is not reasonable in reality.

The original BKT model does not consider forgetting behavior. Qiu et al. [18] extended the BKT model to consider forgetting behavior for the first time. A new day flag was added to BKT to model forgetting one day after the previous interaction. However, this system could not model forgetting that occurred on a much shorter time scale. Khajah et al. then extended the BKT model to estimate the probability of forgetting by applying the number of trials in the past [11]. However, the lag time between the current and previous interactions was not considered.

For the PFA and the related regression models, there are two studies that focused on incorporating forgetting behavior into these models. Pelánek incorporated a time factor into the memory activation, which determines the probability of answering correctly [15]. In this research, applying a staircase function, which boosts the memory activation when the lag time is in a certain bound, resulted in the best performance. On the other hand, Settles and Meeder proposed a half-life regression model which extends the PFA model with the essence of Ebbinghaus's forgetting curve [21]. Although these models incorporated information related to forgetting, the problem still remains. These regression models consider only the information about the skill and neglect the interaction sequence of other skills.

The difference between our proposed approach and the previous works is that we extended DKT, which is a sequential knowledge model, to consider a student's whole sequence of interactions, and incorporate multiple types of information to represent the complex forgetting behavior. Table 1 shows the comparison between our proposed approach and previous works.

3 PRELIMINARIES

In this section, we describe the knowledge tracing task and briefly explain the DKT model, which is the base component of our model.

3.1 Knowledge Tracing Task

The knowledge tracing task aims to model a student's knowledge through interactions with questions and to predict how a student will perform on the future interactions. The task can be formulated as a supervised learning problem: given a student's past interactions $\mathbf{x}_0, \cdots, \mathbf{x}_t$, the student's performance is predicted in the next interaction. An interaction $\mathbf{x}_t = (q_t, a_t)$ is defined as a tuple containing the skill id q_t of a question that a student attempts at time step t, and the label a_t which represents whether the student answers correctly or not. We define the number of skills as Q. In this study, the skill id q_t is identified by either a question tag or an ID, and a_t is a binary variable (one represents correct and zero represents incorrect answers). The values of a_{t+1} are predicted for the given values of q_{t+1}.

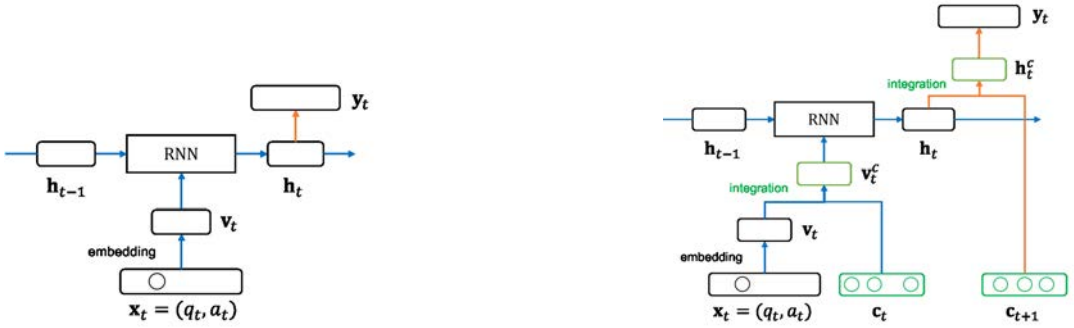
3.2 Deep Knowledge Tracing

The deep knowledge tracing model is the first deep neural network-based knowledge tracing model [17]. The structure of the DKT model is shown in Fig. 2 (a). DKT models a student's knowledge transition by using various RNNs such as Elman RNN [6] and long short term memory (LSTM) [9]. The student knowledge state is represented by a hidden state vector of RNN $\mathbf{h}_t \in \mathbb{R}^k$, where k is the number of hidden state dimensions. The DKT model can be separated into two processes: modeling a student's knowledge and predicting a student's performance.

In the process of modeling a student's knowledge, for a given input $\mathbf{x}_t = (q_t, a_t)$, the model updates a student's knowledge state $\mathbf{h}_t$ at each time step t. The input $\mathbf{x}_t$ is a one-hot vector, which is a Cartesian product of q_t and a_t. The input vector $\mathbf{x}_t$ is then transformed into a low-dimensional and dense real-valued vector $\mathbf{v}_t$. In [17], a random vector $\mathbf{n}_{q,a} \sim N(0, \mathbf{I})$ is assigned to each input tuple as v_t. With the embedding vector $\mathbf{v}_t$ and the previous student knowledge state vector $\mathbf{h}_{t-1}$, the student knowledge vector $\mathbf{h}_t$ is updated as:

$$\mathbf{h}_t = \phi(\mathbf{v}_t, \mathbf{h}_{t-1}),$$

where ϕ is the cell module of RNN.



In the process of predicting a student's performance, the probabilities of answering correctly for all skills $\mathbf{y}_t \in \mathbb{R}^Q$ based on the updated student's knowledge state $\mathbf{h}_t$ is calculated as:

$$\mathbf{y}_t = \sigma(\mathbf{b}^{\text{out}} + \mathbf{W}^{\text{out}}\mathbf{h}_t),$$

where $\sigma(\cdot)$ is the sigmoid function, $\mathbf{W}^{\text{out}} \in \mathbb{R}^{Q \times k}$ is the weight matrix and $\mathbf{b}^{\text{out}} \in \mathbb{R}^Q$ is the bias vector of output.

4 PROPOSED APPROACH

We have utilized the DKT model as our base model because it is a state-of-the-art model in the knowledge tracing task, and a deep neural network that can easily incorporate multiple input sources and capture the nonlinear dynamics among them. By extending DKT so that it can consider forgetting, the model can adapt the student performance to the student's forgetting.

(a) Architecture for deep knowledge tracing.

(b) Architecture for proposed model.

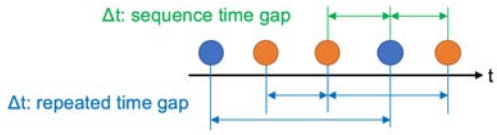


Figure 2: Architectures for (a) deep knowledge tracing and (b) proposed model. The blue arrows describe a process of modeling a student's knowledge. The orange arrows describe a process of predicting a student's performance. Our proposed model incorporates the additional information related to forgetting $\mathbf{c}_t$, $\mathbf{c}_{t+1}$ and an integration component in both processes, which are colored by green. $\mathbf{c}_t$, $\mathbf{c}_{t+1}$ are multi-hot vectors which quantize the information related to forgetting: repeated time gap, sequence time gap, and past trial counts.

4.1 Information related to forgetting

Earlier research has revealed that the retention rate differs depending on the combination of two aspects: the lag time from the previous interaction and the number of times a student learns the learning material. The lag time can be calculated for the repetition of same skill ids or for sequence of any skill ids. Hence, in this study, we have considered the following three features:

- repeated time gap: the lag time between an interaction and the previous interaction with the same skill id,
- sequence time gap: the lag time between an interaction and the previous interaction in the sequence; the skill id of an interaction does not matter, and
- past trial counts: the number of times a student answers questions with the same skill id.

Figure 3 illustrates these features. As for time gap, the repeated time gap has been commonly used in the previous researches [15, 21]. The reason we have used the sequence time gap is if both the skill of the question that student attempts and the skill of the previous question are related to each other, the lag time between these interactions may affect the performance of the question. Incorporating the sequence time gap into the model may capture this effect. The two time gap features are used by the minute and all three features are discretized at $\log_2$ scale.

Time step	t_1	t_2	t_3	t_4	t_5
Repeated time gap	-	-	Δt_{32}	Δt_{41}	Δt_{53}
Sequence time gap	-	Δt_{21}	Δt_{32}	Δt_{43}	Δt_{54}
Past exercise counts	0	0	1	1	2

Figure 3: The additional information related to forgetting from a student's sequence of interactions. Each point corresponds to an interaction and the same color represents the same skill. In the table, the time gap $\Delta_{ij} = t_i - t_j$.

4.2 Model

We extended DKT by incorporating information related to forgetting into two spaces of the model: the input and the output space of the RNN. The overall model architecture is shown in Fig. 2 (b).

To model a student's knowledge process, we have used a trainable embedding matrix $\mathbf{A}$ to calculate the embedded vector for $\mathbf{v}_t$ for the interaction vector $\mathbf{x}_t$ instead of assigning the random values. In addition, we have added the information related to forgetting, $\mathbf{c}_t$, discussed in Sect. 4.1, as the input as well as the interaction at time step t. $\mathbf{c}_t$ is a multi-hot vector because the three features in the information are represented as one-hot vectors and then concatenated. Before passing into the RNN module, the embedding vector $\mathbf{v}_t$ and the additional information vector $\mathbf{c}_t$ are integrated with each other:

$$\mathbf{v}_t^c = \theta^{\text{in}}(\mathbf{v}_t, \mathbf{c}_t),$$

where θ^{in} is the input integration function that incorporates additional information into the student's knowledge state. We describe this integration function in Sect. 4.3. Next, the student's knowledge state vector $\mathbf{h}_t$ is updated with the integrated input $\mathbf{v}_t^c$ and the previous student's knowledge state $\mathbf{h}_{t-1}$:

$$\mathbf{h}_t = \phi(\mathbf{v}_t^c, \mathbf{h}_{t-1}).$$

Thereby, a student's knowledge state is updated considering both the response of a student for the skill and the information related to forgetting. If a student answers correctly with a long time gap, the model updates the skill in the direction of acquiring more mastery.

Similarly in the process of predicting a student's performance, we have integrated the additional information at the next time step $\mathbf{c}_{t+1}$ with the updated student's knowledge state vector $\mathbf{h}_t$:

$$\mathbf{h}_t^c = \theta^{\text{out}}(\mathbf{h}_t, \mathbf{c}_{t+1}),$$

where θ^{out} is the output integration function that brings additional information into the prediction. Thereby, the model can predict

Table 2: Statistics of the data.

Dataset	#interactions	#users	#items
ASSISTments 2012	5,818,868	45,675	266
slepemapy.cz	10,087,305	87,952	1,458

a student's performance considering forgetting: if the student attempts a question with a short time lag, the model revised the probability of answering correctly upward. This integration function is described in detail in Sect. 4.3. Subsequently, the model predicts the probability of answering correctly for all skills $\mathbf{y}_t \in \mathbb{R}^Q$ based on the updated student's knowledge state $\mathbf{h}_t^c$:

$$\mathbf{y}_t = \sigma(\mathbf{b}^{\text{out}} + \mathbf{W}^{\text{out}}\mathbf{h}_t^c).$$

4.3 Integration Methods

In both processes of modeling a student's knowledge and predicting a student's performance, we have incorporated the integration functions, θ^{in} and θ^{out}, into our model to consider the forgetting behavior. We have explored the following four integration methods:

- concatenation: $\theta^{\text{in}}(\mathbf{v}_t, \mathbf{c}_t) = [\mathbf{v}_t; \mathbf{c}_t]$,
- multiplication: $\theta^{\text{in}}(\mathbf{v}_t, \mathbf{c}_t) = \mathbf{v}_t \odot \mathbf{C}\mathbf{c}_t$,
- concatenation and multiplication: $\theta^{\text{in}}(\mathbf{v}_t, \mathbf{c}_t) = [\mathbf{v}_t \odot \mathbf{C}\mathbf{c}_t; \mathbf{c}_t]$, and
- bi-interaction: $\theta^{\text{in}}(\mathbf{v}_t, \mathbf{c}_t) = \sum_i \sum_{j \neq i} \mathbf{z}_i \odot \mathbf{z}_j, \mathbf{z}_i \in \{\mathbf{v}_t, \mathbf{C}_i c_t^i \mid c_t^i \neq 0\}$,

where $\mathbf{C}$ is the trainable transformation matrix, and $\odot$ denotes the element-wise multiplication. For the output integration function θ^{out}, we have used the same integration methods but applied to the student's knowledge vector $\mathbf{h}_t$ instead of $\mathbf{v}_t$. We have shared the transformation matrix C for both the input integration function θ^{in} and the output integration function θ^{out}. Concatenation stacks the interaction vector with the feature vector. Hence, this integration does not change the interaction vector itself. On the other hand, multiplication modifies an interaction vector by the contextual information. Concatenation and multiplication are common ways to integrate vectors. The first three integration methods have been used in [22]. Bi-interaction, which has been proposed in [8], encodes the second-order interactions between the interaction vector and context information vector, and between context information vectors.

4.4 Training

The learning parameters of our proposed model are the embedding matrix $\mathbf{A}$ for the interaction vector $\mathbf{x}_t$, the weights in the RNN module, the weight matrix $\mathbf{W}^{\text{out}}$ and the bias $\mathbf{b}^{\text{out}}$ for the prediction, and the transformation matrix $\mathbf{C}$ for additional information $\mathbf{c}_t$ if we use multiplication or bi-interaction integration. These parameters are jointly learned by minimizing a standard cross entropy loss between the predicted probability of correctly answering the next question for the skill id q_{t+1} and the true label a_{t+1}:

$$\mathcal{L} = -\sum_t (a_{t+1}\log(\mathbf{y}_t^{\mathrm{T}}\delta(\mathrm{q}_{t+1})) + (1 - a_{t+1})\log(1 - \mathbf{y}_t^{\mathrm{T}}\delta(\mathrm{q}_{t+1}))),$$

where $\delta(q_{t+1})$ is the one-hot encoding for which skill id is answered in the next time step $t + 1$.

5 EXPERIMENTS

In this section, we present evaluation results for our model. Firstly, we evaluated the predictive performance by comparing our proposed model with other baselines on two real-world public datasets collected from online learning platforms. Next, we conducted comparative experiments to examine the contribution of features related to forgetting in our proposed model for further model exploration.

5.1 Datasets

We used the two datasets: ASSISTments 2012[1] [7] and slepemapy.cz[2] [13]. The statistics of the two datasets are shown in Table 2.

ASSISTments 2012: This dataset is gathered from the ASSISTments, which is an online tutor system that simultaneously teaches and assesses students in mathematics. For the dataset, we defined *skill_id* as the identifier of a skill id. We also removed users with only one interaction. After preprocessing, the dataset includes 5,818,868 interactions of 45,675 users and 266 skills.

slepemapy.cz: This dataset is from an online system used for practicing geography. We defined *place_asked* as the identifier of a skill id. After removing the users with only one interaction, the dataset includes 10,087,305 interactions of 87,952 users and 1,458 skills.

5.2 Experimental setup

We evaluated the knowledge tracing models using five-fold cross validation in which each dataset was split based on students. We extracted 10% of the students from the training set for a validation set that was used to tune hyperparameters and perform early stopping. On each dataset we used area under the curve (AUC) as an evaluation metric, which ranges from 0 (worst) to 1 (best). We reported the average test AUC.

We used an LSTM for both DKT and our model. To examine the effectiveness of incorporating the forgetting features, we used the same embedding technique for the DKT model, which is described in Section 4.2. The performance of DKT with trainable embedding was almost the same as the original DKT model using random embedding (an AUC of 0.7235 for the DKT with trainable embedding was comparable with an AUC of 0.7233 for the original DKT on ASSISTments dataset). We used the DKT with trainable embedding as our baseline. Both the size of the embedding vector and the dimension of the LSTM hidden state were set to 100. We used the Adam algorithm to optimize the models. The mini batch size was set to 100 for ASSISTments 2012 dataset and 30 for slepemapy.cz dataset. We explored the optimal hyperparameters in terms of weight decay in a validation set.

5.3 Performance Prediction

We compared our proposed models with different integration methods against the DKT and the HLR model, which is the regression model considering forgetting. Table 3 shows the results on the ASSISTments and slepemapy.cz datasets. Because the HLR model can predict only the interactions of questions which a student has attempted in the past, we also evaluated on the subset. In our experiments, the regression-based HLR model performed worse than

[1] https://sites.google.com/site/assistmentsdata/home/2012-13-school-data-with-affect

[2] https://www.fi.muni.cz/adaptivelearning/?a=data

Table 3: Test AUC results for two datasets. We conducted five-fold cross-validation and calculated the average test AUC. *all* is all interactions except the first interaction of each student in a test set. *sub* is the subset of the interactions with questions which a student has attempted even once in the past. The standard deviation values are 0.0014 and 0.0034 on ASSISTments and slepemapy.cz datasets, respectively.

Model	ASSISTments		slepemapy.cz	
	all	sub	all	sub
HLR	-	0.5846	-	0.6317
DKT	0.7235	0.7213	0.7871	0.7929
DKT + forgetting (Ours)				
concat	0.7283	0.7257	0.7999	0.8061
multi	0.7301	0.7280	0.8028	0.8093
concat + multi	**0.7309**	**0.7287**	**0.8046**	**0.8115**
bi-interaction	0.7289	0.7267	0.8037	0.8103

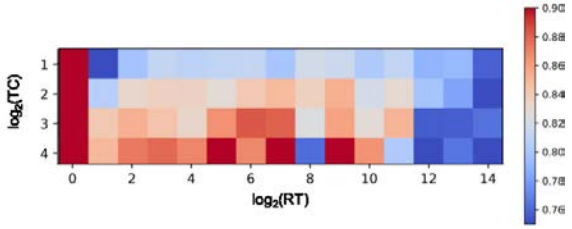

Figure 4: The quantized distribution map of the prediction of our model against the repeated time gap (RT) and the past trial counts (TC) on slepemapy.cz dataset. This figure is similar to Fig. 1, which indicates that our model can reproduce the complex forgetting behaviors.

any of the deep-learning based models. DKT achieved an average test AUC of 0.7235 on the ASSISTments dataset, and an AUC of 0.7871 on the slepemapy.cz dataset. Compared with DKT, our proposed model, which considers the information related to forgetting, performed better ($p < 0.01$ for both datasets). For reference, the Pelánik model [15], which incorporated a time factor into the PFA model, performed with an AUC of 0.7614 on the slepemapy.cz dataset. Although their experimental condition differs from ours, since they filtered the data to remove items with low counts, our model outperforms their model. We also investigated how the prediction of our model differs depending on both the repeated time gap and the number of past trials of the skill id, which is shown in Fig. 4. As in Fig. 1, we aggregated the interactions that students answered the previous question correctly. Our model reproduced the complex forgetting behavior shown in Fig. 1: as the number of trials increases, the student is less likely to forget.

Among the different integration methods, the combination of concatenation and multiplication (hybrid) achieved the best AUC on both the ASSISTments and slepemapy.cz datasets, with values of of 0.7309 and 0.8046, respectively. The multiplication integration achieved the second-best AUC score on ASSISTments dataset while the bi-interaction integration achieved the second-best AUC score on slepemapy.cz. The better result of the multiplication integration method than the concatenate integration method indicates that modifying an interaction vector using the information related to forgetting is better.

Table 4: Comparative analysis of the features related to forgetting. We used one or more features and compared the AUC performance. We used the hybrid integration of concatenation and multiplication. In the table, RT is repeated time gap, ST is sequence time gap, and TC is past trial counts.

Model	RT	ST	TC	ASSISTments	slepemapy.cz
DKT				0.7235	0.7871
DKT + forgetting	✓			0.7288	0.7972
+ one feature		✓		0.7284	0.7940
			✓	0.7258	0.7976
+ two features	✓	✓		0.7292	0.7992
	✓		✓	0.7304	0.7989
		✓	✓	0.7301	0.7993
+ three features (Ours)	✓	✓	✓	0.7309	0.8046

5.4 Comparative Study: Forgetting features

We investigated the effectiveness of incorporating the combination of features related to forgetting in the DKT model. Specifically, we used one or multiple forgetting features for modeling and observed how that affects performance.

Table 4 shows the results of the experiments. During performance comparison, while changing the number of features, we obtained the same trend on both ASSISTments and slepemapy.cz datasets: the more features used for modeling, the better the predictive performance. Adding two features resulted in a better performance than adding one feature with statistical significance ($p = 0.012$). Adding three features had a better performance than adding two features, though not statistically significant. These results support that considering multiple aspects about forgetting is important for modeling a student's knowledge.

The effectiveness of incorporating the combination of the features was different in two datasets. For the ASSISTments dataset, the combination of repeated time gap and trial count (RT+TC) was superior to other combinations. For the slepemapy.cz dataset, the combination of sequence time gap and trial count (ST+TC) seemed slightly more effective. As seen from the result of one feature in Table 4, these combinations do not comprise the top two features that had a good performance. This indicates that these features correlate with each other.

6 CONCLUSION

In this paper, we focused on considering forgetting behavior in knowledge tracing. We extended the DKT model so that the information related to forgetting can be incorporated into the model. The proposed solution achieved better predictive performance compared with the DKT model on two real-world datasets for knowledge tracing. We also revealed that the combination of several types of information which affect the behavior of forgetting resulted in improved performance.

In future work, we intend to extend this study to model forgetting behavior for each student since the tendency of forgetting differs among students. We also consider to use this model for the knowledge tracing with side information.

ABSTRACT

While online review services provide a two-way conversation between brands and consumers, malicious actors, including misbehaving businesses, have an equal opportunity to distort the reviews for their own gains. We propose OneReview, a method for locating fraudulent reviews, correlating data from multiple crowd-sourced review sites. Our approach utilizes *Change Point Analysis* to locate points at which a business' reputation shifts. Inconsistent trends in reviews of the same businesses across multiple websites are used to identify *suspicious* reviews. We then extract an extensive set of textual and contextual features from these suspicious reviews and employ supervised machine learning to detect *fraudulent* reviews.

We evaluated OneReview on about 805K and 462K reviews from Yelp and TripAdvisor, respectively to identify fraud on Yelp. Supervised machine learning yields excellent results, with 97% accuracy. We applied the created model on suspicious reviews and detected about 62K fraudulent reviews (about 8% of all the Yelp reviews). We further analyzed the detected fraudulent reviews and their authors, and located several spam campaigns in the wild, including campaigns against specific businesses, as well as campaigns consisting of several hundreds of socially-networked untrustworthy accounts.

1 INTRODUCTION

Many crowd-sourced review platforms, such as Yelp, TripAdvisor, Google and Foursquare, provide a shared space for people to write reviews and rate local businesses. With the substantial impact of businesses' online ratings on their selling [4], many businesses add themselves to multiple websites to more easily be discovered. Some might also engage in reputation management, which could range from rewarding their customers for a favorable review, or a complex review campaign, where armies of accounts post reviews to influence a business' average review score.

Several previous works have attempted to address this problem. Most of them use supervised machine learning, and only focus on textual and stylometry features [1, 16, 19, 37]. Their obtained ground truth data is also not large and comprehensive [19, 25, 27, 37, 39, 51]. Finally, these works assume a limited attacker model, e.g., an attacker's activity is assumed to be found near sudden shifts in the data [39], or they only try to detect positive campaigns.

In this paper, we propose OneReview, a system for finding fraudulent content on a crowd-sourced review site, leveraging correlations with other independent review sites, and the use of textual and contextual features. Our system leverages the intuition that an attacker may not be able to exert the same influence over a business' reputation on several websites, due to increased cost, with reviews costing between $10 and $25 each [5, 6, 45], and must be customized for each site. Even in the case of machine-generated reviews explored in [47, 49], the text generated by these systems may be customized, but the supporting metadata is not. Even when reviews can be purchased as a service [41, 44], these services charge more to target additional review sites.

OneReview focuses on isolating anomalous changes in a business' reputation across multiple review sites, to locate malicious activity without relying on specific patterns. Our intuition is that a business's reputation should not be very different in multiple review sites; *e.g.,* if a restaurant changes its chef or manager, then the impact of these changes should appear on reviews across all the websites. OneReview utilizes *Change Point Analysis* method on the reviews of every business independently on every website, and then uses our proposed *Change Point Analyzer* to evaluate change-points, detect those that do not match across the websites, and identify them as suspicious. Then, it uses supervised machine learning, utilizing a combination of textual and metadata features to locate fraudulent reviews within the set of suspicious reviews.

We evaluated our approach, using data from two review websites, namely Yelp and TripAdvisor, to find fraudulent activity on Yelp. We

obtained Yelp reviews through the Yelp Data Challenge [50], and used our Change Point Analyzer to correlate this with data crawled from TripAdvisor. Since realistic, varied ground truth data is not currently available, we used a combination of our change point analysis and crowd-labeling to create a set of 5,655 labeled reviews. We used k-cross validation (k=5) on our ground truth and obtained 97% (+/- 0.01) accuracy, 91% (+/- 0.03) precision and 90% (+/- 0.06) recall. Then the model was used on the suspicious reviews, which classified 61,983 reviews, about 8% of all reviews, as fraudulent.

We further detected fraudulent campaigns that are actively initiated by, or targeted toward specific businesses. We identified 3,980 businesses with fraudulent reviews, as well as, 14,910 suspected spam accounts, where at least 40% of their reviews are classified as fraudulent. We also used community detection algorithms to locate several large astroturfing campaigns. These results show the effectiveness of OneReview in detecting fraudulent campaigns.

2 RELATED WORK

Text and Metadata Features. Previous works have explored a multitude of combinations of machine learning techniques and features to help locating fraudulent reviews. Most works rely only on textual [16, 25, 37, 39, 51], and stylometry [16] features. Jindal and Liu [19] first used meta-data features to detect fraudulent reviews on Amazon. OneReview uses some of the suggested features if applicable. Considerable work tried to identify the spam accounts, using regression models [26], heterogeneous graphs [48], unsupervised anomaly detection [22, 31, 32, 46], and behavioral models [32, 33]. OneReview uses user-related metadata features, but does not make any such assumptions about the users in question.

Using Temporal Data for Fraud Detection. Some works [15, 24, 27, 39] take advantage of temporal and spatial information in their detection algorithms. Li et al. [24] observed some correlations between the time of writing reviews on Dianping, and the location of their authors, with the spam reviews. Others use bursts in the number of reviews to locate suspicious patterns [15, 39, 39]. This approach has two limitations compared to OneReview. First, OneReview can distinguish if reviews that have significant impact on the overall score of the business are actually suspicious, by comparing the pattern on the other website, eliminating potential false positives. Second, our threat model considers both the overall review score, as well as the more recent effects of reviews.

Ground Truth Creation. One main obstacle in detecting fake reviews is the absence of ground truth. Some early work leverages duplicate reviews as the source of fraudulent labeled data [19]. Others explore asking humans to write deceptive reviews [25, 37, 51]. However, the ground truth dataset that has been used in these methods might not reflect the dynamics of fraudulent reviews in a commercial website [34]. Rahman et. al [39] leveraged some forums where Elite Yelp users reveal and initiate the discussion on fraudulent Yelp reviews. Unfortunately, these forums are no longer available. In contrast, our dataset (see Section 6) contains data that is user-labeled, not user-generated, and additionally contains reviews chosen based on social graph information, and duplicate reviews.

3 THREAT MODEL

We assume that the adversary wishes to modify the reputation of a business, either positively or negatively, through any means, including both the overall reputation score and its recent reviews. We assume the adversary can utilize any functionality or behavior available to a normal, registered user of the service, including creating accounts, posting reviews, adding social connections, and so on. We also assume the adversary may compromise the accounts of legitimate users, or hire some users to post fraudulent reviews [6, 30, 41, 44].

An active adversary may know of the deployment of a system such as OneReview, and actively attempt to avoid detection by cross-posting the same ratings on all the crowd-sourced review websites over similar time spans. However, there is a trade-off between costs and benefits. Since the adversary needs to avoid detection by each of these review websites, as well as detection by OneReview itself, then it needs to employ complex and expensive techniques equally on all the websites which makes it unprofitable.

4 DATA

In this paper we prototype OneReview with data from two widely popular crowd-review sites, Yelp and TripAdvisor. Both sites allow users to search for businesses in their area; the page for each business offers users an overview of its basic information, reputation, and a list of reviews. Both allow users to submit reviews with "star" ratings. Users can provide feedback about the reviews themselves, such as Yelp's "funny" or "useful" ratings. Both also offer a ranking system for users (Yelp's "Elite", or TripAdvisor's "TripCollective").

Yelp Dataset. We obtained Yelp reviews from the dataset released for the 9th Yelp Data Challenge [50]. For more easily demonstrating our system, we only examine the reviews on restaurants that are located in Pittsburgh, Charlotte, Urbana-Champaign, Phoenix, Las Vegas, Madison, and Cleveland. Our Yelp dataset includes data for 1.4M reviews for about 16K restaurants and 469K users. It also includes metadata about businesses, reviews, and users.

TripAdvisor Dataset. In March 2017, we crawled TripAdvisor, and extracted public reviews and reviewer information about restaurants in the same seven US cities we selected in the Yelp dataset, resulting in about 656K reviews, submitted by 305K users, for 10K businesses. As with Yelp, data from TripAdvisor includes various metadata about each review, reviewer, and business.

Comparing the overall star ratings, we found that businesses on TripAdvisor obtain higher average star ratings (4.11) than those on Yelp (3.76). *The difference between the overall star ratings suggests that when using two sources of data, it might not be helpful (and it can be even misleading) to directly compare the ratings. However, it can be helpful to compare the trends in this data.*

5 ONEREVIEW SYSTEM DESIGN

OneReview is a system to detect *fraudulent reviews* and campaigns in crowd-sourced review websites through comparing trends with other sites, and machine learning. Figure 1 illustrates an overview of OneReview, including: (1) obtaining data, (2) matching businesses, (3) identifying inconsistent and suspicious change points in *star* trends, (4) extracting textual and contextual features, (5) employing

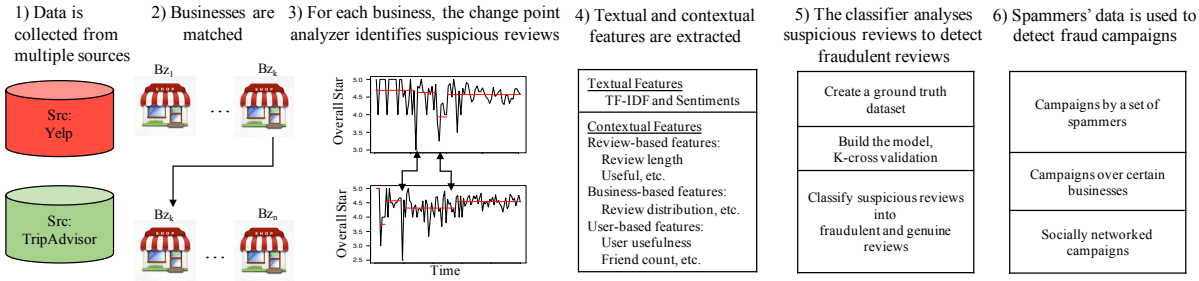

Figure 1: OneReview System Overview.

supervised machine learning to detect fraudulent reviews, and (6) detecting fraud campaigns. We explain each step in more details.

5.1 Linking Multiple Datasets

In crowd-sourced review websites, usually the name and address of businesses are not complete, which makes it not trivial matching a business between multiple websites. Our matching algorithm has two steps. Consider a restaurant in site A, called b_A, located in city c. First, the address attributes of the restaurant are compared with those of all restaurants in a site B that are also located in the same city c. Any restaurant in site B with an address similar to b_A is added to the set of possible matches M. The addresses of two restaurants located in the same city are considered similar if: 1) their ZIP codes are equal or missing, 2) their house numbers are equal or missing, and, 3) the Jaccard similarity index between their street name strings is above a threshold τ_s, or any of their street names is missing. Second, the restaurant name for b_A is compared with the names of all the restaurants in M by computing the Jaccard similarity index between their restaurant name strings. The restaurant b_A is matched to a restaurant b_B in M with the maximum Jaccard similarity index, provided that it is above a threshold τ_n.

For our purpose, the mapping algorithm should have a *perfect precision* score to avoid wrong comparison of businesses. We sampled 700 restaurants (100 restaurants per city) from the two datasets described in Section 4, and for several values of τs manually checked the precision of the mappings. We found that providing $\tau_s = 0.3$ and $\tau_n = 0.3$, the precision of matched restaurants is 1.0. The smaller dataset, Tripadvisor, includes about 10K businesses, and we could successfully match about 60% of them to the Yelp businesses. We believe that over time, eventually all businesses would have precise profiles on all websites, which results in more coverage.

Our final Yelp dataset after matching 6,068 businesses includes 805,608 reviews, and 341,399 reviewers, while our final TripAdvisor dataset includes 462,820 reviews, and 234,577 reviewers.

5.2 Comparing Trends

Intuitively, one would expect that the reputation of a business should be reasonably similar in several crowd-sourced websites. Therefore, we assume that at least the *trends* in terms of the overall ratings on multiple sites match over time, *i.e.,* within a time window, their ratings are either increasing or decreasing. OneReview analyzes the difference of trends by detecting change points in the time series that are created on reviews' overall scores. Change points are those data points at which the statistical properties such as mean, variance, correlation, or spectral density of a series of ratings change. For example, if the star ratings for a business in the months of January and February are $\{5, 5, 4, 5, 5\}$ and $\{2, 1, 5, 4\}$, respectively, then at least one change point is detected at end of month of January, because the ratings are suddenly dropped from 5s at the end of January to 2 and 1.[1]

Not all businesses receive reviews at the same rate, or at a constant rate over time, which can have an impact on the performance of Change Point Analysis. For example, based on our dataset, on Yelp less than 8% of restaurants receive daily reviews, while more than 80% obtain reviews monthly. To overcome this limitation, we compute the mean of overall ratings for each business per month, and use the sequence of these monthly mean values as the data points in the time series. While a period of one month might cause our system to miss short-lived campaigns, it is a good trade-off between detecting suspicious reviews that actually impact a business and not having effective change point analysis.

Change Point Detection. For each set of matched businesses, OneReview generates time-series from the original crawled data, one for a business' star ratings on Yelp and one for its ratings on TripAdvisor. These time-series are the inputs to the change point analysis. More formally, for each business, we have an ordered sequence of data points, $s_{1:n}^{src_1} = (s_1, \ldots, s_n)$, where s_i is the mean of stars in the i^{th} month in a data source, src_1. A change point occur at time $\tau \in \{1, \ldots, n-1\}$, such that the statistical properties of $\{s_1, \ldots, s_\tau\}$ and $\{s_{\tau+1}, \ldots, s_n\}$ are different in some way.

There are a variety of Change Point Analysis methods, differing in terms of which statistics they monitor changes in [7, 14, 21, 42, 43]. The most common method is MeanVar PELT [21], a multi-change point method, which leverages both mean and variance.

Change point analysis is a statistical analysis method. Shifts are detected as change points, if they are above certain thresholds and statistically significant. The number of detected change points then depends on the *penalty* parameter. A lower penalty value results in more change points being identified, *i.e.,* it is more sensitive. In our case study of Yelp and TripAdvisor, we tested several values including $\{p, log(n), 0.5 * log(n)\}$, where n is the number of data points in the time series and p is derived from an "elbow" plot [18].

Using MeanVar PELT method and penalty= p, $log(n)$ and $0.5 * log(n)$, we identified 26,835, 37,339 and 45,086 change points on the

[1]Note that depending on sensitivity threshold of the change point analysis method, more than one change point can be identified in these two months.

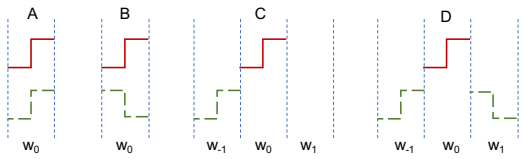

Figure 2: CPA identifies scenarios B and D as suspicious.

Yelp time-series, respectively. The set of change points identified with penalty=p is a subset of those identified with penalty $log(n)$ and $0.5 * log(n)$. The penalty can be used for tuning the sensitivity of OneReview. A more conservative system would choose the larger penalty value, which results in lower number of suspicious reviews.

In addition to identifying change points, OneReview also stores their directions, *i.e.,* positive or negative. We define a positive direction $d_{\uparrow}$ for a change point at time τ when the statistical value of $\{s_1, \ldots, s_\tau\}$ is smaller than that for $\{s_{\tau+1}, \ldots, s_n\}$. For example, a trend is considered positive, if the mean value of a business' star rating in a month is higher than its previous month. Similarly, a negative direction $d_{\downarrow}$ is defined for a change point at time τ when the statistical value of $\{s_1, \ldots, s_\tau\}$ is larger than that for $\{s_{\tau+1}, \ldots, s_n\}$.

Detecting Suspicious Change Points. We propose a Change Point Analyzer (CPA) that evaluates the change points detected in multiple websites with the goal of locating suspicious change points and reviews associated with them. The evaluation is based on several scenarios, from which four are shown in Figure 2.

First, consider at time window w_0, a change point is detected in both sources. If the direction of both change points are the same, both positive (scenario A in Figure 2) or negative, $d_{\uparrow}^{src_1}$ and $d_{\uparrow}^{src_2}$, or $d_{\downarrow}^{src_1}$ and $d_{\downarrow}^{src_2}$, then CPA labels them as *benign*. However, if their directions are not aligned, *i.e.,* one is positive and the other one is negative (scenario B in Figure 2) , $d_{\uparrow}^{src_1}$ and $d_{\downarrow}^{src_2}$, or $d_{\downarrow}^{src_1}$ and $d_{\uparrow}^{src_2}$, then they are labeled as *suspicious*.

Second, at time window w_0, a change point may be detected in src_1 but not in src_2 (scenarios C and D in Figure 2). This can indicate a suspicious behavior, however it also can be due to the sparsity of data in src_2. In other words, sometimes there is a delay in genuine change points simply because no review is provided for the business at some specific date. To minimize the false positives resulting from this phenomenon, when at time w_0 only a change point is detected in src_1 and not in src_2 , CPA extends the comparison to change points in neighbor time windows, w_{-1} and w_1. In particular, if in src_2, in time w_{-1}, any change point exists, then if the direction of any of the detected change points matches with that of the change point in src_1, then that change point in src_1 is labeled as *benign* (scenario C in Figure 2), otherwise as *suspicious* scenario D in Figure 2). This algorithm can be generalized for considering more than two review sources so that change points are labeled as *suspicious* if the majority of the change points differ in direction or do not exist. With penalty= p and $0.5 * log(n)$, CPA identified 26,835 and 61,817 change points as *suspicious*.

Finally, for every suspicious change point, OneReview retrieves the reviews contributed to that change point and label them as *suspicious*. Not all of the suspicious reviews are *fraudulent*; OneReview next employs machine learning using the textual and contextual features to identify fraudulent reviews within this set.

5.3 Feature Selection

For each review, a set of textual and contextual features from the review, its author, and the business are extracted. While inspired by previous work, we proposed some new features: "Author Overall Review Distribution," "Author Fresh Review Distribution," "Author Star Similarity," "Overall Author Usefulness," "Fresh Author Usefulness," and "Business star similarity". In this section, we use the following notations. For a review r, r_{text} and r_{date} are the text of r and the date it is posted. $A(r)$ and $B(r)$ indicate the author and business of r. $R(A)$ and $R(B)$ are reviews posted by A or written for B. A_f indicates "friends" of the author.

Review-based Features

n-grams. We extract bi-grams and uni-grams from all reviews and considered those with TF-IDF values higher than 0.5, which results in 168 uni-grams and about 6K bi-grams [40, 53].

Similarity Score. We use MinHash algorithm [23] to identify pairs of reviews that are similar to each other.

Sentiment. Li et al. [25] showed that over-emphasized sentiment offers robust cues to deceptive reviews. Using *NLTK* [8], each review is assigned a positivity, a negativity, and neutrality score.

Text Length. Previous works find that short reviews are more likely to be fraudulent [28]. Also, in our Yelp dataset, longer reviews are more likely to get *useful* votes. Text Length is defined as a logarithmic function of text length: $log(len(r_t) + 1)$.

Review Usefulness. It is defined as $\sqrt{r_{\text{useful}}}$, where r_{useful} is the number of useful votes received by others. Intuitively, *useful* votes are a gauge of the perceived review quality and trustworthiness.

Author-based Features

Author Overall Review Stars Distribution. We use Maximum Log Likelihood Estimation [2] to measure the similarity between distribution of ratings by an author, and all ratings.

Author "Fresh" Review Stars Distribution. Similar to the previous feature, it measures the similarity between distribution of all reviews stars and that of *fresh* reviews written by the author in the same month that the review has been posted.

Friend Count. This feature is defined as $log(|A(r)_f| + 1)$. Spam reviews are usually posted by users with fewer friends [28].

Elite Score. Yelp users can be recognized as "Elite" for each year they qualify. Elite status is intended to indicate that reviews are more helpful. We define this feature by $\sum_{e \in elites} \frac{1}{(|r_{\text{date}}.\text{year} - e| + 1)^2}$, where e is the year the user was awarded an Elite badge, $elites$ are all the Elite badges received by the author, and r_{date} is the review date. It measures the distance between the time of the review's publication and the user's Elite status being awarded.

Author Review Count. It is a logarithmic function of number of reviews by the author: $\log(|R(A)| + 1)$.

Author Star Similarity. It measures the similarity of a review's rating to the average ratings of all reviews by A: $|r_{stars} - \text{average}(R(A))|$.

Overall Author Usefulness. It measures the number of "useful" votes that an author has received: $\log(|\text{usefulness}(A)| + 1)$.

Fresh Author Usefulness. This feature measures the number of "useful" votes that an author has received for their *fresh* reviews.

Business-based Features

Business Overall Review Stars Distribution. This feature measures the similarity between distribution of all reviews stars and the distribution of reviews stars that have been written for B.

Business Fresh Review Stars Distribution. It compares distribution of all reviews with that of B's *fresh* reviews.

Business Star Similarity. The similarity of a review's rating to the average rating of all reviews for business B: $|r_{\text{stars}} - \text{average}(R(B))|$.

5.4 Classification

OneReview employs supervised machine learning using the features to classify a review as *fraudulent* or *benign*. Obtaining a ground truth of fraud on content containing people's opinions is a hard problem. We discuss our approach in Section 6. For classification, we chose Random Forests [11, 20]. This is due to its usefulness in a wide variety of applications [12], its resistance to over-fitting, and its utility in understanding feature importance [17]. For validating our classification, we apply k-fold cross validation, and use the resulting model to classify *fraudulent reviews*.

6 GROUND TRUTH DATASETS

There is no pre-existing, and reliable ground truth corpus of fraudulent reviews (discussed in Section 2). We employed a combination of human workers and algorithms to create a ground truth dataset of real-world fraudulent reviews. One major advantage of this dataset is that it includes both the *text* of the reviews and their *metadata*.

Obtaining Fraudulent Labeled Data

Our fraudulent ground truth dataset has 841 reviews, including:

379 Yelp "Not Recommended" reviews. Yelp employs a fraudulent detection mechanism to detect *fraudulent reviews* [35], and separate them as 'Not Recommended reviews.' We crawled Yelp on March 2017, about 2 months after Yelp dataset was published, and identified 1,341 reviews that since then Yelp had identified as Not Recommended. Yelp filters reviews for reasons beyond fraud, such as harassment, discrimination, or other offensive language. Therefore, we contribute 379 Not Recommended reviews that are also among suspicious reviews identified during change-point analysis.

370 duplicate reviews. We found 370 duplicate reviews that are posted for the same businesses, and are Yelp-to-Yelp matches. Interestingly, none were written by the same user, therefore, considered as fraudulent reviews. It is not trivial to accurately match users in Yelp to the users in TripAdvisor, and we could not validate if a duplicate review is written by the same user. As a result, we discarded all the 2,761 duplicate Yelp-to-TripAdvisor and TripAdvisor-to-Yelp duplicate reviews that are written for the same businesses. We do not consider identical reviews that have a length shorter than 100 characters, because they can be genuine identical short reviews.

92 crowd-labeled fraudulent reviews. To find reviews above and beyond those that are merely duplicates, or already labeled by Yelp's algorithm, we conduct a study using Amazon Mechanical Turk (AMT) to identify fraudulent reviews. Our research study was approved by the IRB of University of California, Santa Barbara.

Study Design. We created a pool of 1,700 *Human Intelligence Tasks* (HITs) [3]. Each HIT shows five different reviews to the worker, where they decide whether a review is *Strongly Fraudulent*, *Fraudulent*, *Cannot Tell*, *Benign*, and *Strongly Benign*. We only allow a single submission per Turker. Turkers are located in United States, and maintain an approval rating of at least 98% and have more than 10,000 approved HITs. To reduce the risk of dishonest AMT workers [38], we inserted verification questions into each HIT, asking the Turker to pick a specific option. Turkers are expected to spend 15-20 minutes on a HIT, and are paid 2.25 US dollar for an accepted submission. Reviews shown to the workers are sampled randomly. To give the workers some context, we provide them with additional supporting data, including review, author, and business information. We also provide a sample of four reviews posted for this business around the date of the review in question.

Study Results. We employed 1,837 Turkers, and had to discard 137 responses. Previous research [10, 36] has shown that manual labeling of opinions is not easy and human judgment is not particularly accurate at determining a fraudulent review. Therefore, we computed the majority vote by count of four, *i.e.,* if four Turkers identify a review *Strongly Fraudulent (Strongly Benign)* or *Fraudulent (Benign)*, then that review is labeled as *Fraudulent (Benign)*. Ultimately, from 1,700 reviews, we obtained 92 fraudulent reviews.

Obtaining Benign Labeled Data

Useful reviews by Elites. We use two of Yelp's meta-datas, including Elite and Usefulness. To be more cautious, we obtained reviews that are tagged as *useful* at least 3 times. We trust the reviews in the intersection of these two sets to be benign, $\text{Benign}_{\{\text{elite, useful}\}} = R_{\text{elite}} \cap R_{\text{useful}^{\geq 3}}$, which includes more than 46K reviews.

Reviews by trusted real-life acquaintances. We noticed that reviews that users find "useful," and users that Yelp marks as "Elite" share a bias towards longer, more detailed reviews, from very active accounts. Thus, we supplemented the dataset with reviews obtained using the authors' Yelp social connections, yielding 614 reviews.

Unbalanced Dataset

Prior work has shown that constructing labelled datasets, where the ratio of benign to malicious samples does not match that in practice can result in differences of more that an order of magnitude in the classification errors [29, 52]. Thus, we create a more realistic ground truth dataset with a genuine-to-fraudulent ratio of 4:1. We chose this ratio due to an estimation that the ratio of fake reviews on Yelp is 20% [28]. Therefore, we sampled 4,200 useful review by Elites. *Our final benign ground truth dataset is created by union of these samples, Benign* $= \text{Benign}_{\{\text{elite, useful}\}} \cup \text{Benign}_{\{\text{connections}\}}$, *including 4,814 reviews.*

7 EVALUATION

We show the effectiveness of our approach by statistical analysis. We first examined the classifier and the affect of Change Point Analysis on the results. We then apply OneReview on our dataset to detect and characterize real-world fraud campaigns.

Classification Performance. Table 1 shows the performance of the random forest classifier on our ground truth dataset. The classifier successfully detects fraudulent reviews with high accuracy (97%), precision (91%) and recall (90%). The standard error values (+/-) indicate that the performance is not drastically different for different number of trees or cross-folds. The reported results are with $k = 5$ folds, and 1000 trees. We picked Gini impurity to measure the quality of a split, and used bootstrapping when building trees. Table 1 also shows the performance of classifier with only textual features (TF-IDFs and sentiment features). The performance

Table 1: The performance of OneReview.

Features	Accuracy	F1-score	Precision	Recall
All	0.97 (+/- 0.01)	0.90 (+/- 0.04)	0.91 (+/- 0.03)	0.90 (+/- 0.06)
Textual	0.86 (+/- 0.01)	0.59 (+/- 0.05)	0.55 (+/- 0.05)	0.64(+/- 0.11)

is poor with 55% precision and 64% recall. We also tested various subsets of features however, none reached the same level of performance. The results illustrate that using all the contextual features substantially increases the performance. Since *similarity*, *review usefulness*, and *Elite* scores are used in the creation of the ground truth dataset, we did not use these features for classification. We overcome the limitation of unbalanced ground truth dataset, by using a well-known over-sampling technique called SMOTE [13].

Impact of Change Point Analysis. We tested our classifier on all the reviews in our Yelp dataset. It classified 375,359 reviews as fraudulent, which is equivalent to about 47% of all the 805K Yelp reviews. It is not reasonable to consider 47% of the reviews as fraudulent. However, from our MTurk study, we found that fraudulent reviews appear in suspicious reviews with higher probability. In particular, from 92 fraudulent reviews identified by Turkers, about 32% also appear in suspicious dataset while this dataset consists of only 24% of all the reviews. OneReview only performs the classification on the suspicious reviews to predict *fraudulent reviews*. As explained in Section 5.2, we obtained two sets of suspicious reviews with (1) $penalty = p$, and (2) $penalty = 0.5 * log(n)$, where the first set is a subset of the second. From 73K suspicious reviews in the first set, OneReview identified 61,983 fraudulent reviews, about 85% of the suspicious and 8% of all the 805K Yelp reviews. From 165K suspicious reviews in the second set, it identified 96,445 fraudulent reviews, about 58% of the suspicious and 12% of all the reviews. These results provide a lower and upper bound for the number of *fraudulent reviews* in Yelp. In the reminder of the paper, we focus on the *fraudulent reviews* from the smaller set of suspicious reviews.

Comparison with Yelp Reviews. We compared characteristics of detected *fraudulent reviews* and their authors with those of Yelp reviews and Not Recommended reviews. Due to space brevity, we do not provide the details of this comparison. In summary, this analysis showed that OneReview does not detect only one specific type of fraudulent review, it detects both positive and negative reviews, short and long reviews, those posted for both new and popular restaurants, and even those posted by Elite users.

Examining Fraud Campaigns. We refer to a *campaign* as one or more human actors controlling more than one account, with the aim of posting multiple reviews to influence the reputation of a business. These untrustworthy accounts can be bots, sybil accounts or individual spammers. We found that some untrustworthy accounts are created and used only once for a specific campaign while some are used several times for multiple campaigns.

Untrustworthy Accounts. We analyzed untrustworthy accounts, *i.e.,* Yelp users who have posted *fraudulent reviews*. In total, 58,157 untrustworthy accounts are identified (17% of total Yelp users). We found that about 8% of them (i.e., 7,064) have only posted one fake review. In the Yelp dataset, 27,347 of users only posted one review. Thus, OneReview does not simply identify every reviewer with one review as a untrustworthy account. Moreover, 14,910 of them are mainly posting fraudulent reviews with more than 40% of their reviews being fraudulent. This can indicate untrustworthy accounts who post legitimate reviews in an attempt to avoid the detection.

Campaigns Targeting Specific Businesses. Out of 6,068 businesses in our dataset, fraudulent reviews are posted for 3,980 businesses (about 66%). Some businesses have received many fraudulent reviews, *e.g,* 1,332 and 56 of businesses have received more than or equal to 10 and 100 fraudulent reviews, respectively. We further examined if these fraud campaigns are positive or negative. A fraudulent review is considered positive or negative if its rating is bigger or smaller than the overall rating of the business. Overall, the set of *fraudulent reviews* consists of 40,069 (65%) positive and 21,914 (35%) negative reviews. While it is expected that most campaigns are positive, it is interesting that still a good amount of *fraudulent reviews* are negative. Among 3,980 businesses with *fraudulent reviews*, 501 and 344 only have received positive and negative fraudulent reviews, respectively.

Socially-Networked Fraud Campaigns. A set of untrustworthy accounts can simply add each other as friends. OneReview does not consider the structure of the social network as a feature, still it can detect *fraudulent reviews* posted by fraud campaigns. We constructed the social network of untrustworthy accounts, which includes 16,738 nodes and 24,909 edges. We used the Louvain community detection algorithm [9], and found several communities. Some of these communities include several hundreds of nodes, *e.g.,* the top 5 largest communities include 1671, 1428, 1385, 565, and 539 of them. We found some patterns that can indeed distinguish them as untrustworthy accounts. For example, we found 40 untrustworthy accounts from a campaign which posted 40 *fraudulent reviews* for a single restaurant. These 40 users, between them have ever posted only 90 reviews, all within a month, spread across 47 distinct venues, while all sharing one venue in common. We further studied the content of these reviews and compared with the *fraudulent reviews*. We found that the authors of these reviews tended to use more superlative words, such as "definitely", "great" or "really." For example, the word occurrence ratio of the word "love" is almost two times bigger than the corresponding ratio in *fraudulent reviews*, while for the word "like" the opposite trend is observed.

8 LIMITATIONS

We included data from a mix of sources, to help reduce any bias during creation of the ground truth dataset, although any bias still present in the data is inherently difficult to measure. Change Point Analyzer evaluates time-series on a one-month interval. While this may produce some latency between a review being posted and OneReview's classification in a real deployment, this is an artifact of the sparsity of our data sources. This parameter can be adjusted, even at the granularity of a single business, when higher-frequency data is available.

9 CONCLUSION

We presented OneReview, an approach for finding fraudulent activity in crowd-sourced review services, using correlated analysis across multiple independent services. Our method leveraged change point analysis, in tandem with a cross-dataset matching scheme, to find points in the stream of reviews where a significant change in

a business' reputation did not occur evenly across the review websites. We believe our approach of integrating external data sources and features, or "thinking outside the dataset," is an important part of our system's efficacy, and allows our system to perform in a way that no machine or human could before. For future work, we aim to evaluate OneReview when having access to data from a third review website such as Google.

ABSTRACT

Talent Search systems aim to recommend potential candidates who are a good match to the hiring needs of a recruiter expressed in terms of the recruiter's search query or job posting. Past work in this domain has focused on linear and nonlinear models which lack preference personalization in the user-level due to being trained only with globally collected recruiter activity data. In this paper, we propose an entity-personalized Talent Search model which utilizes a combination of generalized linear mixed (GLMix) models and gradient boosted decision tree (GBDT) models, and provides personalized talent recommendations using nonlinear tree interaction features generated by the GBDT. We also present the offline and online system architecture for the productionization of this hybrid model approach in our Talent Search systems. Finally, we provide offline and online experiment results benchmarking our entity-personalized model with tree interaction features, which demonstrate significant improvements in our precision metrics compared to globally trained non-personalized models.

1 INTRODUCTION

The task of *Talent Search* is to connect job seekers with hiring managers or recruiters who are looking for candidates to fill available positions in their companies. The main way we approach this task is from the perspective of the recruiter; that is, we would like to recommend the best candidates to a recruiter who either composes an explicit search query or posts a job description. Previous work in the Talent Search domain aimed to learn a global model for the whole candidate space, by looking at the two-way interactions between recruiters and candidates, such as sending a message for an opportunity (i.e. interest from the recruiter towards the candidate, in the context of the current query or job) and receiving a positive or negative response to such messages (i.e. interest from the candidate for the opportunity) [5], [23]. While there has been considerable success with such methods, they still suffer because there is no personalization of preference inference for recruiters. While context of the job or query aims to contain some degree of personalization, there is often the need to learn different recommendation models at the recruiter level; so that there is a better match with the recruiter and the type of candidates that are recommended to them.

In order to personalize recommendations for different users of the same system, generalized linear mixed (GLMix) Models [27], [17] are often utilized, which generate per-entity linear models. In practice, GLMix models work similar to a decision tree in the way that they retrieve a different set of linear coefficients based on the id of an entity (e.g. they could employ a recruiter id → model coefficients mapping for our application case). While this introduces nonlinearity to the learned models, the features are still combined in a linear manner, and hence does not exploit the full interaction information. On the other hand, nonlinear models such as gradient boosted decision trees (GBDT) are costly to generate per entity, due to the required processing power, the size of each of the learned models, and because they are susceptible to overfitting in the case of limited data available for personalization. In this work, we propose to have the best of both worlds, by having entity-level personalization through GLMix models, while using tree interaction features [10] from a globally learned GBDT model (via XGBoost [2]), utilizing the usage data of our talent search system.

The contributions of the current work are:

- Utilization of entity-level (i.e. recruiters and contracts) personalized models for talent search domain,
- Achieving non-linear feature transformations within GLMix models via the tree interaction features computed by globally trained GBDT models,
- Extensive offline experimentation of such models on recruiter recommendation data, exploring different levels of personalization (i.e. different entity-types), and,
- Real-world online A/B test results demonstrating significant improvements in the successful search sessions, where we improve the two-way interest (both recruiter and candidates are matched within the context of an opportunity) success rate.

The organization for the rest of the paper is as follows. First, we present a brief background of the talent search domain, as well

as previous personalization efforts in Section 2, followed by the details of our methodology for personalized models in Section 3. We present the offline and online architecture for the usage of personalized models in real-world talent search applications in Section 4; and our offline and online experiment results in Section 5. Finally, we conclude the paper with a summary and discussion of future directions in Section 6.

2 BACKGROUND

2.1 Talent Search Models

There have been several previous work that aim to solve the talent search task in different perspectives and under different constraints. One such system which generates candidates' inferred skill expertise scores using collaborative filtering based on matrix factorization, then utilizes them as features in a supervised learning-to-rank model optimizing for normalized discounted cumulative gain (NDCG, [11]) is presented in [6]. An approach which aims to provide in-session personalization due to immediate user feedback is presented in [5]. We distinguish our work from this effort mainly due to the fact that we have access to the globally collected data offline to train warm-start personalized models.

An exploratory work on utilizing representation and deep learning models for talent search is presented in [23]. There has also been a shift from querying by keyword to querying by example in talent search models [8]. Finally, *search by ideal candidates* approach prompts recruiters to enter ideal candidates for their open position's requirements, and a query is generated based on these ideal candidates [7]. Following query generation, the talent search system retrieves and ranks results based on the match to the query.

2.2 Personalized models

Personalized models can be unsupervised learning models used in recommender systems, or supervised learning models, such as extensions of generalized linear models (GLMs) with user-specific model components. Recommender systems can be grouped into three categories: content-based systems, collaborative filtering systems, and latent factor models [22]. Content-based systems use the attributes of items highly rated by users, and recommend similar items to the user [14]. Collaborative filtering based systems, on the other hand, utilize user-to-user similarity based on their item preferences, and recommend the items liked by similar users [16] [3]. Hybrid of content-based filtering and collaborative filtering methods have also been used to improve recommendations [1] [18] [15]. A third approach is latent factor models, using methods such as principal component analysis (PCA), singular value decomposition (SVD), or more recent methods such as the BellKor recommender system, which won Netflix Challenge Prize in 2009 [13].

Supervised personalized models originate from standard machine learning models, with extensions in the form of additional per-entity model components. Among various methods used for prediction of users' responses to items, a common method is to use GLMs. Examples of such models are logistic regression for the case of binary response prediction, and linear regression in the case of real-valued response prediction. In use cases where the data is large and each entity has a sufficiently large dataset to make a generalization, it is possible to build a personalized model for each entity. GLMix models are an improvement over GLMs, where in addition to a global model, entity-level models are added to introduce personalization [17], [27].

2.3 Tree Ensemble Models

Tree-based methods partition the feature space into a set of rectangular subspaces, and then fit a model to each region [9]. Decision trees are widely used for nonlinear prediction tasks, allowing feature interactions. However, decision trees can produce unstable models which change significantly with the training data, resulting in high variance and susceptibility to overfitting. For these reasons, ensemble averaging methods such as bagging and boosting are used to reduce the variance of tree models [4]. Gradient Boosted Trees are tree ensemble models, where the ensemble is generated in a step-wise manner by sequentially fitting a function to residuals at each step. Each individual decision tree model is a weak learner, built by constraining the depth of the tree. Various implementations of Gradient boosted tree models have been proposed, including PLANET [19], XGBoost [2], parallel GBRT for web search ranking [25], stochastic gradient boosted distributed decision trees [26], and PaloBoost [20].

3 METHODOLOGY

3.1 Generalized Linear Mixed models (GLMix)

$$g(\underbrace{P(r,c,re,ca,co)}_{\text{Positive Response Prob.}}) = \underbrace{\beta_{global} \cdot f_{ltr}^{r,c,re,ca,co}}_{\text{Global model}} + \underbrace{\beta_{re} \cdot f_{mem}^{ca}}_{\text{Per-recruiter model}} + \underbrace{\beta_{co} \cdot f_{mem}^{ca}}_{\text{Per-contract model}} \quad (1)$$

where $P(r, c, re, ca, co)$ is the joint probability of recruiter re sending a communication request on the position s/he would like to fill to candidate ca, and the candidate responding positively to it. Search query is represented by request id r, context c (content of the query, properties of the recruiter, its company, the suggested position, etc.), and contract of the recruiter co (an agreement between the recruiter and the company about the recruiting task). $g(P(r, c, re, ca, co)) = log\frac{P(r,c,re,ca,co)}{1-P(r,c,re,ca,co)}$ is the logit function. The first term on the right-hand side is the global model score with β_{global} as the global model (i.e. fixed effect model) coefficients, the second term is the per-recruiter model score with β_{re} as the per-recruiter model coefficients for recruiter re which capture recruiter re's preferences, and the third term is the per-contract model score with β_{co} as the per-contract model coefficients for contract co, which capture contract co's preferences. Here, feature set $f_{ltr}^{r,c,re,ca,co}$ corresponds to Learning-To-Rank (LTR) features for the search impression, uniquely identified by (r, c, re, ca, co), and f_{mem}^{ca} corresponds to standardized member feature vector for candidate ca.

The degree of entity-level personalization in GLMix models depends on the amount of data available per entity. In the Talent Search domain, for the GLMix global model + per-recruiter model + per-contract model represented in Equation 1, there are new recruiters and contracts arriving to the system with almost no historical data, as well as recruiters and contracts who have large enough historical data for entity-level personalization. For recruiters and

candidates with almost no data, the posterior means of corresponding entity-level coefficient vectors β_{re} and β_{co} will be close to zero, and the model for the corresponding impression uniquely identified by (r, c, re, ca, co) tuple will fall back to the global model. On the other hand, for an impression with recruiter re and contract co with sufficient historical data, per-recruiter model with model coefficient vector β_{re} and per-contract model with model coefficient vector β_{co} will have impact on the final GLMix model score, which will be personalized to recruiter re and contract co.

3.2 Gradient Boosted Decision Trees

Gradient Boosted Decision Tree (GBDT) models are tree ensemble models which overcome decision trees' susceptibility to overfitting and high model variance problems via model averaging. GBDT models are computationally intensive to train. Multiple scalable implementations of GBDT model training algorithms exist in literature: [19] [25] [26]. A commonly used GBDT model training algorithm implementation is XGBoost [2]. XGBoost improves upon existing implementations with the following methods: (*i*) an approximate algorithm for enumerating all possible splits on all features using weighted quantile sketching, (*ii*) a sparsity-aware algorithm for parallel tree split finding and learning, (*iii*) a cache-aware block structure for out-of-core tree learning. With these improvements, XGBoost provides a highly scalable end-to-end tree boosting system.

3.3 Best of Both Worlds: GLMix Models with Tree Interaction Features

In the Talent Search domain, where data is abundant, entity-level personalization via GLMix models has a high potential of improving response prediction accuracy when compared to GLM counterparts. However, GLMix models do not allow nonlinear feature interactions. GBDT models enable nonlinear feature interactions through individual decision trees and tree ensembles. On the other hand, it is infeasible to add entity-level personalization to GBDT models, due to the required processing power, size of resulting personalized models, and susceptibility to overfitting in cases of limited data availability. Therefore in this work, we use a hybrid approach: first, we employ a pre-trained GBDT model via XGBoost to generate tree interaction features and scores[1] for each recruiter search impression; next, we utilize raw features, tree interaction features, and GBDT model scores as features to build a personalized GLMix model.

The GLMix global + per-recruiter + per-contract model with tree interaction features for a given (requestId, contextId, recruiterId, candidateId, contractId), represented by (r, c, re, ca, co), can be formulated as follows:

$$g(\underbrace{P(r,c,re,ca,co)}_{\text{Positive Response Prob.}}) = \underbrace{\beta_{global} \cdot f_{all}}_{\text{Global model}} + \underbrace{\beta_{re} \cdot f_{all}}_{\text{Per-recruiter model}} + \underbrace{\beta_{co} \cdot f_{all}}_{\text{Per-contract model}} \quad (2)$$

where,

- $g()$ is the logit function,
- $P(r, c, re, ca, co)$ is the probability of recruiter re communicating with candidate ca for the open position and receiving a positive response,
- β_{global} is the global model coefficient vector,
- β_{re} is the per-recruiter model coefficient vector for recruiter re,
- β_{co} is the per-contract model coefficient vector for contract co,
- $f_{all} = f_{ltr} \bigcup f_{xgb} \bigcup f_{int}$ is the feature vector, where f_{ltr} is the set of Learning-To-Rank (LTR) features; f_{xgb} represents the score from a pre-trained global GBDT model; and f_{int} represents the tree interaction features from the same pre-trained global GBDT model. As an example, if $feature_1$ is one of the LTR features, a GBDT model may generate a rule such as $feature_1 > 0.7$ within one of the internal nodes of one of its decision trees. A tree interaction score represented by one of the leaf nodes in a decision tree of the GBDT model then is a combination of multiple rules encoded into a single rule set.

The two feature sets f_{xgb} and f_{int} are generated by a pre-trained GBDT model used to score the same training set. Let the training set be $D = \{x_i, y_i\}$, where $x_i \in \mathbb{R}^m$, $y_i \in \mathbb{R}$ with $|D| = n$ examples represented using m features each. A GBDT model generated by XGBoost is an ensemble of tree models, which uses K regression trees represented as K additive functions to predict the final score of data point x_i:

$$g_{xgb}(x_i) = \sum_{k=1}^{K} t_k(f_{ltr}(x_i)),\ t_k \in T \quad (3)$$

where $T = \{t(x) = w_{(q(x))}\}$ is the set of regression trees, $q : \mathbb{R}^m \rightarrow L$ represents the structure of tree q which maps a data point $x_i \in \mathbb{R}^m$ to the corresponding leaf index in the tree, w_q represents the leaf weight in the independent tree structure q, L represents the number of leaves in the tree, and $f_{ltr}(x_i)$ represents LTR features of data point x_i. Given this representation, for each data point x_i, we score it using each tree t_k, where $k \in \{1, .., K\}$, and x_i lands on leaf node l_i^k in tree t_k. Each data point ends up in one leaf node of each tree in the ensemble, which encodes a set of rules chosen from the root to the leaf node of the tree. We represent these leaf nodes or tree interaction features for data point x_i as a (name, term, value) triple as follows:

$$f_{int}(x_i) = \bigcup_{k=1}^{K} (k, l_i^k, 1) \quad (4)$$

where k is the tree index, l_i^k is the index of the leaf node for the k-th tree which data point x_i landed on, and binary value 1 represents that data point x_i landed on this leaf node. We also use a third set

[1] Hyper-parameter optimization used for selecting regularization parameters for GLMix utilizes a grid search over a continuous large space for each entity-personalization level. In this work, we have preferred to use the GBDT score, instead of doing a more exhaustive hyper-parameter search with a model using tree interaction features + LTR features only, to regenerate GBDT score itself, especially helpful for global model. This reduces the computational complexity of training the GLMix model, particularly hyper-parameter optimization step.

of feature, $f_{xgb}(x_i)$, which is the GBDT model score:

$$f_{xgb}(x_i) = g_{xgb}(x_i) \tag{5}$$

For the pre-trained XGBoost model, we ran grid search on (training set, validation set) pair for (number of trees, maximum depth) hyperparameter pairs, and 100 trees with maximum depth of 2 was selected as the final hyperparameter. For the GLMix model, our hyperparemeters are the regularization weights for the global model, per-recruiter model, and per-contract model. We also ran grid search on (training set, validation set) pair for this regularization weight triple, and (100, 100, 100) was selected as the regularization weights for the global model, per-recruiter model, and per-contract model respectively. Figure 1 shows the pipeline for building GLMix models using learning-to-rank features, tree interaction features, and GBDT model scores. Learning-to-rank features are used as input to pre-trained GBDT model, which generates tree ensembles that are encoded into tree interaction features and GBDT model score for each data point. Then, using the original learning-to-rank features and their nonlinear transformations in the form of tree interaction features and GBDT model scores, we build a GLMix model with recruiter-level and contract-level personalization.

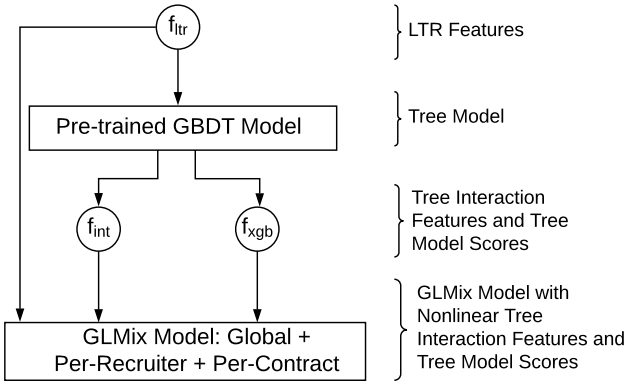

Figure 1: Pipeline for GLMix models with nonlinear tree interaction features.

3.4 Implementation Details

In this section, we summarize the implementation details of the specific GLMix model and GBDT model training algorithms used, as well as the utilized system to combine those into a model training workflow. For GLMix, the open-sourced Photon-ML library [21] was used, and for GBDTs, the open-sourced XGBoost [2] library was used. Both are built on top of the Apache Spark distributed training architecture[2]. Our training implementation used HDFS as the data storage platform, and YARN as the resource manager for Apache Spark.

The Photon-ML algorithm for GLMix model training works as follows. The input data is cloned to create a unique dataset for each fixed and random effect component of the GLMix model. The data in each set is identical, except for the feature vectors, which contain only the features used by that particular fixed/random effect. The data in each dataset is distributed amongst the Spark nodes used for training. The component models are trained one-by-one, starting with the fixed effect model, followed by random-effect models. After each component model is updated, residual scores are computed for all data samples using the updated model. These scores are used to offset the raw scores of successive random effect models during training. Note that the score is the value produced by a GLM prior to the application of any link function [27].

The XGBoost distributed algorithm works as follows. The input data is distributed amongst the Spark nodes in groupings known as blocks. XGBoost then runs a standard gradient tree boosting algorithm, with some modifications. Since the data is distributed, the exact greedy splitting algorithm cannot be used. Instead, XGBoost uses an approximate algorithm which proposes candidate split points according to the percentiles of feature distribution, computed using a weighted quantile sketch algorithm. The features are mapped into buckets along the proposed split points, and XGBoost chooses the best solution from amongst the proposals. XGBoost will also determine a default direction during splitting, used when feature data is missing [21].

In our Talent Search production system, we generate this hybrid modeling approach of entity-level personalization with tree interaction features as follows. In an offline pipeline, we generate a single day worth of training dataset using recruiter search impressions every day, hence we have a day-by-day separated dataset that accumulates over time. Then, we use 45-days of data for training, and one-day of data, immediately following the training set time period, for testing. During training / test data generation step, we also utilize a pre-trained GBDT model trained using XGBoost, in order to generate tree model score and tree interaction features for each search impression. After training and test data are generated, we build the personalized GLMix model on the 45-day training set, and test it on the one-day test set to check for and prevent extreme model performance drifts. We update the GLMix model every day, in order to personalize the model for new entities, recruiters, and contracts. Then, we upload the GLMix global model, per-recruiter model, and per-contract model coefficients into a key-value store for online utilization. More details about the online architecture of this production system are included in *System Architecture* section.

4 SYSTEM ARCHITECTURE

In this section, we first present the offline pipeline we utilize to generate and store GLMix models. Then, we present the online candidate recommendation architecture, which retrieves candidates matching a user query and applies personalized ranking via a GLMix model.

4.1 Offline Architecture

In Figure 2, we present the offline computation details of our layered GLMix model, previously introduced in Figure 1. We first collect the impression data, as well as the action data from the usage of the Recruiter product. This data mainly contains the following information:

[2] https://spark.apache.org

- Raw features collected, at the time of impression, for each candidate recommended to the users of the product[3].
- Recruiter's feedback to the recommended candidates, and the candidate responses to them, as labels. This label is positive/1 if a message was sent to the candidate, and the candidate responded to the message positively. This way, we are able to model two-way interest between recruiters and candidates.

To deal with presentation bias [12], impression and action data is collected from a subset of search query instances where we randomize the order of candidates that are recommended. Later, we feed our dataset into our pre-trained GBDT models[4] [5] to generate the tree interaction features and add them to the feature vector of each training record.

We use a two-level ranking system in online architecture, which we match in the offline architecture. In the first level (L1), top K=1000 candidates are selected by model, and in the second level, a subset of 125 candidates from this L1 ranking result is selected by another model. For our hybrid GLMix model with tree interaction features, we use XGBoost model scores generated in L1, and tree interaction features generated in L2. Note that at each ranking level, available raw LTR feature set is different, that is, L1 XGBoost model generating XGBoost model score and L2 XGBoost model generating tree interaction features are different models.

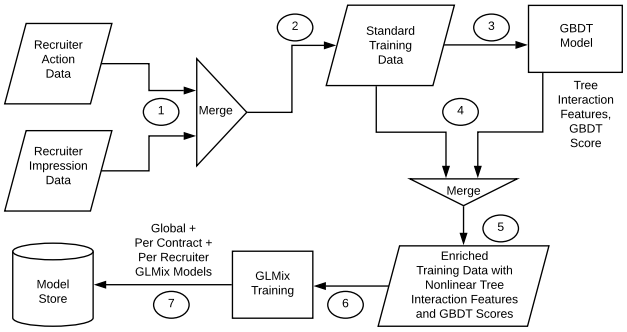

Figure 2: Offline Architecture for generating GLMix models. The numbers denote the order in the workflow.

Once we have our enriched dataset with raw features, tree interaction features, and XGBoost model scores, we train a GLMix model [27] with global, per-recruiter, and per-contract model components (the number of personalized models is on the order of tens of thousands). The overall training process takes between 3 and 5 hours. We currently run this pipeline daily to capture the most recent recruiter and contract data, and to incorporate the latest preferences into the personalized models. Once the GLMix model is learned, the coefficients are uploaded to an online key-value store, to be used during the online serving of candidates.

4.2 Online Architecture

Figure 3 presents the online ranking architecture for candidates which is a two-level system. The first level retrieves and returns

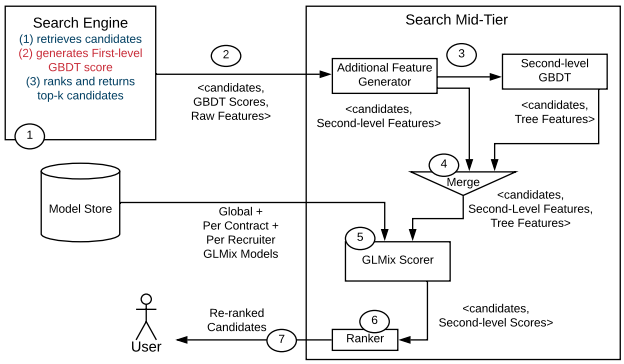

Figure 3: Online Architecture for Ranking with GLMix models.

top-k candidates using a GBDT model. The second level utilizes our proposed GLMix model picked up from the model storage (a key-value store) to re-rank the top candidates with recruiter and contract-level personalization.

At query time, the search mid-tier fetches the personalized models from the key-value store and performs the following steps:

(1) Gets the search request from the front-end (user),
(2) Sends the query belonging to the search request into the search engine. The search engine performs the retrieval and ranking using a GBDT model (trained via XGBoost) and returns top-k candidates along with their scores and computed features. These are the first-level scores and features,
(3) Generates second-level features: There are certain features which are available only in second-level ranking due to performance constraints. Search mid-tier generates these features for the candidates returned in the first-level response,
(4) Generates tree interaction features: Tree interaction features are generated using the GBDT model in the mid-tier, and added to the second-level feature set. The model has to be the same as the one utilized in the offline pipeline to train GLMix models,
(5) Generates the second-level score using the GLMix model,
(6) Re-ranks candidates based on the second-level score, and,
(7) Sends the ranked list of candidates to the front-end (user).

5 EXPERIMENT RESULTS

In order to validate the performance of GLMix models with nonlinear tree interaction features, we ran experiments in Recruiter Search domain. The key evaluation metric is precision@k, more specifically, *Positive Responses*@k[5], for values $k \in \{1, 5, 25\}$, which is averaged over all search requests. In offline experiments, we benchmarked the GLMix model variants against a pointwise GBDT / XGBoost model since that was the online baseline at the time of the offline experiments. In online experiments, we benchmarked GLMix model variants against a pairwise GBDT / XGBoost model,

[3] We are unable to reveal our raw feature list due to company policy.
[4] While we utilize XGBoost [2] to train the utilized GBDT models, the details of how they are trained, features as well as hyper-parameters such as depth and number of trees, are out of the scope of this paper.

[5] Average number of impressions that ended in the recruiter communicating with the candidate for the opportunity, and the candidate responding positively, for the first k recommended candidates.

Model (Type, features)	Precision@1	Precision@5	Precision@25
Pointwise GBDT (Baseline)	-	-	-
GLMix Global, LTR + GBDT Score	+7.352%	+3.637%	+0.766%
GLMix Global + Contract, LTR + GBDT Score	+7.688%	+2.609%	+0.683%
GLMix Global + Contract + Recruiter, LTR + GBDT Score	+5.429%	+2.267%	+0.683%
GLMix Global, LTR + GBDT Score & Interaction Features	+4.753%	+3.185%	+1.144%
GLMix Global + Contract, LTR + GBDT Score & Interaction Features	+5.909%	+3.941%	+1.594%
GLMix Global + Contract + Recruiter, LTR + GBDT Score & Interaction Features	+8.506%	+4.742%	+2.010%

Table 1: Offline experiment results benchmarking GLMix model variants against GBDT/XGBoost model, based on *Precision*@k (*Positive Responses*@k) values. The values are the lifts in Precision@k values, raw Precision@k values not shown due to company policy.

since the baseline had moved between the original offline experimentation and online productization. Note that, other methods have been benchmarked in Talent Search domain in the past, and we use the best performing one, pointwise / pairwise XGBoost models, as baseline models in our experiments [5] [23].

5.1 Offline Experiments

In offline experiments, we benchmarked GLMix model variants against the production model at the time, which is a pointwise GBDT/XGBoost model using learning-to-rank features. We tested GLMix model variants including:

(1) GLMix global model,
(2) GLMix global + per-contract model,
(3) GLMix global + per-contract + per-recruiter model.

For GLMix model variants, we used first-level GBDT model scores and second-level GBDT model tree interaction features, optimizing for Precision@25 (the default number of results on the first page is 25 for recruiters). We employed the grid search approach for hyper-parameter selection (i.e. selection of regularization weights for global and per-entity models). Table 1 shows the comparison of Precision@k values of pointwise GBDT model and GLMix model variants. Based on these offline experiments, we observed 8.5% / 4.7% / 2% lift in Precision @1 / @5 / @25 with the best-performing GLMix model variant, which is GLMix global + per-contract + per-recruiter model using LTR features, GBDT model score, and tree interaction features. Given that we optimize for Precision@25 (first page) for GLMix model when running hyper-parameter optimization, the performance of "GLMix Global + Contract + Recruiter, LTR + GBDT Score & Interaction Features" model is better compared to all other GLMix variants, which is also the case for Precision@1 and Precision@5. This is also the GLMix model variant which we ran our online experiments with, and our A/B test results are presented in the next section.

5.2 Online Experiments

To better understand the effect of personalization on the quality of candidates recommended to the recruiters, we have also performed real-world online tests on our LinkedIn Recruiter users, which are in the order of hundreds of thousands (and we recommend them candidates in the order of tens of millions). We are reporting the results of our A/B test which was run for around three weeks within the months of May and June 2018 in Table 2. In

Metric	Improvement over Baseline	p-value
1-day Positive Response Rate	+2.3%	0.03
3-day Positive Response Rate	+3%	0.01
7-day Positive Response Rate	+2.7%	0.01

Table 2: Online Results of our Three Week A/B Test

the presented results, 1-day positive response rate is the improvement on the percentage of communication requests sent by the recruiters that were positively responded to by the candidates (i.e. candidates were interested in the opportunity), within the first day (first three days for 3-day metric, and first seven days for 7-day metric) of sending the request. Online experiment results in this table show that GLMix model with tree interaction features results in statistically significant improvements of 2.3%, 3%, and 2.7% on the 1-day, 3-day, and 7-day positive response rates, respectively, compared to the baseline pairwise GBDT/XGBoost model (as we have previously mentioned, the baseline GBDT model shifted from pointwise to pairwise during the implementation efforts for GLMix in production). Per our experience, these metrics are quite hard to move, and we can clearly see the advantages of personalization by matching the most suitable candidates based on the preferences of the recruiter and contract. The difference between the online and offline results in terms of the lifts, as presented in Tables 1 and 2, is due to the change of baseline model.

6 CONCLUSION AND FUTURE WORK

In this article, we proposed the utilization of GLMix models with tree interaction features from gradient boosted decision trees (GBDT) for Talent Search, combining the benefits of entity-level personalization and nonlinear feature interactions. We have designed an offline model training and experimentation framework, as well as an online system to employ these GLMix models in production. Our offline experiments show that the best GLMix model variant, a global + per-contract + per-recruiter model using learning-to-rank (LTR) features, GBDT model score, and GBDT model tree interaction features, outperforms the baseline pointwise GBDT model, as well as all other GLMix model variants. Our online experiments also show that the best GLMix model variant improves positive

response rate with statistically significant difference over the baseline pairwise GBDT model. This method can be extended to any application in any domain where the goal is to provide personalized recommendations with nonlinear feature interactions.

For future work, one potential venue we would like to explore is to improve the hyper-parameter selection for GLMix training using Bayesian hyper-parameter optimization [24] in the daily training pipeline, compared to the currently employed grid-search approach. We also are looking into the possibility of training pairwise GLMix models instead of pointwise approach, based on our observation of high performance of pairwise GBDT models, and also due to the need to match the loss function type between our current baseline pairwise GBDT model and the GLMix model in our proposed hybrid-model solution. We also plan to replace pre-trained GBDT model with deep neural models as the nonlinear feature generator that we can feed into personalized GLMix models, which will generate wide-and-deep personalized recommendations for Talent Search.

ABSTRACT

Existing recommendation algorithms mostly focus on optimizing traditional recommendation measures, such as the accuracy of rating prediction in terms of RMSE or the quality of top-k recommendation lists in terms of precision, recall, MAP, etc. However, an important expectation for commercial recommendation systems is to improve the final revenue/profit of the system. Traditional recommendation targets such as rating prediction and top-k recommendation are not directly related to this goal.

In this work, we blend the fundamental concepts in online advertising and micro-economics into personalized recommendation for profit maximization. Specifically, we propose value-aware recommendation based on reinforcement learning, which directly optimizes the economic value of candidate items to generate the recommendation list. In particular, we generalize the basic concept of click conversion rate (CVR) in computational advertising into the conversation rate of an arbitrary user action (XVR) in E-commerce, where the user actions can be clicking, adding to cart, adding to wishlist, etc. In this way, each type of user action is mapped to its monetized economic value. Economic values of different user actions are further integrated as the reward of a ranking list, and reinforcement learning is used to optimize the recommendation list for the maximum total value. Experimental results in both offline benchmarks and online commercial systems verified the improved performance of our framework, in terms of both traditional top-k ranking tasks and the economic profits of the system.

1 INTRODUCTION

Recommender system has become a fundamental service in many online applications. Years of research have witnessed the great advancement on the development of recommendation systems, and various different techniques have been proposed to support better performance in practice, including but not limited to content-based methods [23], user/item-based collaborative filtering methods [8], matrix factorization techniques [17], and the more recent deep learning-based approaches [33]. Most of the existing methods focus on two of the most fundamental tasks, namely, rating prediction and top-k recommendation. They usually aim at the optimization of rating or ranking-related measures, such as root mean square error (RMSE), mean average precision (MAP), and many others.

However, an important and sometimes the ultimate goal of commercial recommendation system is to gain revenue and profits for the platform, but traditional recommendation research are not directly related to this goal. They mostly focus on whether or not the algorithm can predict accurate ratings (rating prediction), or if the system can rank the clicked items correctly (top-k recommendation). Nevertheless, researchers have shown that improved performance on rating prediction does not necessarily improve the top-k recommendation performance in terms of user purchase [5]. And even better performance on top-k recommendation does not necessarily improve the profit of the system [34], because the purchased recommendations may not convert into the best profit due to their difference in price. For example, by recommending daily necessities, the system has a better chance of getting the user to purchase the recommendation, but the expected profit achieved from the purchase may be smaller than if a luxury good was purchased, though the latter has a smaller chance of being purchased.

In this work, we propose value-aware recommendation for profit maximization, which directly optimizes the expected profit of a recommendation list. The basic idea is to balance the unit profit of a recommendation and the chance that the recommendation is purchased, so that we can find the recommendation list of the maximum expected profit. To achieve this goal, we generalize the key concept of click conversion rates (CVR) [1, 19] in online advertising to the conversion rate of arbitrary user actions (XVR), which scales each user action into the monetized profit of the system based on large-scale user behavior logs.

Once the user actions are converted into expected profits, we further design an aggregated reward function based on the monetized user actions, and then adopt reinforcement learning to optimize the recommendation list towards the maximized expected profit for the system. For training, we developed a benchmark dataset by collecting the user behaviors in a real-world E-commerce system. Furthermore, we conducted online experiments on this E-commerce system to validate the online performance of value-aware recommendation in terms of both ranking performance and system profits.

The key contributions of the paper can be summarized as follows:

- We propose *value-aware recommendation* to maximize the profit of a recommendation system directly, which to the best of our knowledge, is the first time to explicitly optimize the profit of the personalized recommendation list in large-scale online system.
- We propose to generalize the basic concept of click conversation rate into the conversion rate of arbitrary user actions, so that each user action can be monetized into the profit of the system.
- By aggregating the monetized user actions into a unified profit reward, we develop a reinforcement learning-based algorithm for value-aware recommendation.
- We conduct both offline experiments with benchmark datasets and online experiments with real-world commercial users to validate the performance of value-aware recommendation on ranking and profit maximization.

2 RELATED WORK

In this section, we introduce the key related work in terms of three perspectives: economic recommendation, computational advertising, and reinforcement learning.

2.1 Economic Recommendation

For a long time, recommendation system research has been working on rating- or ranking-related tasks such as rating prediction, top-k recommendation, sequential recommendation, etc., and a lot of successful models have been proposed, which greatly advanced the performance of recommendation systems. To name a few, this includes content-based methods [23], user/item-based collaborative filtering [8], shallow latent factor models such as matrix factorization [17, 18, 22, 24], and more recent deep learning based methods [14, 31, 33]. However, the related methods seldom consider the economic value/profit that a recommendation list brings about to the system, although this is one of the most important goals for real-world commercial recommender systems. Some recent research on economic recommendation has begun to take care of the economic value of recommendation[3, 7, 39]. For example, Zhang et al. [34] proposed to maximize social surplus for recommendation, Zhao et al. [35] proposed to learn the substitutional and complementary relations between items for utility maximization, and Ge et al. [10] further proposed to maximize the marginal utility per dollar for recommendation to benefit user preference. However, none of the above methods explicitly maximizes the expected profits of a recommendation list to generate recommendations.

2.2 Computational Advertising

Currently, computational advertising [6] has been playing a crucial role in online shopping platforms, rendering it essential to apply an intelligent advertising strategy that can maximize the profits by ranking numerous advertisements in the best order [2, 11, 12]. In this scenario, the goal of advertisers is to maximize clicks and conversions such as item purchase. Therefore, cost-per-click (CPC) and cost-per-action (CPA) models are often adopted to optimize the click-through-rate (CTR) and the conversion-rate (CVR), respectively. Although technically there are a lot of analogy between advertising and recommendation, there is not much work trying to bridge these two principles. This work is one of our first attempts to integrate the economic consideration in adversting into recommender systems for value-aware recommendation.

2.3 Reinforcement Learning

Reinforcement Learning (RL) aims at automatically learning an optimal strategy from the sequential interactions between the agent and the environment by trial-and-error [29]. Some existed works have made efforts on exploiting reinforcement learning for recommendation systems. For instance, conventional RL methods such as POMDP (Partially Observable Markov Decision Processes) [27] and Q-learning [30] estimate the transition probability and store the Q-value table in modeling. However, they soon become inefficient with the sharp increase in the number of items for recommendation. Meanwhile, other approaches have been proven useful with an effective utilization of deep reinforcement learning. For instance, [38] employs Actor-Critic framework to learn the optimal strategy by a online simulator. Furthermore, [37] considers both positive and negative feedback from users recent behaviors to help find optimal strategy. [9] uses the multi-agent reinforcement learning to optimize the multi-scenario ranking. Meanwhile, [36] adopts RL to recommend items on a 2-D page instead of showing one single item each time.

To mitigate the performance degradation due to high-variance and biased estimation of the reward, [4] provides a stratified random sampling and an approximate regretted reward to enhance the robustness of the model. Similarly, [16] introduces DPG-FBE algorithm to maintain an approximate model of the environment to perform reliable updates of value functions.

3 GENERALIZED CONVERSION RATE

In order to maximize the profit of recommender system, we need to measure the the value of different user actions on the platform. In this section, we introduce how to generalize the basic concept of click conversion rate to rescale each user action into monetized profit. Here we use Gross Merchandise Volume (GMV) to measure the profit of the system. GMV is a measure used in online retailing, which indicates the total sales dollar value of the merchandise sold

through a particular marketplace over a certain time frame[1]. We use GMV and profit interchangeably aftermentioned.

3.1 Conversion Rate of Clicks

Click conversion rate (CVR) is widely used in online advertising to estimate the potential profit of an advertising item to the advertising platform [21, 40]. It is usually defined as the result of dividing the number of conversions by the number of total clicks that can be tracked to a conversion during the same period of time. In E-commerce system, it is difficult to learn an optimal recommendation strategy by simply calculating the profits of transactions because purchasing an item is a relatively sparse action of users. Instead, users tend to click an item much more frequently. CVR provides a way to map the dense action of clicking into a scaled range of profits. For E-commerce system, CVR is the first step towards value-aware recommendation[28, 32]. Eq, 1 shows the total estimated GMV brought by click, which shows that CVR plays a crucial role in profit maximization,

$$E[GMV] = \sum_i I(click, i) \cdot CVR(i) \cdot price(i) \tag{1}$$

where price(i) is the unit price of item i, $I(click, i)$ is an indicator of the occurrence of click on item i. If item i is clicked, $I(click, i) = 1$, otherwise, 0.

3.2 Generalization to other Actions

In E-commerce platform, a series of behaviors of a user is often formed step by step with transforming probabilities. In Figure **??**, the general shopping process is simplified into four steps. First, the user sees something of interests and gets an impression on the item, then the user will click to see more details and to eventually add it to the cart. The user can also add it to the wishlist so he can add it to the cart later. Eventually, some items in the cart will be purchased together and contribute to final profits. Adding to wishlist and adding to cart reveal a strong desire for the item even if no transaction is made eventually. Therefore, these actions are also considered to contribute to the value.

Here we generalize the concept of CVR to XVR to map each type of user action x to its monetized economic value. XVR is defined as the possibility of transition from certain action x to purchase. Using XVR, we can estimate the total profits of different actions on platform. By generalizing Eq. 1, we get Eq. 2,

$$E[GMV] = \sum_{x,i} V(x, i) = \sum_{x,i} I(x, i) \cdot XVR(i) \cdot price(i) \tag{2}$$

where E[GMV] denotes the expected GMV of the platform, x represents certain action including *click*, *add to cart*, *add to wishlist*, and *purchase*. Here $V(x, i)$=$I(x, i) \cdot XVR(i) \cdot price(i)$ is the expected profit given user has an action x.

4 REINFORCED PROFIT OPTIMIZATION

The main goal of this work is to maximize the total profit of recommender system in an E-commerce scenario. Here the profit indicate a total sales dollar value for merchandise sold online in a certain time frame. Using the generalized conversation rate, we can transfer all user actions to monetized profit and maximize it. Reinforcement learning (RL) aims to learn a policy that maximizes the accumulated reward. The profit can naturally be used as the reward with which we can find better actions (ranking policy). Besides, the view of interact between the environment (users) and RL agent fits our recommendation scenario well. Therefore, in this paper, we choose reinforcement learning, evolution strategy more specifically[25], as our algorithm for its simplicity and effectiveness.

[1]https://en.wikipedia.org/wiki/Gross_merchandise_volume

4.1 Reinforcement Learning Modeling

Figure 2 illustrates how our value-based RL agent interacts with the user to maximize the profit. First, the user comes to the system at some time and makes an initial request, the system receives some information about the user as well as the candidate items as a state and responds to the request, which virtually means taking an action by generating an order to rank items. Next, the user shows a certain behaviors regarding the items such as click, add to wishlist, add to cart or purchase, which is used to calculate the reward to the system for what kind of action it takes.

In our recommendation platform, items are shown in cascade on a mobile App one by one. Each time the user initiates a request, 50 items are recommended to him/her. As user scrolls down the list and have seen all 50 items, a new request is triggered. This process is repeated until the user leaves the App or return the top of the cascade, labelled as "exit" in Figure 2. We use a metric called "pageid" to distinguish different requests in this interaction, similar to the concept of "page" to a search engine. As the user and the system interact with each other, the system learns how to respond to the state to obtain an optimized accumulative reward.

States: States are used to describe an user's request, including user-side, item-side, and contextual features. The user-side features include *age*, *gender*, *purchase power*. The item-side features are *ctr*, *cvr*, *price*. The contextual features include *pageid*, *request time*. In total, the states in our model can be formulated as <*age*, *gender*, *purchase power*, ctr_0, ..., ctr_{49}, cvr_0, ..., cvr_{49}, $price_0$, ..., $price_{49}$, *pageid*, *request time*>, the subscript i denotes the corresponding features of i^{th} item in the corresponding page.

All these features work together to influence the final GMV. For example, purchase power is calculated by how many and how expensive the bought items are. The higher the level of purchase power is, the more money is spent on the platform. Fig. 3a, 3b, and 3c show average GMV per user, number of users and summed GMV under different purchasing power and degree of activity. Degree of activity indicates the time a user spends on the platform. Fig. 3a shows users with higher purchase power have higher average GMV. Thus the model tends to recommend items with higher price to user who has high purchase power. However, for summed GMV, users with middle level of purchase power contribute most because the large number of users, as shown in Fig. 3b.

Request time (labelled as hour in Fig. 4) and pageid are also features used in our model. Fig. 4 shows that the the first page whose pageid equal to 0 contributes most to the summed GMV, as user scrolls downwards, pages with larger pageid have smaller possibilities to have impression on users. Thus the model should recommend items with higher conversion rate in the first page. Besides, model will learn different weights at different hour as Fig. 4 show the summed GMV varies with request time.

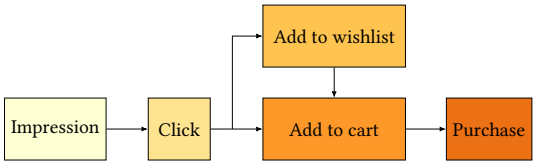

Figure 1: A flow of the user behavior series.

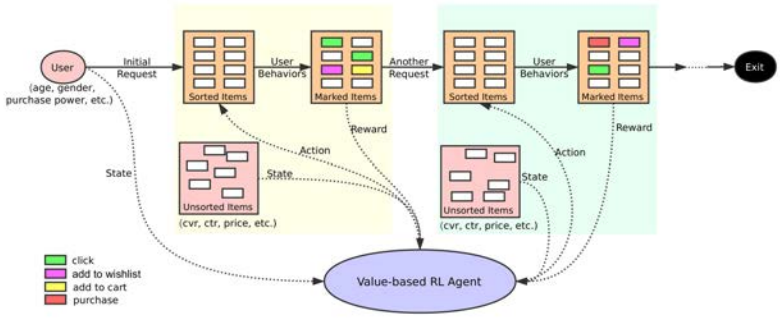

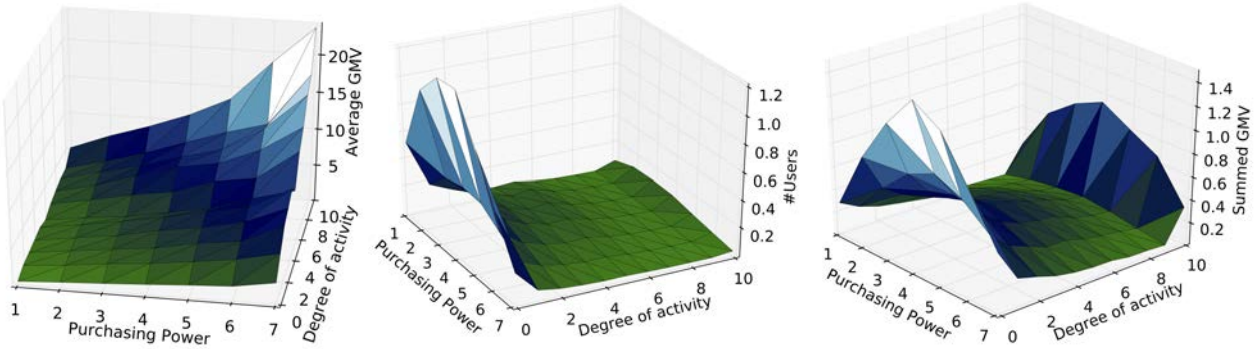

Figure 2: Structure of the model. When user initiates a request, the system will generate a recommendation list, and the user will interact with the list with certain actions. These Actions will be used to calculate the reward to update the RL Agent.

(a) Average GMV. **(b) Number of Users.** **(c) Summed GMV.**

Figure 3: Average/Summed GMV and the number of users under different level of purchasing power and degree of activity.

Actions: Action is the coefficient vector in the ranking formular which decides the order of candidate items. We design a ranking formula shown in Eq. 3 to order the items,

$$rankscore(i) = \sum_{x \in \mathcal{A}} P(x,i)^{\alpha_x} \cdot XVR(i)^{\beta_x} \cdot price(i)^{\gamma} \quad (3)$$

where $\mathcal{A}$ is the user action set which contains click, add to cart, add to wishlist. $P(x,i)$ is the possibility for a given user has action x on item i. $XVR(i)$ is the generalized conversion rate of item i. In total, the action can be formulated as $<\alpha_{click}, \alpha_{cart}, \alpha_{wishlist}, \beta_{click}, \beta_{cart}, \beta_{wishlist}, \gamma>$. If we only consider click in the action set $\mathcal{A}$, rankscore can be simplified to Eq. 4.

$$\begin{aligned} rankscore(i) &= P(click,i)^{\alpha_{click}} \cdot XVR^{\beta_{click}} \cdot price(i)^{\gamma} \\ &= ctr(i)^{\alpha_{click}} \cdot cvr(i)^{\beta_{click}} \cdot price(i)^{\gamma} \end{aligned} \quad (4)$$

Changing an action means to change the coefficient vector for the ranking formula.

Reward: In our value-based method, we use the expected profit as reward, which contains the monetized profit converted from all kinds of user actions. Based the definition of the expected GMV in Eq. 2, for a given item i, the reward R_i can be defined as:

$$R_i = V(click,i) + V(wishlist,i) + V(cart,i) + V(pay,i) \quad (5)$$

In this paper, unless specifically mentioned, we mainly use click and pay in reward, *i.e.*, $R_i = V(click,i) + V(pay,i)$. In the last section, we evaluate the performance when taking adding to cart and adding to wishlist into reward. The total reward of a recommendation list in a page that contains T items can be defined as $R_{page} = \sum_{i=0}^{T} R_i$.

4.2 Model Training

4.2.1 Offline Reward. In the above section, the reward of the model R_{page} is directly calculated with user's feedback online. This requires that the model is deployed online directly and learns the policy from the real-time data streaming. However, the online traffic is expensive. It is risky to let RL model learns directly online before we validate the effectiveness of the value-based method. To overcome this problem, we propose a simulated environment which leverage the historical data to approximate the feedback of the users. The simulated environment adopts a simple idea of NDCG (normalized discounted cumulative gain) that good policy

Table 1: Overview of the benchmark Dataset

clause	size(x10^6)
#distinct users	49
#distinct items	200
#requests	500
#clicks	670
#adding to carts	60
#adding to wishlists	30
#purchases	3

should rank the item user actually clicked and paid in the front. In this way, an offline reward R'_{page} is used to evaluate actions as following:

$$R'_{page} = \sum_{i=0}^{T} R_i * W_{\pi(i)} \tag{6}$$

For a given page with T items $1, \cdots, T$, the ranking policy can generate an order list, where $\pi(i) = k$ means item i is ranked at position k. We assign a discounted weight for each position k and higher position has greater weight, i.e. $W_{\pi(i)}$. Then we represent the reward as the weighted sum of item reward. In this paper, $W_{\pi(i)}$ is represented by exponential function which is $W_{\pi(i)} = \exp(-\pi(i))$.

4.2.2 Learning Algorithm. As the main goal of this paper is to evaluate the effectiveness of the value-aware recommendation, we choose the simplest model in reinforcement learning model family to exclude the influence of complex models. Finally we adopt evolution strategy algorithm (abbreviated ES algorithm). We train the model offline and deploy it online to perform A/B tests. The following introduces how the ES algorithm learns in the training process.

Our task is to learn a policy which maps state to action that maximizes the expected reward. To keep it simple, we use a linear model as the policy and θ is the parameters to be optimized. The ES algorithm starts from initial parameter θ_0 and then updates θ_t in the loop where t=1, 2, ... At each iteration loop t, the user's request for a new page and pass the state vector s_t to the model. The algorithm generates n baby-agent and each baby-agent j samples a set of increments ϵ_t^j from a normal distribution. Each model variant with parameter $\theta_t + \epsilon_t^j$ maps the state to an action. Each action orders the list in a different way and the user reacts to different ranking polices by clicking or purchasing certain items in the list. We calculate the reward of each policy j using Eq. 6 and labeled as $R'_{page}(j) = F(\theta_t + \epsilon_t^j)$. We collect all the rewards together and update θ_t eventually:

$$\theta_{t+1} \leftarrow \theta_t + \alpha_{lr} \frac{1}{n\sigma} \sum_{j=1}^{n} R'_{page}(j) \tag{7}$$

where σ and α_{lr} are hyper parameters, σ is the noise standard deviation and α_{lr} is the learning rate.

5 EXPERIMENTS

In this section, we first introduce the settings of our benchmark dataset used for training or offline evaluation. Then we evaluate our method both online and offline together with baselines. [2]

[2]The code and dataset of the paper are released at https://github.com/rec-agent/rec-rl.

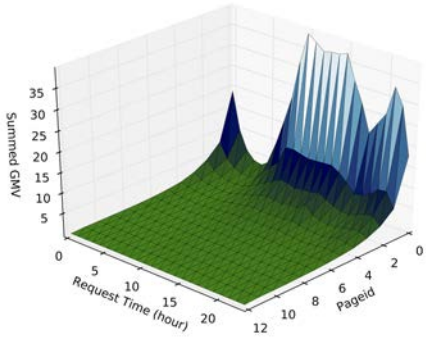

Figure 4: GMV across different pages and time.

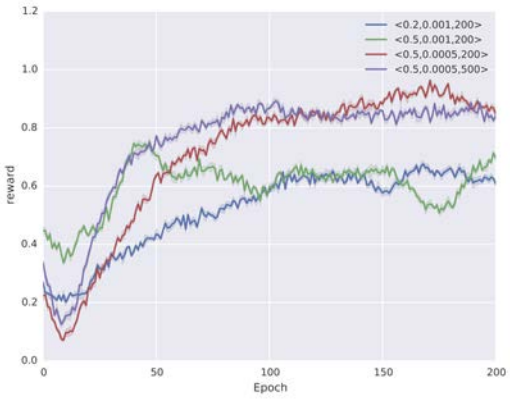

Figure 5: The training curve under different parameters: <noise standard deviation, learning rate, batch size>

5.1 Benchmark Dataset

Our benchmark dataset is collected from real-world E-commerce platform and can simulate the interactive environment and users' behaviors. Each piece of data is comprised of two parts: the *states* and users' feedback: click, add to cart, add to wishlist, purchase. Table 1 lists the details of the dataset.

5.2 Experimental Setup

5.2.1 ***Baselines****:* We use the following three methods as baselines to compare with our value-based RL method: Item-based Collaborative Filtering, LR-based learning to rank(LTR), DNN-based learning to rank.

- **Item-based CF**: The classic Item-based CF [26] is widely used for recommendation. compared to user-based CF [15], Item-based CF is more scalable and accurate in E-commerce recommendation because the relationships between items are more stable. In this paper, we use a fine-tuned item-based collaborative filtering method as one of our baselines. Other CF methods such as matrix factorization can also be used as baselines. However, as they are all non value-aware methods, we omit them in this paper for simplicity.
- **LR-based LTR**: The Point-wise Learning-To-Rank paradigm [20] is adopted to learn the rankings of recommended items with Logistic Regression(LR) as the ranking model. We use clicked and purchased items as positive samples to learn a binary classification model, and the price is used as the weight of loss. To reduce the variance of price and make the optimization stable, we actually use $\log(price)$ as the weight. For fair comparison, here

Table 2: Offline Evaluation Results (p-value < 0.005). Numbers in the brackets are improvements compared to Item-based CF and LR-based LTR.

	E[GMV]	Average R'_{page}	Precision@20(%)	Recall@20(%)	MAP@20(%)
Item-based CF	0.40	19.73	2.96	27.93	8.69
LR-based LTR	0.49 (22.5%/-)	25.87 (31.1%/-)	3.45 (16.6%/-)	32.42 (16.1%/-)	11.04 (27.0%/-)
DNN-based LTR	0.50 (25.0%/2.0%)	25.88 (31.2%/0.04%)	3.65 (23.3%/5.8%)	34.01 (21.8%/4.9%)	12.27 (41.2%/11.1%)
Value-based RL	0.53 (32.5%/8.2%)	27.78 (40.8%/7.4%)	3.74 (26.4%/8.4%)	34.82 (24.7%/7.4%)	12.36 (42.2%/12.0%)

Table 3: Online Evaluation Results (p-value < 0.005).

	GMV	CTR(%)	IPV
Item-based CF	7.57	3.04	2.48
LR-based LTR	8.95 (18.3%/-)	3.26 (7.4%/-)	2.67 (7.5%/-)
DNN-based LTR	9.06 (19.7%/1.2%)	3.28 (8.1%/0.6%)	2.69 (8.3%/0.7%)
Value-based RL	9.68 (27.9%/8.2%)	3.29 (8.2%/0.9%)	2.70 (8.8%/1.1%)

we employ the same feature set as our proposed value-based RL. There are three hyper-parameters involved in the training of LR-based LTR, *i.e.*, the ℓ_2 regularization weight, the learning rate and the batch size. These parameters are set to 0, 0.5 and 128 after tuning. We also test a repression model for predicting the profit. However, it cannot beat classification models like LR. This is consistent with previous work [13], regression model may not be suitable for ranking problems in recommender system.

- **DNN-based LTR**: This method is the same as LR-based LTR, except that the ranking model is a Deep Neural Network (DNN) instead. The neural network involves two hidden layers with 32 and 16 neurons respectively. The ℓ_2 regularization weight, the learning rate and the batch size are set to 0, 0.05 and 1024. We also tested network structures including RNN, attention networks, and Wide&Deep network. Optimizer, activation functions, normalization, and other hyper parameters are tuned by greedy search. However, the improvement of these networks is not significant on very large dataset.

5.2.2 ***Value-based RL****:.* Different hyper parameters are tried by a greedy search to find the better training performance. In ES algorithm, under the same training set, the larger reward a model can achieve, the better the model is. We name some important parameters in Fig. 5 to illustrate this. Having a larger deviation (from 0.2 to 0.5) can greatly improve the maximum reward the model can achieve. However, the model is not stable so that the reward will drop after some iterations. We adjust the learning rate in Adam optimizer from 0.001 to 0.0005 and the training curve become stable. We also try larger batch(from 200 to 500), the improvement is not that much. Finally, <0.5,0.0005,200> are used as noise standard deviation, learning rate and batch size in our RL model respectively.

5.3 Key Results

Offline Evaluation: In offline evaluation, we train the model on the data of one week and evaluate it on the data of the following week. Precision, recall and MAP within the top 20 items is used to measure the performance. Besides the traditional metrics, average R'_{page} (Eq. 6) and E[GMV] (Eq. 2) are used as value-based metrics.

Table 2 shows that the Learning-To-Rank (LTR) baseline outperforms item-based CF in all measures which indicates the LTR methods can predict the profit more effectively. We leverage price in two ways. On one hand, LTR methods use price as one of the features. On the other hand, LTR methods use price as the weight for loss in the learning process. Our value-based approach has 6.0% and 7.3% improvements in E[GMV] and R'_{page} respectively when compared to DNN-based LTR. Besides, Value-based RL achieves better performance in precision(2.5%), recall(2.4%) and MAP(0.7%) than DNN-based LTR with same features. Our approach can precisely monetize an arbitrary user action into the profit by generalizing the basic concept of click conversion rate (CVR) to CXR.

Table 4: Offline performance when considering adding to cart and adding to wishlist (p-value < 0.005).

	E[GMV]	Precision @20(%)	Recall @20(%)	MAP (%)
click	42.2	3.67	34.5	12.1
click,cart,wishlist	43.5	3.88	35.8	12.9
	(3.1%)	(5.7%)	(3.8%)	(6.6%)

Online Evaluation: An online A/B test is used to evaluate different methods. Metrics we use in A/B test are ctr, IPV and GMV. IPV is the absolute number of clicked items on the platform, which acts a supplement metric to ctr. To make the online evaluation comparable, each bucket in A/B test has the same number of users and contains over millions of users.

Table 3[3] shows the average results for one week. Online evaluation shows results are consistent with the offline evaluation. The DNN-based LTR improves both GMV, ctr and IPV by 19.7%, 8.1% and 8.3% respectively compared to Item-based CF. Even though the DNN-based LTR does not explicitly optimizing the GMV, it has 19.7% improvements in GMV compared to item-based CF. By explicitly mapping the value of different actions into the GMV, our value-based RL method can bring another 6.8% improvement on GMV compared to DNN-based LTR. The improvements on ctr and IPV is 0.3% and 0.4% respectively. Online test is done in real-world system (involving 2 hundred million clicks per day, 7 days). Based on significance test (p<0.005), the improvement are all significant and have business values for E-commercial platform, because every thousandth of improvement on ctr means hundreds of millions of extra clicks in real-world systems.

5.4 Click vs. Add to Cart and Add to Wishlist

In this part, we take adding to cart and adding to wishlist into consideration to evaluate the performance of our value-based model. Results in Table 4 show offline performance when considering the value of adding to cart and adding to wishlist actions into the model. The improvement on expected GMV is 3.1%. The improvements on precision, recall and MAP are 5.7%, 3.8% and 6.6% respectively. It

[3]Normalized related value instead of the original absolute value of the online measures are shown for business reason. The relative improvement is consistent with real experimental results.

means adding to cart and adding to wishlist actions are useful for the value-based profit maximization.

6 CONCLUSIONS AND FUTURE WORK

Great advances have been achieved by existing research to improve the accuracy of rating prediction and the quality of top-k recommendation lists. However, the economic value of recommendation is rarely studied. For large-scale commercial recommendation system, state-of-the-art algorithms seldom maximize the final revenue/profit of the system. To eliminate this gap, we propose value-aware recommendation to maximize the profit of commercial recommendation system directly. Specifically, we generalize the basic concept of click conversion rate (CVR) to the conversation rate of an arbitrary user action on the platform (XVR), where different actions of users(*click, add to cart, add to wishlist, purchase*)can be monetized into the profit of the system. Then we use reinforcement learning (RL) to maximize the profit whose reward is the aggregated monetized user actions. Both offline and online experiments show that our value-based RL model not only performs better on traditional metrics such as precision, recall and MAP, but also greatly improves the final profit than existing methods. This paper acts as the first step towards value-aware recommendation and further improvement can be achieved by designing more powerful features and RL models in the future.

ABSTRACT

Entity alignment associates entities in different knowledge graphs if they are semantically same, and has been successfully used in the knowledge graph construction and connection. Most of the recent solutions for entity alignment are based on knowledge graph embedding, which maps knowledge entities in a low-dimension space where entities are connected with the guidance of prior aligned entity pairs. The study in this paper focuses on two important issues that limit the accuracy of current entity alignment solutions: 1) labeled data of priorly aligned entity pairs are difficult and expensive to acquire, whereas abundant of unlabeled data are not used; and 2) knowledge graph embedding is affected by entity's degree difference, which brings challenges to align high frequent and low frequent entities. We propose a **semi-supervised entity alignment** method (SEA) to leverage both labeled entities and the abundant unlabeled entity information for the alignment. Furthermore, we improve the **knowledge graph embedding with awareness of the degree difference** by performing the adversarial training. To evaluate our proposed model, we conduct extensive experiments on real-world datasets. The experimental results show that our model consistently outperforms the state-of-the-art methods with significant improvement on alignment accuracy.

1 INTRODUCTION

Knowledge graphs have been constructed and widely applied to organize and represent the knowledge of different domains, including the most popular ones such as Freebase [1], YAGO [27] and DBpedia [17]. Even in the same domain, knowledge graphs (KG) are generated by different methods in different languages. To comprehensively represent the knowledge in one domain, it is thus essential to connect multiple knowledge graphs in same domain. More specifically, entities in different knowledge graphs are aligned if they are semantically same (as known as entity alignment problem).

Given two knowledge graphs with labeled entities that are known to be same in semantics, existing entity alignment approaches need human-involved feature design [20] or extra resources [16, 22, 27], such as information of the entity and the relation, as the training set, to supervise the learning process of entity alignment. Most of these methods require a sufficient number of labeled entities to generalize well in downstream applications. However, getting labeled entities is difficult and expensive. The number of accessible prior entity is usually a small proportion of a whole knowledge graph [5, 29]. ITransE [41], IPTransE [41], BootEA [29] and KDCoE [4] tried to propose new aligned pairs of entities as training data iteratively during training process. However, the focus is on how to acquire more aligned entities, leaving the abundant unaligned entities without consideration. Therefore, this paper targets on designing **semi-supervised entity alignment** model, which learns from both labeled and unlabeled entities. The underlying distribution of abundant unaligned entities will help on mitigating the risk of generalization errors caused by limited amount of aligned entities [42].

Recently, knowledge graph embedding methods, e.g., TransE [3] and PTransE [18] show significant improvement on entity alignment. For example, MtransE [5] encodes entities and relations of each language in a separated embedding space, and learns transitions to map each embedding vector to its cross-lingual counterparts in other spaces. ITransE [41] and IPTransE [41] were proposed to encode both entities and relations of different KGs into a unified low-dimensional space jointly and iteratively. JAPE [28], KDCoE [4], and Graph Convolutional Network-based approach [34] all jointly model structure and attribute information of knowledge graphs. Our work also takes advantage of embedding methods for building a semi-supervised entity alignment model. However, rather than directly using existing embedding methods, we address an important issue in the embedding process, which is caused by the **degree difference of entities** in different knowledge graphs. This phenomenon is demonstrated in Figure 1.

Entities in KGs have different degrees, i.e., popular entities are more connected with other concepts than rare entities. As pointed in recent study of natural language processing [7, 21] and machine translation [24, 25], word embedding methods encode more frequency information than semantic information of words in the resulted low-dimension space. We also investigate and find the same problem in knowledge graph embedding. Our findings verify

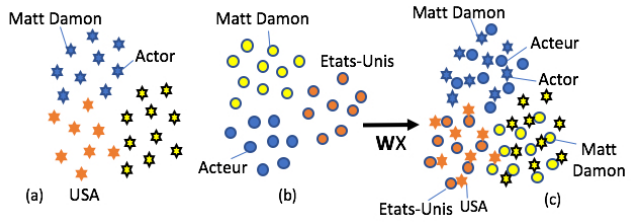

Figure 1: Illustration of the impact of entity's degree difference on embedding and alignment results. (a): embedding of (only entities in) a KG in English, where "Matt Damon" and "Actor" are both popular (with high degree) and thus mapped close in blue. (b): embedding of a KG in French, where "Acteur" is more popular (in blue) than "Matt Damon" (in yellow). (c): alignment of English KG and French KG ("Actor" with "Acteur", and "USA" with "Etats-Unis"), which shows that "Matt Damon" in French is far from the "Matt Damon" in English, even they are actually the same entity.

that entities with similar degree tend to be aggregated into a same region in the embedding space.

This deficiency of embedding methods brings challenges to entity alignment problem. Figure 1 shows a toy example of the problem, when aligning "Matt Damon" in English and French KGs. "Matt Damon" is a very popular name in English KG, while "Matt Damon" in French has fewer records. Embedding results of English KG show "Matt Damon" is close to other popular entities like "Actor" (in color blue in Figure 1 (a)), while the results of French KG (in Figure 1 (b)) have "Matt Damon" in yellow region that is distant to popular entity "Acteur" in blue region. By aligning "Actor" in English and "Acteur" in French, "USA" in English and " Etats-Unis" in French, the embedding space of French KG can be transformed to the embedding space of English KG (e.g., with linear transformation $\mathbf{W}$). The alignment is illustrated in Figure 1 (c)), where we can see that "Matt Damon" in French is far from the "Matt Damon" in English, even they are actually the same entity.

To tackle the above challenges, we propose a **semi-supervised entity alignment** framework called SEA, which takes advantages of both aligned with unaligned entities, which are represented in low-dimension space by knowledge graph embedding with **awareness of the degree difference**. In particular, the impact of degree difference is mitigated by an adversarial training, which prevents entities with similar degree from being aggregated into the same region in the embedding space during training. We also design a cycle-consistency based translation loss using the unaligned entities to reduce the search space when learning the mappings. Thus, the learned mappings can better align the entity in one knowledge graph to the corresponding entity in another knowledge graph.

Our main contributions in this work are summarized as follows:

- We propose to solve entity alignment in a semi-supervised way, not only using the given aligned entity, but also incorporating the unaligned entity to enhance the performance.
- We indicate the impact of entity's degree difference on embedding of knowledge graph, and address the problem under the adversarial training framework.
- We conduct extensive experiments on four real-world datasets to evaluate the proposed SEA model for the task of entity alignment. The results demonstrate its advantages over the state-of-the-art methods, with significant improvement on several datasets.

The rest of the paper is organized as follows. We discuss the related works in Section 2. The proposed method is described in Section 3 and followed by the experimental results in Section 4. Finally Section 5 concludes the whole paper.

2 RELATED WORK

2.1 KG Embedding

Knowledge graph (KG) embedding has became an important tool for knowledge graph analysis and semantic information modeling tasks with the fast growth of large-scale knowledge graphs. The KG embedding approaches can be roughly categorized into two groups: translational distance models and semantic matching models [33].

TransE [3] is the most representative translational distance model. It considers a relation as the translation from its head entity to its tail entity and represents both entities and relations as vectors into a same low dimensional vector space. TransE [3] characterizes a triple (h, r, t) following a common assumption $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$, where $\mathbf{h}$ and $\mathbf{t}$ are the representations of h and t, $\mathbf{r}$ is the representation of r. TransE has shown its feasibility for KG modeling, and it has been improved by many following studies, such as TransH [35], TransR [19], TransD [12], TranSparse [13], and PTransE [18].

Semantic matching models use the similarity-based scoring functions instead of the distance-based scoring functions. RESCAL [23] and Bilinear [11] model each relation as a matrix and associate each entity with a vector. DistMult [36] restricts the relation matrices to diagonal matrices. And HolE combines RESCAL [23] and DistMult [36] to get expressive and efficiency model. ComplEx [31] introduces complex-valued embeddings for better asymmetric relations modeling. Several works in [2, 26] conduct semantic matching using neural network.

The effect of word's frequency difference on embedding results has been recognized in [7, 21] and [24, 25], but the effect of entity's degree difference on embedding results has not been explored. In this paper, we address the effect of entity's degree on the embedding and propose to improve the most widely-used TransE method by mitigating the effect of entity's degree difference. The obtained KG embedding are used for improving entity alignment, especially for the rare and popular entities.

2.2 Entity Alignment

Some forerunners proposed to address the entity alignment problem using crowdsourcing [17, 32] and well-designed hand-crafted features [20]. However, the approaches suffer from the requirement of heavy human efforts, and is thus costly and labor-expensive. Many works leverage the extra resources, such as OWL properties [9], entity descriptions [37], information of entities and relations [16, 22, 27]. Such methods are complex and usually limited by the availability of the extra information about a knowledge graph.

In recent study, KG embedding-based approaches become the most popular solution for entity alignment. MTransE [5] is the representative work which encodes entities and relations of each

language in a separated embedding space, and learns transitions to map each embedding vector to its cross-lingual counterparts in the other space. Then ITransE [41] and IPTransE [41] are proposed to encode both entities and relations of different KGs into a unified low-dimensional space jointly by an iterative and parameter sharing method. BootEA [29] addresses the lack of labeled data by bootstrapping strategy and tries to reduce error accumulation during iterations by employing an alignment editing method. It also proposes an improved KG embedding approach with the limit-based loss and truncated uniform negative sampling. BootEA achieves a significant performance improvement. Further, several works, such as JAPE [28] and KDCoE [4], consider to jointly model the structure and attributes information of KGs. Recently, a Graph Convolutional Network-based entity alignment approach [34] uses GCNs to embed entities of each language into a unified vector space combining structural and attributes information.

All the methods above focus on the utilization of aligned entities, including BootEA [29], which tried iteratively enlarge the labeled entity pairs based on the bootstrapping strategy. The abundant unaligned entities that have rich content information are not used in the alignment process. Therefore, we propose a semi-supervised framework to align entities in different KGs based on both labeled and unlabeled data.

3 METHODOLOGY

In this section, we firstly introduce the notation and problem definition, then describe the proposed method in detail.

3.1 Notation and Problem Definition

A knowledge graph can be noted as $G = (E, R, T)$, where E is the set of entities, R is the set of relations, and T is the set of triples, each of which is a triple (h, r, t), including the head entity h, the relation r and the tail entity t. By using KG embedding, each triple can be presented as $(\mathbf{h}, \mathbf{r}, \mathbf{t})$, in which boldfaced $\mathbf{h}$, $\mathbf{r}$, and $\mathbf{t}$ represent the embedding vectors of head h, relation r, and tail t, respectively.

Let $G_1 = (E_1, R_1, T_1)$ and $G_2 = (E_2, R_2, T_2)$ be two KGs in different languages. $AS^L = \left\{(e_{i_1}, e_{i_2}) | e_{i_1} \in E_1^L, e_{i_2} \in E_2^L\right\}$ is a set of labeled entity pairs that are same in semantics, e.g., e_{i_1} in G_1 shares same meaning with its counterpart e_{i_2} in G_2. Entity alignment is a task to find and align the remaining semantically same entities $\{e_{i_1} \in E_1^U\}$ and $\{e_{i_2} \in E_2^U\}$ where $E_1^U = E_1 \setminus E_1^L$ and $E_2^U = E_2 \setminus E_2^L$. Unlike the previous study which builds alignment model based on AS^L only, our approach SEA builds the semi-supervised alignment model based on both AS^L and E_1^U and E_2^U.

The framework of our proposed method SEA is shown in Figure 2. SEA has two modules, knowledge graph embedding with awareness of degree difference of entities (called degree-aware KGE for short), and semi-supervised entity alignment. We introduce them in details next.

3.2 Degree-Aware Knowledge Graph Embedding

Like the previous works in [4, 5, 41], we build our degree-aware KG embedding model by following TransE [3], which is the most representative translational distance model. It is worth mentioning that our ideas of mitigating the effect of entity's degree difference on embedding can also be applied to other KG embedding methods, which is not the focus of this work.

When applying TransE on both knowledge graphs G_1 and G_2, entities and relations are projected into the same low-dimensional vector space by encoding the triples (h, r, t), and making $\mathbf{h}+\mathbf{r} \approx \mathbf{t}$ when (h, r, t) holds. Specifically, the embeddings of relations can translate the embeddings of head entities to tail entities. The margin-based ranking object function minimized by TransE over a knowledge graph G_i is defined as:

$$L_{G_i}(G_i; \varphi^i, \theta_e^i) = \sum_{(h,r,t) \in T_i} L_t(h, r, t) \tag{1}$$

where φ^i refers to the model parameters for G_i, θ_e^i presents the learned embedding from G_i, and $L_t(h, r, t)$ is the object function for a triple (h, r, t):

$$L_t(h, r, t) = \sum_{(h', r, t') \in T'_{(h,r,t)}} \left[\gamma + E(h, r, t) - E(h', r, t')\right]_+ \tag{2}$$

where $[x]_+ = \max\{0, x\}$ denotes the positive part of x, γ is a margin hyper-parameter which is greater than 0, and $E(h, r, t)$ indicates the energy function:

$$E(h, r, t) = \|\mathbf{h} + \mathbf{r} - \mathbf{t}\|_2 \tag{3}$$

and T' denotes the negative sample set for the triple (h, r, t):

$$T'_{(h,r,t)} = \{(h', r, t) | h' \in E\} \cup \{(h, r, t') | t' \in E\} \tag{4}$$

where (h', r, t) and (h, r, t') are the Bernoulli negative-sampled triples by replacing h or t in (h, r, t). Finally, we can get the object function for both knowledge graphs G_1 and G_2:

$$L_G = L_{G_1} + L_{G_2} \tag{5}$$

Next, we present the degree-aware KGE method to address the impact of entity's degree difference on the knowledge graph embedding. As discussed before, the entities with similar degree values tend to be aggregated into the same regions in the embedding space. However, for entity alignment, entities with similar semantic information are expected to be closer without the impact of entities' degree. Thus, we design the degree-aware KGE model by training the knowledge graph embeddings in an adversarial framework, inspired by Generative Adversarial Network (GAN) [8]. Given a graph G_i, we design two discriminators to classify the entities with different degrees in G_i, and the degree-aware KGE model can be regarded as a generator which produces "Good" embeddings to fool the discriminators. We catalog the degree of entities into three levels, *high* degree, *normal* degree, and *low* degree. One discriminator D_1 categorizes the entities with *high* degree and *normal* degree, while the other discriminator D_2 is in charge of classifying the entities with *low* degree and *normal* degree. The expectation is: the learned knowledge graph embeddings not only minimize the margin-based ranking loss function defined above, but also can fool the two discriminators. The impact of degree is thus removed from the learned embeddings when the two discriminators cannot distinguish entities according to the information of degree.

Let D_1 be the first discriminator with parameters ϕ_1^i, and D_2 be the other discriminator with parameter ϕ_2^i. The inputs of D_1 are the entities from E_{hd}^i and E_{nd}^i, which are entities with *high* degree and *normal* degree in graph G_i. The inputs of D_2 are the entities

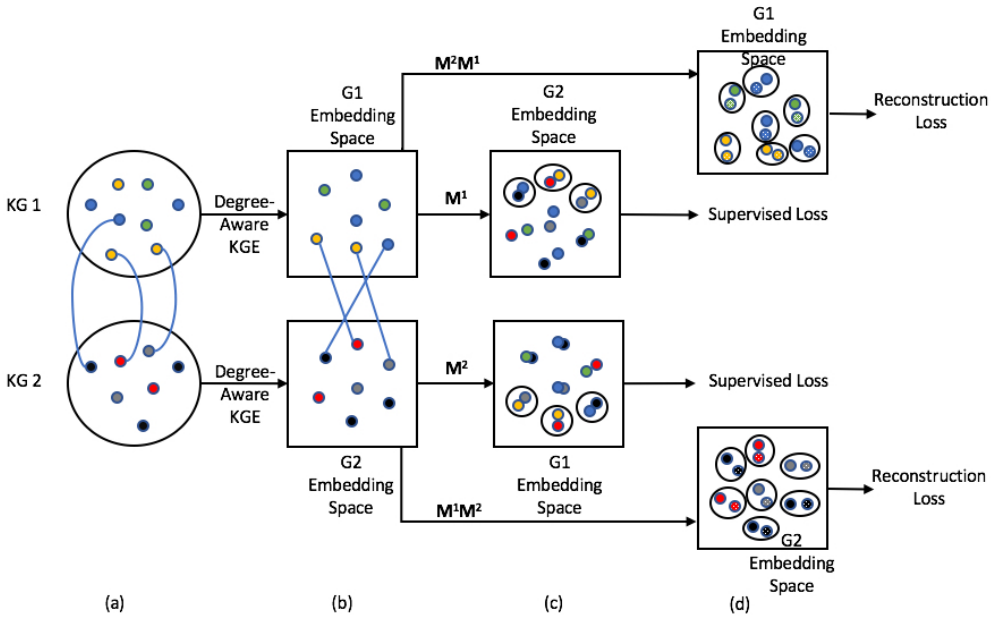

Figure 2: Framework of SEA for semi-supervised entity alignment. (a) shows two knowledge graphs G_1 and G_2 with three pairs of aligned entities. (b) presents the learned embeddings via the degree-aware KG embedding approach. (c) demonstrates the embedding spaces after transferring G_1 to G_2 and G_2 to G_1 using $\mathbf{M}^1$ and $\mathbf{M}^2$ learned by the pairs of aligned entities. The entities within small circles are close due to the supervised alignment guidance. (d) shows the cycle consistency of entities after being transferred back the original embedding spaces. The transferred embedding of each entity should be close to the original embedding of this entity in the original embeddings spaces (as indicated in the small circles).

from E^i_{ld} and E^i_{nd}, which are entities with *low* degree and *normal* degree in graph G_i. Both discriminators are learned to minimize loss functions:

$$L_{D_1} = \frac{1}{|E^i_{hd}|}\sum_{e\in E^i_{hd}} \log D_1(\theta^i_e, \phi^i_1) + \frac{1}{|E^i_{nd}|}\sum_{e\in E^i_{nd}} \log(1 - D_1(\theta^i_e, \phi^i_1)) \tag{6}$$

$$L_{D_2} = \frac{1}{|E^i_{ld}|}\sum_{e\in E^i_{ld}} \log D_2(\theta^i_e, \phi^i_2) + \frac{1}{|E^i_{nd}|}\sum_{e\in E^i_{nd}} \log(1 - D_2(\theta^i_e, \phi^i_2)) \tag{7}$$

Taking also the objective function Eq. (1), the over all minimax object function for learning embeddings of G_i will be:

$$\min_{\varphi^i,\theta^i_e}\max_{\phi^i_1,\phi^i_2} L_{G_i}(G_i;\varphi^i,\theta^i_e) - \alpha L_{D_1}(E^i_{hd}, E^i_{nd};\phi^i_1,\theta^i_e) - \alpha L_{D_2}(E^i_{ld}, E^i_{nd};\phi^i_2,\theta^i_e) \tag{8}$$

where α is a tradeoff parameter. In the adversarial training, L_{G_i} is minimized w.r.t. φ^i and θ^i_e to produce "Good" embeddings to fool D_1 and D_2. Meanwhile, D_1 and D_2 are trained w.r.t. ϕ^i_1 and ϕ^i_2 to distinguish entities with different degree levels. Following the iterative training process of GAN [8], we first train the KG embedding model with D_1 and D_2 fixed, and then train the discriminators with KG embedding model fixed. The same process will be applied to G_1 and G_2.

3.3 Semi-Supervised Entity Alignment

After obtaining entity embeddings of graph G_1 and G_2, labeled entities are aligned to minimize

$$\sum_{(e_i,e_j)\in AS^L} \left\|\mathbf{M}^1\theta^1_{e_i} - \theta^2_{e_j}\right\|_2 + \left\|\mathbf{M}^2\theta^2_{e_j} - \theta^1_{e_i}\right\|_2 \tag{9}$$

where $\mathbf{M}^1$ and $\mathbf{M}^2$ are the $d \times d$ translation matrices, d is the dimension of embeddings of entities. Note that our model jointly learns the translation of embeddings of entities in both directions for each knowledge graph. That is to say, $\mathbf{M}^1$ is learned to transfer the embeddings of G_1 into the embeddings space of G_2, and $\mathbf{M}^2$ is to transfer the embeddings of G_2 into the embeddings space of G_1. Due to the limited labeled set, the learned $\mathbf{M}^1$ and $\mathbf{M}^2$ cannot be generalized well to all entities in the two knowledge graphs.

To improve generalizability and incorporate unlabeled entities of two knowledge graphs in the alignment process, we define a cycled consistent loss, inspired by the work of CycleGAN [38] in computer vision field, where transitivity is used to regularize structured data [38] to do visual tracking [14, 30], 3D shape matching [10], co-segmentation [39, 40] and depth estimation [6]. Translation $\mathbf{M}^1$ and $\mathbf{M}^2$ should be able to

1) bring e_i in G_1 back after mapping cycle $e_i \to e_j \to \hat{e}_i$, i.e., the distance d_{g_1} between e_i and $\hat{e}_i$ should be small;

2) bring bring e_j back after mapping cycle $e_j \to e_i \to \hat{e}_j$, i.e., the distance d_{g_2} between e_j and $\hat{e}_j$ should be small.

Formally, the cycle process is:

$$\theta^1_{e_i} \rightarrow \mathbf{M^1}\theta^1_{e_i} \rightarrow \mathbf{M^2}\mathbf{M^1}\theta^1_{e_i} \tag{10}$$

$$\theta^2_{e_j} \rightarrow \mathbf{M^2}\theta^2_{e_j} \rightarrow \mathbf{M^1}\mathbf{M^2}\theta^2_{e_j} \tag{11}$$

Combing the alignment loss function in Eq. (9) and the cycle consistency restriction, we define the loss function of our semi-supervised entity alignment as:

$$\begin{aligned} L_{SEA}(\mathbf{M^1}, \mathbf{M^2}) = \alpha_1 \sum_{(e_i,e_j)\in AS^L} \left\|\mathbf{M^1}\theta^1_{e_i} - \theta^2_{e_j}\right\|_2 + \left\|\mathbf{M^2}\theta^2_{e_j} - \theta^1_{e_i}\right\|_2 \\ + \left\|\mathbf{M^2}\mathbf{M^1}\theta^1_{e_i} - \theta^1_{e_i}\right\|_1 + \left\|\mathbf{M^1}\mathbf{M^2}\theta^2_{e_j} - \theta^2_{e_j}\right\|_1 \\ + \alpha_2 \sum_{e_i\in E^U_1} \left\|\mathbf{M^2}\mathbf{M^1}\theta^1_{e_i} - \theta^1_{e_i}\right\|_1 + \alpha_2 \sum_{e_j\in E^U_2} \left\|\mathbf{M^1}\mathbf{M^2}\theta^2_{e_j} - \theta^2_{e_j}\right\|_1 \end{aligned} \tag{12}$$

where α_1 and α_2 are the tradeoff parameters for balancing the loss between labeled and unlabeled data.

We initialize the embeddings of KGs by drawing from a Gaussian initialization, and initialize the matrices by using orthogonal initialization. We use SGD as our optimizer, and normalize all embeddings by $L2$ norm. The trade-off parameter α, α_1 and α_2 are set by grid search. Once $\mathbf{M}^1$, $\mathbf{M}^2$ are learned, an entity e in G_1 can be aligned by first transferring to G_2 as $\mathbf{M}^1\theta_e$ and then selecting the most similar entity in G_2. Similarly, an entity e in G_2 can be aligned by first transferring to G_1 as $\mathbf{M}^2\theta_e$ and then selecting the most similar entity in G_1.

4 EXPERIMENTS

In this section, we conduct experiments on several real-world datasets with different sizes, and evaluate our proposed method for entity alignment.

4.1 Datasets and Baselines

To comprehensively evaluate the effectiveness of our SEA method, we use two trilingual knowledge graph datasets from WK31 provided in [5]. WK31 datasets consist of English(En), French(Fr), and German(De) knowledge graphs which are extracted from Person domain of DBpedia's with known aligned entities as ground truth. WK31 includes two datasets with different sizes, which are WK31-15K and WK31-120K. The statistics of the datasets are given in Table 2 and Table 3. For datasets WK31-15K and WK31-120K, we extract the aligned entities from aligned triples.

To verify the effectiveness of our proposed method, we include the following methods for performance comparison, including: **MTransE** [5], **ITransE** [41], **JAPE** [28], **GCN-based method**[34], **BootEA**[29], **SEA w/o DA** (a variant of the proposed SEA, by removing the degree-aware KGE part), and **SEA**.

4.2 Evaluation Metrics and Parameter Settings

We adopt two popular metrics, *Hits@k* and *MRR* for evaluating entity alignment results. *Hits@k* measures the proportion of correctly aligned entities ranked in the top k proposed candidates. In our work, we report *Hits*@1, *Hits*@5 and *Hits*@10. Both metrics are preferred to be higher to present better performance.

Table 1: Statistics of the WK31 dataset

dataset	#Triple	#Entity	#Relation
WK31-15K En-Fr	En: 203,502 Fr: 170,605	En: 15,170 Fr: 15,393	En: 2,228 Fr: 2,422
WK31-15K En-De	En: 203,502 De: 145,616	En: 15,127 De: 14,603	En: 1,841 De: 596
WK31-120K En-Fr	En: 1,376,011 Fr: 767,750	En: 119,749 Fr: 118,591	En:3,109 Fr:2,336
WK31-120K En-De	En: 1,376,011 De: 391,108	En: 67,650 De: 61,942	En: 2,393 De: 861

Table 2: Number of aligned entity in different datasets.

Dataset	En-Fr	Fr-En	En-De	De-En
WK31-15K	10,108	10,164	11,594	11,445
WK31-120K	117,947	117,212	55,640	54,287

For all methods compared in 4.3, we set the dimension of knowledge graph embeddings $d = 100$ on all datasets. We find the optimal parameter settings for all baseline methods.

For our SEA method, we set that the *high* degree entities are those with top 20% degree values, while the *low* degree entities are those with bottom 20% degree values, and the rest are the *normal* degree entities. we search the margin γ among $\{0.5, 1, 1.5, 2\}$, and the tradeoff parameter α among $\{0.1, 0.3, 0.5, 0.7, 1.0\}$, α_1 and α_2 among $\{1, 2.5, 5, 7.5\}$ and $\{0.05, 0.15, 0.25, 0.35, 0.45\}$, respectively. The best configuration is $\gamma = 0.5$, $\alpha = 0.5$, $\alpha_1 = 2.5$ and $\alpha_2 = 0.25$. Discriminators are set as two-layers MLPs with 500 hidden units. We use Adam [15] to optimize the object function. Meanwhile, we use $L2$ norm to avoid potential over-fitting.

We randomly sample 30% of the aligned entities as the training set, and the rest aligned entities for testing. Each evaluation is repeated 5 times and we report the averaged *Hits@k* and *MRR*.

4.3 Performance Evaluation Results

The evaluation results are presented in Table 3-4. The best results are shown in bold among the group of methods, along with the percentage of improvement when comparing SEA without degree-aware (SEA w/o DA) and SEA with the best baseline methods. From these evaluation results, we have the following findings:

(1) **Our proposed SEA consistently outperforms the baseline methods on all datasets under different evaluation metrics**. This observation verifies that our proposed model effectively unifies the labeled and unlabeled data for improving entity alignment accuracy. In particular, our method achieves significant improvement when matching the top-1 ranked entity (*Hits*@1 is improved by more than 10%, or even 30-56%). Especially on the largest dataset WK31-120k, our SEA method has improvements on all metrics from 18% to 56%. BootEA is often the second best baseline due to the effective bootstrapping strategy for selecting labeled data. However, on the largest dataset WK31-120k, it sometimes performs worse than MTransE, mainly because it is difficult for bootstrapping to propose effective entities to label in a large dataset. In addition, bootEA need more time to calculate the similarity between each

Table 3: Entity alignment results of different methods on WK31-15K dataset. The best results are in bold, along with the percentage of improvement when comparing SEA w/o DA and SEA with the best baseline methods.

entity pair in the dataset except the training data. All the results show that the advantage of our semi-supervised method.

(2) **Our proposed degree-aware knowledge graph embedding approach produces improved entity representations, and thus improves entity alignment results**. This conclusion is drawn from the comparison of improvement made by SEA w/o DA and SEA. After mitigating the effect of entity's degree difference on embedding results, SEA can further improve the semi-supervised results obtained by SEA w/o DA, with only few exceptions. It is worth noting here that the aligned entities with *high* and *low* degree is a small proportion of the whole aligned entity set. How much degree-aware KE embedding can help is limited by this small proportion of entities with *high* and *low* degree levels. Therefore, the improvement made from SEA w/o DA to SEA is justifiable.

5 CONCLUSION

Entity alignment is an important research problem in knowledge graph analysis and management. In this work, we propose a semi-supervised method with degree-aware KG embedding to do the entity alignment. We design a cycle-consistency based translation loss to leverage the unaligned entity to enhance the ability of alignment instead of only using labeled aligned entities. In addition, we observe that the entity degree can influence the learned embeddings and degrade the performance of downstream application. We thus adopt adversarial training to alleviate the problem and improve the embedding results. We conduct experiments on four real-world datasets. The experimental results show that our model consistently outperforms the state-of-art methods on the entity alignment task. Based on the success of this first attempt of semi-supervised entity alignment, in future, we will consider the relation information in the graph to enhance the model.

ABSTRACT

Online social movements (OSMs) play a key role in promoting democracy in modern society. Most online activism is largely driven by critical offline events. Among many studies investigating collective behavior in OSMs, few has explored the interaction between crowd dynamics and their offline context. Here, focusing on the *Black Lives Matter* OSM and utilizing an event-driven approach on a dataset of 36 million tweets and thousands of offline events, we study how different types of offline events—police violence and heightened protests—influence crowd behavior over time. We find that police violence events and protests play important roles in the recruitment process. Moreover, by analyzing the re-participation dynamics and patterns of social interactions, we find that, in the long term, users who joined the movement during police violence events and protests show significantly more commitment than those who joined during other times. However, users recruited during other times are more committed to the movement than the other two groups in the short term. Furthermore, we observe that social ties formed during police violence events are more likely to be sustained over time than those formed during other times. Contrarily, ties formed during protests are the least likely to be maintained. Altogether, our results shed light on the impact of bursting events on the recruitment, retention, and communication patterns of collective behavior in the *Black Lives Matter* OSM.

1 INTRODUCTION

Social movements often signify social change [5, 30, 35]. They help transform what have been considered radical ideas of one generation to the common sense of the next [14]. Social media has become instrumental in driving and facilitating politically contentious online social movements (OSMs) throughout the world [12, 20, 36, 44].

Previous research studied various OSMs such as the 2010 Arab Spring [28], the 2011 Egyptian Revolution [41, 50], the 2011 Occupy Wall Street [9, 20], through the lens of social media, mainly Twitter [2, 3, 22, 32, 40]. Topics they investigated range from participant motivation [44], movement framing [24, 43], informal learning [20], to information diffusion [22, 28, 41]. There are also studies focusing on crowd behavior in OSMs. Subjects they examined include recruitment process [23], user engagement [6, 9, 40], and online interactions [34], as well as the temporal evolution of crowd behavior [2, 4, 9, 11, 48]. Although these studies focus on different OSMs that were driven by very different political agendas, most of them convey the same message: *the unique characteristics of crowd behavior are often associated with critical offline events*. Yet, there is limited research on investigating how different types of offline events influence the behavior of online crowds and affect their interactions with the movement over time.

An event helps a person think about how the world diverges from his basic values [25]. On one hand, exogenous shocking events such as police shootings can contribute to the recruitment into the *Black Lives Matter* movement by creating "moral shocks" that can transform the public emotion from dread to outrage [17, 18, 25]. These complex emotional processes usually generate broader impact on the public sphere and can suddenly cause wide-scale unplanned movement participation of peripheral users in online social networks [8, 27, 31]. On the other hand, endogenous events such as self-organized protests can have an effect on crowd behavior with the help of movement networks in two stages. First, planned protests in physical locations are likely to be preceded by considerable communication and coordination among highly involved activists. Second, participants in offline protests often interact with the movement on social media to gain awareness, articulate their core beliefs, and offer a frame to the public [24]. As a result, offline events can generate massive participation in OSMs and are thus crucial to the emergence, growth, and decline of online activism [13].

In this paper, we analyze crowd dynamics in the *Black Lives Matter (BLM)* online movement using a combination of 36 million tweets and thousands of compiled offline events. We focus our analysis on crowd dynamics around three types of time periods: cases of police violence, large-scale offline protests, and periods of neither police violence or protests referred to as "other times". Our event-driven investigation provides two major contributions. First, we find that police violence events and protests not only act as magnets to mobilize people around the movement, but they also greatly encourage user commitment in the long term. Second, we reveal that police violence events and protests have significantly different impact on the maintenance of social interactions established during these events. Altogether, our results shed light on how online crowds behave during bursting events.

2 RELATED WORK

Online Social Movements, Crowds, and Events. Social media is now used as an organizing tool for collective action and has enabled the proliferation of online low-risk activism [31], which may indeed have been a productive component of recent political uprisings [41]. In addition, studies have revealed that social media largely promotes social movements by means of influencing individual decisions about participation [20], providing new sources of information beyond the control of authorities, and shaping the discourse, logistics, and outcomes of protests [44]. This suggests that social media facilitates the emergence of massive offline mobilization and can serve as a good proxy of studying OSMs.

Several studies in OSMs have been conducted through the lens of Twitter [2, 6, 22, 28, 32, 41, 48]. Existing work tends to focus on the characteristics of information generated during the course of various online movements. They are interested in analyzing movements along dimensions including the variation of the amount of information produced, the way how information spreads [22, 28, 41], and the contribution from different social actors involved in the movement [2, 6, 32, 48].

Other research examines crowd behavior and its dynamics in OSMs. Topics covered range from online social interactions [34], the recruitment dynamics [23], and community polarization [50], to opinion evolution [4]. There are also studies exploring the connections between the dynamics of OSMs and relevant offline events [7, 52]. In [42], Steinert et al. studied the relationship between online activities and the volume of protests on the ground. The work in [3] explored the possibility of forecasting onsite protests using social media stream data. Spiro et al. found that key time points with unique online social structure often map to exogenous events in physical locations [40]. These studies inform us about the relationship between the movement dynamics and relevant protests unfolded on the ground. However, to our knowledge, there is little work investigating how different types of offline events affect crowd dynamics in OSMs.

Outside of movement research, the interplay between crowd behavior and shocking events has been a rising theme of considerable interest in setting such as organizations [37], crowdsourcing platforms [53, 54], and global scale mobile communications [1]. Bagrow et al. analyzed the behavioral change and societal response of crowds to external perturbation during emergencies [1]. Romero et al. investigated the link between stock market shocks and the structure of the communication network in a large hedge fund [37]. A recent work [53] studied the collective response of editors of Chinese Wikipedia to the government censorship in mainland China. These studies reveal that online crowds are especially sensitive during external perturbations [19, 21, 46]. The above literature thus forms a significant part of the motivation for our effort on analyzing crowd dynamics in OSMs using an event-driven approach.

Research in the *BLM* Movement. *BLM* is an international activist movement initiated by the African American community in the U.S. after the killing of Trayvon Martin in 2012. The movement is centered around issues related to racial inequality and police brutality. Since the extensive adoption of the hashtag *#BlackLivesMatter* on social media after the death of Eric Garner and Michael Brown in 2014, the movement has generated thousands of on-site protests and demonstrations globally. Over time, the *BLM* movement gained worldwide recognition and the general public began to participate in the movement using a variety of hashtags on Twitter [24].

Several studies have analyzed the *BLM* online movement. In [33], Olteanu et al. provided a demographic characterization of users involved in this movement. Stewart et al. examined the frame process between competing online communities in the *BLM* movement through the use of related hashtags [43]. Ince et al. investigated how Twitter users interact with the *BLM* movement through hashtags and thus modify its framing [24]. A recent work [16] studied the divergent discourse between the *#BlackLivesMatter* protest and the *#AllLivesMatter* counter-protest on Twitter. Twyman et al. studied the dynamics of attention and knowledge production related to the *BLM* movement using Wikipedia [45]. However, as far as we know, there is limited work focusing on crowd dynamics in the *BLM* online movement and its relationship to offline events.

Most related to our work, De Choudhury et al. investigated the participation in the *BLM* online movement over time in different geographical locations and explored its relationship with protests unfolded on the ground [11]. Our work differs in that we systematically investigate the dynamics of user participation and patterns of social interactions, and explore how different types of offline events affect these dynamics in the *BLM* online movement.

3 DATA AND BACKGROUND

Twitter Dataset. Research indicates that the public use hashtags to interact with *BLM* to promote their messages, articulate core beliefs, and offer political solutions [11, 24, 33]. Here, we use data collected by [6] which includes tweets that are tagged with 53 *BLM* related hashtags. These race-related hashtags cover the stream of demonstrations and riots against the systemic racism and police violence toward African Americans [6].

The dataset spans from Jan. 2014 to May 2015, which covers the initial periods of the *BLM* movement on Twitter since it did not gain enough momentum until 2014 [11, 33]. It includes *every tweet* posted during this time period that contained one of the 53 *BLM* related hashtags mentioned above. There are 36 million tweets posted by 4 million users, among which we obtain 27 million retweets.

Offline Events. We compiled a list of *BLM* related events including police violence against African Americans and numerous on-site protests. The police violence events are based on news media reports and here we focus on the most prominent ones, which are shown in Table 1. The protest events are collected from *Elephrame*[1] [11]. This website keeps track of the *BLM* related demonstrations using information from multiple online sources. It estimates the number of demonstrators based on photos, videos, and media reports about each demonstration. Here we focus on protests with significant public awareness and potential impact on online crowds by defining a threshold $\mathcal{T}_{\text{protest}}$ of the number of participants and filtering those below it. We are able to identify 37 heightened protests with $\mathcal{T}_{\text{protest}} = 500$ in this study (The qualitative result does not change for $\mathcal{T}_{\text{protest}} = 100$).

Table 1: Five police violence events used in our analysis and their number of NYTimes articles.

Victim	Date	Location	# articles
Eric Garner	2014-07-17	New York City	518
Michael Brown	2014-08-09	Ferguson, Missouri	820
Tamir Rice	2014-11-23	Cleveland, Ohio	67
Walter Scott	2015-04-04	Charleston, South Carolina	47
Freddie Gray	2015-04-12	Baltimore, Maryland	169

Event Categorization. To explore the interplay between crowd behavior on Twitter and identified offline events in the *BLM* movement, we create an event-type categorization of the Twitter dataset.

For each instance of police violence, we label the week after the time when the event occurs as a *police violence* period. For each protest, we label the week before and the week after the event as a *protest* period, reflecting the possibility that participants use social media to organize and recruit for the upcoming protest [16]. We combine adjacent time periods of the same event type into a single period. When a protest period overlaps with a police violence period, it is likely that the former is immediately driven by the latter, thus the overlapping period is labeled as *police violence*. Time periods between different events are labeled as *other times*, which can be considered as normal times when public interactions with the movement are not induced by external factors. Throughout this study, we exclude tweets posted before July 17, 2014 since there is no protest data in *Elephrame* before this date. The event categorization is shown as the *background* in Figure 1.

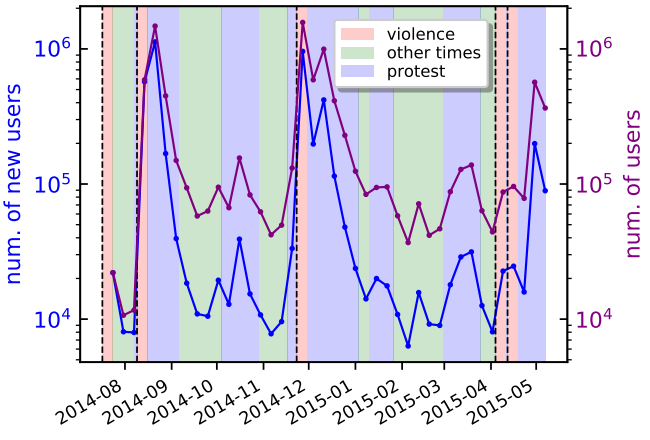

Figure 1: Number of new/all participants in each of the non-overlapping, one-week time windows starting from the first police violence event in the offline dataset. (*Background*): Event categorization of the twitter dataset used in this analysis. Five dashed vertical lines represent five police violence events in Table 1. A rectangular area denotes a time period, and its color represents its event type.

We first analyze the recruitment process in the *BLM* online movement using this event categorization. We split the whole periods into non-overlapping bins of one week starting from the time of the police violence against Eric Garner. We define the arrival time D_u of user u, as the time when u tweeted for the first time. For a given time window w_i, let n_i denote the number of new adopters whose arrival time D_u is during week w_i. Let p_i denote the number of participants who posted at least one tweet in week w_i. Figure 1 illustrates the time series of n_i and p_i respectively. It shows that there are repeating temporal variations in terms of the participation volume in the movement, with police violence events generating initial spikes followed by slight declines during protests and then fluctuating in other times. We also see that police violence events and protests function as magnets to attract new participants and mobilize people around the movement over time, which highlights the importance of examining mobilization patterns from the perspective of such events. The increase in activity during these events naturally leads to the question of whether users who became activated during different events behave and interact differently with the movement in the future.

4 DYNAMICS OF USER PARTICIPATION

Identifying characteristics of continued participation has been the central theme in recent OSM research [2, 6, 32, 48]. Yet, little is known about the evolution of user commitment as a function of offline events. In this section, we explore how arriving at the movement during a type of event is related to continued user participation in the *BLM* online movement.

We define a tracking window of t weeks to measure, for each user u, their commitment using their re-participation intensity within t weeks starting from D_u (their join time) along three dimensions. The first dimension is a binary variable y_u indicating if u re-participated or not within t weeks. The second one is the number of times f_u that u re-participated within t weeks (tweets in the movement). The third one is the number of days p_u that u re-participated within t weeks (active days in the movement). These three dimensions are meant to construct a thorough characterization of user commitment.

Modeling re-participation dynamics is complex. In addition to the events happening when they join, many other factors can directly influence users' re-participation behavior. To test whether the event during which users join the movement is related to their future participation, we utilize a prediction framework to control for potential confounds. For the first dimension, we adopt a logistic regression model where y_u is used as the dependent variable (Eq. 1). We employ a linear regression model for the second and the third dimensions separately, where $\log(f_u + 1)$ and $\log(p_u + 1)$ are used as the dependent variable, respectively (Eq. 2).

$$logit(p(y = 1)) = \beta_1 I + \sum_2^k \beta_k x_k + \epsilon \quad (1)$$

$$\log(y + 1) = \beta_1 I + \sum_2^k \beta_k x_k + \epsilon \quad (2)$$

The 8 independent variables are the same in all regressions, which are listed in Table 2. Variable 1 is categorical for which we use *other times* as the baseline, with two dummy variables indicating *police violence* and *protest*, respectively (I in Eq. 1 and Eq. 2). Variables $2-8$ are numerical and are used as controls in the regressions. Variables $2-4$ take into account the fact that users arrived at different time and the events following a user's start date can impact their re-participation dynamics irrespective of the events that occurred when they arrived. For instance, users may be more likely

Table 2: Independent variables for predicting user re-participation.

1	the event type of D_u (categorical)
2	the week number of D_u
3	the fraction of days labeled as *violence* in t weeks starting from D_u
4	the fraction of days labeled as *protest* in t weeks starting from D_u
5	the tweet count of u at D_u
6	the friend count of u at D_u
7	the follower count of u at D_u
8	the account age (in days) of u at D_u
Note: Variables $5-8$ are user meta data.	

to return to the movement if there is an upcoming police violence event since these events usually encourage participation. Variables $5-8$ control for the effect that can be explained by the difference between various user attributes. The Variance Inflation Factor (VIF) of all controls are below 5 in a multicollinearity test, which suggests that all of them should be included in the model. We standardize all numerical variables before performing the regression.

We train 10 models for each dimension by varying the tracking window from $t = 1$ to $t = 10$. To avoid right censoring bias, we focus on the same set of users whose join time D_u allow us to track their future participation for at least 10 weeks in our dataset. In total, we have 3.8 million users, among which 54% joined the *BLM* online movement during police violence periods, 42% joined during protest periods, and 4% joined during other times.

Our main objective is to estimate the impact of offline events on user commitment, therefore we focus on the first independent variable—the event type of users' starting time, and measure the relative change for *police violence* and *protest* over *other times*. Namely, for each dummy variable, we calculate the percentage increase in each dimension over the baseline. In figure 2, we show the effects of events on user commitment in the *BLM* online movement.

How likely are users to re-participate? The results indicate that both police violence events and protests have a time-dependent effect on users' likelihood of re-participation. We find that, in the long term, users who joined the movement during police violence and protest periods are significantly more likely to come back than those who joined during other times. Figure 2A shows that, compared to users who came during other times, the odds of re-participating in the movement within $8-10$ weeks are nearly doubled for users who started in violence periods ($p < 10^{-10}$), while the odds of re-participation for users who joined during protests is 50% higher than the baseline group (other times) ($p < 10^{-10}$).

However, in the short term, the odds of re-participating in the movement decrease by about 40% for users in the protest group over the baseline ($p < 10^{-10}$), and users in the other two groups are comparable overall with no clear dominance of one group over the other in terms of the likelihood of re-participation.

How frequently and how persistently do they re-participate? Merely assessing the presence or absence of continued participation in an activist movement is not enough to measure user dedication. We thus further examine users' commitment by investigating their participation frequency and persistence, namely the number of tweets a user has posted and the number of days that he has participated in a given time window. The latter complements the former by capturing more nuanced participation dynamics—some users can post up to hundreds of tweets a day but stay silent thereafter.

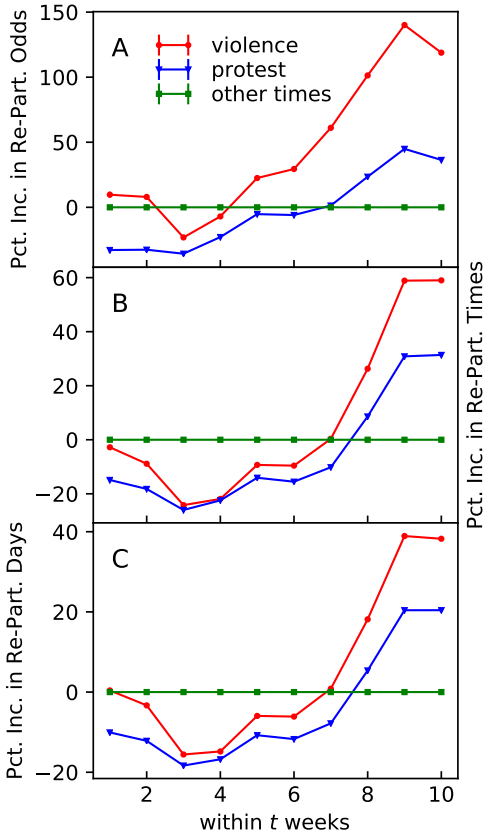

Figure 2: (A) The percentage increase in odds of re-participation within t weeks for users who joined during police violence and protest periods over those who joined during other times. The error bars indicate a 95% confidence interval. (B) The same as (A), but for the percentage increase in users' re-participation times (Frequency dimension). (C) The same as (A), but for the percentage increase in users' re-participation days (Persistence dimension).

We find that police violence events and protests have similar two-fold effects on users' future commitment. According to Figure 2 B and Figure 2C, in the long term, joining the movement during violence periods contributes to an approximate 60% increase in re-participation frequency and a 40% increase in persistence over those recruited during other times, and protest group experiences about a 25% and a 20% increase, respectively. In the short term, however, the two groups have a $10\% - 20\%$ decrease in the frequency and the persistence dimensions compared to other times group.

Discussion of findings. Overall, we find that police violence events and heightened protests significantly affect individual participation in the *BLM* online movement. These events have both short and long term effects on the dynamics of user commitment. One possible explanation is that users who joined during other times are

self-motivated and thus are more active in the initial periods, but their energy decreases over time. On the other hand, arriving to the movement during high activity events, when the entire movement is more energized, may influence users to be less active in the short term as they process the large volume of information they are being exposed to, but more active in the long term. Indeed, studies have shown that attending protests leads to higher long term political and protest participation [29, 39]. Another plausible reason is that people who joined during different periods may respond differently to changes in the movement composition over time [26, 51]. Alternatively, people joining the movement during different types of events can have different motivations and thus different responses to insufficient gratification that affect long term movement commitment [47]. We acknowledge that future work is needed to determine which, if any, of these factors drive the time-dependent participation response.

5 PATTERNS OF SOCIAL INTERACTIONS

Individual participation is only one component of OSMs. The interactions among movement participants make the community strong and robust [19]. It has been suggested that crowds display higher strong tie interactions and interpersonal exchanges during shocks and societal upheavals [19, 37]. But to what extend do external events affect tie strength over time? In this section, we characterize the formation and maintenance of social ties formed during different types of offline events in the *BLM* online movement.

Specifically, we consider retweets as social interactions between participants involved in the movement. For a social tie $e_{i,j} = (u_i, u_j)$, we define $D_{e_{i,j}}$ as the first time u_i retweeted a tweet by u_j that contains one of the hashtags. We measure tie strength using its interaction intensity within t weeks (the tracking window) starting from $D_{e_{i,j}}$ along three dimensions similar to the ones we applied to user re-participation. The first dimension is a binary variable $y_{e_{i,j}}$ indicating if u_i retweeted u_j again within t weeks ($e_{i,j}$ recurred or not). The second one is the number of times $f_{e_{i,j}}$ that u_i retweeted u_j again within t weeks (the recur frequency of $e_{i,j}$). The third one is the number of days $p_{e_{i,j}}$ that u_i retweeted u_j again within t weeks (the recur persistence of $e_{i,j}$). These three dimensions can provide a rich description of the strength of social interactions.

Similar to user participation, many factors can influence the patterns of social interactions. To test whether the creation time (event type) of a tie is related to its recur patterns, we leverage a prediction framework to control for possible confounding factors. We follow the same pipeline for each dimension as in Section 4 (Eq. 1 for the first dimension and Eq. 2 for the other two).

The 20 independent variables are the same in all regressions, which are listed in Table 3. We define D_0 as the time of the first tweet in our dataset. Variables 2−20 are used as controls in the regressions, which capture the variations between ties' creation time in the movement (4, 19, 20), the tendency for users to retweet (11, 13), the tendency for users to be retweeted (12, 14), users' activity level prior to and after tie creation ($5-10, 17, 18$), number of users they retweeted in common (16), and users previous interactions (15), etc.

The Variance Inflation Factor (VIF) of all numerical variables ($4-20$) are below 5 in a multicollinearity test. We standardize all numerical variables before performing the regression. Again, we train 10 models for each dimension by varying the tracking window from $t = 1$ to $t = 10$. We focus on the same set of social ties whose creation time $D_{e_{i,j}}$ allow us to track their future interactions for at least 10 weeks in the dataset. In total, we obtain 17 million social ties, among which 41% were created during police violence events, 53% during protest periods, and 6% in other times.

Table 3: Independent variables for predicting tie strength.

1	the event type of $D_{e_{i,j}}$
2	the event type of D_{u_i}
3	the event type of D_{u_j}
4	the week number of $D_{e_{i,j}}$
5	the # protest tweets of u_i in $[D_0, D_{e_{i,j}}]$
6	the fraction of (5) in *violence*
7	the fraction of (5) in *protest*
8	the # protest tweets of u_j in $[D_0, D_{e_{i,j}}]$
9	the fraction of (8) in *violence*
10	the fraction of (8) in *protest*
11	the times u_i has retweeted others in $[D_0, D_{e_{i,j}}]$
12	the times u_i has been retweeted by others in $[D_0, D_{e_{i,j}}]$
13	the times u_j has retweeted others in $[D_0, D_{e_{i,j}}]$
14	the times u_j has been retweeted by others in $[D_0, D_{e_{i,j}}]$
15	the times u_j has retweeted u_i in $[D_0, D_{e_{i,j}}]$
16	the # users u_i and u_j have retweeted in common in $[D_0, D_{e_{i,j}}]$
17	the # protest tweets of u_i in t weeks from $D_{e_{i,j}}$
18	the # protest tweets of u_j in t weeks from $D_{e_{i,j}}$
19	the fraction of days labeled as *violence* in t weeks from $D_{e_{i,j}}$
20	the fraction of days labeled as *protest* in t weeks from $D_{e_{i,j}}$
Note: Variables $5-20$ are calculated based on our dataset.	

We apply the same procedure to the first independent variable as we did in Section 4. We measure the relative change in the strength for social ties formed during police violence events and protests over those in the baseline group. The results are shown in Figure 3.

How likely are interactions to recur? We find that social interactions started in police violence periods are significantly more likely to be sustained in the long term than those created during other times. Figure 3A shows that, within $8-10$ weeks, the odds of recur for social ties created in violence periods are $10\%-20\%$ higher than that of other times group ($p < 10^{-15}$). However, the short term differences between two groups are less pronounced as there is oscillation between them. On the other hand, protests have a more unified influence on the maintenance of social interactions, i.e., irrespective of the time effect, communication bonds established in protests are less likely to recur than do those started in other times (about 10% decrease overall, $p < 10^{-9}$).

How frequently and how persistently do they recur? We further examine tie strength along the frequency and persistence dimensions. Figure 3B and 3C show that the overall influence of police violence events and protests on the recur frequency and persistence of social ties are similar to what we observe in the first dimension, but the result also indicates that violence events and protests have marginal influence on the sustainability of social ties compared to the baseline group (only 1% increase or decrease, $p < 10^{-10}$). This may be explained by the fact that, in general, people communicate

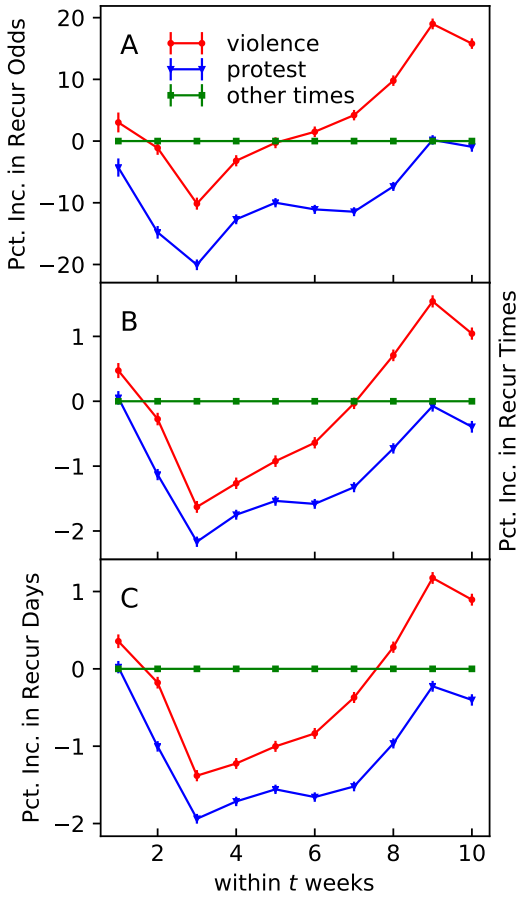

Figure 3: (A) The percentage increase in odds of recur for social interactions started during police violence and protest events over those created during other times. The error bars indicate a 95% confidence interval. (B) The same as (A), but for the percentage increase in recur frequency. (C) The same as (A), but for the percentage increase in recur persistence.

less selectively and form short-lived connections during political upheavals [38], thus reducing the influence of external events on tie strength and its evolution.

Discussion of findings. In summary, we find that communications started in police violence events are more likely to be maintained over time than interactions formed in normal times, which supports the idea that communities bond and build strong ties during shocks [15, 19, 37]. However, social ties formed during protests recur less likely, less frequently and less persistently than do those established in other times. We conjecture that social connections forged during protests are more about informational support which may be less likely to persist compared to emotional support [10, 49].

6 CONCLUSION

We conduct a large-scale empirical investigation of crowd dynamics in the *BLM* online movement using a combination of social media data and a comprehensive list of offline events. By analyzing user participation and social interactions through the lens of different types of events, we are able to reveal the dynamics of online crowd behavior and its relationship to offline events in a politically contentious movement around race.

First, we find that both police violence events and intensified protests have time-dependent effects on users' future commitment. In the long term, users who joined the movement during two type of events are significantly more likely to re-participate than those who joined during other times. However, in the short term, joining the movement in these events are associated with decreased future commitment. **Second**, we find that police violence events and protests have different effects on the continuation of social interactions formed during these periods, with the former showing both long-term and short-term effects while the latter displaying a more unified pattern. Specifically, we find that communications started in police violence events are significantly more likely to be sustained in the long run than those started in other times. But in the short term, they are less likely to be maintained. However, regardless of the time, social ties established during protests are less likely to recur compared to other times group.

Implications. Our study has implications for policymakers, movement organizers, and online social movement observers. These escalated events, unexpected or expected, function as driving forces that organize people to participate in the movement over time. They also play a great role in user retention and motivating social interactions. Knowing about these patterns, movement organizers and organizations may allocate more resources on the recruitment process during normal times. A social movement similar to the *BLM* would also try to encourage newcomers who arrived when no special event was happening to sustain participation in the long term, since they are known to drop out over time. Similarly, cultivating stronger social relationships formed during protests may be an effective way to stimulate sustained communications and facilitate information sharing about the movement in the future. Finally, this study provides insights to research on collective behavior and crowd response in the face of bursting events.

Limitations and future work. This work has limitations. First, we measure user commitment solely based on twitter dataset. However, it's unclear whether individuals who participated in the movement at its initial stage did not divert their participation to other places that are not captured in our data. Second, users may participate on Twitter in ways other than using hashtags. Third, we only study one online social movement, which limits the generalizability of our findings to other type of movements. Furthermore, although we find strong correlation between online crowd dynamics and different types of offline events, we cannot make causal claims based on these findings. Investigating whether users were intrinsically different or they were just influenced by the events when they joined the movement is an open direction for future research.

ACKNOWLEDGMENTS

This research was partly supported by the National Science Foundation Grants No. IIS-1617820 and IIS-1815875. We would like to thank David Jurgens for helpful discussion, and Lia Bozarth for data preparation.

ABSTRACT

A major drawback of cross-network recommender solutions is that they can only be applied to users that are overlapped across networks. Thus, the non-overlapped users, which form the majority of users are ignored. As a solution, we propose CnGAN, a novel multi-task learning based, encoder-GAN-recommender architecture. The proposed model synthetically generates source network user preferences for non-overlapped users by learning the mapping from target to source network preference manifolds. The resultant user preferences are used in a Siamese network based neural recommender architecture. Furthermore, we propose a novel user-based pairwise loss function for recommendations using implicit interactions to better guide the generation process in the multi-task learning environment. We illustrate our solution by generating user preferences on the Twitter source network for recommendations on the YouTube target network. Extensive experiments show that the generated preferences can be used to improve recommendations for non-overlapped users. The resultant recommendations achieve superior performance compared to the state-of-the-art cross-network recommender solutions in terms of accuracy, novelty and diversity.

1 INTRODUCTION

Cross-network recommender systems utilize auxiliary information from multiple source networks to create comprehensive user profiles for recommendations on a target network. Therefore, unlike traditional recommender solutions which are limited to information within a single network, cross-network solutions are more robust against cold-start and data sparsity issues [17]. For example, the additional information from Twitter and Flicker, increased recommender precision on Delicious by 10% [1]. Similarly, the transfer of information from various source networks to target networks such as Google+ to YouTube [10], Twitter to YouTube [20, 24] and Wikipedia to Twitter [18] have consistently improved recommender accuracy. Furthermore, cross-network solutions allow user preferences to be captured from diverse perspectives, which increases the overall recommender quality in terms of diversity and novelty [20, 21]. However, despite the growing success of cross-network recommender solutions, the majority of existing solutions can only be applied to users that exist in multiple networks (overlapped users). The remaining non-overlapped users, which form the majority are unable to enjoy the benefits of cross-network solutions.

Deep learning and generative modeling techniques have been successfully used in the recommender systems domain in the past few years. For example, restricted Boltzmann machines [26], Autoencoders [19], Hidden Markov Models [25] and Recurrent Neural Networks (RNN) [13] are some of the models used for rating prediction tasks. Recent advancements in Generative Adversarial Networks (GANs) have also drawn recommender systems researchers to apply the new minimax game framework to information retrieval. For example, IRGAN [28] and RecGAN [5] were designed to predict relevant documents to users. Existing solutions use GAN to generate simple rating values [5, 28, 30] or synthetic items (e.g., images [14]). In contrast, we use GAN to generate complex user data (i.e., user preferences on the source network).

We propose a novel GAN model (CnGAN) to generate cross-network user preferences for non-overlapped users. Unlike the standard GAN model, we view the learning process as a mapping from target to source network preference manifolds. The proposed model solves two main tasks. First, a generator task learns the corresponding mapping from target to source network user preferences and generates auxiliary preferences on the source network. Second, a recommender task uses the synthetically generated preferences to provide recommendations for users who only have interactions on the target network. Furthermore, we propose two novel loss functions to better guide the generator and recommender tasks. The proposed solution is used to provide recommendations for YouTube users by incorporating synthesized preferences on Twitter. However, the solution is generic and can be extended to incorporate multiple source networks.

In this paper, we first briefly provide preliminaries to the proposed model and present the proposed CnGAN solution detailing its two main components, the generator and recommender tasks. Then, we compare the proposed model against multiple baselines

to demonstrate its effectiveness in terms of accuracy, novelty and diversity. We summarize our main contributions as follows:

- To the best of our knowledge, this is the first attempt to apply a GAN based model to generate missing source network preferences for non-overlapped users.
- We propose CnGAN, a novel GAN based model which includes a novel content loss function and user-based pairwise loss function for the generator and recommender tasks.
- We carry out extensive experiments to demonstrate the effectiveness of CnGAN to conduct recommendations for non-overlapped users and improve the overall quality of recommendations compared to state-of-the-art methods.

2 MODEL

2.1 Model Preliminaries

2.1.1 Bayesian Personalized Ranking (BPR):. Learning user preferences from implicit feedback is challenging since implicit feedback does not indicate preference levels toward items, it only indicates the presence or absence of interactions with items. BPR [23] was proposed to rank items based on implicit feedback using a generic optimization criterion. BPR is trained using pairwise training instances $S = \{(u, i, j) | u \in U \wedge i \in I_{u+} \wedge j \in I \setminus I_{u+}\}$, where I is the set of all items and I_{u+} is the set of items user u has interacted with. BPR uses a pairwise loss function to rank interacted items higher than non-interacted items, and maximizes their margin using a pairwise loss as follows:

$$L_{BPR}(S) = \sum_{(u,i,j)\in S} -\ln \sigma(\hat{r}_{uij}) + \lambda_\Theta \|\Theta\|^2 \quad (1)$$

where $\hat{r}_{uij} = \hat{r}_{ui} - \hat{r}_{uj}$, Θ are model parameters, $\sigma(x) = e^x / e^{x+1}$ is a sigmoid function and λ_Θ are regularization parameters.

2.1.2 Feature extraction on a continuous space: CnGAN is trained using target network interactions of each user at each time interval and their corresponding source network interactions. We used topic modeling to capture user interactions on a continuous topical space since CnGAN is a GAN based model and requires inputs in a continuous space. Let $u_o \in U = [Tn_u^t, Sn_u^t]$ denote an overlapped user at time t, where Tn_u^t and Sn_u^t are target and source network interactions spanned over $T = [1, \ldots, t]$ time intervals. A non-overlapped user $u_{no} \in U = [Tn_u^t]$ is denoted only using target network interactions. We used YouTube as the target and Twitter as the source network to conduct video recommendations on YouTube. Therefore, Tn_u^t is the set of interacted videos (i.e., liked or added to playlists) and Sn_u^t is the set of tweets. We assumed that each interaction (video or tweet) is associated with multiple topics, and extracted the topics from the textual data associated with each interaction (video titles, descriptions and tweet contents). We used the Twitter-Latent Dirichlet Allocation (Twitter-LDA) [32] for topic modeling since it is most effective against short and noisy contents. Based on topic modeling, each user u on the target network is represented as a collection of topical distributions $tn_u = \{\boldsymbol{tn_u^1}; \ldots; \boldsymbol{tn_u^t}\} \in \mathbb{R}^{T \times K^t}$ over T time intervals, where K^t is the number of topics. Each vector $\boldsymbol{tn_u^t} = \{tn_u^{t,1}; \ldots; tn_u^{t,K^t}\} \in \mathbb{R}^{K^t}$ is the topical distribution at time t, where $tn_u^{t,k} = \hat{tn}_u^{t,k} / \sum_{c=1}^{K^t} \hat{tn}_u^{t,c}$ is the relative frequency of topic k, and $\hat{tn}_u^{t,k}$ is the absolute frequency of the corresponding topic. Similarly, on the source network, interactions are represented as $sn_u = \{\boldsymbol{sn_u^1}; \ldots; \boldsymbol{sn_u^t}\} \in \mathbb{R}^{T \times K^t}$. The resultant topical frequencies indicate user preference levels towards corresponding K^t topics. Therefore, $u = \{tn_u, sn_u\} \in \mathbb{R}^{T \times 2K^t}$ represents user preferences over T time intervals on a continuous topical space, and forms the input to the proposed model.

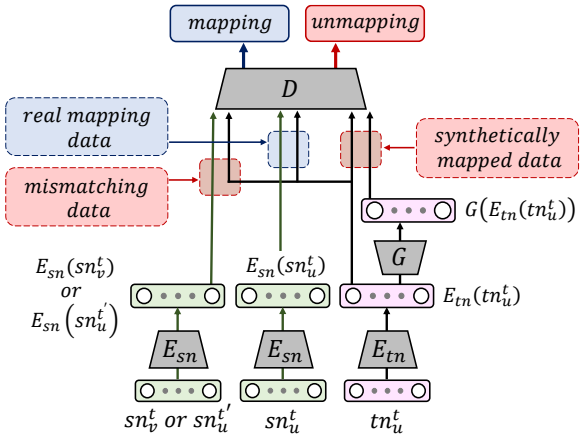

Figure 1: Adversarial learning process between *E*, *D* and *G*.

2.2 Generator Task

The generator task learns the function that maps the target network preferences manifold to the source network preferences manifold using Encoders (E), Discriminator (D) and Generator (G).

2.2.1 Encoders: User preferences captured as topical distribution vectors ($\boldsymbol{tn_u^t}$ and $\boldsymbol{sn_u^t}$) become sparse when $\boldsymbol{K^t}$ is set to a sufficiently large value to capture finer level user preferences, and/or the number of interactions at a time interval is low. One of the most effective methods to train machine learning models with highly sparse data is to model interactions between input features [7] (e.g., using neural networks [12]). Therefore, we used two neural encoders E_{tn} and E_{sn} for target and source networks to transform the input topical distributions to dense latent encodings. The resultant encodings are represented as $E_{tn}(tn_u) \in \mathbb{R}^{T \times En}$ and $E_{sn}(sn_u) \in \mathbb{R}^{T \times En}$, where En is the dimensionality of the latent space. These encodings form the input to the generator task.

2.2.2 Generator task formulation: For a non-overlapped user u, let $E_{tn}(\boldsymbol{tn_u^t})$ denote the target network encoding at time interval t. The generator task aims to synthetically generate the mapping source network encoding that closely reflects the missing source network encoding $E_{sn}(\boldsymbol{sn_u^t})$. Hence, G uses target encoding $E_{tn}(\boldsymbol{tn_u^t})$ and attempts to generate the mapping source encoding to fool D. Similarly, D tries to differentiate between real source encoding $E_{sn}(\boldsymbol{sn_u^t})$ and generated encoding $G(E_{tn}(\boldsymbol{tn_u^t}))$. Note that, we refer to the actual and generated target and source network encodings of non-overlapped users $\left(E_{tn}(\boldsymbol{tn_u^t}), G(E_{tn}(\boldsymbol{tn_u^t}))\right)$ as *synthetically mapped data* and the actual target and source network encodings of overlapped users $\left(E_{tn}(\boldsymbol{tn_u^t}), E_{sn}(\boldsymbol{sn_u^t})\right)$ as *real mapping data.*

2.2.3 Discriminator: Analogous to D in standard GANs, the real and synthetically mapped pairs could be used to learn D. However, D may only learn to differentiate between actual and generated source network encodings in a given pair of inputs, without learning to check if the given pair is a mapping pair. Therefore, during training, we input mismatching source and target network encodings to ensure that an effective mapping is learned. We modified the loss function for D to minimize output scores for mismatching pairs and maximize output scores for matching pairs. For a given target network encoding, we drew mismatching source encodings only from real data to avoid potential biases. Mismatching pairs were created by pairing real encodings from different users at the same time interval or by pairing encodings from the same user at different time intervals (see Figure 1). Accordingly, the loss function for D is formed as follows:

$$\begin{aligned}
&\max_{E_{tn},E_{sn},D} V(E_{tn},E_{sn},D) \\
&= \mathbb{E}_{\boldsymbol{tn_u^t},\boldsymbol{sn_u^t}\sim p_{data}(tn,sn)} L_{real}\Big(E_{tn}(\boldsymbol{tn_u^t}), E_{sn}(\boldsymbol{sn_u^t})\Big) \\
&+\mathbb{E}_{\boldsymbol{tn_u^t}\sim p_{data}(tn)} L_{fake}\Big(E_{tn}(\boldsymbol{tn_u^t}), G\Big(E_{tn}(\boldsymbol{tn_u^t})\Big)\Big) \\
&+\mathbb{E}_{\boldsymbol{tn_u^t},\overline{\boldsymbol{sn}}_{\boldsymbol{u}}^{\boldsymbol{t}}\sim \overline{p}_{data}(tn,\overline{sn})} L_{mismatch}\Big(E_{tn}(\boldsymbol{tn_u^t}), E_{sn}(\overline{\boldsymbol{sn}}_{\boldsymbol{u}}^{\boldsymbol{t}})\Big)
\end{aligned} \tag{2}$$

where $p_{data}(tn,sn)$ and $\overline{p}_{data}(tn,\overline{sn})$ are matching and mismatching target and source network topical distributions, $p_{data}(tn)$ are the target network topical distributions and $G(x)$ is the generated matching source network encoding for the given target network encoding x. Furthermore, $L_{real}(x,y) = [\log(D(x,y))]$, $L_{fake}(x,y) = [1-\log(D(x,y))]$ and $L_{mismatch}(x,y) = [1-\log(D(x,y))]$, where $D(x,y)$ is the probability that x and y are matching target and source network encodings. Therefore, D and E work together to maximize the discriminator value function $V(E_{tn},E_{sn},D)$. The encoders (E_{tn} and E_{sn}) assist the process by encoding the topical distributions that are optimized for learning D (e.g., extract encodings that express the latent mapping between target and source networks).

2.2.4 Generator: Once D and E are trained, they adversarially guide G by effectively identifying real and synthetically generated data. Specifically, G takes in a target network encoding $E_{tn}(\boldsymbol{tn_u^t})$ and synthetically generates the mapping source network encoding that resemble $E_{sn}(\boldsymbol{sn_u^t})$ drawn from real mapping data.

GAN models are typically used to generate real-like images from random noise vectors. For a given noise vector, different GANs can learn multiple successful mappings from the input space to the output space. In contrast, CnGAN aims to learn a specific mapping from target to source network encodings. Hence, for given pairs of real mapping data $(\boldsymbol{tn_u^t},\boldsymbol{sn_u^t})$, G minimizes an additional content loss between the generated $G(E_{tn}(\boldsymbol{tn_u^t}))$ and real $E_{sn}(\boldsymbol{sn_u^t})$ source encodings to provide additional guidance for G. Therefore, we formulated the loss function for G as follows:

$$\begin{aligned}
&\min_G V(G) = \mathbb{E}_{\boldsymbol{tn_u^t}\sim p_{data}(tn)} L_{fake}\Big(E_{tn}(\boldsymbol{tn_u^t}), G\Big(E_{tn}(\boldsymbol{tn_u^t})\Big)\Big) \\
&+\mathbb{E}_{\boldsymbol{sn_u^t},\boldsymbol{tn_u^t}\sim p_{data}(tn,sn)} L_{content}\Big(E_{sn}(\boldsymbol{sn_u^t}), G\Big(E_{tn}(\boldsymbol{tn_u^t})\Big)\Big)
\end{aligned} \tag{3}$$

where $L_{content}(x,y) = \|x,y\|_1$ is the content loss computed as the $\ell 1$-norm loss between real and generated encodings.

2.3 Recommender Task

The recommender task uses the generated preferences to conduct recommendations for non-overlapped users.

2.3.1 Recommender task formulation: Let $E_{tn}(\boldsymbol{tn_u^t}), G(E_{tn}(\boldsymbol{tn_u^t}))$ denote a non-overlapped user u at time t based on synthetically mapped data, which reflects current preferences. To capture previous preferences, we used a previous interaction vector $R_u^{t-} \in \mathbb{R}^M$, where M is the number of items. Each element $r_{u,i}^{t-} \in \boldsymbol{R_u^{t-}}$ is set to 1 if the user had an interaction with item i before time t, and 0 if otherwise. Thus, we formulated the recommender task as a time aware Top-N ranking task where, current and previous user preferences are used to predict a set of N items that the user is most likely interact with, in the next time interval $t+1$.

2.3.2 Recommender loss: Typically, BPR optimization is performed using Stochastic Gradient Descent (SGD) where, for each training instance (u,i,j), parameter (Θ) updates are performed as follows:

$$\begin{aligned}
\Theta &\leftarrow \Theta - \alpha \frac{\partial}{\partial \Theta} L_{BPR}(S) \\
\Theta &\leftarrow \Theta + \alpha\left(\frac{e^{-\hat{r}_{uij}}}{1+e^{-\hat{r}_{uij}}} \cdot \frac{\partial}{\partial \Theta}\hat{r}_{uij} + \lambda_\Theta \Theta\right)
\end{aligned} \tag{4}$$

where α is the learning rate, $\hat{r}_{uij} = \hat{r}_{ui} - \hat{r}_{uj}$ is the pairwise loss for a given (u,i,j) triplet and $\hat{r}_{ui}$ is the predicted rating for user u and item i. Since BPR is a generic optimization criterion, $\hat{r}_{ui}$ can be obtained using any standard collaborative filtering approach (e.g., MF). Considering the rating prediction function in MF ($\hat{r}_{ui} = \sum_{f=1}^{K} \boldsymbol{w_{uf}} \cdot \boldsymbol{h_{if}}$, where $\boldsymbol{w_{uf}} \in \mathbb{R}^K$ and $\boldsymbol{h_{if}} \in \mathbb{R}^K$ are latent representations of user u and item i), $\hat{r}_{uij}$ for MF based BPR optimization can be defined as $\hat{r}_{uij} = \sum_{f=1}^{K} w_{uf} \cdot (h_{if} - h_{jf})$.

For each (u,i,j) instance, three updates are performed when $\Theta = w_{uf}$, $\Theta = h_{if}$ and $\Theta = h_{jf}$. For each update on the latent user representation (w_{uf}), two updates are performed on the latent item representations (h_{if} and h_{jf}). Hence, the training process is biased towards item representation learning, and we term the standard BPR optimization function as an *item-based* pairwise loss function. Since our goal is to learn effective user representations to conduct quality recommendations, we introduce a *user-based* pairwise loss function (R loss), which is biased towards user representation learning.

We used a fixed time-length sliding window approach in the training process where, at each time interval, the model is trained using the interactions within the time interval (see Section 3.2.1). Thus, we denote the training instances for the new user-based BPR at each time interval t as $S^t = \{(u,v,i) | u \in U_{i+}^t \wedge v \in U \setminus U_{i+}^t \wedge i \in I\}$ where U_{i+}^t is the set of users who have interactions with item i, at time t. Compared to (u,i,j) in the standard item-based BPR, user-based BPR contains (u,v,i) where, for item i at time t, user u has an interaction and user v does not. Thus, intuitively, the predictor should assign a higher score for (u,i) compared to (v,i). Accordingly, we defined the user-based loss function to be minimized as follows:

$$L_{UBPR}(S^t) = \sum_{(u,v,i)\in S^t} -\ln \sigma(\hat{r}_{uvi}^t) + \lambda_\Theta \|\Theta\|^2 \tag{5}$$

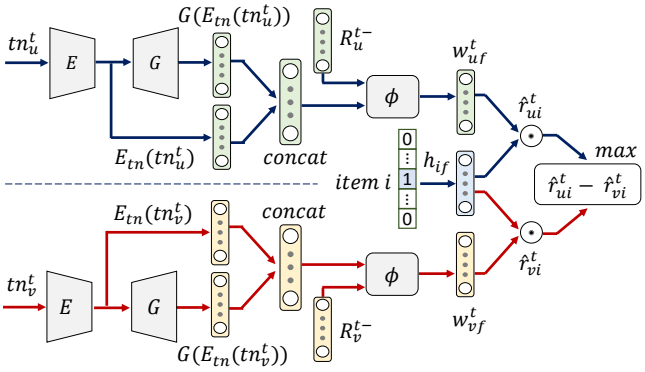

Figure 2: Recommender task architecture as a Siamese network.

where $\hat{r}_{uvi}^t = \hat{r}_{ui}^t - \hat{r}_{vi}^t = \sum_{f=1}^{K}(w_{uf}^t - w_{vf}^t)h_{if}$. During optimization, Θ updates are performed as follows:

$$\Theta \leftarrow \Theta + \alpha\left(\frac{e^{-\hat{r}_{uvj}^t}}{1+e^{-\hat{r}_{uvj}^t}} \cdot \frac{\partial}{\partial\Theta}\hat{r}_{uvj}^t + \lambda_\Theta\Theta\right) \tag{6}$$

For different Θ values, the following partial derivations are obtained:

$$\frac{\partial}{\partial\Theta}\hat{r}_{uvj}^t = \begin{cases} h_{if}, \text{if } \Theta = w_{uf}^t \\ -h_{if}, \text{if } \Theta = w_{vf}^t \\ (w_{uf}^t - w_{vf}^t), \text{if } \Theta = h_{if} \\ 0, \text{otherwise} \end{cases} \tag{7}$$

Since the user-based BPR performs two user representation updates for each training instance, it is able to efficiently guide G to learn user representations during training.

2.3.3 Recommender architecture: We used a Siamese network for the recommender architecture since it naturally supports pairwise learning (see Figure 2). Given a non-overlapped user u with current preferences $E_{tn}(\boldsymbol{tn_u^t})$, $G(E_{tn}(\boldsymbol{tn_u^t}))$ and previous preferences $\boldsymbol{R_u^{t-}}$ at time t, we learned a transfer function Φ, which maps the user to the latent user space $w_{u,f}^t$ for recommendations as follows:

$$w_{u,f}^t = \Phi(E_{tn}(\boldsymbol{tn_u^t}), G(E_{tn}(\boldsymbol{tn_i^t})), \boldsymbol{R_u^{t-}}) \tag{8}$$

The transfer function Φ is learned using a neural network since neural networks are more expressive and effective than simple linear models. Accordingly, for a non-overlapped user u at time t, the predicted rating $\hat{r}_{ui}$ for any given item i is obtained using the inner-product between the latent user and item representations as follows:

$$\hat{r}_{ui}^t = \sum_{f=1}^{K} \Phi(E_{tn}(tn_u^t), G(E_{tn}(tn_u^t)), \boldsymbol{R_u^{t-}}) \cdot \boldsymbol{h_{if}} \tag{9}$$

2.4 Multi-Task Learning (MTL)

Although the generator and recommender tasks are separate, they depend on each other to achieve a higher overall performance. The generator task increases the accuracy of the recommender by synthesizing source network encodings that effectively represent user preferences. The recommender task guides the generator to efficiently learn the target to source mapping by reducing the search space. Therefore, we trained both interrelated tasks in a MTL environment to benefit from the training signals of each other. Hence, we formulated the multi-task training objectives as follows:

$$\min_{G} \max_{E_{tn}, E_{sn}, D} V(E_{tn}, E_{sn}, G, D) \tag{10}$$

$$\min_{w_{uf}^t, w_{vf}^t, h_{if}} L_{UBPR}(S^t) \tag{11}$$

where $V(E_{tn}, E_{sn}, G, D)$ is the value function for E, G and D, $L_{UBPR}(S^t)$ is the R loss function, and w_{uf}^t, w_{vf}^t and h_{if} are model parameters. The R loss is back-propagated all the way to G since w_{uf}^t and w_{vf}^t are compositions of the functions G and Φ (see Equation 8) and the generator and recommender tasks are trained as an end-to-end process. Hence, equation 11 can be restated as follows:

$$\min_{\Phi, G, h_{if}} L_{UBPR}(S^t) \tag{12}$$

3 EXPERIMENTS

3.1 Dataset

Due to the lack of publicly available timestamped cross-network datasets, we extracted overlapped users on YouTube (target) and Twitter (source) networks from two publicly available datasets [16, 29]. We scraped timestamps of interactions and associated textual contents (video titles, descriptions and tweet contents) over a 2-year period from 1st March 2015 to 29th February 2017. In line with common practices, we filtered out users with less than 10 interactions on both networks for effective evaluations. The final dataset contained 2372 users and 12,782 YouTube videos.

3.2 Experimental Setup

The recommender systems literature often uses training and testing datasets with temporal overlaps [9], which provides undue advantages as it does not reflect a realistic recommender environment. To avoid such biases, at each time interval, the proposed model is trained using only the interactions during the current and previous time intervals. We randomly selected 50% of users as non-overlapped users and removed their source network interactions. The model was first trained offline using overlapped users (see Section 3.2.1). Then, testing and online training were conducted using both overlapped and non-overlapped users (see Section 3.2.2).

3.2.1 Offline Training: We used the sliding window approach and data from the first 16 months ($2T/3$) of overlapped users to learn the mapping from target to source network preferences for the generator task, the neural transfer function (Φ), and item latent representations (h_{if}) for the recommender task. At each training epoch, the generator task is learned first. Hence, E, D and G are trained using real mapping data and the trained G is used to generate synthetically mapped data. The generated preferences are used as inputs to the recommender task to predict interactions at the next time interval. The ground truth interactions at the same time interval are used to propagate the recommender error from the recommender to the generator task and learn parameters of both processes.

3.2.2 Testing and Online Training: We used data from the last 8 months ($2T/3$ onward) to test and retrain the model online in a simulated real-world environment. At each testing time interval t, first, mapping source network preferences are generated for non-overlapped users based on their target network preferences. Second, the synthetically mapped data for non-overlapped users are used as inputs to conduct Top-N recommendations for $t+1$ (see Equation 9). The entire model is then retrained online before moving to the next time interval, as follows: First, the recommender parameters (Φ and $\boldsymbol{h}^t_{if}$) are updated based on the recommendations for both overlapped and non-overlapped users. Second, the components of the generator task (E, D and G) are updated based on the real mapping data from overlapped users. Finally, to guide G from the training signals of the recommender, the model synthesizes mapping data for overlapped users, which are used as inputs for recommendations. The error is back-propagated from the recommender task to G, and consequently, the parameters G, Φ and $\boldsymbol{h}^t_{if}$ are updated. This process is repeated at subsequent time intervals as the model continues the online retraining process. In line with common practices in sliding window approaches, the model is retrained multiple times before moving to the next time interval.

3.3 Evaluation

We formulated video recommendation as a Top-N recommender task and predicted a ranked set of N videos that the user is most likely to interact with at each time interval. To evaluate model accuracy, we calculated the Hit Ratio (HR) and Normalized Discounted Cumulative Gain (NDCG) [11]. Both metrics were calculated for each participating user at each time interval and the results were averaged across all users and testing time intervals.

3.3.1 Baselines. We evaluated CnGAN against single network, cross-network, linear factorization and GAN based baselines.

- **TimePop**: Recommends the most popular N items in the previous time interval to all users in the current time interval.
- **TBKNN** [8]: Time-Biased KNN computes a set of K neighbors for each user at each time interval based on complete user interaction histories, and recommends their latest interactions to the target user at the next time interval. Similar to the original work, we used several K values from 4 to 50, and the results were averaged.
- **TDCN** [20]: Time Dependent Cross-Network is an offline, MF based cross-network recommender solution, which provides recommendations only for overlapped users. TDCN learns network level transfer matrices to transfer and integrate user preferences across networks and conduct MF based recommendations.
- **CRGAN**: Due to the absence of GAN based cross-network user preference synthesizing solutions, we created Cross-network Recommender GAN, as a variation of our solution. Essentially, CRGAN uses the standard D and G loss functions and does not contain the $L_{mismatch}$ and $L_{content}$ loss components.
- **NUBPR-O** and **NUBPR-NO**: Due to the absence of neural network based cross-network recommender solutions, we created two Neural User-based BPR solutions, as variations of our solution. Essentially, both models do not contain the generator task. NUBPR-O considers both source and target network interactions and NUBPR-NO only considers target network interactions to conduct recommendations.

3.4 Model Parameters

We used Adaptive Moment Estimation (Adam) [15] for optimizations since Adam adaptively updates the learning rate during training. We set the initial learning rate to 0.1, a fairly large value for faster initial learning before the rate is updated by Adam. We used only one hidden layer for all neural architectures, and given the size of the output layer H_L, the size of the hidden layer was set to $H_L \times 2$ to reduce the number of hyper-parameters. We used the dropout regularization technique and the dropout was set to 0.4 during training to prevent neural networks from overfitting.

4 DISCUSSION

4.0.1 Offline training loss: We compared the offline training loss of D, G and R (see Figure 3). All three processes converge around 50 epochs, and compared to D and R, the drop in G is low. Therefore, we further examined the proposed G loss against the vanilla G loss for the same training process (see Figure 4). Inline with standard GANs, the vanilla G loss component in the proposed G loss increases while the proposed G loss slowly decreases. Hence, despite the low decrease in the overall G loss, $L_{content}$ loss has notably decreased.

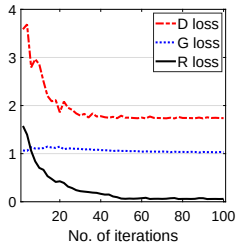

Figure 3: Offline training loss of D, G and R.

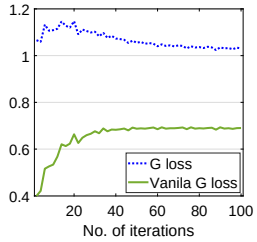

Figure 4: Offline training loss of G and vanilla G.

4.0.2 Online training loss: We observed R loss during the online training process (see Figure 5). Updates are most effective within the first 10-15 iterations and after around 20 iterations, the recommender accuracy reaches its peak. Additional iterations tend to overfit the model and degrade performance. Therefore, the proposed solution is feasible in real-world applications since online training requires only a few iterations and retraining is costly.

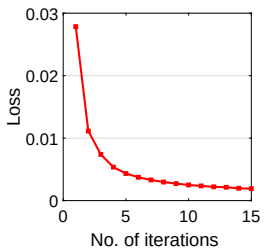

Figure 5: Online training loss of the recommender task.

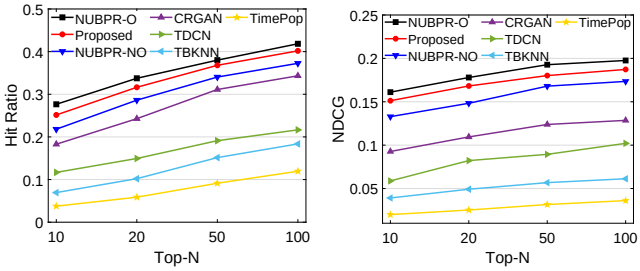

Figure 6: Hit Ratio and NDCG for different Top-N values.

4.0.3 Prediction accuracy: We compared recommender accuracy (HR and NDCG) against multiple Top-N values (see Figure 6). The neural network based solutions (Proposed, NUBPR-O, NUBPR-NO and CRGAN) show a higher accuracy since they capture complex relationships in user preferences. Among the non-neural network based solutions, TimePop has the lowest accuracy since it is based on a simple statistic - the popularity of videos. TDCN outperforms TBKNN and TimePop since it effectively utilizes both source and target network interactions to model user preferences.

As expected, NUBPR-O which does not have a data generation process and is only trained and tested with real mapping data from overlapped users has the best accuracy. We used NUBPR-O as the benchmark, since the goal is to synthesize data similar to the data used to train NUBPR-O. The proposed model shows the closest accuracy to NUBPR-O and consistently outperforms NUBPR-NO, which only used target network interactions. Therefore, the proposed model is able to generate user preferences that increases the recommender accuracy, even when the user overlaps are unknown. Furthermore, the improvements gained over CRGAN, which uses vanilla GAN loss functions, show the effectiveness of the proposed D and G loss functions.

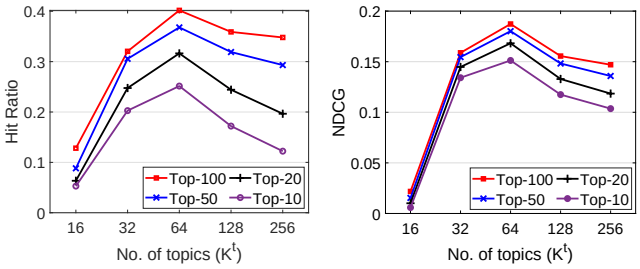

Figure 7: Hit Ratio and NDCG for different number of topics.

4.0.4 Prediction accuracy for different number of topics (K^t): We compared recomender accuracy against the dimensionality of the encoded topical space (K^t) (see Section 2.1.2 and Figure 7). A grid search algorithm was used to select an effective K^t value, and the highest accuracy is achieved when K^t is around 64 topics for all Top-N values. Smaller number of topics fail to effectively encode diverse user preferences, while a higher number of topics create highly sparse inputs and reduce recommender performance. Further experiments using the standard perplexity measure [6] showed that 64 topics lead to a smaller perplexity with faster convergence.

4.0.5 Diversity and novelty: A higher recommendation accuracy alone is insufficient to capture overall user satisfaction. For example, continuously recommending similar items (in terms of topics, genre, etc.) could lead to a decline in recommendation accuracy as users lose interest over time. Therefore, we compared the diversity [4] and novelty [31] of recommended items. The proposed model was able to recommend videos with better novelty and diversity, and was the closest to NUBPR-O model (only a 2.4% and 3.8% novelty and diversity drop). Compared to the single-network based solutions, cross-network solutions showed better results as they utilize rich user profiles with diverse user preferences. Against the closest CRGAN approach, the proposed model showed considerable improvements in novelty (by 8.9%) and diversity (by 12.3%).

4.0.6 Alternative GAN architectures: Designing and training GAN models can be challenging due to the unbalance between D and G, diminishing gradients and non-convergence [2, 27]. Various GAN architectures and training techniques were recently introduced to handle such issues. Therefore, despite the effectiveness of CnGAN, we designed two alternative solutions based on two widely popular GAN architectures, Deep convolutional GAN (DCGAN) [22] and Wasserstein GAN (WGAN) [3] to replace the G and D learning processes. We found that DCGAN becomes highly unstable in this environment, where D error is constantly increased. This can be because, DCGAN is based on Convolution Neural Networks, known to capture the local features within the input data. However, unlike typical image data, user preferences in the vectors may not provide any interesting local features. Hence, DCGAN was less effective. Further experiments using WGAN also did not improve the performances.

5 CONCLUSION AND FURTHER WORK

Typical cross-network recommender solutions are applied to users that are fully overlapped across multiple networks. Thus to the best of our knowledge, we propose the first Cross-network Generative Adversarial Network based model (CnGAN), which generates user preferences for non-overlapped users. The proposed model first uses a generator task to learn the mapping from target to source network user preferences and synthesize source network preferences for non-overlapped users. Second, the model uses a recommender task based on a Siamese network to incorporate synthesized source network preferences and conduct recommendations. The proposed model consistently outperformed multiple baselines in terms of accuracy, diversity and novelty of recommendations. As future work, we plan to investigate the recommender quality improvements when using both generated and real data for overlapped users. Furthermore, the model can be extended to use social information of the users. Overall, CnGAN alleviates a significant limitation in cross-network recommender solutions, and provides a foundation to make quality cross-network recommendations for all users.

ABSTRACT

When information or infectious diseases spread over a network, in many practical cases, one can observe when nodes adopt information or become infected, but the underlying network is hidden. In this paper, we analyze the problem of finding communities of highly interconnected nodes, given only the infection times of nodes. We propose, analyze, and empirically compare several algorithms for this task. The most stable performance, that improves the current state-of-the-art, is obtained by our proposed heuristic approaches, that are agnostic to a particular graph structure and epidemic model.

1 INTRODUCTION

Diffusion processes in networks include spreading of infectious diseases [14], spread of computer viruses [36], promotion of products via viral marketing [16], propagation of information [31], etc. In many practical scenarios one can observe when nodes become infected but the underlying network is hidden. For instance, during an epidemic, a person becomes ill but cannot tell who infected her; in viral marketing, we observe when customers buy products but not who influenced their decisions; in Twitter, for each retweet only information about the root node of the cascade is available. The problem of hidden network inference received a lot of attention recently [7, 27, 29, 30]. While these papers aim to recover the actual network connections, in many applications only some global properties of the underlying network are important. For example, in viral marketing, one may wish to find the most influential users, while for recommendation systems one may look for groups of users with similar preferences.

In this paper, we analyze the problem, which recently attracted interest in the literature [5, 26], of inferring *community structure* of a given network based solely on *cascades* (e.g., information or epidemic) propagating through this network. Communities are groups of highly interconnected nodes with relatively few edges joining nodes of different groups [9], such as groups by interests in social networks or pages on related topics on the Web. Discovering communities is one of most prominent tasks in network analysis. Compared to the traditional community detection, our work is quite different, because we do not have the network available to us, we have only cascade data observed on this network. For each cascade, we observe only infected nodes and their infection timestamps.

We propose and analyze several algorithms to solve this problem and compare them to the state-of-the-art. The contributions of this paper are the following. First, we give a systematic treatment to the new problem of inferring community structure based on cascade data, as stated formally in Section 3. Second, we propose two types of approaches for this task: based on likelihood maximization under specific model assumptions, and based on clustering of a surrogate network (Section 4). Third, we conduct extensive experiments on a variety of real-world networks (see Section 5). We conclude that the most stable performance is obtained by our proposed heuristics that are agnostic to a particular graph structure and epidemic model. These heuristics work equally well on different networks, for epidemics of different types.

2 RELATED WORK

2.1 Network Inference from Cascades

A series of recent papers addressed the following task: by observing infection (activation) times of nodes in several cascades, infer the edges of the underlying network. NetInf algorithm developed in [11] is based on the maximization of the likelihood of the observed cascades, based on a specific epidemic model. To make optimization feasible, for each cascade NetInf considers only the most likely propagation tree. This was later improved by MultiTree [30] that includes all directed trees in the optimization and has better performance if the number of cascades is small. NetRate algorithm [28] infers not only edges, but also infection rates. NetRate builds on an epidemic model that is more tractable for theoretical analysis (we describe this model in Section 3.2). For this model the likelihood optimization problem turns out to be convex. ConNIe algorithm [21] also uses convex optimization, with the goal to infer transmission probabilities for all edges. In [13, 29], it is additionally assumed that the underlying network is not static and the proposed algorithm InfoPath provides on-line estimates of the structure and temporal dynamics of the hidden network. KernelCascade [8] also extends NetRate, here the authors avoid assumptions about a particular parametric form of the influence function. The DANI algorithm [27] is interesting because it explicitly accounts for the

community structure to enhance the inference of networks' edges. There are some other network inference algorithms not covered here, see, e.g., [7, 12, 22, 32, 34, 35, 37, 38, 40].

2.2 Community Inference from Cascades

To the best of our knowledge, the paper [4] extended in [5] for the first time addressed the problem of community detection given cascades. In [4, 5], the cascade model includes influence of individual nodes, and a membership level of a node in each community is inferred using the maximum likelihood approach. The authors propose two algorithms: C-IC takes into account only participation of a node in a cascade; C-Rate includes the time stamps, but limits the node's influence by its own community. Recently, [26] proposed an alternative maximum likelihood approach, which exploits the Markov property of the cascades. As an input, similarity scores of node pairs are computed, based on their joint participation in cascades. The R-CoDi algorithm in [26] starts with a random partition, while D-CoDi starts with a partition obtained by DANI [27]. We use all four mentioned algorithms as our baselines.

3 PROBLEM SETUP

3.1 General Setup

Cascades. We observe a set of cascades $\mathcal{C} = \{C_1, \dots, C_r\}$ that propagate on a latent undirected network $G = (V, E)$ with $|V| = n$ nodes and $|E| = m$ edges. Each cascade $C \in \mathcal{C}$ is a record of observed node activation times, i.e., $C = \{(v_i, t^C_{v_i})\}_{i=1}^{n_C}$, where v_i is a node, $t^C_{v_i}$ is its activation time in C, $|C| = n_C$ is a size of a cascade. Note that we do not observe who infected whom.

Communities. We assume that G is partitioned into communities: $\mathcal{A} = \{A_1, \dots, A_k\}$, $\cup_{i=1}^k A_i = V$, $A_i \cap A_j = \emptyset$ for $i \neq j$. We expect to observe a high intra-community density of edges compared to inter-community density. In our experiments, the ground truth partitions $\mathcal{A}$ are available for all datasets (see Section 5.1.1). By observing only a set of cascades $\mathcal{C}$ we want to find a partition $\mathcal{A}'$ similar to $\mathcal{A}$.

3.2 Cascade Models

3.2.1 SIR model. The main model for our experiments is a well-known SIR (Susceptible-Infected-Recovered) model [15]. Each node in the network can be in one of the three states: susceptible, infected, or recovered. An infected node infects its susceptible neighbors with rate α, the infection is spread simultaneously and independently along all edges. An infected node recovers with rate β and then stops spreading infection in the network. For each cascade C we sample its own infection rate α_C from the Lomax (shifted Pareto) distribution in order to model a variety of cascades: there can be minor or widely circulated news, small scale epidemics or pandemics, etc. The source node of a cascade is chosen uniformly at random.

3.2.2 SI model with bounded duration (SI-BD). In some cases, SIR model might not be tractable for theoretical analysis, so we assume a simpler diffusion model introduced in [28]. In this model, again, an activated node infects its neighbors after an exponentially distributed time with intensity α, but there is no recovery rate. Instead, all nodes recover simultaneously at some threshold time T_{max} and the epidemic stops. For simplicity we further assume T_{max} to be fixed, but our methods allow varying T_{max} for different epidemics.

3.2.3 Community-based SI-BD model (C-SI-BD). Another model which allows for a simpler theoretical analysis is based on the setting from [33]. It is assumed that the spreading does not occur over the edges of a graph G but depends solely on the community structure $\mathcal{A}$. As before, the first node of a cascade is chosen uniformly at random. Each activated node can infect all other susceptible nodes independently after an exponentially distributed time. If a susceptible node belongs to the same community, then the infection rate is α_{in}, otherwise it is α_{out}, $\alpha_{out} < \alpha_{in}$. Epidemic stops at time T_{max}.

4 ALGORITHMS

4.1 Background on Likelihood Maximization

Recall that t_i^C denotes the activation time for node i in cascade C; we often omit the index C when the context is clear. Without loss of generality, for the first node of a cascade, we set $t_i = 0$. Finally, if a node i is not infected during an epidemic, then we set $t_i = T_{max}$.

Denote $\Delta^C_{i,j} = \Delta_{i,j} = |t_i - t_j|$. The log-likelihood $\log L(C)$ of the cascade C for SI-BD with varying infection rates (i infects a susceptible neighbor j after an exponentially distributed time with rate $\alpha_{i,j}$) is given in [28]. For our purposes, it is convenient to write this expression as:

$$\log L(C) = -\sum_{i,j:i<j} \alpha_{i,j}\Delta_{i,j} + \sum_{i:t_i\in(0,T_{max})} \log \sum_{j:t_j<t_i} \alpha_{j,i}\,. \quad (1)$$

The log-likelihood for all cascades is $\log L(\mathcal{C}) = \sum_{C\in\mathcal{C}} \log L(C)$. We will next introduce two methods based on maximizing $\log L(C)$.

4.2 ClustOpt

Consider the C-SI-BD model described in Section 3.2.3. Denote by $a(i)$ the community assignment for a node i. Then C-SI-BD is equivalent to the model used in [28] with $\alpha_{i,j} = \alpha_{in}$ if $a(i) = a(j)$ and $\alpha_{i,j} = \alpha_{out}$ otherwise. The log-likelihood in (1) becomes:

$$\log L(C, \mathcal{A}) = -(\alpha_{in} - \alpha_{out}) \sum_{\substack{i,j:i<j,\\ a(i)=a(j)}} \Delta_{i,j} - \alpha_{out} \sum_{i,j:i<j} \Delta_{i,j}$$
$$+ \sum_{i:t_i\in(0,T_{max})} \log\Big((\alpha_{in} - \alpha_{out})|\{j : t_j < t_i, a(j) = a(i)\}|$$
$$+\alpha_{out}|\{j : t_j < t_i\}|\Big)\,. \quad (2)$$

.

We propose the following algorithm to maximize (2).

ALGORITHM 1: ClustOpt

(1) Find initial partition $\mathcal{A}_{init}$;
(2) Find $\hat{\alpha}_{in}, \hat{\alpha}_{out} = \arg\max_{\alpha_{in},\alpha_{out}} \log L(C, \mathcal{A}_{init})$;
(3) For fixed $\hat{\alpha}_{in}, \hat{\alpha}_{out}$ find $\hat{\mathcal{A}} = \arg\max_{\mathcal{A}} \log L(C, \mathcal{A})$.

Let us now discuss how the steps (1)–(3) are implemented.

Step (1): We have noticed that a stable and fast approach is to start from some initial reasonable partition and optimize over α_{in}, α_{out} and $\mathcal{A}$ only once, thus avoiding iterations of the costly optimization

steps (2) and (3). In the current paper we propose to start from Clique(0) explained in Section 4.4.

Step (2): Without loss of generality, we set $\alpha_{in} = (\delta + 1)\alpha_{out}$. Substituting this into (2), we find optimal α_{out} in terms of δ and $\mathcal{A}$:

$$\hat{\alpha}_{out} = \frac{\sum_{C \in \mathcal{C}} (|C| - 1)}{\sum_{C \in \mathcal{C}} \left(\delta \sum_{i,j:a(i)=a(j)} \Delta^C_{i,j} + \sum_{i,j} \Delta^C_{i,j} \right)}. \quad (3)$$

Unfortunately, due to the summation of logarithms in (2), we cannot find another simple analytical relation between the optimal values of δ and α_{out}. Hence, we resort to a numerical solution. Due to (3), it is sufficient to numerically find only the optimal δ, this will give us the optimal values for both α_{in} and α_{out}.

Step (3): We follow [25], where the Louvain algorithm [6] is modified for optimizing a wide range of functions that depend on community structure, besides the original modularity measure. We adapt this algorithm for the likelihood given in (2) by computing the gain in $\log L(\mathcal{C}, \mathcal{A})$ obtained by moving a node v from one community to another. In view of computational complexity, we consider only moving single nodes from one community to another and do not attempt to move groups of nodes or merge communities.

4.3 GraphOpt

In this section, we drop the assumption of fixed infection rates within and between communities. Instead, we assume the SI-BD cascade model defined in Section 3.2.2. Our task is much more complex in this setting because now we have a hidden graph G.

We propose an expectation-maximization-based method, where G is a latent variable. We assume the following generative probabilistic process. For a given partition $\mathcal{A}$ of n nodes we construct a graph G according to some model (distribution) $\mathrm{P}(G|\mathcal{A})$. Then, based on G, we generate a set of cascades $\mathcal{C}$ according to another model $\mathrm{P}(\mathcal{C}|G)$. We observe $\mathcal{C}$ and our aim is to recover the partition $\bar{\mathcal{A}}$ which maximizes the likelihood, i.e., $\bar{\mathcal{A}} = \arg\max_{\mathcal{A}} \mathrm{P}(\mathcal{C}|\mathcal{A})$. Let us first explain how the standard expectation-maximization (EM) approach applies to this problem:

(1) Choose some initial partition $\hat{\mathcal{A}}$;
(2) Find the distribution $\mathrm{P}(G|\mathcal{C}, \hat{\mathcal{A}})$;
(3) Update $\hat{\mathcal{A}}$: $\hat{\mathcal{A}} = \arg\max_{\mathcal{A}} \mathbb{E}_G \log \mathrm{P}(\mathcal{A}\, G|\mathcal{C})$;
(4) Iterate (2)-(3) until convergence.

This algorithm cannot be applied directly because, as we explain below, steps (2) and (3) are computationally intractable. Our algorithm GraphOpt is obtained by simplifying these two steps.

First, let us rewrite the distribution in (2):

$$\mathrm{P}(G|\mathcal{C}, \hat{\mathcal{A}}) = \frac{\mathrm{P}(\mathcal{C}\, G\, \mathcal{A})}{\mathrm{P}(\mathcal{C}\, \hat{\mathcal{A}})} = \frac{\mathrm{P}(\mathcal{C}|G, \hat{\mathcal{A}})\mathrm{P}(G\, \hat{\mathcal{A}})}{\mathrm{P}(\mathcal{C}|\hat{\mathcal{A}})\mathrm{P}(\hat{\mathcal{A}})}$$
$$= \frac{\mathrm{P}(\mathcal{C}|G)\mathrm{P}(G|\hat{\mathcal{A}})}{\mathrm{P}(\mathcal{C}|\hat{\mathcal{A}})} \propto \mathrm{P}(\mathcal{C}|G)\mathrm{P}(G|\hat{\mathcal{A}}), \quad (4)$$

where we used that $\mathrm{P}(\mathcal{C}|\hat{\mathcal{A}})$ does not depend on G and $\mathrm{P}(\mathcal{C}|G, \hat{\mathcal{A}}) = \mathrm{P}(\mathcal{C}|G)$ since, given the graph, the division into communities does not affect the cascades.

Now, we rewrite the probability in (3): $\mathrm{P}(\mathcal{A}\, G|\mathcal{C}) = \frac{\mathrm{P}(\mathcal{C}\, G\, \mathcal{A})}{\mathrm{P}(\mathcal{C})} = \frac{\mathrm{P}(\mathcal{C}|G)\mathrm{P}(G|\mathcal{A})\mathrm{P}(\mathcal{A})}{\mathrm{P}(\mathcal{C})}$. Since we do not have any prior assumptions for $\mathcal{A}$, we assume that $\mathrm{P}(\mathcal{A})$ is constant. Also, $\mathrm{P}(\mathcal{C})$ and $\mathrm{P}(\mathcal{C}|G)$ do not depend on $\mathcal{A}$, so

$$\arg\max_{\mathcal{A}} \mathbb{E}_G \log \mathrm{P}(\mathcal{A}\, G|\mathcal{C}) = \arg\max_{\mathcal{A}} \mathbb{E}_G \log \mathrm{P}(G|\mathcal{A}). \quad (5)$$

From (4) and (5) we see the computational bottlenecks of the EM algorithm. Indeed, even if for each G we can estimate the probability in (4), it is still impossible to even compute $\mathbb{E}_G \log \mathrm{P}(G|\mathcal{A})$, because the expectation is over all possible realizations of G. Clearly, we cannot hope to maximize this expression over $\mathcal{A}$. Therefore, we simplify the procedure: instead of computing the entire probability distribution over all graphs G in (4), we find only the most likely graph $\hat{G}$, with the idea that $\hat{G}$ gives the largest contribution to $\mathbb{E}_G \log \mathrm{P}(G|\mathcal{A})$. Then the optimization problem in (5) is solved only for $\hat{G}$. As a result, we obtain the following algorithm.

ALGORITHM 2: GraphOpt

(1) Choose some initial partition $\hat{\mathcal{A}}$ and graph $\hat{G}$;
(2) Update $\hat{G}$: $\hat{G} = \arg\max_G \left(\log \mathrm{P}(\mathcal{C}|G) + \log \mathrm{P}(G|\hat{\mathcal{A}}) \right)$;
(3) Update $\hat{\mathcal{A}}$: $\hat{\mathcal{A}} = \arg\max_{\mathcal{A}} \log \mathrm{P}(\hat{G}|\mathcal{A})$;
(4) Iterate (2)-(3) until convergence.

Let us describe how each step of Algorithm 2 is implemented.

Step (1): We start from a trivial partition $\hat{\mathcal{A}}$ in which each node belongs to its own cluster. We also create an initial graph[1] $\hat{G} = (V, E_0)$ as follows: for each cascade C consider the path of $|C| - 1$ edges, where each edge connects two nodes that are subsequently activated in this cascade; E_0 is a union of such paths over all $C \in \mathcal{C}$.

Step (2): $\mathrm{P}(G|\hat{\mathcal{A}})$ is defined by the ILFR model proposed in [25], where the formula for $\log \mathrm{P}(G|\hat{\mathcal{A}})$ is also provided. This model was shown to give the best fit to a variety of real-world networks in terms of likelihood. For $\mathrm{P}(\mathcal{C}|G)$, we assume the SI-BD cascade model, so we use (1) with $\alpha_{i,j} = \alpha$ if i and j are connected in G and $\alpha_{i,j} = 0$ otherwise. Then $\log \mathrm{P}(\mathcal{C}|G) = \sum_{C \in \mathcal{C}} \log \mathrm{P}(C|G)$ with

$$\log \mathrm{P}(C|G) = -\alpha \sum_{(i,j) \in E(G)} \Delta_{i,j} + (|C| - 1) \log \alpha$$
$$+ \sum_{i:t_i \in (0, T_{max})} \log |\{j : t_j < t_i, (i,j) \in E(G)\}|. \quad (6)$$

A nice feature of (6) is that for given $\mathcal{C}$ and G it is easy to compute α that maximizes the overall likelihood:

$$\alpha_{opt} = \frac{\sum_{C \in \mathcal{C}} (|C| - 1)}{\sum_{C \in \mathcal{C}} \sum_{(i,j) \in E(G)} \Delta^C_{i,j}}. \quad (7)$$

Finally, we need to find $\hat{G} = \arg\max_G \left(\log \mathrm{P}(G|\hat{\mathcal{A}}) + \log \mathrm{P}(\mathcal{C}|G) \right)$. We use a greedy approach to approximately find $\hat{G}$: we iteratively add and remove edges to increase $\log \mathrm{P}(G|\hat{\mathcal{A}}) + \log \mathrm{P}(\mathcal{C}|G)$ (the detailed description is omitted due to space constrains).

Step (3): This is a standard likelihood optimization task used in community detection. We use the Louvain-based algorithm proposed in [25].

[1] This initial graph is needed for step (2), since our update algorithm requires initialization with non-zero likelihood.

4.4 Clustering of Surrogate Graphs

In this section, we present simple yet effective methods that construct a surrogate graph $\hat{G}$ and then cluster this graph (using the Louvain algorithm [6]). It is crucial that $\hat{G}$ does *not* need to be similar to G, it just needs to capture the community structure on an aggregated level. Our experiments show that clustering of $\hat{G}$ often performs better than first inferring G and then clustering it.

4.4.1 Path algorithm. Assume again that cascades $\mathcal{C}$ are generated by the SI-BD model. Now, for $C \in \mathcal{C}$ let $G' = G'(C)$ be a graph with exactly $|C| - 1$ edges that maximizes the probability $\mathrm{P}(C|G')$ in (6). It is easy to check that G' is merely a path connecting subsequently activated nodes. Note that we have already used such paths to initialize Algorithm 2. This leads to the following algorithm.

ALGORITHM 3: Path

(1) Construct weighted graph $\hat{G}$, where the weight of each edge e in $\hat{G}$ is the number of $G'(C)$ including e;[2]
(2) Find clusters in $\hat{G}$ using the Louvain algorithm.

4.4.2 Clique. Another approach is to include *all* possible edges that could participate in the cascade weighing them by the proxy of their likelihood. Then each cascade C results in a weighted clique of size $|C|$. The weights can be chosen, for example, as follows. For a cascade C and two nodes i, j let us consider the probability $P^C(i,j) = \mathrm{P}(j \text{ was infected from } i|C)$. If $t_i > t_j$, then, obviously, $P^C(i,j) = 0$. If $t_i < t_j$, then, as in [11], we assume that $P^C(i,j)$ decreases exponentially with $\Delta_{i,j}$; namely, $P^C(i,j) = c_j\, e^{-a\Delta_{i,j}}$, where c_j is a constant depending on j. Since j was infected from exactly one previous node, we must have $\sum_{i:t_i<t_j} P^C(i,j) = 1$. Therefore, $P^C(i,j) = \frac{e^{-a\Delta_{i,j}}}{\sum_{l:t_l<t_j} e^{-a\Delta_{l,j}}}$.

Clique constructs $\hat{G}$ as the weighted graph with weight of $\{i,j\}$ given by $\sum_{C\in\mathcal{C}}(P^C(i,j) + P^C(j,i))$, which, under our assumptions, is the expected number of times infections passed between i and j. Note that we directly model $P^C(i,j)$ rather than making assumptions about infection times. Parameter a essentially balances between paths and cliques: if a is large, then we mostly take into account subsequent nodes with small $\Delta_{i,j}$; for small a all pairs of nodes participated in C are important. To make Clique insensitive to the speed of epidemics, we take $a = \frac{1}{\Delta}$, where Δ is the average time between infected times (we average over all pairs of infected nodes belonging to the same cascade). We also consider Clique(0) with $a = 0$, which is a natural choice for the SI-BD model because it mimics the memory-less property of exponential infection times.[3]

ALGORITHM 4: Clique

(1) Construct $\hat{G}$ as the weighted graph with weight of $\{i,j\}$ given by $\sum_{C\in\mathcal{C}}(P^C(i,j) + P^C(j,i))$.
(2) Find clusters in $\hat{G}$ using the Louvain algorithm.

[2]Weighting edges is important, since for large $|C|$ unweighted union of edges can be a complete graph, with no meaningful partition.
[3]We noticed that Clique is not too sensitive to varying a in a reasonable interval, while for too large a Clique becomes very similar to Path.

4.5 Baselines

MultiTree uses the algorithm from [30] to find an inferred graph $\hat{G}$, which is then clustered by the Louvain algorithm [6].

Oracle algorithm can be considered as superior for all possible network inference algorithms: we construct a graph $\hat{G}$ consisting of all edges participated in cascades (assuming these edges are known, hence, the name Oracle). The obtained graph $\hat{G}$ is clustered by the Louvain algorithm.

Finally, we used algorithms proposed for solving the same problem as in our work: C-IC and C-Rate [5], as well as R-CoDi and D-CoDi [26]. We use the publicly available implementations provided by the authors. For C-IC and C-Rate we use the real number of communities as an input parameter.[4]

5 EXPERIMENTS

5.1 Experimental Setup

5.1.1 Networks. We used real-world datasets of different sizes and nature, for which the ground truth partition of nodes into k non-overlapping communities is available: Zachary's karate club [39] ($n = 34$, $m = 78$, $k = 2$), dolphin social network [20] ($n = 62$, $m = 159$, $k = 2$), American college football [24] ($n = 115$, $m = 613$, $k = 11$), books about politics [23] ($n = 105$, $m = 441$, $k = 3$), political blogs [1] ($n = 1224$, $m = 16715$, $k = 2$), email-Eu-core dataset [19] ($n = 986$, $m = 16064$, $k = 42$).

5.1.2 Metric. We evaluate the quality of the obtained communities compared to the ground truth using the Normalized Mutual Information (NMI) similarity measure [2, 9]. Let $V_0 \subset V$ denote the set of all nodes that participated in cascades. To compute NMI, we assign all nodes in $V \backslash V_0$ to one cluster labeled "unknown".

5.1.3 Cascades. We took the datasets with ground truth communities described in Section 5.1.1 and, in order to cover various possible diffusion processes, we generated the cascades according to all models discussed in Section 3.2. Importantly, there are both edge-based and community-based models.

W.l.o.g., we set $\beta = 1$ for the SIR model and $T_{max} = 1$ for SI-BD and C-SI-BD. We noticed that to get an informative set of cascades, the parameters α, α_{in}, α_{out}, and the parameter of the Lomax distribution used by SIR have to be different for different datasets. For SIR and SI-BD we choose parameters so that the average size of a cascade is 2; for C-SI-BD we take $\alpha_{in} = 10\alpha_{out}$ and choose α_{out} such that the number of cascades consisting of one node is about 20%. We checked that the obtained distribution of cascade sizes is similar to observed for real data [3, 10, 12, 17, 18]. Single-node cascades were removed.

5.2 Results

We have run the algorithms on all datasets and varied the number of cascades $|C|$. Figures 1 and 2 show the results obtained for SIR and C-SI-BD models, respectively.[5] All results are averaged over 5 samples of generated cascades $\mathcal{C}$.

[4]Although there are modifications of these algorithms automatically choosing the number of communities, these modifications often failed on our data.
[5]Due to space constraints, we omit plots for the SI-BD model since they lead to similar conclusions.

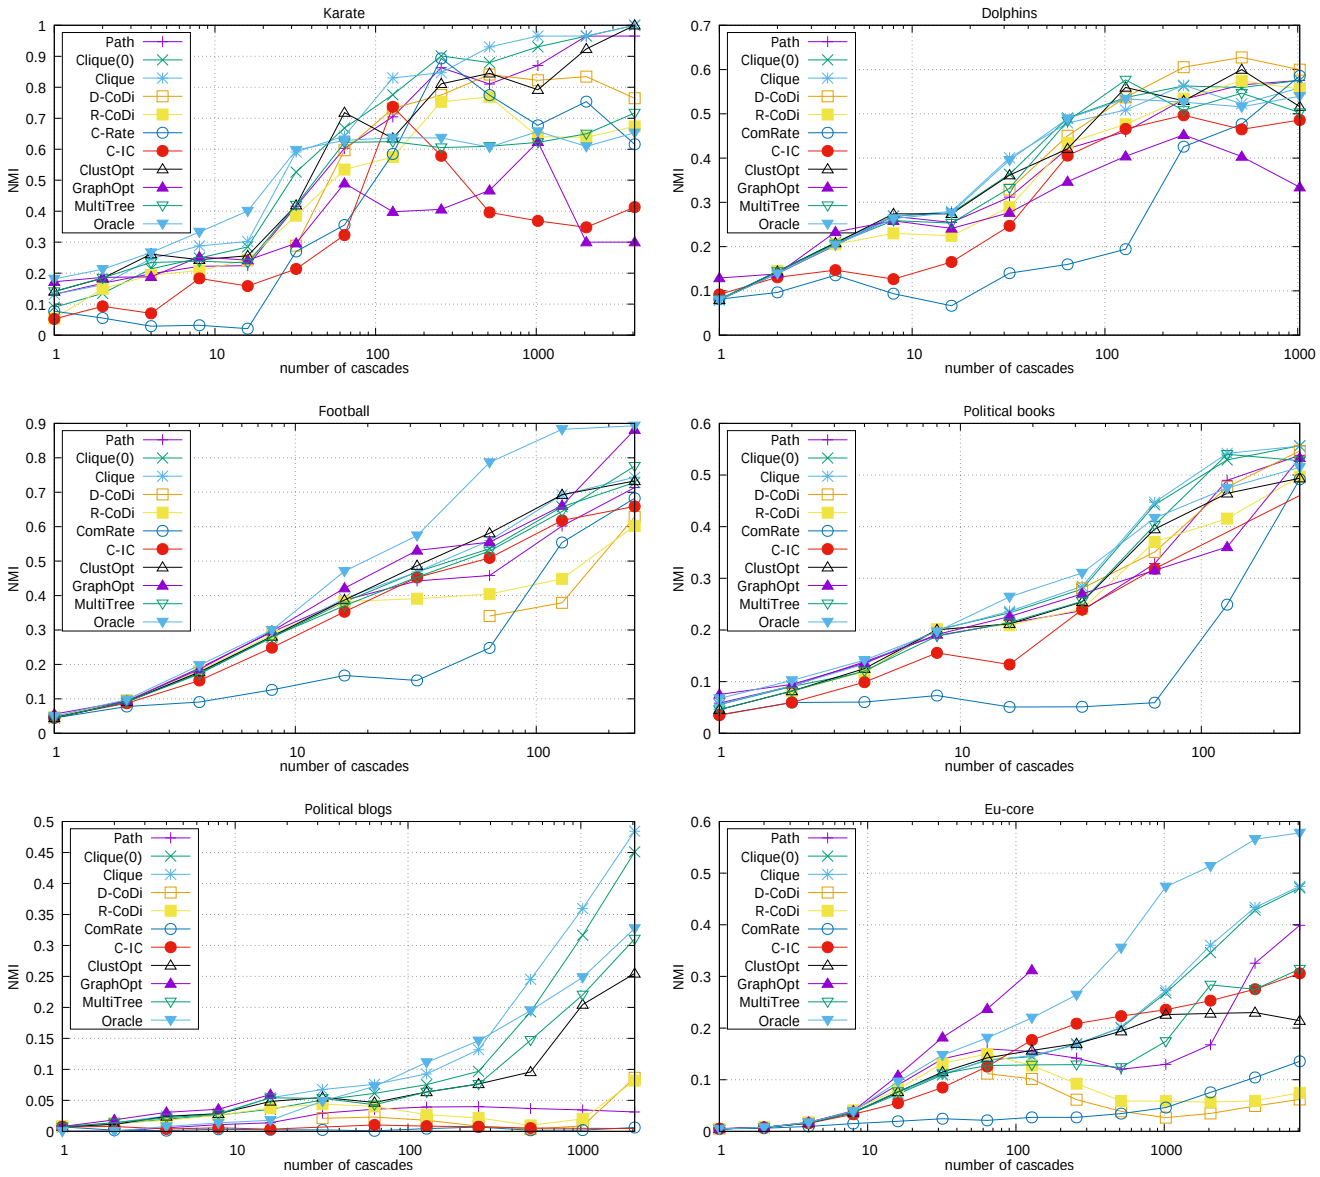

Figure 1: Comparison of algorithms on real-world datasets, SIR cascades

We noticed that the results are quite different for different datasets and cascades models. Nevertheless, the proposed Clique algorithm has the most stable performance, implying that the corresponding surrogate graph is able to capture the information about the community structure. Importantly, both Clique(0) and Clique work equally well for all cascade models since they are not based on a particular one, as discussed in Section 4.4.

Note that Path is usually worse than Clique as it uses less information.

The baselines C-IC and C-Rate are very unstable and in many cases they show the worst results. This is expected, since C-IC and C-Rate are based on a specific community-based model. Indeed, on C-SI-BD C-IC shows a reasonable performance in some cases, especially on Political blogs. Note that C-IC is almost always better than C-Rate (except for some cascade sizes on Karate with SIR model). D-CoDi and R-CoDi are essentially based on clustering of a surrogate graph, so their performance is stable for all epidemic models. However, in all cases D-CoDi failed on cascades of small sizes (we included only successful points). D-CoDi can be both better and worse than R-CoDi. Having reasonable performance in many cases, these two baselines may have unexpectedly bad points: see, e.g., the large number of cascades on Political blogs and Eu-Core with all epidemic models. MultiTree turns out to have

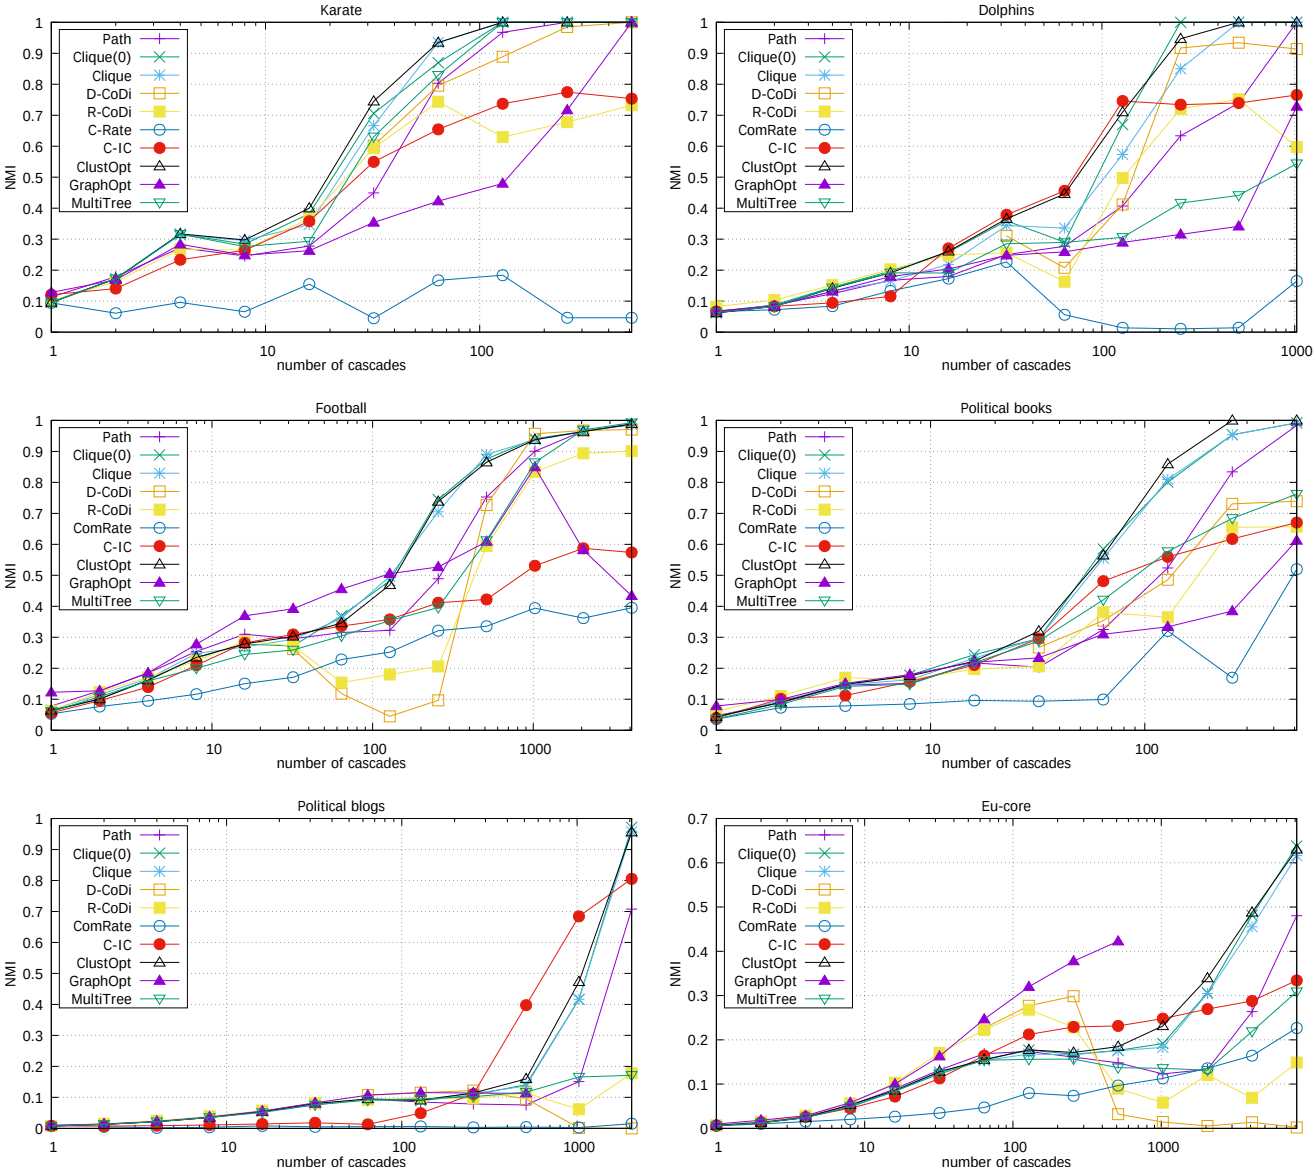

Figure 2: Comparison of algorithms on real-world datasets, C-SI-BD cascades

the most stable performance among the baselines but it is usually beaten by Clique(0) and Clique.

GraphOpt shows an excellent performance, e.g., on Eu-core for all types of epidemics, on Football for SIR cascades and for small number of C-SI-BD cascades. However, in general its quality is unstable, and it is also much slower than surrogate-based methods.

Oracle is considered only as an upper bound for all network inference algorithms.[6] If the number of cascades is large enough, then Oracle essentially clusters the original graph. Interestingly, in many cases Oracle is beaten by the surrogate-graph-based algorithms. This basically means that errors made by Louvain on original graph can be reduced by clever weighting of edges provided by the surrogate-graph-based algorithms.

To conclude, we propose using the universal Clique method for the problem of community inference based on cascade data. This algorithm is simple, efficient, and works well for all considered cascade models.

[6]We do not plot Oracle for C-SI-BD, since in this model graph is not used by the propagation processes and. In particular, for large $|C|$ we may get a complete graph.

ABSTRACT

While test collections provide the cornerstone of system-based evaluation in information retrieval, human relevance judging has become prohibitively expensive as collections have grown ever larger. Consequently, intelligently deciding which documents to judge has become increasingly important. We propose a two-phase approach to intelligent judging across topics which does not require document rankings from a shared task. In the first phase, we dynamically select the next topic to judge via a multi-armed bandit method. In the second phase, we employ active learning to select which document to judge next for that topic. Experiments on three TREC collections (varying scarcity of relevant documents) achieve $\tau \approx 0.90$ correlation for P@10 ranking and find 90% of the relevant documents at 48% of the original budget. To support reproducibility and follow-on work, we have shared our code online[1].

1 INTRODUCTION

Cranfield-based evaluation of information retrieval (IR) systems [4, 23] relies on the construction of a *test collection*: a document collection, a set of search topics, and human judgments of document relevance for those search topics. However, large-scale IR evaluation is becoming increasingly challenging and economically infeasible because there are too many documents in the collection to be judgedConsequently, there is a growing need for improved methods to create test collections at minimal cost.

Developing a reliable, low-cost IR test collection requires intelligent budget allocation across search topics and careful selection of documents for human annotation. However, existing approaches [28, 32] either allocate the same budget across all topics or estimate a budget per topic rather than allocating the total budget dynamically across topics based on their judgment needs. For example, in TREC, each topic is traditionally allotted a budget that equals the size of its *top-k* pool, constructed by pooling the highest ranked k documents from the submitted runs for that topic.

However, developing a test collection by running a shared task has several drawbacks. First of all, running a shared task is difficult, slow, and expensive. In some cases, it may be nearly impossible to garner enough participants, such as for less studied languages (e.g., Turkish) or search tasks (e.g., historical search). In addition, Li and Kanoulas [17] recently noted that some document selection approaches based on participant rankings [9, 18] may overly bias selection toward the best-performing runs. Furthermore, Voorhees [28] reports empirical evidence that some dynamic document selection methods [18] can also produce less reusable test collections.

Consequently, if our goal is simply to build a new test collection at minimal cost, it would be preferable to be able to do this without having to run a shared task [26]. However, this poses its own set of challenges. In the absence of document rankings from shared task participants, we must find another means to select which documents should be judged for relevance to search topics. In addition, while the size of the *top-k* pools for different topics are known to vary widely, since we have no document rankings with which to apply pooling, we must find another means of allocating the judging budget across search topics.

We propose a two-phase approach to constructing test collections without needing to organize a shared task. Because it is known that evaluation becomes more reliable as more relevant documents are found [24], our main goal is to find as many relevant documents as possible for a given budget. In the first phase (topic selection), we want to select whichever topic is most likely to supply relevant documents. In the second phase (document selection), we want to select one or more documents for the given topic that are the most likely to be relevant. We implement the first phase via a multi-armed bandit (MAB) [21] method. We are not familiar with any prior work exploring MAB for intelligent topic selection. During the second phase, we investigate several alternative active learning [25] (AL) strategies to select which documents to judge for each search topic. Finally, we use the collected relevance judgments to update both the active learning classifier for document selection and the bandit statistics for topic selection, thereby iteratively improving topic and document selection in successive rounds.

Across three TREC collections with varying scarcity of relevant documents, our best method achieves $\tau \approx 0.90$ Kendall correlation on average with the original system ranking for P@10, using less than 50% of the budget allotted in the original pool. Results for MAP-based evaluation are weaker but still encouraging, suggesting the approach is promising but future work is still needed.

2 RELATED WORK

A considerable amount of research [1, 2, 8, 9, 17–20, 30, 31] has been conducted to select documents for human annotation. These approaches can be mainly categorized into two groups: i) static [1, 2, 19, 30, 31] and ii) dynamic [8, 9, 17, 18, 20] selection. In a static selection process, the relevance judgment process is initiated only after the document selection process is completed. In contrast, in a dynamic selection process, document selection and relevance judgment process occur in a feedback loop, where the relevance judgments that are collected so far affect the selection process of the subsequent documents. Our proposed approach is closely related to the dynamic selection approaches. However, our approach does not require organizing a shared-task while prior work relies on the runs submitted by participants of a shared-task.

2.1 Document Selection Strategies

Various dynamic document selection methods have been proposed to intelligently select which of the documents retrieved in a shared task should be judged. The *Move-to-front* (MTF) pooling [9] is one of the pioneer examples of the dynamic document selection process. For a given topic, MTF maintains a priority list of submitted runs. At any round, MTF selects the top-ranked unjudged document from the current highest priority run for annotation. Then based on the relevance judgment of the selected document, MTF updates the priority of the selected run and moves to the next round.

Carterette et al. [3] propose to construct minimal test collections to judge ranking systems with confidence. They select documents to be judged iteratively such that the document that might differentiate systems' performances the most is selected at each iteration. However, their method completely depends on submissions from multiple systems, while the main goal of our work is eliminating the massive cost of running shared-tasks.

Rajput et al. [20] develop a framework to construct test collections using an iterative reinforcement method between nuggets and documents. Their iterative process starts with a few manually created nuggets which are utilized to select documents for the relevance judgment. The relevant documents found in the relevance judgment are used to update the weights of the existing nuggets and extract new nuggets automatically which are then used in the subsequent iteration of document selection. However, should automatic nugget extraction fails (e.g. Web Track 2009), their document selection process solely depends on the submitted runs of the shared task, whereas we consider a no shared task context.

Losada et al. [18] develop a document selection process by utilizing several multi-armed bandits [21] approaches. Their best performing approach, the *MaxMean* (MM) approach, assigns a weight to a run proportional to the ratio of the number of relevant documents found, and the total number of documents judged so far for that run; then it selects the run with the highest weight. Losada et al. empirically prove their superiority over MTF in terms of the number of relevant documents found.

However, Li and Kanoulas [17] point out that dynamic document selection based on a shared task context creates a bias towards the good runs (e.g., runs with more relevant documents). Their proposed approach also utilizes a shared task by inducing a probability distribution from the participating systems, and a probability distribution over the ranks of the documents; then it actively samples documents from the joint distribution to construct a test collection.

Recently, Voorhees [28] further supports Li and Kanoulas's statement by developing the TREC 2017 Common Core track collection via utilizing *MaxMean*(MM) proposed by Losada et al. [18]. The author finds out that only a single run contributes the large percentage of relevant documents in the collection [28]. In contrast, our test collection construction approach in the absence of a shared task is free from this bias towards good runs.

The use of AL in our document selection phase closely follows work by Cormack and Grossman [7] (and we adopt their nomenclature). However, their study is situated in a rather different domain, "e-discovery", focusing on set-based retrieval rather than ranked retrieval. Moreover, the judging cost is measured differently in this domain: no document can be selected automatically since all of the documents must be reviewed for privilege following discovery.

2.2 Topic Selection Strategies

Previous studies [11, 12, 14, 24, 28, 32] treat topic selection as a budget allocation problem. These studies either allocate an immutable budget for a topic at the outset of the relevance judgment using various information e.g., the number of relevant documents at the *top-k* pool [28, 32], or recommend to utilize many topics with a fewer number of relevance judgments [24].

Zobel [32] proposes to collect more judgments for topics with a higher estimated number of relevant documents. The estimation is computed using the relevance judgment collected for each topic in its *top-k* pool, and according to Zobel, it follows the power law distribution with the rank of the document. Voorhees follows the same *top-k* pool with a different formulation ([28], Page 411) to estimate the budget for a topic. However, none of the approaches treat the budget allocation as a topic selection problem as we have done here, where the selection of a subsequent topic for relevance judgment depends on the relevance judgments collected so far. Besides, both of the approaches [28, 32] utilize a shared task which is absent in our task setting.

Prior work [11, 12, 14] also investigates the possibility of selecting a subset of topics. Guiver et al. [11] experimentally show that if we can find a "right" subset of topics, we can achieve a ranking of systems that is very similar to the ranking when all of the topics are used for evaluation. Even though they do not propose a method for finding the "right" subset of topics, their work motivated many researchers to work on the topic selection problem [12, 14]. Studies on topic selection treat each selected topic equally (i.e. collect the same amount of judgments per each), while no judgments are selected for the topics that are not selected. On the contrary, we collect a varying number of judgments per topic.

3 PROPOSED APPROACH

Our approach consists of two phases which alternate between topic selection and document selection. In topic selection phase, we estimate the prevalence of relevant documents for each topic, and select the topic with the highest estimated prevalence. In document selection phase, we use a classifier to predict the relevance of all unjudged documents for the selected topic, and use those predictions

to select which documents to judge next for that topic. We then use the collected relevance judgments to update both the given classifier and the topic statistics. This iterative process of topic and document selection continues until the budget is exhausted.

Algorithm 1 describes our two-phase approach in detail.

Algorithm 1: Two-phase Topic and Document Selection

Input : Unjudged documents U • batch size N • Budget b • Document selection policy p
Output: Relevance judgments $R^{1:J}$ for topics $1:J$

$R^{1:J} \leftarrow \emptyset$
for *topic* $j \leftarrow 1$ **to** J **do**
  Select seed document set $S^j \in U$ for topic j
  $R^j \leftarrow$ judge_relevance (j, S^j) ▷ Collect judgments
  $U \leftarrow U - S^j$ ▷ Update set of unjudged documents
  $b \leftarrow b - |S^j|$ ▷ Update remaining budget
  $C^j \leftarrow$ train_classifier (S^j, R^j)
  $\alpha_j \leftarrow 1, \beta_j \leftarrow 1$ ▷ Initialize Beta distribution for bandit

while remaining budget b >= batch size N **do**
  for *topic* $j \leftarrow 1$ **to** J **do**
    $P_j \leftarrow$ sample probability from $Beta\,(\alpha_j, \beta_j)$
  Selected topic $j \leftarrow \underset{j}{\text{argmax}}\, P_j$
  $\widehat{R^j} \leftarrow$ predict_relevance (C^j, U) ▷ for all unjudged
  S^j = select_documents (U, $\widehat{R^j}$, batch size N, policy p)
  $R^j \leftarrow$ judge_relevance (j, S^j) ▷ Collect judgments
  $U \leftarrow U - S^j$ ▷ Update set of unjudged documents
  $b \leftarrow b - N$ ▷ Update remaining budget
  $C^j \leftarrow$ update_classifier (C^j, S^j, R^j)

  for *document* $i \leftarrow$ **to** N **do** ▷ Update bandits
    if $R^j(i)$ *is relevant* **then**
      $\alpha_j \leftarrow \alpha_j + 1$
    else
      $\beta_j \leftarrow \beta_j + 1$

3.1 Phase 1: Topic Selection

Each topic may need different number of judgments based on the number of relevant documents found in the collection. Thus, allocating a static pre-defined budget for all topics may incur more/less cost than required for topics. Therefore, we prefer to allocate the budget across topics dynamically based on the needs of each topic. Given the fact that we do not have any prior knowledge about the number of judgments needed for a topic, an exploration-exploitation situation arises naturally, which can be approached using the multi-armed bandits (MAB) techniques [21].

In the standard MAB problem, we have to repeatedly make a choice among J bandits (or slot machines), each of which has a hidden probability of winning and losing. Depending on the slot machine j we select at round t, we receive a reward (e.g. 1 for winning, or 0 for losing). In the long run, we want to maximize our final reward. This multi-armed bandits problem is a natural fit for our topic selection problem. Each topic j can be referred to as a slot machine and each of these topics has a hidden probability of supplying a relevant document. At each round t, based on the selected topic j, we either receive a relevant or non-relevant document. At any round t, we can estimate which topic is more likely to provide more relevant documents. The exploration-exploitation dilemma arises when deciding between whether we should keep selecting that topic or we should explore other topics; we do not know which decision will help us maximize the number of relevant documents.

To allocate the budget across topics dynamically, we apply a Bayesian approach [10] where each topic's hidden probability distribution over relevant and non-relevant documents is endowed with a prior distribution. With no prior knowledge about the topic's prevalence, we start with a uniform prior for each topic. Note that a uniform distribution is a special case of a $Beta(\alpha, \beta)$ distribution, when $\alpha = 1$ and $\beta = 1$. In our Algorithm 1, α and β denote the number of relevant and non-relevant documents found so far for a topic j, respectively. At any round t, we start by selecting a topic j from the $Beta(\alpha, \beta)$ distribution. Next we select N documents to judge using a document selection process (Section 3.2) for topic j. Finally, the binary outcome, O, (either relevant or non-relevant) for each selected document is used to update the hidden probability distribution of topic j. With a $Beta(\alpha, \beta)$ prior and a binary outcome, the posterior O is also a $Beta(\alpha + O, \beta + 1 - O)$ distribution.

3.2 Phase 2: Document Selection

In this phase, we select N documents to judge for a given topic j. However, in the absence of a shared-task, we do not have any ranking information of documents. Therefore, if we select documents randomly, it is very unlikely to find any relevant document. Thus, we employ active learning [25], a learning paradigm where a classifier decides which document should be annotated next in order to maximize the learning curve of the classifier.

3.2.1 Task Definition and Learning Model. To train a topic-specific active classifier, we must collect the topic-specific training data. Let us assume that a training pair for a topic j is denoted by $\langle x^i, y^i_j \rangle$, where x^i denotes the feature representation of document, i and y^i_j denote the binary relevance judgment for <document i, topic j>. We adopt logistic regression as a classifier to infer the probability of relevance $P(y^i_j|x^i)$ of each document x^i for topic j:

$$p(y^i_j|x^i) = h_\theta(x_i) = \frac{1}{1 + \exp(-\vec{\theta}^T x_i)} \tag{1}$$

with $\vec{\theta} \in \mathbb{R}^D$ denotes model parameters.

3.2.2 Document Selection Criteria. Utilizing the posteriori probability of documents for a given topic j, we can select documents to be judged in two different ways: *Simple Active Learning* (SAL) and *Continuous Active Learning* (CAL).

SAL [15] selects a document for relevance judgment when the classifier is most uncertain about the label of that document. We employ an entropy-based uncertainty function [25] for this:

$$Uncertainty(x) = -\sum_{y \in Y} P(y|x) \log P(y|x) \tag{2}$$

Table 1: Test collection statistics. As collections have grown larger, judging budgets have also shrunk, leading to increased prevalence of relevant documents in later tracks.

Track	Collection	Topics	#Docs	#Judged	%Rel
WT'14[6]	ClueWeb12[4]	251-300	52M	14,432	39.2%
WT'13[5]	ClueWeb12	201-250	52M	14,474	28.7%
TREC-8[29]	Disks45-CR[5]	401-450	528K	86,830	5.4%

where y is either relevant or non-relevant. With binary relevance, SAL selects:

$$x^{\star} = \underset{i}{\operatorname{argmin}} \ |p(relevant|x^i) - 0.5| \tag{3}$$

In contrast, CAL selects a document based on how likely the document is to be relevant according to the prediction of the classifier.

$$x^{\star} = \underset{i}{\operatorname{argmax}} \ p(relevant|x^i) \tag{4}$$

3.2.3 Seed Document Selection. In order to learn an initial classifier for each topic, a minimal *seed set* of relevance judgments for each topic is required. We assume a *single* off-the-shelf or in-house IR system (e.g., Apache Lucene[2] or Indri[3]) is used to produce a document ranking for each topic. The assessor is then asked to proceed down the document ranking for each topic until at least m number of relevant and m number of non-relevant documents have been found, or some maximum effort is reached without success, in which case, the topic is discarded. In this paper, we assume $m = 5$. Note that this single IR system is used only once at the outset to guide seed set annotation, and one might even do without this if one is willing to resort to boolean search or random selection to identify the seed documents [7].

4 EXPERIMENTS

4.1 Experimental Setup

Datasets. We conduct our experimental evaluation on three TREC test collections (See **Table 1**). We assume binary relevance and collapse NIST graded relevance judgments to binary.

We use only pooled documents of each collection because unpooled documents are not judged and typically assumed to be not-relevant. However, relevant documents may exist outside the pool, and assuming them to be non-relevant could hurt classifier training and prediction. One could judge the unpooled documents selected by our method, though this could yield inconsistency between the original judgments and new judgments. This issue could be usefully revisited in future work. In the remainder of this paper, we refer to the set of pooled judged documents as the "qrels."

Document Selection. In the document selection phase, we have to represent the documents in a feature vector for the classifier of the active learning approach. We first pre-process the documents using `IndriBuildIndex`[6]. The pre-processing consists of text normalization, stopword [16] removal, and Krovetz stemming [13]. Finally, each pre-processed document is represented using a 15K dimensional TF-IDF [22] vector. Each iteration of AL selects one document to be judged next. In order to select the seed documents of AL, we randomly select one of the runs for each test collection and assume it as our off-the-shelf IR system.

Baselines. We have one baseline method for document selection and another baseline method for topic selection.

- **Simple Passive Learning (SPL):** This baseline method for document selection uses uniform random selection.
- **Round-Robin (RR):** RR simply cycles through topics and then repeats, thus allocating the same budget for each topic. No information is used regarding topic prevalence ratio or collected relevance judgments.

Upperbound. We develop **Oracle** as the upperbound for our topic selection method. Whereas MAB must learn the prevalence ratio of topics during dynamic topic selection, the Oracle knows the exact prevalence ratio of each topic at each round t. To do this, we initialize the α and β parameters of each topic with the topic's total number of relevant and non-relevant documents in the original qrels. At each round t, we update the parameters, decreasing α and β based on the relevance judgments collected during that round.

Table 2: Avg. number of relevant documents found under varying budget per topic on TREC-8. For MoveToFront (MTF), MaxMean Non-Stationary (MM-NS), and MAB+CAL topic selection, MAB+CAL consistently performs best.

	Average number of judgments per topic						
Method	**100**	**300**	**500**	**700**	**900**	**1100**	**all**
MTF	34.06	58.48	71.78	79.22	84.5	87.58	94.04
MM-NS	36.96	64.62	77.3	82.5	86.34	89.2	94.04
MAB+CAL	**46.3**	**78.4**	**86.5**	**90.3**	**91.3**	**93.5**	94.04

4.2 Results and Discussion

Effectiveness of topic selection. How well can MAB identify relevant documents? **Figure 1** compares the recall of MAB with Oracle and RR for WT2014 and WT2013 collections. The overall Area Under Curve (AUC) effectiveness across all budget points is reported in Figure 1. The x-axis of each plot represents the total allotted budget. Ultimately, each strategy achieves complete recall because all pooled documents are judged. As expected, RR is the weakest performing topic selection method across all six plots of Figure 1, suggesting that we should select topics intelligently to maximize recall of relevant documents. Also as expected, Oracle performs best in every case, and the recall curve of MAB consistently lies between Oracle and RR.

Dynamic vs. random document selection. Figure 1 also reports the performance of the three document selection strategies. We observe that CAL outperforms the SPL baseline in both test collections and in all topic selection strategies. However, we cannot infer the same conclusion about SAL because SAL outperforms SPL only in 3/6 of cases based on AUC scores. CAL selects the documents that are most likely to be relevant, yielding a higher recall than others. On the other hand, SAL selects documents whose relevance is uncertain, and thus tends to select more non-relevant documents, ultimately decreasing its recall.

The allotted budget for each topic. In **Figure 2**, we report the budget allotted to each topic using CAL for document selection, and MAB and RR for topic selection on TREC8, WT2013, and WT2014

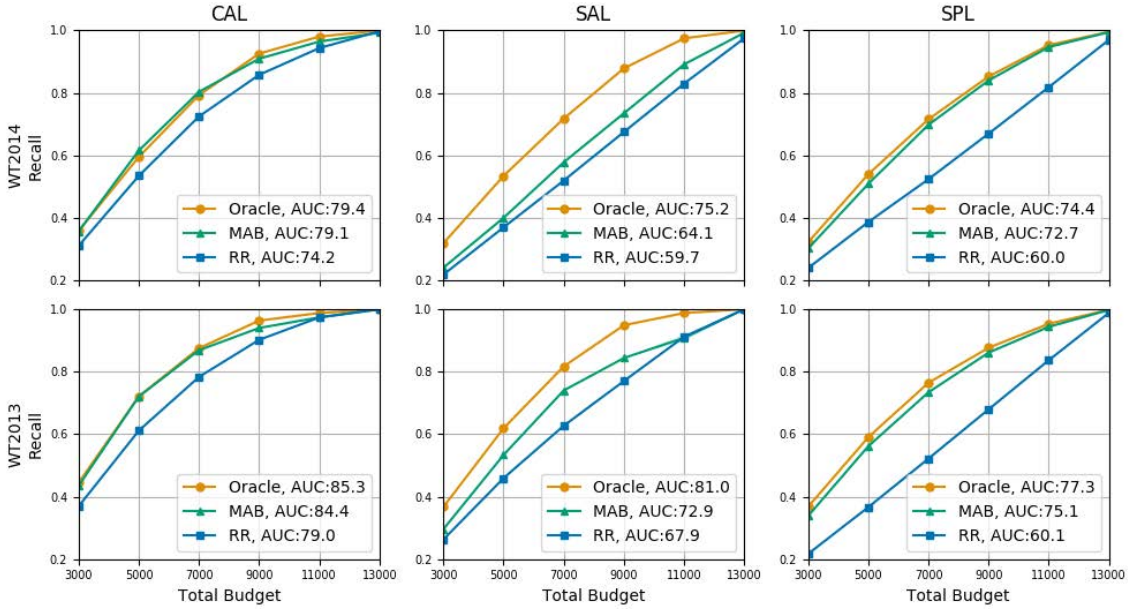

Figure 1: Recall of relevant documents achieved by Oracle, Multi-armed bandits (MAB), and Round-robin (RR) topic selection methods as a function of varying evaluation budget on WT2014 and WT2013 collections. The x-axis shows total cost over all topics. Plots are grouped vertically for CAL, SAL, and SPL document selection methods.

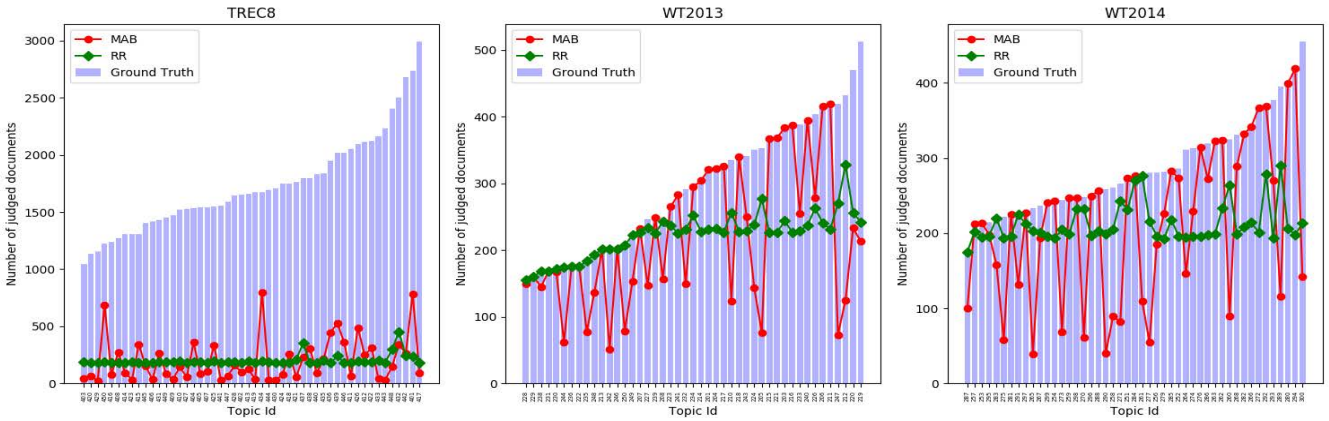

Figure 2: The budget (# of judged documents) across topics using MAB and RR with CAL document selection on TREC8, WT2013 and WT2014 test collections with total budget of 10,000. The bar plots show per-topic budget in the original qrels.

when the overall budget is 10,000. We can see that MAB-based topic selection varies the judging budget used across topics. For RR, the number of judgments per topic varies only due to the varying number of seed documents used to start AL. Ignoring the cost of seed documents, all topics would have the same number of judgments per topic in RR. Thus as expected, RR has a lower variance in budget allocation per topic than MAB.

Comparison against pool-based methods. We compare our approach, MAB with CAL (MAB+CAL) against two state-of-the-art pool-based dynamic document selection methods: MoveToFront (MTF) [9] and the MaxMean Non-Stationary (MM-NS) [18]. **Table 2** presents the average number of relevant documents found per topic of TREC-8 collection. We copy the MM and MTF results reported in [18]. Note that for MTF and MM-NS, we have to manually specify a fixed budget per topic. In contrast, MAB+CAL intelligently learns the budget allocation per topic dynamically.

Table 2 shows that MAB+CAL finds a higher average number of relevant documents per topic than MTF and MM-NS in all cases, *despite* the fact that both MTF and MM-NS utilize the document ranking information from the submitted runs in a shared task.

Rank Correlation. One of the ways to evaluate the reliability of a low-cost evaluation method is to compare the resultant ranking of IR systems with the ranking produced by all qrels. Thus, we build qrel sets using CAL for document selection, and RR, MAB, and

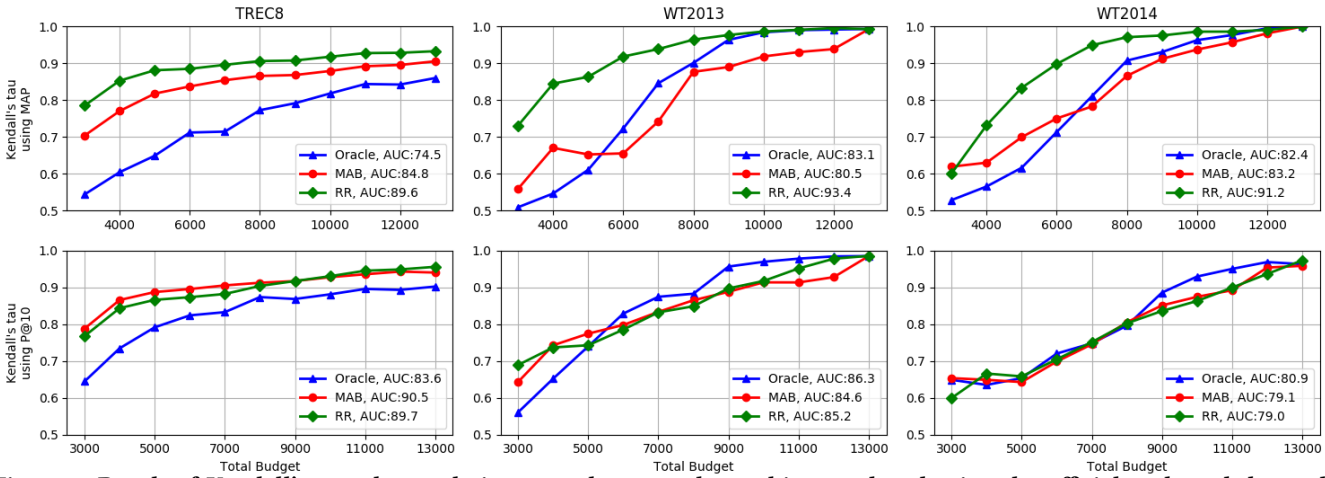

Figure 3: Result of Kendall's τ rank correlation score between the ranking produced using the official qrels and the ranking produced using qrels created by Oracle, MAB and RR with CAL over varying budgets on TREC8, WT2014 and WT2013 collections. Rankings are produced using MAP (top row) and P@10 (bottom row).

Oracle for topic selection varying the total budget from 3K to 13K, and calculate Kendall's τ rank correlation between ground truth ranking and the resultant ranking for each case. We use MAP and P@10 as the evaluation metric. The results are shown in **Figure 3** for TREC8, WT2013 and WT2014 test collections.

For the bottom row of Figure 3 (Kendall's τ rank correlation for P@10 evaluation), we see that with low judging budget, MAB provides better τ correlation than RR for test collections with lower prevalence ratio per topic (i.e., TREC8). Specifically, MAB achieves $\tau = 0.9$ (a traditionally-accepted threshold for acceptable correlation [27]) when the total budget is 6500, which is only 7.4% of the original allotted budget for TREC8. However, results are less clear for test collections with a higher prevalence ratio. For example, MAB outperforms RR for WT2014 but RR outperforms MAB for WT2013 in terms of AUC.

When we compute Kendall's τ for MAP evaluation (Figure 3, Top Row), both Oracle and MAB actually perform worse than RR across test collections. Since MAP is a recall-based metric, it considers the full judgment pool for each topic, whereas P@10 takes account only the first 10 documents. This suggests the current MAB approach may work well for shallow metrics but not for deep ones.

Recall that RR allocates the same budget across all topics, whereas MAB-based topic selection yields a varying number of documents across topics (Figure 2). This is because MAB seeks to optimize the number of relevant documents [9, 18]. Oracle optimizes this same objective function as MAB but even better, knowing the exact prevalence ratio of each topic, which MAB must learn. Results thus suggest that our MAB-based approaches spend the budget excessively on topics with high prevalence ratio, causing judging few documents for the topics with low prevalence ratio. Sometimes, MAB outperforms Oracle seemingly because its imperfect estimate of prevalence leads it to explore more and exploit less. Thus, while MAB approaches succeed in finding more relevant documents, we observe a metric divergence between what is being optimized (recall) and what we actually care about: reliable evaluation, as measured by rank correlation. Moreover, results underscore the importance of evaluating test collection creation methods via rank correlation, and not only by recall of relevant documents [18].

Furthermore, when we compare the results across collections for MAP score in Figure 3, we find that the performance difference between RR and MAB-based approaches are much higher in collections with a high prevalence ratio (i.e., WT2013 and WT2014) than a low prevalence ratio (i.e., TREC8). This signifies the fact that in terms of MAP, MAB-based approach produces a more reliable evaluation for test collections with a low prevalence ratio than test collections with a high prevalence ratio. This is another promising result of our MAB-based approach which encourages further empirical evaluation.

5 CONCLUSION AND FUTURE WORK

This work investigates the feasibility of developing a minimal cost test collection without organizing a shared task. In the absence of shared task document rankings to prioritize relevance judging, we utilize active learning [25] instead. Furthermore, we intelligently and dynamically allocate judging effort across topics via multi-armed bandits [21]. Results on the three different TREC test collections indicate that by utilizing an average of only 48% of the total budget (Table 1) allocated in these test collections, our best approach, MAB+CAL, not only finds 90% of the relevant documents (Figure 1) but also achieves a Kendall's τ rank correlation value of 0.90 with the original system ranking when the correlation is computed using P@10 (Figure 3, Bottom Row). However, further work is needed to effectively support more recall-oriented IR evaluation metrics such as MAP. Current results suggest that our MAB-based approaches spend the budget excessively on topics with high prevalence ratio, judging too few documents for topics with low prevalence ratio. Future work might usefully explore more sophisticated bandit approaches (e.g. contextual bandits).

ABSTRACT

Counterfeit apps impersonate existing popular apps in attempts to misguide users. Many counterfeits can be identified once installed, however even a tech-savvy user may struggle to detect them before installation. In this paper, we propose a novel approach of combining *content embeddings* and *style embeddings* generated from pre-trained convolutional neural networks to detect counterfeit apps. We present an analysis of approximately 1.2 million apps from Google Play Store and identify a set of potential counterfeits for top-10,000 apps. Under conservative assumptions, we were able to find 2,040 potential counterfeits that contain malware in a set of 49,608 apps that showed high similarity to one of the top-10,000 popular apps in Google Play Store. We also find 1,565 potential counterfeits asking for at least five additional dangerous permissions than the original app and 1,407 potential counterfeits having at least five extra third party advertisement libraries.

1 INTRODUCTION

Availability of third party apps is one of the major reasons behind the wide adoption of smartphones. The two most popular app markets, Google Play Store and Apple App Store, hosted approximately 3.5 million and 2.1 million apps by early 2018 [16, 24]. Handling such large numbers of apps is challenging for app market operators since there is always a trade-off between how much scrutiny is put into checking apps and encouraging developers by providing fast time-to-market. As a result, problematic apps of various kinds including malware have made it into the app markets [42, 56].

One category of such problematic apps is *counterfeits* (i.e. apps that attempt to impersonate popular apps). Reasons behind app impersonations include harvesting user credentials, increasing advertising revenue, and spreading malware. Many popular apps such as *Netflix*, *IFTTT*, *Angry Birds*, and *banking apps* have been reported to be affected by counterfeits [8, 25, 39, 50]. In Figure 1, we show an example counterfeit named *Temple Piggy*[1] which shows a high visual similarity to the popular arcade game *Temple Run*.[2]

a) Original (Temple Run) b) Counterfeit (Temple Piggy)

Figure 1: An example counterfeit for the game Temple Run

In this paper, we propose a neural embedding-based approach to identify counterfeit apps from a large corpus of apps. We leverage the recent advances in Convolutional Neural Networks (CNNs) to generate feature embeddings from given images using pre-trained models such as VGGNet [45]. In contrast to commonly used *content embeddings* generated from fully connected layers before the last soft-max layer, we show that combining *content embeddings* with *style embeddings* generated from the Gram matrix of convolutional layer feature maps achieve better results in detecting visually similar app icons. Following are the main contributions of this paper.

- We show that the novel method of using combined *style* and *content* embeddings generated from pre-trained CNNs outperforms many baseline image retrieval methods for the task of detecting visually similar app icons. We also validate this method using two standard image retrieval datasets.
- Using a large dataset of over 1.2 million app icons, we show that *combined content and style embeddings* achieve 8%–12% higher *precision@k* and 14%–18% higher *recall@k*.

[1] *Temple Piggy* is currently not available in Google Play Store.
[2] *Temple Run* - https://play.google.com/store/apps/details?id=com.imangi.templerun.

- We show that adding *text embeddings* [31] as an additional modality, further increases the performance by 3%–5% and 6%–7% in terms of *precision@k* and *recall@k*.
- We identify a set of 7,246 potential counterfeits to the top-10,000 apps in Google Play and show that 2,040 of them may contain malware. We further show that out of those; 1,565 ask for at least five extra dangerous permissions and 1,407 have at least five extra third party ad libraries.

2 RELATED WORK

2.1 Mobile Malware & Greyware

While there is a plethora of work on detecting mobile malware [14, 22, 44, 52, 54] and various fraudulent activities in app markets [15, 21, 43, 47, 53], only a limited amount of work focused on the *similarity of mobile apps*. Viennot et al. [49] used the Jaccard similarity of app resources in the likes of images and layout XMLs to identify clusters of similar apps and then used the developer name and certificate to differentiate clones from rebranding. Crussell et al. [17] proposed to use features generated from the source codes to identify app clones. In contrast to above work, our work focuses on identifying visually similar apps (i.e. counterfeits) rather than the exact similarity (i.e. clones), which is a more challenging problem.

Limited amount of work focused on identifying visually similar mobile apps [7, 35, 36, 46]. For example, Sun et al. [46] proposed DroidEagle that identifies the visually similar apps based on XML layouts. While the results are interesting this method has several limitations. First, all visually similar apps may not be necessarily similar in XML layouts and it is necessary to consider the similarities in images. Second, app developers are starting to use code encryption methods, thus accessing codes and layout files may not always possible. Third, dependency of specific aspects related to one operating system will not allow to make comparisons between heterogeneous app markets. Recently, Malisa et al. [35] studied how likely would users detect a spoofing application using a complete rendering of the application itself. In contrast to above work, the proposed work intends to use neural embeddings derived from app icons and text descriptions that will better capture visual and functional similarities.

2.2 Visual Similarity & Style Search

Several work focused on transferring style of an image to another. For example, Gatys et al. [18, 20] proposed a *neural style transfer* that is able to transfer the stylistic features of well-known artworks to target images. Other methods proposed to achieve the same objective either by updating pixels in the image iteratively or by optimising a generative model iteratively and producing the styled image through a single forward pass. A summary of style transfer algorithms can be found in the survey by Jing et al. [27].

Johnson et al. [28] proposed a feed-forward network architecture capable of real-time style transfer by solving the optimisation problem formulated by Gatys et al. [20]. Similarly, to style transfer, CNNs have been successfully used for image searching. In particular, Bell & Bala [12] proposed a Siamese CNN to learn a high-quality embedding that represent visual similarity and demonstrated the utility of these embeddings on several visual search tasks such as searching similar products. Tan et al. [48] and Matsuo & Yanai [37] used embeddings created from CNNs to classify artistic styles. In contrast to these works, our work focuses on retrieving visually similar Android apps and we highlight the importance of style and combined (multi-modal) embeddings in this particular problem.

3 DATASET

We collected our dataset by crawling Google Play Store using a Python crawler between January and March, 2018. The crawler was seeded with the web pages of the top apps as of January, 2018 and it recursively discovered apps by following the links in the seeded pages and the subsequently discovered pages. For each app, we downloaded the metadata such as app name, app description, and number of downloads as well as the app icon in *.jpg* or *.png* format (of size 300 x 300 x 3 - height, width, and three RGB channels).

We collected information of ***1,278,297 apps*** during this process. For each app, we also downloaded the app executable using *Google Play Downloader* [1] by simulating a Google Pixel. We were able to download APKs for ***1,023,521 apps*** out of the total ***1,278,297 apps*** we discovered. The reasons behind this difference are the *paid apps* and the apps that did not support the used virtual device.

Labelled set: To evaluate the performance of various image similarity metrics we require a ground truth dataset that contains similar images to a given image. We used a heuristic approach to shortlist a possible set of visually similar apps and refined it by manual checking. Our heuristic is based on the fact that there are apps having multiple legitimate versions. For example, popular game app *Angry Birds* has multiple versions such as *Angry Birds Rio*, *Angry Birds Seasons*, and *Angry Birds Go* with similar app icons and descriptions.

Thus, we first identified the set of developers who has published more than two apps and one app having at least 500,000 downloads. In the set of apps from the same developer, the app with the highest number of downloads was selected as the *base app*. For each other app in the set, we calculated the *character level cosine similarity* of its *app name* to the base app name and selected the apps having over 0.8 similarity and in the same *app category* as the base app. We identified 2,689 such groups. Finally, we manually inspected each group and discarded the apps that were not visually similar.

During our later evaluations, the highest number of neighbours we retrieve is 20. Therefore, we ensured that the maximum number of apps in a group was 20 by randomly removing apps from the groups having more than 20 apps. At the end of this process we had 806 app groups having a total of 3,539 apps as our ***labelled set***.

Top-10,000 popular apps: To establish a set of potential counterfeits, we used top-10,000 apps since counterfeits majorly target popular apps. We selected top-10,000 popular apps by sorting the apps by the number of downloads, number of reviews, and average rating similar to what was proposed in [42].

Other image retrieval datasets: To benchmark the performance of our proposed combined embeddings, we use two existing ground-truth datasets; UKBench [38] and Holidays [26]. Both datasets contain groups of similar images, containing images of same scenes or objects from different angles and illumination levels.

4 METHODOLOGY

The main problem we are trying to address is that *"given an app can we find potential counterfeits from a large corpus?"*. Since counterfeit

apps focus more on being visually similar to original apps, we mainly focus on finding similar app icons to a given app icon. We also focus on the similarity between text as an additional modality.

4.1 App Icon Encoding and Embeddings

We encode the original app icon image of size 300×300×3 to a lower dimension for efficient search and to avoid false positives happening due to L_2 distance at large dimensions [4]. We create several low dimensional representations of the images. As baseline methods, we use state-of-the-art image *hashing methods*, *feature-based image retrieval methods*, and SSIM (Structural Similarity). From a pre-trained VGGNet, we derive *content* and *style embeddings*.

i) Hashing methods: Hashing methods we evaluate include *average* [29], *difference* [30], *perceptual* [55], and *wavelet* [5] hashing. All four methods first scale the app icon to a 32×32 grayscale image and represent it as a $1x1024$ binary feature vector.

ii) Feature-based image retrieval methods: Feature-based methods extract features from an image and describe them using neighbouring pixels. Thus, such methods have two steps; *feature detection* and *feature description*. Some algorithms perform both tasks together while others perform them separately. In this paper, we use four feature matching methods; *Scale-Invariant Feature Transform (SIFT)* [34], *Speeded-Up Robust Features (SURF)* [11], *Accelerated KAZE (AKAZE)* [6], and *Learned Arrangements of Three Patch Codes (LATCH)* [32]. SIFT and SURF describe an app icon by a $f_i \times 128$ integer descriptor matrix, where f_i is the number of features detected for app icon i. AKAZE and LATCH describe the app icon by a $f_i \times 64$ binary descriptor matrix.

iii) Structural Similarity Index Matrix (SSIM): SSIM [51] compares the local pattern of pixel intensities in two images and calculate a similarity score. This method gives a high similarity score even for images with significant pixel-wise difference as it does not compare images point-by-point basis. SSIM does not represent an image by a vector/matrix. Therefore, we scale the input app icons into a 32×32 grayscale images and calculate the similarity score.

iv) Content embeddings: To extract the content representation of an icon, we used a pre-trained *VGGNet* [45]. We fed all 1.2M app icons to the VGGNet, and used the *content embeddings*, $C \in \mathbb{R}^{4096}$, generated at the last fully connected layer of VGGNet (fc_7 layer) that have shown good results in the past [10, 13].

v) Style embeddings: Content similarity alone is not sufficient for counterfeit detection as sometimes developers keep the visual similarity and change the content. Thus, we require an embedding that represents the style of an image.

Several work demonstrated that the Gram matrix of filter responses of CNNs can be used to represent the style of an image [19, 20]. We followed a similar approach and used the fifth convolution layer ($conv5_1$) of the VGGNet to obtain the style representation of the image, as previous work indicated that $conv5_1$ provides better performance in style similairty [37]. We passed each icon through the VGGNet, and at $conv5_1$ the icon was convolved with pre-trained filters and activated through *ReLU* function. The $conv5_1 - layer$ of the VGGNet we used had 512 filters, resulting a Gram matrix of size $G^5 \in \mathbb{R}^{512\times512}$. We only considered the upper half of the Gram matrix as our style representation vector, $S \in \mathbb{R}^{131,328}$ as the Gram matrix is symmetric. To further reduce the dimension of style embeddings we used the *very sparse random projection* [33] and ensured the size of style embeddings is $1x4096$. In Figure 2, we show a summary of our icon encoding process.

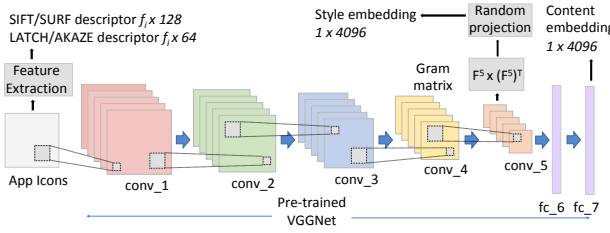

Figure 2: Image embeddings generation process

4.2 Text Embeddings

The app descriptions from Google Play Store can contain a maximum of 4000 characters, describing the apps' functionalities and features. As such, counterfeits are likely to show some similarities to original apps' description. To capture this similarity, we first used standard text pre-processing methods on app descriptions and trained a Paragraph Vectors Model [31] to create vectors of size 100.

4.3 Retrieving Similar Apps

During the similar app retrieval process we take an app and calculated the required embeddings and search in the encoded space for *k nearest neighbours* using *cosine distance*, L_2 *distance*, or *hamming distance* based on the applicability to the embedding under consideration. Let X_i^y be a vectored representation of an app i using the encoding scheme y and X_t^y be the corresponding representation of the target app we are comparing, we calculate the various distance metrics for different representations as summarised in Table 1.

5 RESULTS

5.1 Evaluation of Embeddings

To quantify the performance of the different embeddings, we evaluate them in four different test scenarios using multiple datasets. In each scenario, for a given query embedding, we retrieved *k-nearest neighbours* (k-NN) based on the distances considered in Table 1. We tested four values of k; 5, 10, 15, and 20. The four scenarios are:

i) Holidays dataset: Holidays dataset contains 1,491 images from 500 groups. We took the encoded representation of the first image to search the entire corpus and retrieved the *k-nearest neighbours*.

ii) UKBench dataset: UKBench dataset contains 10,200 images from 2,550 groups. Same method as the Holidays dataset was used.

iii) Apps - Labelled set only: Labelled set contains 3,539 images from 806 groups. From each group, the *base app icon embedding* was taken as the query to retrieve *k-NNs* among remaining icons.

iv) Apps - Labelled set and all remaining icons and text: This dataset contains 1.2M images. The embedding of the base app icon of each group in the labelled set was taken as the query to retrieve the *k-NNs* from the entire dataset.

Table 1: Summary of encoding methods and distance metrics

Encoding Method	Size (n)	Distance function
Hashing methods (Hamming distance)		
Average	1,024	$\|\|X_i^{avg} \oplus X_t^{avg}\|\|_1$
Difference	1,024	$\|\|X_i^{diff} \oplus X_t^{diff}\|\|_1$
Perceptual	1,024	$\|\|X_i^{perc} \oplus X_t^{perc}\|\|_1$
Wavelet	1,024	$\|\|X_i^{wave} \oplus X_t^{wave}\|\|_1$
Feature based methods (L_2 distance)		
SIFT	$f_i^{sift} \times 128$	$\sum_{x_i \in X_i} \min_{x_t \in X_t} [\|\|x_i^{sift} - x_t^{sift}\|\|_2]$
SURF	$f_i^{surf} \times 128$	$\sum_{x_i \in X_i} \min_{x_t \in X_t} [\|\|x_i^{surf} - x_t^{surf}\|\|_2]$
Feature based methods (Hamming distance)		
AKAZE	$f_i^{akaze} \times 64$	$\sum_{x_i \in X_i} \min_{x_t \in X_t} [\|\|x_i^{akaze} \oplus x_t^{akaze}\|\|_2]$
LATCH	$f_i^{latch} \times 64$	$\sum_{x_i \in X_i} \min_{x_t \in X_t} [\|\|x_i^{latch} \oplus x_t^{latch}\|\|_2]$
Structural similarity		
SSIM	Directly returns a dissimilarity	
Neural embeddings (Cosine distance)		
Content (C_{cos})	4,096	$1 - \frac{X_i^{cont}.X_t^{cont}}{\|\|X_i^{cont}\|\|_2 \|\|X_t^{cont}\|\|_2}$
Style (S_{cos})	4,096	$1 - \frac{X_i^{style}.X_t^{style}}{\|\|X_i^{style}\|\|_2 \|\|X_t^{style}\|\|_2}$
Text (T_{cos})	100	$1 - \frac{X_i^{text}.X_t^{text}}{\|\|X_i^{text}\|\|_2 \|\|X_t^{text}\|\|_2}$
Content+Style	8,192	$\alpha\ C_{cos} + \beta\ S_{cos}$
Content+Style+Text	8,292	$\alpha\ C_{cos} + \beta\ S_{cos} + \gamma\ T_{cos}$

The intuition behind above scenarios is that if a given embedding is a good representation, the *k-NN*s we retrieve must be from the same group as the query. Thus, for each scenario, we present ***precision@k*** and ***recall@k***, where $k \in \{5, 10, 15, 20\}$, as the performance metrics. ***Precision@k*** gives the percentage of relevant images among the retrieved images. ***Recall@k*** is the percentage of relevant retrieved images out of the all relevant images.

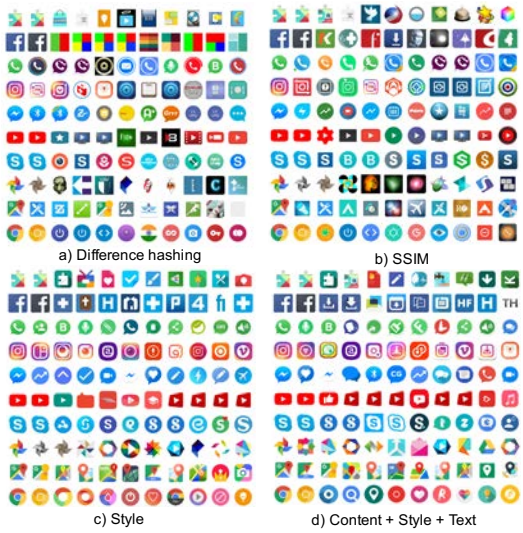

Figure 3: 10-Nearest neighbours of the top-10 popular apps

We present precision@k and recall@k values for all four test scenarios in Table 2 and Table 3. To choose the best β and γ values in multi-modals neural embeddings, we varied β and γ from 1 to 10 with an interval of one. We achieved the best results when $\beta = 5$ and $\gamma = 4$ and we report those results in Tables 2 and 3. The main takeaway messages from results in these two tables are:

- In all scenarios, neural embeddings outperform other methods. For example, for all four k-NN scenarios, the style embeddings have approximately 4%–14% and 11%–26% higher performance in precision@k and recall@k in all apps dataset.
- In UKBench and Holidays datasets, content, style, and combined embeddings increase *precision@k* and *recall@k* by 10%–15% and 12%–25%, respectively when retrieving five nearest neighbours. Combining style embeddings with content embeddings achieves 12% higher precision@k and 14% higher recall@k in all apps dataset compared to hashing and feature-based baselines when $k = 5$. Only scenario where combined content and style embeddings did not outperform all other methods is the UKBench dataset.
- It is also noticeable that adding text embedding further increases the performance by 3%-5% and 6%-7% in terms of precision@k and recall@k, respectively, compared to the best neural embedding method when $k \in \{5, 10\}$.
- Results also show that increasing the k value increases the recall@k, however, significantly decreases precision@k. The main reason is that average number of images per groups in all four datasets is less than 5 and thus the number of false positive images in the retrieved image set increases with k.

To elaborate further on the performance of the embeddings qualitatively, in Figure 3, we present the 10-nearest neighbours we retrieved using difference hashing, SSIM, style embeddings, and content+style+text embeddings for the top-10 most popular apps in Google Play Store. Figure 3-(a) shows that hashing methods do not identify visually similar apps apart from the first 1-2 similar apps (E.g. row 9 - Google Maps). Neural embeddings based methods in Figure 3-(c) and Figure 3-(d) have identified better fits in several cases (E.g. row 1 - Google Play Services and row 9 - Google Maps). Also, Figure 3-(c) shows that style embeddings have retrieved app icons that have the same *"look and feel"* in terms of colour.

5.2 Retrieving Potential Counterfeits

We next use the embeddings that performed best ($\text{Content}_{cos} + \beta\text{Style}_{cos} + \gamma\text{Text}_{cos}$ where $\beta = 5$ and $\gamma = 4$) to retrieve 10-nearest neighbours for ***top-10,000 apps*** from the corpus of 1.2 million apps that are not from the same developer. The 10-nearest neighbour search is forced to return 10 nearest apps, irrespective of the distance. As such, there can be cases where the nearest neighbour search returns apps that are very far from the query app. Thus, we applied a distance threshold to further narrow down the results. From the retrieved 10 results for each query app, we discarded the results that are having distances greater than an empirically decided threshold. The threshold was chosen as the knee-point [40] of the cumulative distribution of all the distances with the original apps. This process returned 60,638 unique apps that are potentially counterfeits of one or more apps with in top-10,000 popular apps. Out of this 60,638 we had APK files for 49,608 apps.

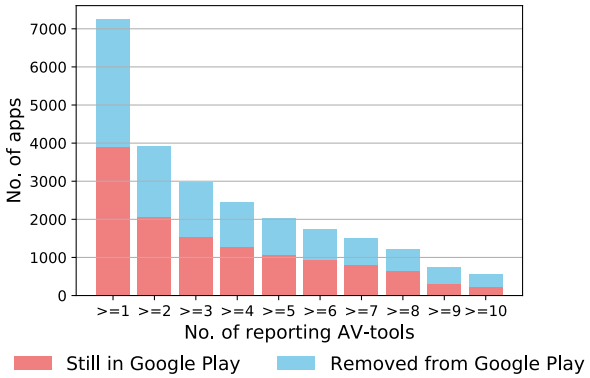
5.3 Malware Analysis

We then checked each of the 49,608 potential counterfeits using the private API of the online malware analysis tool *VirusTotal* [2]. VirusTotal scans the APKs with over 60 commercial anti-virus tools (AV-tools) and provides a report on how many of those tools identified whether the submitted APKs contain malware. In Figure 4, we show a summary of the number of apps that were tagged as possible malware by one or more AV-tools in VirusTotal and their availability in Google Play Store as of *24-10-2018*. There were 7,246 APKs that are tagged by at least one of the AV-tool.

However, a single AV-tool tagging an APK as malware may not mean that the APK contains malware. Thus, previous work used different thresholds for the number of AV-tools that must report to consider an APK as malware. Ikram et al. [23] used a conservative threshold of 5 and Arp et al. [9] used a relaxed threshold of 2. Figure 4 shows that we have 3,907 apps if the AV-tool threshold is 2 and 2,040 apps if the threshold is 5, out of which 2,067 and 1,080 apps respectively, are still there in Google Play Store. ~46% of the apps (3,358) that were tagged by at least one AV-tool are currently not available in Google Play Store. One possible reason is that these apps were removed by Google after binary analysis. In Table 4, we show some example apps that were tagged as containing malware.



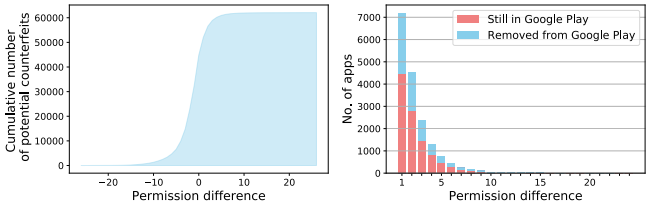


Figure 4: No. of apps against the no. of reporting AV-tools

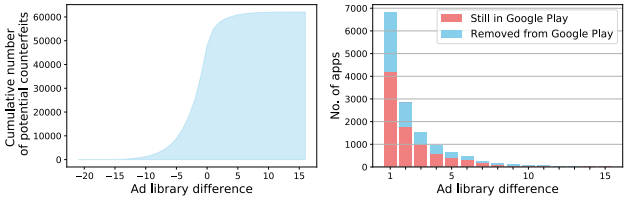
Table 4: Example similar apps that contain malware

Original app	Similar app	AV-tools	Downloads (Original)	Downloads (Similar)
Clean Master	Ram Booster*	12	500 million - 1 billion	500 - 1,000
Temple Run	Endless Run*	12	100 million - 500 million	5,000 - 10,000
Temple Run 2	Temple Theft Run*	12	500 million - 1 billion	500, 000 - 1 million
Hill Climb Racing	Offroad Racing: Mountain Climb	9	100 million - 500 million	1 million - 5 million
Parallel Space	Double Account*	17	50 million - 100 million	100, 000 - 500, 000



*The app is currently not available in Google Play Store

(a) Cumulative number of apps against *permission difference*

(b) Play Store availability of apps with positive *permission difference*

Figure 5: Counterfeits requesting extra permissions

(a) Cumulative number of apps against *ad library difference*

(b) Play Store availability of apps with positive *ad library difference*

Figure 6: Counterfeits with additional ad libraries

5.4 Permission Requests

Another motivation behind counterfeiting can be collecting personal data. We considered the 26 dangerous Android permissions [3] and to identify the potential counterfeits that ask for more permissions than the original app, we define a metric, ***permissions difference***, which is the difference between the number of dangerous permissions requested by the potential counterfeit but not the original app and number of dangerous permissions requested by the original app but not by the potential counterfeit app. If the ***permissions difference*** is a positive value that means the counterfeit asks for more dangerous permissions than the original app and vice versa if it is negative. For the 49,608 potential counterfeits we had the APK files, we calculated the *permission difference*.

The cumulative sum of number of apps against the *permission difference* is shown in Figure 5a. The majority of the potential counterfeits did not ask for more dangerous permissions than the original app. However, there are 17,230 potential counterfeits that are asking at least one dangerous permission than the original app (13,857 unique apps), and 1,866 potential counterfeits (1,565 unique apps) asking at least five additional dangerous permissions. In Figure 5b we show Google Play Store availability of the 17,230 apps with positive ***permissions difference*** as of *24-10-2018*. Figure shows approximately 37% of the potential counterfeits with a permission difference of five is currently not available in the Google Play Store.

5.5 Advertisement Libraries

Another motivation behind developing counterfeits can be monetisation using advertisements. To quantify this, we defined; ***ad library difference*** using the list of 124 mobile advertising and analytics libraries provided in [41]. ***Ad library difference*** is the difference between the number of advertisement libraries embedded in the potential counterfeit but not in the original app and number of advertisement libraries embedded in the original app but not in the potential counterfeit app. We show the cumulative number of counterfeits over the range of ***ad library difference*** in Figure 6a. According to the figure, 13,997 apps (11,281 unique apps) have a positive ad library difference and out of that 1,841 (1,407 unique apps) have an ad library difference greater than or equal to five. Figure 6b shows the Google Play store availability of apps with a positive ad library difference. Approximately 33% of the apps we identified are currently not available in the Google Play Store.

6 CONCLUSION

We proposed an icon encoding method that allows to efficiently search potential counterfeits to a given app, using neural embeddings generated by CNNs. Specifically, for app counterfeit detection problem, we showed that content and style neural embeddings generated from a pre-trained VGGNet significantly outperforms hashing and feature-based image retrieval methods.

We used our multi-modal embedding method to retrieve potential counterfeits for the top-10,000 apps in Google Play and investigated the possible inclusion of malware, permission usage, and embedded third party ad libraries. We found that 2,040 potential counterfeits we retrieved were marked by at least five commercial antivirus tools as malware, 1,565 asked for at least five additional dangerous permissions, and 1,407 had at least five additional embedded third party ad libraries. Finally, we showed that as of now (6-10 months since we discovered the apps), 27%–46% of the potential counterfeits we identified are not available in Google Play Store, potentially removed due to customer complaints.

ACKNOWLEDGEMENT

This project is partially funded by the Google Faculty Rewards 2017, NSW Cyber Security Network's Pilot Grant Program 2018, and the Next Generation Technologies Program. Authors would

like to thank VirusTotal for kindly providing access to the private API, which was used for the malware analysis in this paper.

ABSTRACT

Sequential history of user interactions as well as the context of interactions provide valuable information to recommender systems, for modeling user behavior. Modeling both contexts and sequential information simultaneously, in context-aware sequential recommenders, has been shown to outperform methods that model either one of the two aspects. In long sequential histories, temporal trends are also found within sequences of contexts and temporal gaps that are not modeled by previous methods. In this paper we design new context-aware sequential recommendation methods, based on Stacked Recurrent Neural Networks, that model the dynamics of contexts and temporal gaps. Experiments on two large benchmark datasets demonstrate the advantages of modeling the evolution of contexts and temporal gaps – our models significantly outperform state-of-the-art context-aware sequential recommender systems.

1 INTRODUCTION

In a world of overwhelming number of choices, recommender systems have become indispensable as personalized information filters, especially for e-commerce. Developing accurate recommendation algorithms poses several challenges [1] and continues to be of great interest to both industry and academia. Among the large number of algorithms developed, arguably, the most well known are Collaborative Filtering methods that factorize the historical user-item preference matrix to obtain latent user representations, that, in turn, are used to predict future behaviour.

Sequential history of users provide valuable clues to predict future behaviour. Recommender systems based on Markov chains [2] and combinations of matrix factorization and Markov chains [15] leverage such historical sequential behavior. But, methods based on Markov chains only capture local sequential patterns, and Recurrent Neural Networks (RNN) are found to be more effective in capturing global sequential history [24] thereby yielding better recommendations. However, these methods do not explicitly model the dependencies on the temporal gaps (also called *temporal context* in previous literature) between events.

Additional *input context* information, such as location, time of day, and local holiday information, include another dimension of information, that is often available (e.g., through smartphone apps). Context-aware recommender systems, effectively use such information and have been extensively studied [16, 18]. Although most of the previous literature has studied them separately, contexts and sequential information are not independent. For example, gap statistics between purchases can differ with location and other contextual variables. Liu *et al.* demonstrate the advantages of simultaneous modeling of context and sequential history over modeling either of them separately through their method Context-Aware RNN [10], that also explicitly models the temporal context. However, their model requires the number of possible input and temporal contexts (through discretizing time intervals into specific bins) to be pre-specified. A separate parameter matrix is learnt for each user-specified context, during training. Thus, the number of model parameters grow with the number of input and temporal contexts, making the task of training increasingly more difficult.

With long sequential histories of users, we observe that temporal trends are found even within changing input and temporal contexts, that, to our knowledge, has not been modeled by previous recommendation methods. We design new context-aware sequential recommender methods using stacked RNNs that model the dynamics of input and temporal contexts. Thus, instead of modeling separate contexts with different parameter matrices, we model how the context evolves with a single recurrent parameter matrix. This also effectively addresses the limitation of previous models: (1) different possible temporal contexts need not be specified in advance during training and (2) number of temporal context parameters do not increase with increasing number of contexts. To summarize, our main contributions in this paper are:

- We design new context-aware sequential recommendation methods:
  - that model the dynamics of input and temporal contexts, that has not been modeled in previous methods.
  - where model parameters do not depend on the number of temporal contexts; in the best previous models, the

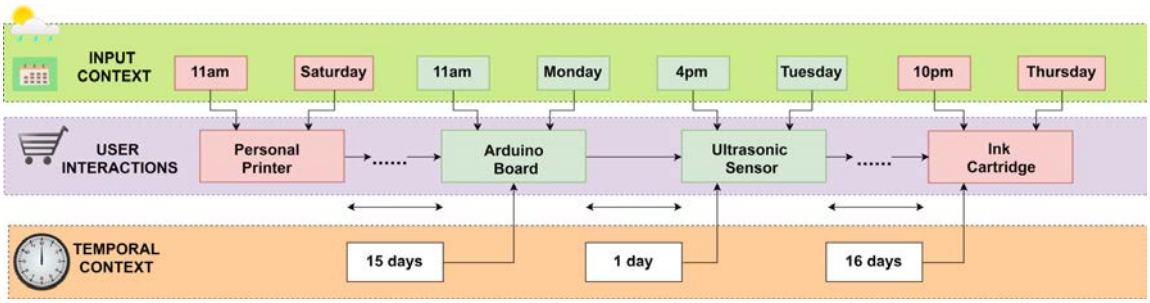

Figure 1: Schematic of user interactions with input and temporal contexts

number of parameters increase with increasing number of temporal and input contexts, thereby making training increasingly harder.

- Our experiments on two large benchmark datasets show that our models significantly outperform state-of-the-art context-aware sequential recommendation methods.

2 PROBLEM DEFINITION

Let u denote a user. Let $X = \{x_1^u, x_2^u, ...\}$ denote the sequence of items the user u has interacted with: x_t^u denotes the item that the user u has interacted with at timestep t. Interaction could be purchase, click, view or any other activity relevant to the application. With each interaction x_t^u of a user, we associate an **input context**, c_t^u, and a **temporal context**, z_t^u. Input context can represent physical or social context. For s types of input contexts, the input context c_t^u is represented by an se-dimensional embedding. We have Σ such embeddings for each possible value of an input context. Temporal context represents the interval between consecutive interactions, i.e., z_t^u refers to the time interval between interactions x_t^u and $x_{(t-1)}^u$. It is a scalar, in a suitable unit (like days) that can be application dependent. Figure 1 shows a schematic of user interactions and both contexts. The sequential recommendation task is to predict $x_{(t+1)}^u$ for a user u, given historical data consisting of past interactions $\{x_1^u, \ldots, x_t^u\}$ together with their input contexts $\{c_1^u, \ldots, c_t^u\}$ and temporal contexts $\{z_1^u, \ldots, z_t^u\}$.

3 RELATED WORK

Sequential Recommendation. Sequential (or next basket) recommendation algorithms based on Markov chains (e.g., [2]) use features derived from past transactions to predict a user's next interaction. These methods typically estimate a transition matrix from past data of all users, which in turn is used to predict the probability of the next interaction. Factorizing Personalized Markov Chains (FPMC) [15] combine the strengths of Markov chains and matrix factorization. In FPMC, a transition cube is estimated, the added third dimension for personalizing user-specific transitions. This transition tensor is factorized to learn latent factors and enables information propagation among similar users, items and transitions. Since the operations used are linear, FPMC cannot capture interactions among multiple factors because each component influences a user's next interaction independently [22]. The Hierarchical Representation Model (HRM) addresses this problem by summarizing multiple interacting factors through a nonlinear max pooling operation [22]. HRM uses continuous-valued representations of users and items and builds a hybrid representation over users and items from the previous interaction. Both FPMC and HRM model only local interactions between consecutive transactions.

There may be correlations between items that are not adjacent in a user's interaction history, e.g., many users may purchase an ink cartridge after buying a printer, but the time interval between the purchases may differ across users, depending on their usage differences. Further, the purchases may not be in consecutive baskets. The Dynamic REcurrent bAsket Model (DREAM) uses a pooling operation, similar to that of HRM, but uses Recurrent neural networks (RNN) to model global sequential interactions[24]. The hidden layer within the RNN is used as the dynamic user representation which is used to compute a per-item score at a time-step, with a higher score corresponding to higher likelihood of interaction. The Bayesian Pairwise Ranking (BPR) objective function [14] is optimized using Back Propagation Through Time (BPTT) [17]. DREAM significantly outperforms HRM and FPMC demonstrating the effectiveness of RNNs in mining global sequential interactions.

Context-Aware Recommendation. Contextual information such as weather, location, holidays etc. can provide significant performance improvement to personalized recommendations [12]. For instance, users may buy some items before a specific social occasion that they may not purchase often. Context-aware recommendations, broadly, use three types of strategies. In pre-filtering strategies, data may be filtered before applying collaborative filtering. In post-filtering strategies, collaborative filtering is applied first, ignoring contextual information, and then the recommendations are adjusted taking the context into account [1]. Thirdly, the context can directly be taken into account in the recommendation model using generalizations of matrix factorization, such as collective matrix factorization [19] and tensor factorizations [8], or through the use of factorization machines FM [16]. Treating the context in a way similar to users or items, cannot model the semantic operations of contexts. Both CARS2 [18] and COT [11] address this problem through the use of context-specific latent representations. Recent related work include the use of attention-based neural models in predicting next item within a transactional context [23]. However, these methods do not model sequential dependencies in the user history.

Sequential Context-Aware Recommendation. To model both contextual information and sequential dependencies, the Context-Aware

Recurrent Neural Network (CARNN) model was proposed [10]. They use an RNN based dynamic representation of users (similar to that of DREAM). Modeling both contextual and sequential information yields significant performance improvements over both sequential recommendation methods (like DREAM, FPMC and HRM) and context-aware recommendation methods (like CARS2 and FM).

Other Related Work. Collaborative nowcasting for 'intent monitoring' also models contexts and sequential evolution of user representations [20, 21]. However they do not model sequential evolution of contexts. Moreover, their models, based on Kalman filters, can only capture linear dynamics of user representations that are not as flexible as RNNs that can capture non-linear dynamics. A Bayesian Hidden Markov Model for modeling user contexts was proposed in [7] where sequential dependencies in contexts were modeled and effectively utilized for personalized context recognition. They do not evaluate their model for sequential recommendations. Further, their model is semi-supervised and models only linear dynamics. The method CDUE integrates vector autoregressive and dynamic topic modeling of contents information and matrix factorization [4]. They learn users' interests and items' topics and their evolutions collaboratively and simultaneously. But their problem setting is different: they assume access to the user's browsing history (that can be considered a specific type of contextual information), through which topic evolution is learnt, to predict a future item.

4 CONTEXT-AWARE SEQUENTIAL RECOMMENDATION

4.1 Background

Recurrent Neural Networks (RNN) effectively model sequential user interactions by learning a recurrent hidden user representation h_t, from the user's current interaction x_t^u, at each time step t:

$$h_t = g(x_t^u M + h_{t-1} W) \tag{1}$$

where g is a non-linear activation function (e.g. sigmoid). Transition matrix M models user behavior with respect to the current interaction and weight matrix W models the recurrent connection that propagates signal between consecutive hidden states. Both M, W are learnt from historical data. In the following we call this RNN, the user RNN or *URNN*.

CARNN [10] models contextual effects through input and temporal context matrices within URNN. Specifically, the hidden representation of a user, h_t, at timestep t is given by:

$$h_t = g(x_t^u M_{c_I} + h_{t-1} W_{z_T})$$

where M_{c_I} and W_{z_T} are context-specific weight matrices for input contexts (c_I) and temporal contexts (z_T) respectively. In CARNN, the number of input and temporal context matrices (M_{c_I} and W_{z_T}) have to be pre-specified during training. For instance, the day of the week and hour of the day can be used as contexts yielding a total of $7 \times 24 = 168$ different contexts (requiring up to 168 parameter matrices). Also, since it is impossible to learn transition context weight matrix (W_{z_T}) for every possible time interval, the intervals are discretized into chosen bins, and a matrix is learnt for each such discretized interval. For long sequences, the number of temporal contexts can be very large. They could be reduced by choosing larger bins but that may not be able to capture the effects of different temporal contexts. Liu, Wu and Wang [11] also recognize the problem of growing number of context-specific parameters with increase in number of contexts and address the problem in their context-aware (but not sequential) recommendation model.

4.2 Our Approach

We model the dynamics of temporal and input contexts and their effects on hidden representations of users. The evolution of temporal contexts (z_t^u) is modeled through an RNN (that we call *TCRNN*):

$$p_t = g(z_t^u E + p_{t-1} Q),$$

and the evolution of input contexts (c_t^u) is modeled through another RNN (that we call *ICRNN*):

$$v_t = g(c_t^u A + v_{t-1} K),$$

in addition to URNN (equation 1) that models the evolution of user representation. In URNN, since matrix W propagates information between consecutive time steps, we replace W with a signal from TCRNN to incorporate the effects of evolving temporal contexts. Similarly we replace M with a signal from ICRNN to model the effects of evolving input contexts. The details of how these signals are effected are given below.

Thus we have two (or more) interacting RNNs where the evolving hidden representation of the user h_t is also affected by the recurrent hidden context representations. Our models can be seen as variants of stacked RNNs [3, 13]. Stacked RNNs are constructed by stacking multiple recurrent hidden layers, with the goal of capturing representations at different timescales in each recurrent level. However, in our models, each RNN models a distinct temporal process with different inputs at each time step. Thus, they can also be viewed as multiple interacting RNNs.

We describe three models – STAR, SIAR and SITAR. STAR and SIAR model evolving temporal and input contexts respectively, and SITAR models the evolution of both temporal and input contexts.

STAR: Evolving Temporal Contexts

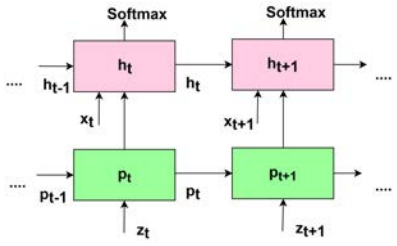

Figure 2: Stacked Temporal-context Aware RNN (STAR)

A schematic of our model Stacked Temporal-context Aware RNN (STAR) is shown in figure 2. Each block is an RNN cell at a single timestep (t). The RNN shown above in figure 2 models the user's evolving representation (h_t) and is dependent on not just the current interaction (x_t^u) and previous user representation (h_{t-1}) but also the hidden representation (p_t) of the evolving temporal context (z_t^u) modeled by the lower TCRNN.

In TCRNN, the recurrent connection weight matrix Q propagates sequential signals between consecutive hidden representations p_t and p_{t-1}, and E is a transition matrix between the temporal context and its hidden representation. We use an intermediate feedforward layer to transform p_t to J_t – to maintain a lower dimension of d in the TCRNN's hidden representation p_t and transform to a higher dimension of $d \times d$ in J_t that is used, instead of W, in URNN. The dynamic d-dimensional hidden user representation h_t is given by:

$$\begin{aligned} p_t &= g(z_t^u E + p_{t-1} Q) \\ J_t &= g(p_t L) \\ h_t &= g(x_t^u M + h_{t-1} J_t) \end{aligned}$$

where g denotes the activation function. Matrix M plays the role of a transition matrix between the user interaction (x_t^u) and user representation (h_t). The transformed temporal context representation J_t (reshaped from $1 \times d^2$ to $d \times d$) is used to propagate the signal between h_{t-1} and h_t. Weight matrices E, Q, L and M are of dimensions $1 \times d$, $d \times d$, $d \times d^2$ and $d \times d$ respectively, and are learnt during training. The key difference between URNN (equation 1) and STAR is that the weight matrix W that propagates information between consecutive time steps in URNN, is replaced by J_t from TCRNN to incorporate the effects of evolving temporal contexts.

SIAR: Evolving Input Contexts

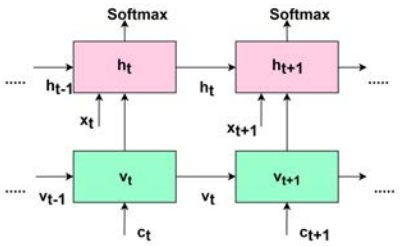

Figure 3: **Stacked Input-context Aware RNN (SIAR)**

A schematic of our model Stacked Input-context Aware RNN (SIAR) is shown in figure 3. Each block is an RNN cell at a single timestep (t). The RNN shown above in figure 3 models the user's evolving representation (h_t) and is dependent on not just the current interaction (x_t^u) and previous user representation (h_{t-1}) but also the hidden representation (v_t) of the evolving input context (c_t^u) modeled by the lower ICRNN. In ICRNN, the recurrent connection weight matrix K propagates sequential signals between consecutive hidden representations v_t and v_{t-1}, and A is a transition matrix between the input context and its hidden representation. Just like in the case of STAR, we use an intermediate feedforward layer to transform v_t to I_t. This is done to maintain a lower dimension of d in the ICRNN's hidden representation v_t and transform to a higher dimension of $d \times d$ in I_t that is used, instead of M, in URNN. The dynamic d-dimensional hidden user representation h_t is given by:

$$\begin{aligned} v_t &= g(c_t^u A + v_{t-1} K) \\ I_t &= g(v_t F) \\ h_t &= g(x_t^u I_t + h_{t-1} W) \end{aligned}$$

where g denotes the activation function. The matrix W is learnt to propagate the signal between h_{t-1} and h_t. The transformed input context representation I_t (reshaped from $1 \times d^2$ to $d \times d$) is used to model the transition matrix between the user interaction (x_t^u) and user representation (h_t). A, K, F and W are weight matrices of dimensions $se \times d$, $d \times d$, $d \times d^2$ and $d \times d$ respectively that are learnt during training. For s types of input contexts, the input context c_t^u is represented by an se-dimensional embedding. The main difference between URNN (equation 1) and SIAR is that the weight matrix M that models the effect of current interaction in URNN, is replaced by I_t from ICRNN to incorporate the effects of evolving input contexts.

SITAR: Evolving Temporal and Input Contexts

Our model, Stacked Input-context and Temporal-context Aware RNN (SITAR), models both evolving temporal and input contexts through TCRNN and ICRNN respectively and signals from both the RNNs are used to model the recurrent user representation as shown in figure 4.

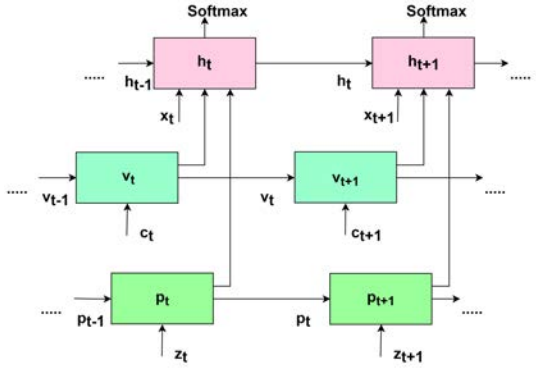

Figure 4: **Stacked Input-context and Temporal-context Aware RNN (SITAR)**

The user's evolving representation (h_t) is thus dependent on the current interaction (x_t^u), the previous user representation (h_{t-1}) as well as the hidden representations (p_t, v_t) of the evolving input context (c_t^u) and temporal context (z_t^u). The dynamic d-dimensional hidden user representation h_t is given by:

$$\begin{aligned} v_t &= g(c_t^u A + v_{t-1} K) \\ I_t &= g(v_t F) \\ p_t &= g(z_t^u E + p_{t-1} Q) \\ J_t &= g(p_t L) \\ h_t &= g(x_t^u I_t + h_{t-1} J_t) \end{aligned}$$

where weight matrices A, K, F, E, Q, L (as defined in models STAR and SIAR earlier) are learnt during training. Comparing this model with URNN (equation 1) and CARNN, we can view this model as using time-dependent parameters for both input and temporal contexts (through I_t and J_t), that implicitly model different possible input and temporal contexts through their temporal evolution, instead of explicitly modeling different possible contexts.

4.3 Training and Hyperparameter Settings

Backpropagation Through Time (BPTT) was used to learn the model parameters in all our models. We used the Adam optimizer [9] for training our models with a learning rate of 0.001, $\beta_1, \beta_2, \epsilon$ values set to 0.9, 0.999 and 10^{-8} respectively. We used cross-entropy loss with L2 regularization, sigmoid activation function (g), and random initialization. The source code for our models and all experimental results are available on our public repository.[1]

Number of Context-dependent Parameters. For s input context types, let Σ be the sum of possible values and Π be the number of combinations of values of the input contexts. E.g., with weekday and hour as contexts, $s = 2, \Sigma = 7 + 24 = 31, \Pi = 7 \times 24 = 168$. With p temporal contexts, d-dimensional hidden representation, and e-dimensional input embedding, the number of context-dependent parameters to be learnt in our models and CARNN are listed in table 1.

Table 1: Number of context-dependent parameters

Model:	STAR	SIAR	SITAR	CARNN
# Parameters:	0	$sed + e\Sigma$	$sed + e\Sigma$	$(\Pi + p)d^2$

Both d, e are fixed numbers that do not grow with increasing number of contexts. In our experiments, the models perform well at $e = d = 20$ and the performance does not significantly change at higher values of d (figures 5 and 6). However, the number of temporal contexts (p) can potentially be very large in long sequential user histories. The number of parameters in SIAR and SITAR are independent of the number of temporal contexts while in STAR, they are independent of both input and temporal contexts. In contrast, number of parameters in CARNN increase with both contexts.

Time Complexity. The per-timestep training time complexity is $O(d^3)$ for STAR and $O(d^3 + sed)$ for SIAR and SITAR.

4.4 Prediction

In our models, we use a softmax layer that takes the hidden representation of the user h_t at each timestep to generate a probability vector for all the items. The user representation is transformed to a vector m of size N through a linear transformation, $m = h_t B$, where N is the total number of items, to which probabilities are assigned at each time step, and B is learnt during training. The probability of the next item j is obtained through softmax: $\frac{e^{m_j}}{\sum_k e^{m_k}}$. The most probable item is used as the prediction. In our experiments, BPR [14] (instead of softmax) did not improve results.

5 EXPERIMENTS

5.1 Datasets

We used two large benchmark datasets:
1. **Movielens-1M** data[2]: that contains 1,000,209 movie ratings of 3,900 movies that has been collected from 6,040 users [5].
2. **Amazon Books** data[3]: that has 22,507,155 user ratings of 2,330,066 books from 8,026,324 users that was collected between May 1996 to July 2014 [6].

[1] https://bitbucket.org/cdal/stackedcontextawarernn
[2] http://grouplens.org/datasets/movielens/1m/
[3] http://jmcauley.ucsd.edu/data/amazon/

In each dataset, we utilised the first 80% of each user's history for training and the remaining 20% as the test set. We did not use data of users and items with very few interactions to avoid data sparsity: in the Movielens dataset, we selected users with at least 10 records and items with at least 3 records. In the Amazon dataset, we chose users and items with at least 25 records each. We extracted both input and temporal contextual information from the timestamps of ratings in both datasets. For temporal contexts, we measured time intervals in days using upward rounding. All intervals greater than 30 days were mapped to a single value. For input contexts, we only used the day of the week and the hour of the day to have a fair comparison with our main baseline CARNN (that used the same contexts), to have 7 day-based contexts and 24 hour-based contexts.

5.2 Baselines

CARNN [10] is our main baseline since it is a state-of-the-art method that models both contextual information and sequential dependencies. It was shown to outperform both context-aware recommenders (CARS2 and FM) and sequential recommenders (DREAM, FPMC and HRM) in their experiments. In addition, we use the RNN-based model **DREAM** [24] and Markov chain based model **FPMC** [15] as baselines, to compare with competitive sequential recommender models. The parameter transaction length is set to 1 week in both these methods. Methods that take neither context nor sequential information into account, **BPR** [14] (using matrix factorization) and **POP**, are used as additional baselines. Publicly available code provided by the authors were used for these baselines, except for POP, where items are ranked by frequency and the most frequent item is recommended.

5.3 Evaluation Metrics

For each user we predict the final 20% of the interactions. We denote this list of items, concatenated over all users, by Y and Y_q denotes the item in the q^{th} position in this list. At each step, our models output a list of probabilities (through softmax). Let $\hat{Y}_q$ denote this list, $\{\hat{Y}_q^1, \hat{Y}_q^2, \ldots, \hat{Y}_q^N\}$ at the q^{th} step with top-N predictions. The j^{th} element of this list, at the q^{th} step, is denoted by $\hat{Y}_q^j$. Following Liu et al. [10], we use metrics Recall@N (R@N), Precision@N (P@N), F1@N and normalized discounted cumulative gain (nDCG) averaged over the total number of items (where I denotes the indicator function) as follows:

$$P@N = \frac{1}{|Y|} P_q@N = \frac{1}{|Y|} \sum_{p=1}^{|Y|} \frac{|Y_q \cap \hat{Y}_q|}{|\hat{Y}_q|}$$

$$R@N = \frac{1}{|Y|} R_q@N = \frac{1}{|Y|} \sum_{p=1}^{|Y|} \frac{|Y_q \cap \hat{Y}_q|}{|Y_q|}$$

$$F1@N = 2 \times \frac{P@N \times R@N}{P@N + R@N}$$

$$nDCG = \frac{1}{|Y|} \sum_{q=1}^{|Y|} \sum_{j=1}^{|\hat{Y}|} \frac{2^{I(|\hat{Y}_q^j \cap Y_q|)} - 1}{log_2(j+1)}$$

5.4 Results

Table 2 show the results of all our models and the baseline methods on the Movielens-1M dataset. Among the baselines, CARNN has the best performance over all the metrics. Note that *all* the three

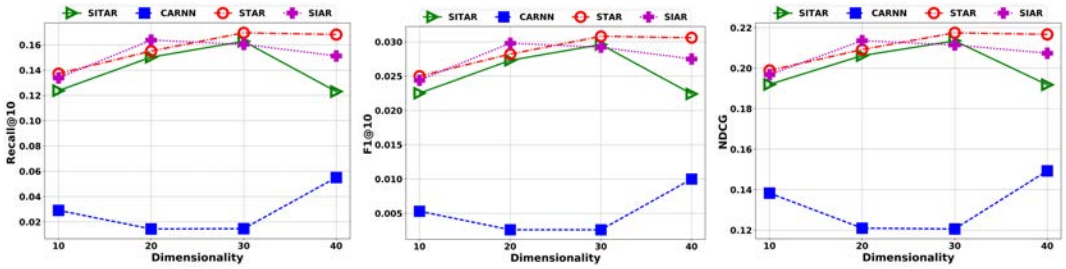

Figure 5: Performance of STAR, SIAR, SITAR and CARNN with varying dimensionality on Movielens dataset

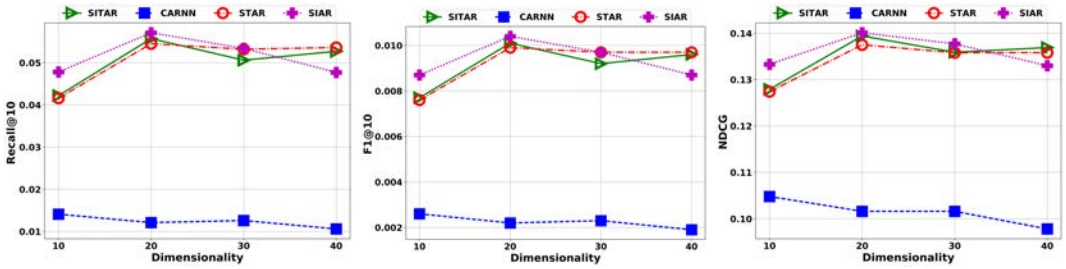

Figure 6: Performance of STAR, SIAR, SITAR and CARNN with varying dimensionality on Amazon Books dataset

models, STAR, SIAR, and SITAR, outperform CARNN in all the metrics. STAR is overall the best performing model.

Table 2: Performance of our models and baselines on the Movielens-1M dataset. Column-wise best results in bold, best baseline results in italics.

Model	R@1	R@5	R@10	F1@1	F1@5	F1@10	nDCG
POP	0.0016	0.0052	0.0118	0.0016	0.0017	0.0021	0.0434
BPR	0.0043	0.0237	0.0436	0.0043	0.0079	0.0033	0.1188
FPMC	0.0054	0.0255	0.0440	0.0054	0.0085	0.0080	0.1291
DREAM	0.0063	0.0318	0.0484	0.0063	0.0106	0.0088	0.1364
CARNN	*0.0075*	*0.0394*	*0.0551*	*0.0075*	*0.0131*	*0.0100*	*0.1493*
STAR	**0.0334**	**0.1070**	**0.1682**	**0.0334**	**0.0357**	**0.0306**	**0.2167**
SIAR	0.0303	0.1003	0.1604	0.0303	0.0334	0.0292	0.2115
SITAR	0.0300	0.1011	0.1628	0.0300	0.0337	0.0296	0.2135

Table 3 shows the results of all our models and the baseline methods on the Amazon Books dataset. Among the baselines, FPMC has the best performance over all the metrics. Note that all the three models, STAR, SIAR, and SITAR, outperform FPMC in all the metrics. Model SIAR has the best performance for metrics R@10, F1@10 and nDCG, whereas model STAR has the best performance for metrics R@1, R@5, F1@1 and R@5.

These results indicate that modeling the temporal evolution of input and temporal contexts yields significant improvement in recommendation performance. In the Movielens-1M dataset temporal context dynamics appears to have a more prominent role, whereas in the Amazon Books dataset, dynamics of both the contexts seem to be important. Although SITAR has significantly better performance than CARNN, it does not outperform STAR or SIAR. This could be due to the larger number of parameters that has to be learnt in SITAR.

5.4.1 Impact of Dimensionality. Figures 5 and 6 compare the performance of our models – STAR, SIAR and SITAR with CARNN, using evaluation metrics R@10, F1@10 and NDCG, at dimensions

Table 3: Performance of our models and baselines on the Amazon Books dataset. Column-wise best results in bold, best baseline results in italics.

Model	R@1	R@5	R@10	F1@1	F1@5	F1@10	nDCG
POP	0.0005	0.0016	0.0036	0.0005	0.0005	0.0007	0.0843
BPR	0.0008	0.0041	0.0078	0.0008	0.0014	0.0014	0.1016
FPMC	*0.0039*	*0.0163*	*0.0285*	*0.0039*	*0.0054*	*0.0052*	*0.1231*
DREAM	0.0008	0.0034	0.0063	0.0008	0.0011	0.0011	0.0915
CARNN	0.0015	0.0060	0.0106	0.0015	0.0020	0.0019	0.0978
STAR	**0.0247**	**0.0419**	0.0536	**0.0247**	**0.0140**	0.0097	0.1358
SIAR	0.0209	0.0413	**0.0571**	0.0209	0.0138	**0.0104**	**0.1401**
SITAR	0.0180	0.0397	0.0557	0.0180	0.0132	0.0101	0.1394

10, 20, 30 and 40. In all cases, our models outperform CARNN. In the Movielens-1M dataset, figure 5, performance of STAR, SIAR and SITAR are comparable at $d = 30$ whereas STAR outperforms the others at $d = 40$. In the Amazon Books dataset, figure 6, the best results of STAR, SIAR and SITAR are comparable, at $d = 20$, with SIAR marginally better than the others. In both the datasets, increasing the dimension beyond 20 does not significantly change the performance of STAR, SIAR and SITAR.

6 CONCLUSION

We design and evaluate context-aware sequential recommendation methods that, for the first time, model the dynamics of input and temporal contexts. Further, the number of parameters in STAR, one of our best performing models does not increase with the number of contexts, which was a limitation of the best previous model. Our experiments on large benchmark datasets show that modeling the evolution of contexts has considerable impact on recommendation performance – all our models significantly outperform state-of-the-art context-aware sequential recommendation models.

ABSTRACT

We perform cross-lingual question retrieval in community question answering (cQA), i.e., we retrieve similar questions for queries that are given in another language. The standard approach to cross-lingual information retrieval, which is to automatically translate the query to the target language and continue with a monolingual retrieval model, typically falls short in cQA due to translation errors. This is even more the case for specialized domains such as in technical cQA, which we explore in this work. To remedy, we propose two extensions to this approach that improve cross-lingual question retrieval: (1) we enhance an NMT model with monolingual cQA data to improve the translation quality, and (2) we improve the robustness of a state-of-the-art neural question retrieval model to common translation errors by adding back-translations during training. Our results show that we achieve substantial improvements over the baseline approach and considerably close the gap to a setup where we have access to an external commercial machine translation service (i.e., Google Translate), which is often not the case in many practical scenarios. Our source code and data is publicly available.[1]

1 INTRODUCTION

Question retrieval is an important task in community question answering (cQA) that allows us to use the existing knowledge which is present in cQA platforms to automatically answer non-factoid questions. We do so by retrieving previously answered questions that are similar to the input question (or query) with the goal of selecting one of their answers as the output [6, 10, 24, 30, 38].

Even though this is a research field with a long-standing history, approaches to question retrieval were traditionally proposed for monolingual scenarios only. However, *cross-lingual* question retrieval is crucial when considering languages other than English because there exists substantially less cQA data in these cases. This is particularly apparent within technical domains, on which we focus in this work, where English platforms such as StackOverflow[2] and AskUbuntu[3] are predominant.

To date, cross-lingual question retrieval has only been explored by two previous works for the language pair English/Arabic and only for general domains, i.e., questions from the Qatar Living forum[4]. However, cross-lingual question retrieval for specialized domains, such as technical cQA, presents us with different challenges because there exists less non-English in-domain data.

First, Joty et al. [22] use adversarial training with feed-forward networks to learn language-invariant feature representations for question pairs. Adversarial training requires in-domain questions from both languages, which are typically not available for specialized domains (e.g., there is no Arabic StackOverflow). And second, Martino et al. [27] apply a mixture of a cross-lingual tree kernel with a dictionary and machine translation with monolingual features. Importantly, the effects from using machine translation were relatively small in their case. However, applying machine translation (MT) to specialized domains is typically more error-prone because large parallel corpora which are used to train MT models mostly contain sentences from general domains [12, 26].

In this work we explore cross-lingual question retrieval for technical domains, i.e., for cQA platforms that cover programming and operating systems topics. Similar to Martino et al. [27] we first use a standard approach to cross-lingual information retrieval, which is to machine translate the query to our target language and then continue with a monolingual question retrieval model [17, 25]. Different to previous work, machine translations would lead to a higher performance decrease for cross-lingual question retrieval in to our specialzed domain. To remedy, we extend this approach with two cross-lingual adaptations that (1) improve the in-domain

[2]www.stackoverflow.com
[3]www.askubuntu.com
[4]www.qatarliving.com/forum

translation quality and (2) increase the robustness of the question retrieval model to common translation errors.

We achieve this by (a) performing domain-adaptation for the Transformer [42], a state-of-the-art neural machine translation (NMT) approach, by extending the training corpus with synthetic parallel in-domain sentences from cQA platforms. The method we use is known as back-translation in MT literature and has proven to be effective before [3, 11, 23, 31, 37]. In contrast, we test this method extrinsically within question retrieval.

And (b) we increase the robustness of RCNN [24], a state-of-the-art neural question retrieval model, to common translation errors by adding back-translated texts during training. Back-translating is sometimes used to automatically generate paraphrases, e.g., to train paraphrastic sentence embeddings [43] or to obtain more diverse sentences for other (monolingual) tasks [9, 19, 45]. Different to them, we adapt this method to our cross-lingual retrieval scenario.

We perform experiments for the language pair English/German and evaluate our approaches on two datasets from different technical cQA domains—the Askubuntu benchmark [10, 24] and a dataset that we create based on questions from StackOverflow.

Our results show that there exists a substantial cross-lingual performance decrease compared to the monolingual setup, which is in contrast to previous work that performed cross-lingual question retrieval in general domains [27]. In our analysis we observe that this is mostly due to translation errors in our specialized domains. Finally, our proposed adaptations substantially improve the cross-lingual question retrieval performance and close the gap by up to 85% to a scenario where we use a state-of-the-art external commercial MT service (Google Translate) with no adaptations.

Our contributions:

(1) We are the first to explore cross-lingual question retrieval in *technical cQA* and we observe that the retrieval performance is strongly influenced by the translation quality.
(2) We evaluate the impact of NMT domain adaptation extrinsically in cQA question retrieval.
(3) We reduce the cross-lingual performance gap to a setup that has access to an external state-of-the-art commercial MT service with no adaptations by up to 85%. This demonstrates that we can use freely available NMT approaches for cross-lingual question retrieval within technical cQA.

2 RELATED WORK

Early approaches to **monolingual question retrieval** use translation models [2, 20, 44, 49], which can further be enhanced with question category information [6], and topic models [21, 46].

More recent work, especially in the context of the SemEval cQA challenges [30], improve upon this and use tree kernels [8, 34], text alignment features [13], multi-task learning [4], and unsupervised methods with shallow lexical matching and mismatching [47].

In technical cQA domains, neural representation learning methods have proved to be most effective. Dos Santos et al. [10], for example, learn representations of questions with CNNs and compare them with cosine similarity for scoring. Lei et al. [24] propose RCNN, which extends the CNN with a recurrent mechanism (adaptive gated decay). This approach was further extended with question-type information [16], which relies on a question taxonomy for general cQA domains that does not cover the different types of technical questions (e.g., for programming topics).

Other approaches that were applied to technical cQA focus on adversarial domain transfer [38] and on programming-specific association features [48].

Cross-lingual question retrieval has received considerably less attention. Martino et al. [27] explore the language pair English/Arabic within general domains and used a combination of a cross-lingual tree-kernel and machine translation for retrieval. Similarly, Joty et al. [22] explore the language pair English/Arabic within general domains and instead use adversarial training in order to learn language invariant feature representations of question pairs.

Highly related fields are cross-lingual information retrieval and cross-lingual question answering, which was also part of challenges in CLEF 2008 [14], NTCIR-8 [29], and BOLT [39]. Most approaches in this context rely on standard machine translation systems or dictionaries to map questions to their target language [5, 17, 25, 32] and some combine results from multiple MT systems [41], multiple translation outputs from the same MT system [36], or jointly train SMT and IR components [18] to achieve better results.

To the best of our knowledge, we are the first to explore cross-lingual question retrieval in *technical* cQA domains. In contrast to previous work in cross-lingual question retrieval, because specialized domains are more affected by translation errors, we explore the standard approach to cross-lingual information retrieval with two adaptations to (1) improve the translation quality and (2) increase the robustness of a question retrieval model to translation errors.

3 TASK AND METHOD

Given an input question q_0 (the query) and a list of N (potentially) related questions $Q = q_1, q_2, \ldots, q_N$ from a cQA platform that are retrieved with a search engine, the goal is to re-rank this list according to each related question's relevance in regard to q_0.

In our cross-lingual setup, the query is given in a source language L1 (German) and the related questions are in a target language L2 (English). We indicate languages with a superscript, e.g., q_0^{L1} stands for the query in the source language and q_0^{L2} stands for the query in the target language. To perform question retrieval given q_0^{L1} and Q^{L2} we first translate q_0^{L1} to L2 using neural machine translation (NMT). Then we continue with a monolingual L2 question retrieval model to re-rank Q^{L2} according to the translated q_0^{L2}.

This is a standard technique in cross-lingual information retrieval [17, 25] and it has been applied to cross-lingual question retrieval in general domains [27]. We go beyond this by exploring the effects of NMT to the performance of neural question retrieval in specialized domains, i.e., programming and operating systems cQA.

Most importantly, our domains contain a specialized vocabulary which makes NMT—and thus also this standard retrieval approach—more error-prone. This could be even more the case for statistical machine translation [7], which has been used in previous question retrieval work [27]. Thus, in §4 we present two adaptations to improve the translation and ranking performances in our domains.

In the following, we present the NMT model and the neural re-ranking approach. We visualize the full pipeline in Figure 1.

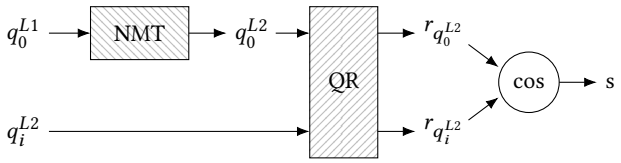

Figure 1: The cross-lingual pipeline. The question retrieval (QR) model learns (monolingual) question representations, which are then compared with cosine similarity to determine a ranking score s. L2 is always English in our setup.

Table 1: Examples for our two data-driven adaptations.

3.1 Neural Machine Translation (NMT)

NMT is a popular research field that has seen rapid progress in recent years. The most effective approaches use the encode-decoder architecture [40] and integrate various forms of attention [1, 15, 42].

In this work, we use Transformer [42], which is a state-of-the-art NMT approach and is based on multi-head self-attention layers. Because it does not make use of recurrent units, Transformer can be efficiently trained on modern hardware while achieving better translation results compared to computationally more expensive models. Edunov et al. [11], for example, use this approach and achieve state-of-the-art results on the WMT'14 en-de benchmark.

For our cross-lingual question retrieval approach we train two models, one for each direction en→de and de→en using the public WMT13 and WMT18 training corpora with more than 4.5M parallel sentences. Even though a small number of sentences in the training data are on technical topics, there is no specific data that is related to technical cQA. To the best of our knowledge there are no publicly available parallel corpora that cover technical questions from cQA.

In addition, for a more thorough comparison, we use an external commercial translation service, namely Google Translate. Even though we expect Google Translate to produce higher quality translations because their model was trained on large amounts of proprietary parallel data, it is not suitable for many practical cQA scenarios due to (1) potential technical restrictions (requiring internet access), (2) legal reasons (confidential information might be transmitted), or (3) associated costs (commercial translation services are not free). The same restrictions do not apply to Transformer models because they are available on-premise.

In the rest of this work we indicate the use of Transformer with TR and the use of Google Translate with GT.

3.2 Question Retrieval (QR)

We use RCNN [24] as a basis for our experiments. This approach combines recurrent units and convolutional neural networks, and it achieves state-of-the-art results on the AskUbuntu question retrieval benchmark [10, 24]. Even though RCNN was recently extended with a separate question type classifier and information from a question taxonomy to improve performances within general domains [16], we use standard RCNN to avoid introducing an additional in-domain question taxonomy (question-type classification would be another source of error in our cross-lingual setup).

For an input question q RCNN learns a fixed-size dense vector representation r_q. This representation is obtained by applying the recurrent CNN sequentially on each token in q where the last output state is considered as the question representation. Model details are given in [24]. This is a strictly monolingual model, which means that we can only learn representations for texts that are in L2.

To rank a related question q_i^{L2} in regard to the query q_0^{L2}, we compare the learned representations with cosine similarity to determine a ranking score s:

$$s = \cos\left(r_{q_i^{L2}},\ r_{q_0^{L2}}\right)$$

To train RCNN we obtain labeled question paraphrases (also called duplicates) from the cQA platform, i.e., q_0^{L2} and q_+^{L2}. We also obtain one negative sample q_-^{L2} by randomly selecting N questions from the whole corpus and choosing the one with the highest ranking score according to the currently trained model. We then minimize the max-margin hinge loss:

$$\mathcal{L} = \max\left[0,\ m - \cos\left(r_{q_0^{L2}}, r_{q_+^{L2}}\right) + \cos\left(r_{q_0^{L2}}, r_{q_-^{L2}}\right)\right]$$

where m is a non-negative margin.

We additionally perform unsupervised pre-training as proposed in [24], where RCNN is pre-trained in an encoder/decoder setup. The encoder RCNN learns a suitable representation of the question title and/or body and the decoder tries to reconstruct the title form the learned representation.

In general, RCNN can use both the question title and the question body during scoring by applying the element-wise average over the learned representations for both texts. In this work, we use only question titles because it allows us to compare individual sentences for error analysis in our cross-lingual setup. In addition, the performances of models that utilize body information was only marginally better compared to the title-only variant (with pre-training).

4 CROSS-LINGUAL ADAPTATIONS

4.1 In-Domain NMT with Synthetic Parallel Sentences

One disadvantage of training Transformer models on public WMT corpora is that they only contain texts from common domains—they do not include parallel sentences from technical cQA.

Because applying NMT models in out-of-domain scenarios often leads to sub-par translation performances [12, 26], we adapt the Transformer to our specialized domains. There exist several options for domain adaptation, which range from data-centric methods that extend the training corpus to model-centric methods that change the neural network architecture (see [7] for a survey).

In this work we choose a data-centric approach based on back-translation, which has been proven to be effective in both statistical MT [3, 23] and NMT [11, 31, 37] before. Here we train a Transformer model on synthetic parallel sentences which we generate from monolingual in-domain texts. To generate these parallel sentences we apply another Transformer model, which we originally trained on the general WMT corpora, on sentences from technical cQA.

Because we translate queries from L1 to L2 in our cross-lingual question retrieval approach (see Figure 1), we use monolingual L2 data to generate L1 sentences, i.e., the synthetic data is generated by translating in-domain sentences from the target to the source language. This is suitable in our setup because L2 is always English, which means that large-scale in-domain data exists for L2. Also, Lambert et al. [23] show that using translations that were obtained from target to source side results in better domain adaptation compared to using translations from source to target side.

An example of our synthetic data is shown in Table 1. We introduce the source dataset later in §5.1. Based on the synthetic data we then train the in-domain Transformer model, which we denote `TR-cQA`, by back-translating the generated sentences from L1 to L2. During training we also include the WMT corpora.

4.2 QR Data Augmentation

In addition to adapting the NMT model to our specialized domain, we also enhance the monolingual question retrieval model with the goal of increasing its robustness to common translation errors.

Similar to our NMT adaptation we choose a data-centric approach because it allows us to use the same `RCNN` network architecture with pre-training as before. In contrast, however, we now augment the training data with back-translated texts, i.e., we translate the titles in the training data from L2 to L1 and back to L2 and use these generated texts during training.

Back-translations are often used as an automatic method to obtain paraphrases, e.g., they can be used to train sentence embeddings [43], to increase the model robustness against adversarial attacks [19], or to obtain more syntactically diverse sentences for training [9, 45]. Here we use them to introduce the QR model to common translation errors. An example is given in Table 1 (bottom), where the aspect of converting sth. *to a list* is lost during translation.

We use `GT` to obtain back-translations because in initial experiments we found that `TR` back-translations were too noisy and in many cases they completely altered the meaning of a sentence. The reason is that in the direction en→de we cannot obtain a good `TR-cQA` model because there exists no large German/L1 technical cQA platform from which we could generate synthetic parallel sentences.

We use back-translated texts in the pre-training and in the regular model training of `RCNN` (see §3.2). In both phases we add a new training example for every data point by replacing the original question title with its back-translated text.

In the rest of this work we denote the augmented model `RCNN-A`.

5 EXPERIMENTS

5.1 Experimental Setup

Data. We test our approaches on two datasets from different technical domains. The dataset statistics are shown in Table 2.

Dataset	Number of Examples			N	Paraphrases
	Train	Valid	Test		Valid+Test
AskUbuntu	12,724	189	186	20	6.0
StackOverflow	23,558	1,770	2,779	20	1.3

Table 2: Dataset statistics. N is the number of (potentially) related questions for re-ranking.

First, we use the publicly available *AskUbuntu* benchmark [10] which has been extended with additional manual relevance annotations in [24]. For our cross-lingual setup we got the queries in the validation and test splits translated to German by a German native speaker with proficient English skills and in-domain knowledge.

Second, we obtained questions with labeled duplicates from StackOverflow to create a similar dataset for a different technical domain. We removed all questions that were not tagged with Java or Python so that our dataset has a similar size compared to AskUbuntu. We used BM25 [33] to obtain 20 potentially related questions for every query in our validation and test splits. Questions that were labeled as duplicates by StackOverflow users are considered as relevant (i.e., should be retrieved). In contrast to AskUbuntu we chose much larger validation and test splits to better reduce the effects from random neural network initialization. Due to this larger size, we used Google Translate to obtain the German query questions. Using Google Translate to obtain cross-lingual data has been used before and it was shown that this only minorly impacts the evaluation outcome in other NLP tasks [35].

In the rest of this work we refer to this dataset as *StackOverflow*.

Models and baselines. We evaluate our cross-lingual approach as described in §3 (`RCNN TR`) with all combinations of our extensions, i.e., `RCNN` with in-domain NMT (`RCNN TR-cQA`), with data augmentation (`RCNN-A TR`) and with both extensions (`RCNN-A TR-cQA`). We also evaluate the same approach with Google Translate instead of Transformer to provide a comparison to a commercial state-of-the-art MT system (`RCNN GT` and `RCNN-A GT`).

Additionally, we evaluate `TF*IDF`, `RCNN`, and `RCNN-A` in the monolingual setup to provide the monolingual baseline and upper-bound.

Training procedure. We train the `TR` models with the official Transformer implementation[5]. To obtain synthetic in-domain training data for `TR-cQA` we use `TR` to translate the titles from the training split of both AskUbuntu and StackOverflow datasets to German (no data from the evaluation splits was used in `TR-cQA`).

To train `RCNN` models we use the code provided by Lei et al. [24].

Neural network setup. We use the standard hyperparameters of `RCNN` except for the batch size and margin parameter m where we perform grid search for each model and dataset combination. This is necessary due to the different sizes of the datasets and our data augmentation. The values for the batch size and margin are in {128, 256} and {0.1, 0.5, 1.0} respectively.

For our AskUbuntu experiments we use the 200D word embeddings of Lei et al. [24], which were trained on in-domain data. For StackOverflow we train new 200D word embeddings with Word2Vec [28] on text from stackoverflow.com.

[5] https://github.com/tensorflow/tensor2tensor

Evaluation. For all models we report mean average precision (MAP), mean reciprocal rank (MRR), and precision@1 (P@1; accuracy). To mitigate the effects from random initialization of neural network weights, we report averaged scores over five runs.

5.2 Experimental Results

Table 3 compares the monolingual and cross-lingual performances of the different models for both tasks.

The results show that there exists a considerable performance gap between both setups, e.g., compared to the monolingual RCNN, RCNN TR decreases by 6.6 MAP on StackOverflow and by 3.1 MAP on AskUbuntu.[6] This is in contrast to previous work, where much smaller effects were observed when applying phrase-based MT to cross-lingual question retrieval for general domains [27].

Furthermore, we observe that the translation quality greatly varies in technical cQA and has strong effects on the cross-lingual question retrieval performance—with GT we can achieve substantially better results compared to TR (3.1 MAP on average).

The results also show that our proposed adaptations are effective. They consistently outperform RCNN TR and they substantially close the performance gap to RCNN GT. This is visualized in Figure 2 where we measure the performance improvements in terms of how much they close this performance gap. It shows that adapting TR to technical cQA domains by using synthetic training data has the strongest impact, i.e., it closes the performance gap by over 50% (question retrieval performance increases by 1.8 MAP, 1.9 MRR, and 2.1 P@1, on average). Augmenting the training data of RCNN with back-translated questions further increases the performance and closes the gap by another 19pp to 34pp (+0.6 MAP, +0.9 MRR, and +1.4 P@1). At the same time we observe that data augmentation is also effective for RCNN GT and within the monolingual scenario. The reason for this is that during training the model receives a form of regularization (through noisy samples) and processes additional variations of the monolingual training questions.

The combined model RCNN-A TR-cQA finally substantially reduces the gap to RCNN GT by 75–85%.

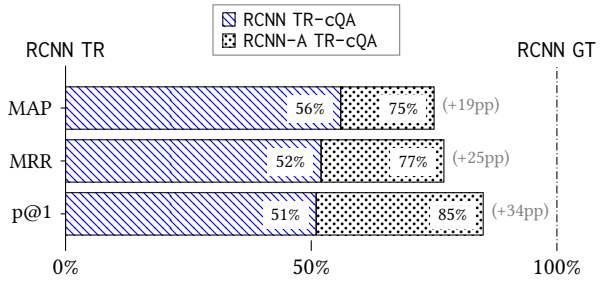

Figure 2: A visualization that shows how much our adaptations close the performance gap between RCNN TR and RCNN GT. Results are averaged over both datasets.

6 ANALYSIS

In-domain NMT performance. To test if the improvements with TR-cQA over TR are due to improved translations, we evaluate both models with our human translations from the AskUbuntu evaluation splits and measure their translation performance for de→en. TR-cQA achieves 54.96 BLEU whereas TR has a substantially lower score of 41.70 BLEU. Even though the number of parallel sentences is small (375), the large difference suggests that the improvements of RCNN TR-cQA are indeed due to more accurate translations.

At the same time TR-cQA only decreases marginally on the WMT'14 en/de benchmark (28.04 BLEU vs. 28.30 BLEU).[7]

Error analysis. We compared all cases in which RCNN-A TR-cQA ranks a relevant question first whereas RCNN TR ranks an unrelated question first. Generally, RCNN-A TR-cQA is more robust if the translations slightly differ from the English original query, e.g., when translating "throwing an exception" to "triggering an exception" (which is not semantically equal). In most cases, however, the effects from the improved translations are more apparent.

Figure 4 shows a case where TR discards information (i.e., "discrete graphics"). In contrast, TR-cQA generates a translation that is mostly equal to the English source text. During analysis we found that this is a common error of TR, which is greatly improved by TR-cQA due to its better in-domain translation quality. In a small number of cases, however, TR-cQA still discards important information, e.g., when translating long compounds. Another common issue of TR is that it translates words without considering their in-domain meaning, e.g., Figure 5 shows an example where TR translates "null" to "zero".[8] Such errors are often avoided by TR-cQA.

We also compared RCNN GT, RCNN-A TR-cQA, and the monolingual RCNN to understand how we can further improve the cross-lingual question retrieval performances. Most importantly, both RCNN GT and RCNN-A TR-cQA suffer from the same type of problems as described before, but on a smaller scale. This suggests that further improvements are likely with better MT domain adaptation.

7 DISCUSSION

Commercial MT services often achieve better results compared to publicly available models[9] because they have access to large proprietary parallel corpora. In §5.2 we observed a similar trend where RCNN GT still performed better than TR with cross-lingual adaptations. Further, data augmentation in RCNN showed improvements in all cases, including GT. *Why can't we just use Google Translate then?*

There exist several disadvantages when using external MT services in practical scenarios. For example, they can be costly and the data is transferred to third parties. Consider, for example, a non-English company that wants to provide an automatic tool to their software developers that helps them to find related English questions within the StackOverflow data dump (if nothing is found the input question will be sent to colleagues via an internal cQA platform). Because questions of software developers can contain critical and confidential information—e.g., information about the

[6] We also evaluated cross-lingual variants of TF*IDF (with the same NMT approaches), and we tested Spanish RCNN GT with a Spanish version of our StackOverflow dataset. They showed the same trends as the reported RCNN models. We omit the results here for clarity and due to space reasons.

[7] BLEU scores in AskUbuntu are higher because the sentences (i.e., question titles) are considerably shorter compared to WMT'14 sentences.

[8] Null in German typically refers to the number zero. There exist many similar cases, e.g., TR translates (http-) post to "mail".

software architecture, stack traces, etc.—it is not suitable to send this data to an external service for translation. In such cases MT needs to be performed with a model that is available on-premise to avoid exposing internal information to third parties.

8 CONCLUSION

In this work we performed cross-lingual question retrieval for *technical cQA* by machine translating the queries to our target language and continuing with a monolingual question retrieval model.

We observed a considerable performance decrease in the cross-lingual scenario compared to the monolingual setup, which is due to a high number of MT errors within our specialized domains.

To remedy this, we first performed domain adaptation for a state-of-the-art NMT model by adding synthetic in-domain parallel sentences to the training corpus. This greatly improved the cross-lingual question retrieval performance due to better in-domain translations. Second, we added back-translated texts during the training of the question retrieval model to increase its robustness, which further improved cross-lingual question retrieval. Finally, the combination of both adaptations substantially closed the performance gap by up to 85% to a model that has access to an external state-of-the-art commercial MT system (with no adaptations), which is often not the case in many practical scenarios.

ACKNOWLEDGEMENTS

This work has been supported by the German Research Foundation (DFG) as part of the QA-EduInf project (grant GU 798/18-1 and grant RI 803/12-1) and by the German Federal Ministry of Education and Research (BMBF) as part of the Software Campus program under the promotional reference 01IS17050.

ABSTRACT

Workers in crowd markets struggle to earn a living. One reason for this is that it is difficult for workers to accurately gauge the hourly wages of microtasks, and they consequently end up performing labor with little pay. In general, workers are provided with little information about tasks, and are left to rely on noisy signals, such as textual description of the task or rating of the requester. This study explores various computational methods for predicting the working times (and thus hourly wages) required for tasks based on data collected from other workers completing crowd work. We provide the following contributions. *(i)* A data collection method for gathering real-world training data on crowd-work tasks and the times required for workers to complete them; *(ii)* TurkScanner: a machine learning approach that predicts the necessary working time to complete a task (and can thus implicitly provide the expected hourly wage). We collected 9,155 data records using a web browser extension installed by 84 Amazon Mechanical Turk workers, and explored the challenge of accurately recording working times both automatically and by asking workers. TurkScanner was created using ~150 derived features, and was able to predict the hourly wages of 69.6% of all the tested microtasks within a 75% error. Directions for future research include observing the effects of tools on people's working practices, adapting this approach to a requester tool for better price setting, and predicting other elements of work (*e.g.*, the acceptance likelihood and worker task preferences.)

1 INTRODUCTION

Workers on crowd platforms struggle to earn adequate wages [18, 20, 27]. This is problematic, given that one of the main motivators for crowd workers is to earn sufficient money to make a living [4, 5, 25, 26]. It is usually difficult for workers to earn higher than minimum wage, because crowd markets provide limited information on the offered microtasks. Workers struggle to gauge how much time a task will require, and to make informed judgements on whether tasks are worth their time. In this study, we introduce a machine learning approach to estimate the time required to complete a task and the approximate hourly wage of the task.

Our work builds on recent work investigating crowd work wages. Callison-Burch et al. developed the CrowdWorkers browser extension [6], which records working times on Amazon Mechanical Turk (AMT). An analysis of this data revealed that the median hourly worker wage was only 2 USD/h [12]. This is significantly lower than the U.S. minimum wage (7.25 USD/h). TurkBench leveraged historical records of completions of specific microtasks (called HITs on AMT) to suggest lucrative work to workers [11], but this was limited by which tasks had previously be seen. TurkBench could not estimate the hourly wage the first time that a particular type of task was performed. New tasks are frequently posted in crowd marketplaces, and so it is important to be able to predict hourly wages for previously unseen microtasks.

In this paper, we present TurkScanner, a machine learning approach for predicting the working times of microtasks to calculate their hourly wages based on previous logs of other workers for other tasks. This allows workers to judge whether microtasks are worth doing, even for new tasks that no other workers have completed.

The first challenge we addressed in building TurkScanner was to collect reliable ground truth data on the working times of real tasks. Estimating working times automatically is difficult, because we know that worker behavior patterns during microtasks and the motivations behind them are diverse [23], such as visiting external websites to complete the tasks, taking breaks, or accepting a number of tasks and completing them in a row [12]. Rather than attempting to calculate a single working time, we collected three different times (two types of automatic recording and manual recording by

the worker), along with the workers' a posteriori judgments on which were likely to be most accurate. Our extension collected 9,155 data records of microtask submissions from 84 unique workers. For each worker, we collected information on each of the tasks they completed, including the task (HIT) metadata and HTML content, the reputation of the requester, and the worker profile. We aimed to collect all of the data that workers would view before actually completing a task. Intuitively, we expected results such as "HITs with longer times provided in their metadata may take longer," "HITs posted by requesters with better ratings pay better," and "HITs that included many input elements take longer to complete."

Our second challenge was to predict working times (and thus hourly wages) for microtasks using a machine learning-based approach. To the best of our knowledge, TurkScanner represents the first work to utilize machine learning to estimate the working times of microtasks. We extracted ~150 features from our data collected from AMT. Our cross-validated results showed that TurkScanner achieved hourly wage predictions within a 75% working-time error for 69.6% of all the microtasks (and within a 100% error for 84.3%).

We conclude this paper by suggesting future research directions, to apply TurkScanner to support tools that empower both workers and requesters. We believe these types of machine learning mechanisms will enable a future in which crowd work becomes a more transparent and beneficial activity for all stakeholders.

2 RELATED WORK

A wealth of previous literature has shown that workers are underpaid and unfairly treated in crowd markets [15, 17, 24]. Most crowdsourcing platforms allow requesters to freely create their microtasks and set their prices. Requesters can also assess worker performances to control the quality of their answers, such as by screening workers' eligibility to work with qualifications [12], or by rejecting submitted tasks that do not meet their criteria [3]. On the other hand, workers are usually provided with very limited information to select better microtasks [20]. For instance, most crowd markets only provide the task price, the name of the requester, a title, and a simple description. Such a lack of information makes it very challenging for workers to find good microtasks and requesters. This power imbalance between requesters and workers limits workers' ability to ensure that they receive fair wages, and this results in many workers being paid below minimum wage [14, 16, 18, 20, 21, 26, 27]. This problem was formalized after Hara et al. recently revealed that AMT workers earn a median hourly wage of only 2 USD/h, based on their data-driven analysis [12]. This surprising fact clearly emphasizes the necessity of tools to help crowd workers earn better wages.

Several researchers and practitioners have explored approaches to provide workers with better opportunities to obtain information on microtasks when selecting tasks [27]. There are several web-based platforms on which workers communicate with each other about microtasks and requesters. For instance, Turkopticon [20] is an online forum and a tool where workers post reputation scores of requesters concerning several criteria, as well as free comments. Among other support tools, Turkopticon is highly appreciated and actively utilized by workers [23]. Many workers also join online social communities, such as Turker Nation [1] and MTurk Crowd [2]. On these community websites, workers not only share reputations, but also recommend specific tasks and introduce tools and skills utilized by expert workers. Web tools are also available to workers to directly facilitate crowd work within the crowd market [8]. CrowdWorkers [6] is a web browser extension for AMT workers, which collects microtask submission logs and visualizes the average hourly wage for each posted task. TurkBench [11] is another web platform for AMT workers, which renders a personalized, adaptive working schedule based on collected task logs, to suggest the most lucrative microtasks.

Like other tools, we aim to help workers select better microtasks. More specifically, the goal of TurkScanner is to "predict" the hourly wages of new unseen microtasks, based on other tasks completed by other workers, rather than by calculations based on worker records for the same task. We not only contribute the prediction algorithm, but also address the challenge of defining the "working time" of a microtask, so that we can calculate hourly wage based on this, which has not been sufficiently discussed in prior work.

3 METHODS

In this section, we first describe our approach to defining the "working time" of a microtask. Next, we explain our browser extension for data collection, designed based on our working time definitions. We then explain the features of the dataset and its statistical analysis results. Finally, we present the details of TurkScanner, which predicts the working times of microtasks and their hourly wages.

3.1 Defining Working Time

The "working time" refers to the amount of time required for workers to complete particular tasks. To predict the working time using machine learning, it is essential to collect real-world data on actual working times. However, measuring the working times is highly challenging. We know that various worker behavior patterns exist, which prevents us from stably obtaining the correct working time using simple methods. During microtasks, workers often browse external websites in other tabs (either related or unrelated to the task), take breaks, work on multiple tasks in parallel, and so on.

In our approach, we recorded three different types of working time for every microtask. Each of these has unique advantages and disadvantages. When workers submitted microtasks, they were subsequently asked to choose one of the working times to finally label the collected data with. The options were as follows:

- **TIME_ALL**. Automatic recording method, consisting of the time from when workers accept the task until they finish it. *Pros*: This is the most reliable working time when a worker immediately starts and completes a task without taking a break. *Cons*: All of the time during which the worker is distracted (by checking emails, getting coffee, etc.) is counted.
- **TIME_FOCUS**. An automatic recording method similar to TIME_ALL, but only recording the time during which the microtask page tab is in focus. *Pros*: This is a reliable working time even if a worker is distracted by task-irrelevant content in other tabs. *Cons*: This approach cannot count the working time for microtasks that guide workers to other tabs at which the actual task resides (*e.g.,* surveys or Google searches).

- **TIME_BTN**. A manual recording method carried out by workers themselves, by toggling buttons to indicate when they are in the working status. *Pros*: This is the most accurate working time when a worker utilizes the button correctly, covering all possible worker behavior patterns. *Cons*: This approach is vulnerable to human error (*e.g.,* spams).

For workers' final decisions, we also introduced the following working-time type as a fourth option:

- **TIME_CUSTOM**. Manual input for the working time by workers in the case that none of the above three options seem to be correct. *Pros*: This can provide workers with a last-resort option, to label the correct working time when all recording methods failed. *Cons*: Errors may be present in workers' answers.

We proposed a few hypotheses concerning workers' judgments of the working time. We expected the most dominant choice would be TIME_BTN, because we anticipated that most workers would browse external websites or temporarily leave their computers for diverse reasons, and that the working time manually recorded by themselves would look more reliable in most cases. Next, we supposed that TIME_ALL would be the second most dominant choice. However, we expected that this would still be chosen less than TIME_BTN, because there are a certain number of workers who interleave tasks on crowdsourcing platforms [23], such that the working time cannot be correctly measured by this approach. Finally, we expected that TIME_FOCUS and TIME_CUSTOM would be chosen considerably less, but would still be useful when workers accidentally ignored the recording button.

3.2 Data Collection With Web Browser Script

We developed a Google Chrome extension for data collection, which crawls data from every completed microtask together with the actual working time. The extension records the working time automatically, provides AMT workers with a button for manually recording the working time, and asks workers to select the best choice for the working time with which to finally label the data.

3.2.1 Worker Recruitment with Pre-Survey. To recruit AMT workers, we prepared a pre-survey that asks for worker profile information (*e.g.*, gender, age, country, household income, worker experience, and worker hours per week). After the survey, we asked workers to install our extension according to instructions and a URL for the installation page. After installation, each participant was given a unique "installation code," to be copy-and-pasted back into the HIT to verify that they both installed the extension and completed the task. The survey took about 4 min to complete, including the extension installation. We paid workers 0.60 USD (*i.e.,* an expected 9 USD/h) to complete the pre-survey and correctly paste the installation code.

3.2.2 HIT Crawling using Chrome Extension. When workers finished installing the extension, they were ready to begin data collection. Workers were asked to work on microtasks as usual. The extensions collected data for up to 10 days after being installed, yet allowing the workers to uninstall it at any time (the workers were paid in proportion to their contribution until uninstallation). The data collection proceeded according to the three following steps (a), (b), and (c) (with workers paid a 5-cent bonus for completing each of (b) and (c) for each a HIT):

Table 1: List of input features parsed from the collected data. The features consist of three categories and 12 subcategories. The parenthesized numbers in bold text represent the feature dimension sizes.

HIT (71) – HIT-relevant information		
META	**(3)**	HIT metadata set by requesters (*e.g.,* reward, # of available HITs)
TMPL	**(11)**	HIT templates natively provided by AMT as of October 2018 (one-hot vector)
URL	**(6)**	URL counts per content type included in a HIT page (*e.g.,* anchor links, images, audios)
INP	**(18)**	Input tag counts per type included in a HIT page ("type" attributes such as *radio* and *text*)
TXT	**(1)**	Visible word counts in a HIT page
KW	**(32)**	Task-relevant keyword occurrence in either HIT title, HIT description, or a HIT page (keywords such as "survey" and "summarize" arbitrary extracted by the authors)
WKR (28) – Worker-relevant information		
PRFL	**(16)**	Worker profile information collected in pre-surveys (*e.g.,* age, worker experience in years, est. hourly wage)
EXT	**(8)**	AMT worker helper extension tools installed in web browser (*e.g.,* CrowdWorkers [6], MTurk Suite [13])
HIST	**(4)**	Working history information as workers (*e.g.,* approval rate, total earnings, # of HIT submission in a HIT group)
REQ (49) – Requester reputation information		
TO	**(7)**	Turkopticon [20] (*e.g.,* average of 5-point scale requester evaluation of generosity, promptness, etc.)
TO2	**(34)**	Turkopticon 2 [21] (*e.g.,* average of 5-point scale HIT evaluation of recommendability, communicativeness, etc.)
TV	**(8)**	TurkerView [9] (*e.g.,* requester reputation for hourly wage settings, # of reviews, etc.)

(a) Background data scraping. Once workers installed the extension, they were asked to select and work on any HIT as they would usually do on the platform. The extension recorded the following data features, as shown in Table 1. When a worker visited a HIT page, the extension scraped HIT-relevant information (`HIT`), such as the HIT metadata and HTML contents of the HIT page (*i.e.,* the text/media content information) that would possibly define task goals and required interactions in the task. In addition, the extension crawled worker-related information (`WKR`) from the worker dashboard and the list of installed AMT-relevant extensions once per day. `WKR` would also be important, because its features would represent worker capabilities for microtasks [28], such as their skill levels and the learning-curve effects [29]. Our extension also obtained requester-relevant information (`REQ`) concerning the reputations of requesters, provided via RESTful APIs in some third-party platforms (*i.e.*, Turkopticon [19], Turkopticon 2 [22], and TurkerView [9]). This would help to understand how reasonably the microtask would be paid based on the requester ratings.

(b) Manual working time recording. While working on HITs, workers were asked to manually record the working time they spent on each HIT. When workers accepted HITs, a red button was shown on the project details bar located at the top of a HIT page (Figure 1a). Workers recorded times at which they paused and resumed working on microtasks by toggling the button. The two following additional

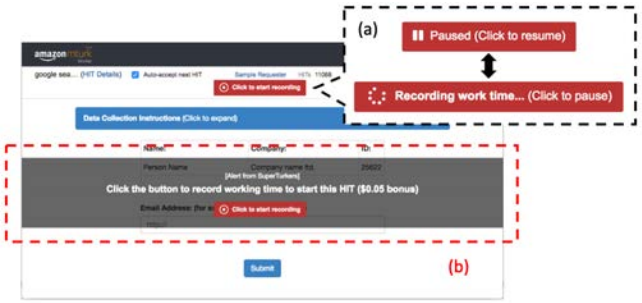

Figure 1: Interface to record TIME_BTN. (a) The button at the top of the HIT page can be toggled to pause/resume recording working time. (b) A black screen is rendered over the HIT at the beginning as a reminder workers to start the timer.

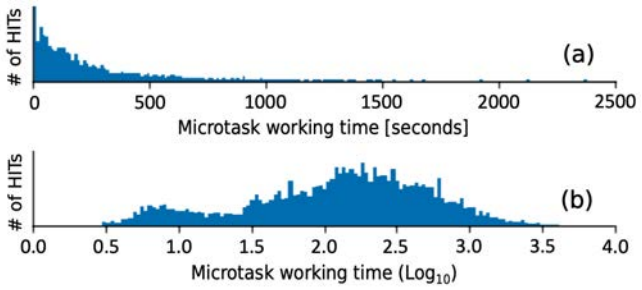

Figure 2: Working time distribution of microtasks in the dataset. (a) Working time in seconds, which admits a long-tail distribution. (b) log_{10} working time, which can suppress the prediction error due to outliers.

features were implemented to remind workers to click the button when they start working on the HIT. First, workers were prompted with a black screen rendered over the page (Figure 1b). This screen disappeared immediately once they clicked the button. This made it less likely for workers to complete a HIT without dismissing the alert. Second, a red frame was displayed around the window while the button was in the recording state, to assist workers in recognizing the recording state. When workers interleaved HITs, (*i.e.*, worked on multiple HIT pages in multiple tabs simultaneously, by moving back and forth), none of the HITs would record their working times simultaneously, because we assumed that perfect multi-tasking of HITs is not possible.

(c) Post-HIT survey. As soon as workers submitted a HIT, they were prompted with a "Post-HIT survey" in a popup window and they were asked to select the most accurate working time from the various methods with which to label HIT records. The survey suggested four options for the HIT working time: TIME_ALL, TIME_FOCUS, TIME_BTN, and TIME_CUSTOM (see Section 3.1 for details). Workers were required to input working time, in the form of X minutes and X seconds, only when they chose TIME_CUSTOM. The pop up window disappeared immediately after workers submitted their choices by clicking a “Submit” button.

3.3 Data Description

Data collection was conducted for 10 days during late October 2018. Our task dataset consisted of 9,155 HIT submission records collected by 84 unique workers. The recorded HITs belonged to 1,641 unique HIT groups, posted by 998 unique requesters. On average, workers contributed for 6.5 days (SD = 3.5; Median = 8.1) and worked on 109 HITs (Min = 1; Max = 1,958; SD = 238.1; Median = 34).

Data Cleaning. To guarantee the quality of the dataset, we filtered out the following HIT submission records: *(i)* All HIT records of spam workers who used automated scripts (N=230); *(ii)* HIT records for which the reported working time was abnormally short or long (N=213); *(iii)* A large part of all the HIT records in the top three most-submitted HIT groups, keeping only as many HIT records as in the fourth largest HIT group, in order to reduce bias in the dataset (N=1,104). After the data cleaning, 7,608 (83.1%) HITs remained from 83 unique workers, for 1,587 HIT groups posted by 977 unique requesters. This dataset was utilized for the analysis in the remainder of the paper.

Working Time Labels. On average, the reported working time was 277.9 s (SD = 380.2; Median = 148.3). As in Figure 2(a), the distribution of the working time had a long-tail; 69.0% of all the working times were below the average. The hourly wage averaged $9.15 (SD = 29.11; Median = 4.23). Among all HIT records, 2,270 (29.8%, in 674 HIT groups (42.4%)) were above the U.S. minimum wage (7.25 USD).

For the final labels for the working time, workers chose TIME_ALL for 3,802 (50.0%) HIT records, TIME_BTN for 2,525 (33.2%) records, TIME_FOCUS for 748 (9.8%) records, and TIME_CUSTOM for the rest 533 (7.0%) records. This partly supported our hypotheses, in that TIME_FOCUS and TIME_CUSTOM occurred less than the others, but went against our expectation that TIME_ALL would occur more than TIME_CUSTOM by 16.8 points.

We then conducted a follow-up analysis on TIME_BTN. Our investigation into the workers’ button usage showed that the button was clicked at least once in 7,037 (92.5%) HITs, that the usage per worker averaged 95.8%, and that merely 16 workers (19.3%) were below the average. The button appeared to be correctly utilized in most cases. However, the analysis also revealed that participants seldom stopped the timer. The timer was stopped once in 73 HITs, twice in 8 HITs, and three times or more in 8 HIT,s while the timer was never stopped in the remaining 6,948 HITs. We then analyzed the differences between TIME_BTN and TIME_ALL for microtasks which TIME_BTN was chosen for the final choices. The results showed that the differences in 72.5% of the records were less than 5 s, and those in 85.1% were less than 10 s. The results indicate that most of the TIME_BTN records that were chosen for the final labels were nearly equal to TIME_ALL, (*i.e.,* the button was immediately clicked when tasks started and finished without taking a break). On the other hand, it was not possible for us to rigidly evaluate whether the button was correctly used, because our collected dataset did not contain tracking information of workers during HITs. We leave this as a topic for future work.

3.4 TurkScanner: Hourly Wage Prediction

TurkScanner predicts the hourly wages of microtasks in two steps: 1) estimate the working times of microtasks based on `HIT`, `WKR`,

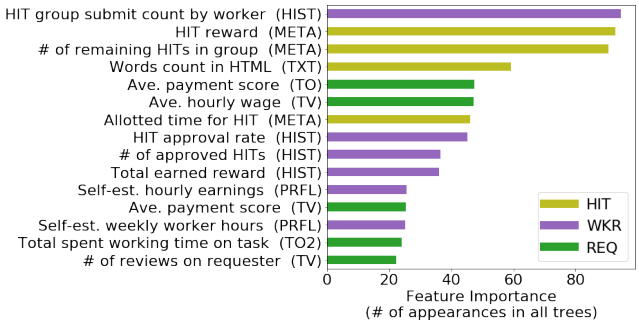

Figure 3: Top-15 feature importance rankings. Features for batch size, submission counts, and some explicit features (*i.e.,* price, time, microtask contents) seem to implicate working time length. Worker profiles are possibly effective, representing workers' proficiency on tasks.

and REQ, in a machine learning-based approach; 2) calculate the hourly wage from the rewards and the estimated working times.

We predicted the working times of microtasks through regression using gradient boosted decision tree (GBDT) [10]. The model was trained with 148-dimensional feature vectors of task-relevant information (see Section 3.2), by minimizing the mean absolute error between the predicted and actual working times. Upon training and testing, our GBDT model outputs the working times of microtasks on a *log scale (base=10)*. As shown in Figure 2, the working times of microtasks in our dataset admit a long-tail distribution. Taking the logarithm prevents the model from being excessively optimized for short-length microtasks and being affected by outliers.

The model evaluation was conducted through four-fold cross validation. When partitioning the dataset, we picked 25% of the 83 workers, and used all their HIT submission records for the test set. This means that the same worker never belonged to both the training and test sets. Therefore, the validation results indicate the extent to which the model is capable of predicting the working time without being trained using HIT submission records of the same worker. To obtain the predicted working times for all the microtasks in the dataset, we tested the model for all the validation pairs, and analyzed them all together. To prevent the results from being too dependent in each trial, we iterated training and testing 50 times, and then calculated the average working time for each HIT record to obtain the results for subsequent analysis.

4 RESULTS AND DISCUSSION

In this section, we describe the evaluation results of TurkScanner. We first analyze feature importance, followed by analyses of the prediction accuracy for the working time and hourly wage.

4.1 Feature Importance

We first measured the feature importance, to better understand how each feature dimension contributes to predicting the working time. Among the diverse methods available to measure the feature importance, we selected "weight" provided by XGBoost [7], which counts how many times a feature is utilized for splitting across all generated trees. We iterated the training of the initial model 50 times, and then took the averages of the feature importance values for the following analysis.

Figure 3 visualizes the importance ranking of the features for the working time prediction. Features that could provide indications to estimate the microtask size appeared to be especially important. For instance, larger HIT group submission count numbers (first place in the ranking), the number of remaining HITs in the group (third), and the word count in the HTML would imply how quickly HITs can be completed, because shorter HITs are more likely to be performed repeatedly. More intuitively, features concerning the price (HIT reward: second), time (time allotted for a HIT: seventh), and task contents (word count in HTML: fourth) could also help to represent the working time. These features also appeared to be effective as reputations by workers (REQ features: fifth, sixth, 12th, 14th, and 15th). Worker profiles and task submission histories were also thought to be effective (WKR features: 8th–11th and 13th). All these features represent workers' proficiencies with their working hours, accepted HITs, and earned rewards. This could possibly help to ensure the reliability of the working time prediction.

4.2 Working Time Prediction

Figure 4 presents a heat map of the confusion matrix representing the distribution of the working time prediction results per working time bin. The size of each bin increases gradually towards the right, where the bin of the leftmost columns gathers all the HIT records whose actual working times are between 3 and 8 s, whereas that of the second right-most column includes those between 600 and 1,200 s. Note that we only utilized this binning rule for the analysis: TurkScanner outputs consist of float values for the working time.

The heat map indicates that a large proportion of the predicted working times hit the bin or a nearby bin. Seventeen percent of all the HIT submission records are in the diagonal cells in the heat map, surrounded by bold grid lines, (*i.e.*, they are categorized in the correct bins). Allowing the prediction results to be categorized into neighboring bins, the proportion of correct predictions increases to 47.4% with a one-cell difference (indicated by thin grid lines), and 70.8% with a two-cell difference (indicated by dotted lines). We also note that the predicted working times of HIT records with shorter working time labels (less than 60 s) are likely to be longer. Likewise, the predicted working times of HITs with longer working time labels (more than 600 seconds) tend to be shorter. This may be because the distribution of the logarithmic working time labels is closer to the normal distribution (see Figure 2b). As mentioned in Section 3.4, the objective function of the GBDT algorithm trains the model such that the overall error across all the data is minimized. Therefore, the model may have been trained to reduce the prediction error for HIT records with medium-length working times, where the largest amount of data samples are.

4.3 Hourly Wage Calculation

We calculated the hourly wage using the rewards and predicted working times of microtasks. Over all the tested HIT records, the predicted hourly wage averaged 5.21 USD (SD = 4.53; Median = 4.20). For N = 5,297 (69.6% of all the collected HIT records) the hourly wage was predicted within a 75% error, and for N = 6,412 (84.3% of all the records) it was predicted within a 100% error.

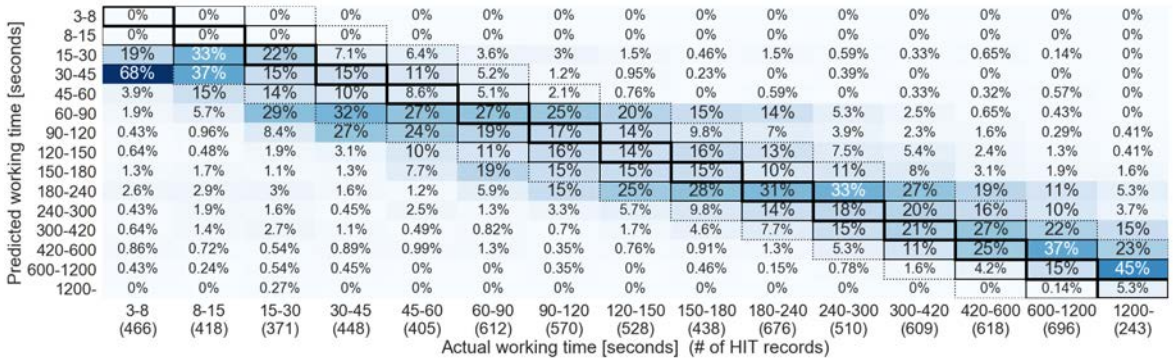

Figure 4: Working time prediction results in a confusion matrix, illustrated by a heat map. A large portion of the prediction results are distributed diagonally, which implies that the model successfully captured the trend in the working time prediction.

The prediction performed reasonably well for HIT records with actual hourly wages lower than around 15 USD. On the other hand, many of the HIT records with higher hourly wages were not predicted to be as high as they actually were. To further analyze the incorrect results, we directly inspected the corresponding HIT records. As a result, we determined that most of these were *(i)* survey HITs with external URL(s) and *(ii)* microtasks for which contents were dynamically rendered with JavaScript. These two types of HITs are very similar in that they do not have much static HTML content by themselves. Because we revealed in our feature analysis that some types of HTML content (*e.g.*, text counts in the HIT page, URL counts, and input tags) affected the prediction results, the model might have not been able to predict these HITs accurately.

5 LIMITATIONS AND FUTURE WORK

5.1 Limitations

We first describe limitations concerning the data cleaning described in Section 3.3. Our data cleaning method could be improved by scraping additional information, so that more noisy data are removed from the dataset. First, tracking the statuses of completed microtasks (*i.e.,* accepted or rejected) could filter out unreliable data. If microtasks are rejected, then some of the scraped data are likely to be inconsistent. For instance, the working time may be too short compared to the task. Second, we could track worker behavior such as cursor movements, scrolling, and the keyboard input for a certain time window. Using such information, we can verify whether the history of recorded working times corresponds to the user behavior, and remove records if not.

We could also collect a more refined dataset by tracking microtask bonuses. TurkScanner only considered fixed rewards for microtasks, and bonuses were not taken into account for the hourly wage prediction. This would underestimate the value of microtasks whose reward schemes largely depend on bonuses for the microtask content. Tracking the sizes of bonuses paid for each microtask would help TurkScanner to build a more accurate prediction model.

5.2 Future Work

Our next step will be to develop TurkScanner as a support tool for workers and requesters to solve real-world problems. We will observe how TurkScanner could help workers reach better decisions on which microtasks to start. We will also incorporate aspects that can be found in other similar recommender systems, such as predicting HIT acceptance rates, or recommending HITs based on workers' task preferences. TurkScanner could also assist requesters with performing better price setting. It could predict the hourly wage for microtasks prior to posting on the platform, and suggest that requesters increase their rewards for better wages. This would greatly contribute to improving the average microtask price in the market, and accelerate future crowdsourcing research.

More generally, TurkScanner represents a new approach to understanding and predicting the times required for arbitrary user interface tasks. This could be utilized in a variety of settings, such as setting wages in other domains, helping people to better organize or schedule their time, or in automated usability testing. One can imagine a scenario in which every new task a government or company posts comes accompanied with an estimate of the cost of introducing the new task. It may still be required to fill out an extra web form to justify conference travel, but at least it would be explicitly known how much time (and thus money) would be required to do so.

6 CONCLUSION

In this study, we tackled the challenge of predicting the hourly wages of microtasks based on data collected from previous workers. We first presented a data collection method with our web browser extension for gathering data about crowd work and labeling the data with accurate working times. We asked workers to select their answers from choices of working times recorded either automatically and manually by the workers themselves. We then proposed TurkScanner, a system based on the GBDT regression model, to predict working times, and thus calculate hourly wages as its final output. Our evaluation results indicated TurkScanner would need further improvement on its prediction performance. Nonetheless, we clearly showed the possibility that workers can know whether their crowd work will be worth the pay before actually embarking on it, which would make crowd work more transparent and beneficial for workers and requesters.

ABSTRACT

The Web is one of the most successful Internet application. Yet, the quality of Web users' experience is still largely impenetrable. Whereas Web performances are typically gathered with controlled experiments, in this work we perform a large-scale study of one of the most popular websites,namely Wikipedia, explicitly asking (a small fraction of its) users for feedback on the browsing experience. We leverage user survey responses to build a data-driven model of user satisfaction which, despite including state-of-the art quality of experience metrics, is still far from achieving accurate results, and discuss directions to move forward. Finally, we aim at making our dataset publicly available, which hopefully contributes in enriching and refining the scientific community knowledge on Web users' quality of experience (QoE).

1 INTRODUCTION

Since its inception, the World Wide Web has sometimes been dubbed as World Wide "Wait" [9]. Slow rendering of webpages happened due to dial-up connections in the 80s, slow 2G connections in the 90s and so on, but it also persists nowadays for several reasons including unexpected sources of latencies [16], interactions between network protocols [22], the growingly more complex structure of websites [45], an increased usage of mobile devices [19, 34] and the emergence of new protocols [40]. Yet, whereas the study of Web performance is commonly [19, 22, 29, 34, 40, 45–47] tackled via simple objective metrics [20], and rather typically the Page Load Time (PLT), the quality of Web users' experience is still largely impenetrable [15, 28]. As such, a number of alternative metrics that attempt at better fitting the human cognitive process (such as SpeedIndex, user-PLT etc.) have been proposed as a proxy of QoE.

At the same time, studies involving more advanced metrics are typically validated with rather small-scale experiments, either with a small number of volunteers, or by using crowdsourcing platforms to recruit (cheap) labor and produce a dataset labeled with user opinion. Often, *videos* of Webpages rendering process is used (as opposite to actual browsing), with possibly very specific instruction (e.g., such as in A/B testing, by clicking on the fastest of two rendering processes) that are however rather different from the cognitive process in action during the typical user browsing activities. Additionally, such tests are carried on a limited number of fixed conditions, with a small heterogeneity of devices, OSs and browsers, and are not exempt from cheating so that ingenuity is needed to filter out invalid answers from the labeled dataset [24, 44]. Finally, because these tests are carried on a limited number of pages, it is possible to evaluate computationally costly metrics, such as those that require processing the visual rendering of the webpage, which would hardly be doable in the World "Wild" Web.

Our aim is instead to take a completely different approach and perform a large-scale study of a popular website in operation, by explicitly asking a fraction of users for feedback on their browsing experience. Clearly, the approach is challenging but it opens the possibility to gather more relevant user-labels, as they are issued from *real users of a real service*, as opposite to crowdworkers payed to play a game (e.g., find which video completes first as in A/B testing). We do so by launching a measurement campaign over Wikipedia, that at time of writing has gathered over 62k survey responses in nearly 5 months. We complement the collection of user labels with objective metrics concerning the user browsing experience (ranging from simple PLT [20] to sophisticated SpeedIndex [1]), and harvest several data sources to further enrich the dataset so that each user survey answer is associated with over 100 features. Summarizing our main contributions:

- first, we use survey data to characterize user satisfaction, finding that on average 85% of users are satisfied;
- second, we build a supervised data-driven model of user experience: despite our features include state-of-the art quality of experience metrics, we find that they fall short to model user QoE in operational settings;
- third, in spirit with research reproducibility, we plan to release both the collected *dataset* and our developed *code* as

open-source, as we hope this can help the scientific community in refining its understanding of Web users' experience.

After overviewing the related work (§2), this paper describes our feedback collection process and dataset (§3), that we leverage to build a data-driven model of Wikipedia user experience (§4), finally discussing its current limits and directions to circumvent them (§5).

2 BACKGROUND

Assessment of Web users' quality of experience can be traced back to [36], that was among the first to adapt classic results of psycho-behavioral studies gathered in the *computer* domain [30] (in turn inspired by work by Weber and Fechner in the late 1800s), to the *computer-network* domain. This knowledge was later embedded into standards ITU-T G1030 [26, 39] (and models [23]) that encode the Weber-Fechner logarithmic [26, 39] (or exponential [23]) relationship between a stimulus (e.g., a delay) and its perceived impact (e.g., nuisance for Web users). However, while logarithmic models are valid for simple waiting tasks (e.g., file downloads), the case of interactive Web browsing is knowingly much more complex, as ITU-T G1031 [27] and [21] first pointed out.

Still, with few exceptions [15, 18, 44, 48] most studies still rely on simple metrics such as the Page Load Time (PLT) to assess the expected impact of new Web protocols [22, 40, 45, 47], Web accelerators [29, 46] and devices [34, 37]. While reducing delay is clearly a desirable objective, it is however unclear if (and by how much) a latency reduction translate into a better perceived experience, which is the ultimate goal of the above studies. In other words, while the importance of *delay* in human perception is agreed upon, the exact relationship between the Web response time and user satisfaction appear much less clear than it appeared to be [33], and motivated a proliferation of new metrics proposals and validation studies attempting at going beyond PLT.

Web QoE metrics: As we are interested in measuring browsing experience on individual pages, *engagement* metrics such as those used in [11, 31] are clearly out of scope. As such, objective metrics of interest for Web user QoE can be divided in two classes. On the one hand, there are metrics that either *pinpoint precise time instants*: notable examples include the time at which the DOM is loaded or becomes interactive (TTI), the time at which the first element is painted (TTFP) or the time when the Above The Fold (ATF) portion of the page is rendered [14] etc. Most of these metrics are available from the browser navigation timing [20], and are easy to include (though not necessarily relevant) as proxy of user experience.

On the other hand, there are metrics that *integrate all events of the waterfall* representing the visual progress of the page, such as SpeedIndex [1] and variants [2, 12, 24], that have received significant attention lately. Denoting with $x(t) \in [0, 1]$ the visual completeness ratio of a page, metrics in the SpeedIndex family are defined as the integral of the residual completion $\int (1 - x(t))dt$ and differ in the way they express $x(t)$. Initial definitions in this family required capturing movies of the rendering process [1], or to further use similarity metrics SSim [24], making them difficult to use outside a lab environment. To counter this issue, simple approximations such as the ObjectIndex/ByteIndex [12] that merely count the fraction of objects/bytes received (over the total amount), or as the RUM SpeedIndex (RSI) [2] that use areas of rectangles for objects as they are painted on screen (over the total screen size) have been proposed. In this paper, we use RSI, which is among the most advanced Web QoE metrics considered to be the current industry standard. Finally, while we are aware that more complex approaches involving the spatial dimension (i.e., eye gaze) also exist [15, 28], we prefer to leave them for future work (cfr §5).

Metrics Validation: At the same time, the above metrics suffer from a limited validation with user feedback. Typical approaches are to crowdsource the validation with A/B testing [24, 44], or by performing experiments on real pages in controlled conditions [18, 33, 35]. Both approaches have their downsides. Controlled experiments with real HTTP server/clients and emulated network conditions for a more faithful and interactive browsing experience, but are harder to scale, topping to few hundreds users and few thousands data points [18]. A/B tests try to circumvent this limit, but introduce other limitations. First and foremost, A/B testing is hardly representative of Web browsing activity, since crowdworkers are instructed to select which among two videos, that they are passively screening side-by-side and that correspond to two different Web rendering processes, appears to finish first – whereas it is known that even for a simple Web browsing task such as information seeking, already different types of searches are rather different from the user standpoint in terms of cognition, emotion and interaction [32]. In other words, these experiments inform us that humans can perceive differences in these rendering processes, however they fail to signify if these perceptible rendering changes would impact the user satisfaction through the course of a normal browsing session.

The time at which users consider the process finished is denoted as user-PLT (uPLT)[44] or Time To Click (TTC) [24] and is often used as a ground truth of user perception. Yet, when users select a uPLT in [44], they are proposed with similar frames at earlier times, which has the beneficial effect of clustering answers and make uPLT more consistent at the price of possibly inducing a bias. Similarly, [24] employs SpeedIndex and TTC to forecast which among the left or right video was selected by the user at time TTC: the classifier in [24] is accurate in predicting which of the two videos is perceived as fastest by users. Yet, findings in [24] are not informative about whether the user would have been dissatisfied from the slower rendering had s/he been truly browsing.

Our contribution: To get beyond these limitations, in this work we are the first to query, at scale, Web users for their feedback on the quality of their browsing experience. which, to the best of our knowledge, has not been attempted before on the wide and wild Web. Instead of collecting user feedback on a 5-grade ACR scale, we ask for a (slightly more than) binary feedback (see §3), which let us formulate a simple (yet hard, see §4) binary classification problem.

Compared to recent literature , we are the first to involve a large number of real users ($62k$ from $59k$ distinct IP addresses) accessing a diverse set of pages ($46k$ Wikipedia pages, which are more likely similar among them than the set of different websites used in other studies), gathering over $62k$ user responses overall (more than twice the survey responses collected in similar large-scale Wikipedia studies [41]). Particularly, whereas most of the studies involving lab volunteers & crowdworkers employ a single browser and hardware (since crowdworkers are shown videos rendered with a single

browser and hardware combination) on a relatively small set of synthetic controlled network conditions, in our dataset we observe 45 distinct browsers software used on over 2,716 hardware devices on 3,827 ISPs – a significant change with respect to controlled lab conditions, which make the dataset of particular interest.

3 USER FEEDBACK COLLECTION

Wikipedia is, according to Alexa [3], the 5th most popular website, with over 1 billion monthly visitors, that spend over 4 minutes over 3 pages on average per day on the site. We engineer a survey that is triggered after the page ends loading and collects user feedback (§3.1), that we augment with additional information (§3.2).

We note that, while this paper is not the first in leveraging Wikipedia surveys in general (see e.g., [41]) this is the first to gather user feedback on quality of Web browsing experience from operational websites, for which we believe releasing the dataset can be valuable for the community. To make sharing of the dataset possible[1], we take special care into making user and content deanonymization as hard as possible, without hurting the dataset informative value as much as possible (§3.3). In this section, we also perform a preliminary assessment of the collection methodology, to confirm the absence of bias in the response process (§3.4).

3.1 Technical aspects of the survey collection

Due to limitations in Wikimedia's caching infrastructure, the survey is injected into the page via client-side code. Wikimedia continuously collects navigation timing performance of a randomly selected sample $\mathcal{T}$ of page views (less than 1 every 1,000 pageviews); the survey is displayed to a randomly selected sub-sample $\mathcal{S}$ of this population (less than 1 every 1,000 of the pageviews with navigation timing information) and only part of the surveys do receive an answer $\mathcal{A}$. Since $\mathcal{A} \subset \mathcal{T}$, several features (that we detail in §3.3) related to page loading performances are also available for pages sampled in the survey responses.

The survey appears on Russian, French and Catalan Wikipedias, as well as English Wikivoyage, and it is displayed in the appropriate language to the viewer. We collect the survey on mobile & desktop version of the site (but not on the mobile app). Instead of asking users a 5-grade Absolute Category Ranking (ACR) score, we opt for a simpler yet still very relevant feedback [25], as users can respond with a *positive*, *neutral* or *negative* experience. Neutral feedback is meant for, e.g, users that have no honest opinion, as well as users who were not paying attention during the rendering, or users that do not understand the question, etc. to avoid biasing the results (§3.4). For the sake of completeness, a snapshot of the survey as it is rendered for English readers is reported in Fig. 1.

The survey is injected in the DOM after the page finished loading (i.e., when `loadEventEnd`[20] fires). In order to give the survey visibility, it is consistently inserted in the top-right area of the wiki article, ensuring that it typically appears above the fold, with randomization of answer order. However, as the users can freely browse the page before the survey appears, it might be out of sight when it's injected in the DOM, which is why we also record the time elapsed between the `loadEventEnd` and the moment the user sees the survey. Also users that are shown the survey are free *not* to respond to the survey, or might as well respond very late (e.g., possibly browsing to other tabs in the meanwhile).

[1]The Wikimedia feature vetting process is still ongoing at time of writing.

Figure 1: Appearance of the Survey in the English Wikipedia (answer order is randomized).

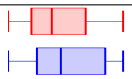
Table 1: Collected corpus of Wikipedia users' QoE feedback.

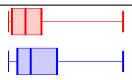
Period	May 24th – Oct 15th		
No. of survey requests	$\lvert\mathcal{S}\rvert$ =	1746799	
No. of survey answers	$\lvert\mathcal{A}\rvert$ =	62740	$\lvert\mathcal{S}\rvert/\lvert\mathcal{A}\rvert$=3.6%
No. of positive answers	$\lvert\mathcal{A}^+\rvert$ =	53208	$\lvert\mathcal{A}^+\rvert/\lvert\mathcal{A}\rvert$ = 84.8%
No. of neutral answers	$\lvert\mathcal{A}^0\rvert$ =	4838	$\lvert\mathcal{A}^0\rvert/\lvert\mathcal{A}\rvert$ = 7.7%
No. of negative answers	$\lvert\mathcal{A}^-\rvert$ =	4694	$\lvert\mathcal{A}^-\rvert/\lvert\mathcal{A}\rvert$ = 7.5%

Overall, users responded as reported in Tab.1 to about 3.6% of the over 1.7M surveys that have been displayed in the period, for a total of over 62k anwers: 84.8% of the users respond positively to the survey with an almost equal split of the remaining answers to a neutral (7.7%) or negative (7.5%) grades.

3.2 Collected features

We enrich the collected corpus with external sources that are instrumental to the purpose of feedback prediction (§4). A terse summary of the metrics collected is reported in Tab.2, while rationales of the selection for those publicly available is given in §3.3.





Page: For each page, we record 15 features that concerns it (e.g., its URL, revision ID, size, etc.) and that thus are critical from a privacy point of view. We additionally record the time lapse at which the survey is shown to users, which is instead innocuous.

Performance: Since $\mathcal{S} \subset \mathcal{T}$, then all the 32 navigation-timing performance-related metrics (such as DOM, PLT, TTI, TTFP, connection duration, number of HTTP redirect, DNS wait time, SSL handshake time, etc.) are also collected. Finally, we compute the page download speed which is a simple, yet non linear, transformation of page size and connection duration. These informations are specific to page views, and are less critical to be shared.

User: The 32 collected user-related metrics include the browser, device and OS families. Additionally, we know whether users are logged in Wikipedia, if they are accessing Wikipedia through a tablet device and the number of edits that users have made (coarse bins). These informations are of course highly critical.

Environment: The 36 environmental collected features pertain time, network, geolocation and techno-economic aspects. Except for the time information, directly available from the survey query, we extensively use external data to extract environmental features.

Table 2: Summary of the available/collected (A/C) features that are associated to each users' survey response. The mutual information between the survey answer and A/C features in the class is reported as a boxplot.

Class	A/C	Sample features	MI(x,y)
Page	2/15	Page ID, Page size, Survey viewtime, etc.	
Performance	26/32	DOM, PLT, TTI TTFP, RSI, etc.	
User	21/32	Device, Browser, OS, editCountBucket, etc.	
Environment	12/36	Connection Type, Time, Geolocation, etc.	
Overall	61/115		

As for the network, we leverage MaxMind [4] for IP to ASN and ISP mappings and for geolocation at country (and city) granularity. ISP and ASN mappings are potentially interesting as it can be expected that performances (for the same access technology) vary across ISPs (access technology is also available for about 2/3 of the samples). Concerning geolocation, whereas databases are known not to be reliable for city-level geolocation of server addresses [38], they are generally sufficiently accurate for resolving customer IP addresses, and especially when only ISO-3166-2 country-level precision is required. Country-level precision also allows us to relatively compare performances across users in the same environment, i.e., we normalize the page download speed with respect to the median per-country speed observed in our dataset (in terms of ratio, absolute and relative error).

Additionally, ties between country wealth and network traffic volumes have been established in the literature (particularly, deviation from expected volume [42]): it is thus worth investigating whether there also exist ties between wealth and users' impatience. We use the Gross Domestic Product (GDP) information made available by the World Bank Open Data project [5]. The per-country economic features we consider (namely, per-country GDP, per-country per-capita GDP, etc.) are expressed in terms of Geary-Khamis dollars, which relate to the purchasing power parity, i.e, how much money would be needed to purchase the same goods and services in two countries. The rationale in so doing is that, albeit Web users perception is tied to psychophysics laws [39], there may be environmental conditions tuning this law differently in each country. For instance, a fixed amount of delay may have a smaller perceptual value to users of countries with poor Internet access which GDP-related features might capture: e.g., in other words, one can expect users in a high-GDP country to have better average performance and thus be more impatient than users from a low-GDP one.

Finally, we expect user-home gateways [43] and particularly end-user devices [19, 34] to have a direct impact on the overall performance. As such, we complement the ISP-level view with a device-level information. Particularly, we harvest the Web [6] to find techno-economic information about user devices and in particular, collect device CPU, memory and pricing[2] information. Intuitively, this information complements the per-country GDP information as, e.g., there may be further perceptual differences between users with a costly smartphone in low-GDP vs high-GDP countries. We recognize that device CPU and memory specs are only an *upper-bound* of the achievable performance, as it is the mixture of applications installed and running on a device that determine the amount of *available* CPU and RAM resources, from which user perception will be ultimately affected [19, 34]. Missing this information on a per-sample basis, we attempt to at least construct the per-device statistics, by considering navigation timing information of a large representative sample of Wikipedia users. Particularly, we consider the month of August 2018 during which we observe over 30 million navigation time samples from 29,336 different devices, including all 2,716 devices in our survey. We then construct *deciles* of per-device performance (e.g., of page load time and similar timing information): indeed, it can be expected that users of knowingly slow devices be less impatient, which this additional data source could provide.

3.3 Ethics

The dataset we collect contains obviously sensitive information allowing to deanonymize Wikipedia visitors (such as IP addresses, version of their browser and handsets), as well as linking them to the content they visited (e.g., page, revision ID, time of their visit, etc.). Despite the dataset release policy explicitly forbids user deanonymization, in the interest of respecting personal privacy we have to obscure information so to render user deanonymization as hard as possible, while still allowing meaningful information to be extracted from the data.

Method: Specifically, we opt for an approach where we transform data in a non bijective way (e.g., IP to ASN and ISP mappings that provide network-related properties, while preventing user deanonymization at the same time), or aggregate at a sufficiently coarse grain (e.g., country-level geolocation; obfuscation of browser major/minor version; aggregation of unpopular devices, etc.). For the same reason, we decide to aggregate time-related information at a coarse-grain (hour-level) and drop most content-related features (e.g., page ID). We quantize the page size with a resolution of 10KB, to also make it hard to reverse-engineer which page was visited. We maintain most of the navigation timing related performance, that have the highest mutual information, which we obfuscate wherever necessary (e.g., given that with precise PLT and download speed one could easily reverse engineer the page size, and thus the content, we quantize the download speed in steps of 100Kbps). We point out that, since the Wikimedia feature vetting process is still ongoing at time of writing, shall the bag of available features ultimately differ from the one described here, it will be properly documented.

Results: As a consequence, this loss of information potentially has

[2]Note that we collect pricing information at the time of our query, and not at the time when the device was actually bought; we also ignore price differences among countries, and per-ISP offer bundles.

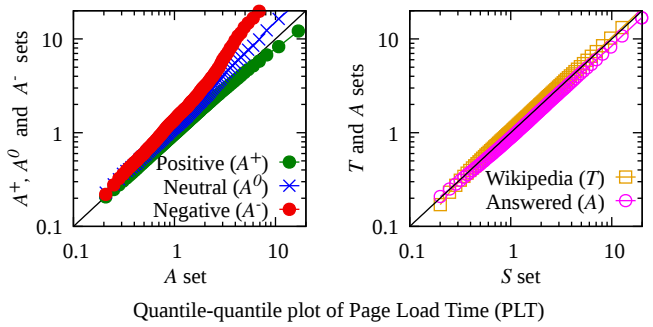


Figure 2: Quantile-quantile plot of PLT statistics for different sets ($\mathcal{T} \supset \mathcal{S} \supset \mathcal{A} = \mathcal{A}^+ \cup \mathcal{A}' \cup \mathcal{A}^-$).

an impact on the global prediction accuracy, which we assess in §4: at the same time, from results presented in Tab. 2, we can expect this effect to be rather limited. Indeed, Tab. 2 reports the number of the publicly available out of the collected (A/C) features in each class (second column), and additionally reports boxplots of the mutual information $MI(x, y)$ between features in the class and the survey answer (last column). *MI* expresses the amount of information (in bits) that can be obtained about the survey answers through the observed variable. Tab. 2 shows that, while we only report about half of the collected features, the available ones overall have a *higher MI* (particularly, note that the 25th percentile, median and 75th percentile are higher in the available feature set, and the feature having the maximum MI is also exported). Particularly, under this angle it is fortunate that features belonging to the performance class, which are those exhibiting the highest mutual information with the user grade, are also the least critical to share.

3.4 Validity of the collection methodology

Despite our care in engineering the survey questioning process, we cannot exclude a-priori the existence of bias in the user survey answer process. For instance, users might refrain to answer when the page loading experience was positive, and be more willing to express their opinion in case of bad experience, which would lead to under-estimate the user satisfaction.

To assess whether our survey collection methodology yields to such (or other) biases, we compare three sets of page view experiences, namely (i) the set $\mathcal{T}$ where we record navigation timing information from the browser (ii) the set $\mathcal{S}$ where users have been *shown* the survey (iii) the set $\mathcal{A}$ where users have actually *answered* to the survey. Finally, we further slice the set of answered surveys $\mathcal{A}$ according to the answer in three additional datasets with (iv) positive $\mathcal{A}^+$, (v) neutral $\mathcal{A}^0$ and (vi) negative $\mathcal{A}^-$ grades.

Among the numerous features we collect, without loss of generality we now limitedly consider the Page Load Time (PLT) distribution. Since $\mathcal{S} \subset \mathcal{T}$ is selected with uniform random sampling, by construction we have that $\mathcal{S}$ and $\mathcal{T}$ are statistically equivalent as far as individual features, such as PLT, are concerned. However, in case where users *decision* to answer to the survey would be biased by the performance of the page, then the PLT statistics should differ among the set of displayed $\mathcal{S}$ vs answered $\mathcal{A}$ surveys. The right-side of Fig. 2 reports a quantile-quantile (QQ)-plot of the empirical PLT distribution, using quantiles of $\mathcal{S}$ on the x-axis and $\mathcal{T}$, $\mathcal{A}$ on the y-axis, from which one can clearly remark the absence of such bias.

Conversely, one would expect that, shall the PLT affect the actual grading of the browsing experience, then PLT statistics should differ among the $\mathcal{A}^+ \cup \mathcal{A}^0 \cup \mathcal{A}^- = \mathcal{A}$ sets. This is shown in the left-side of Fig. 2, comparing the quantiles of the answer set $\mathcal{A}$ on the x-axis to its per-grade slices on the y-axis. Several remarks are in order. First, it can clearly be seen that browsing experience with negative scores fall above the equality line, confirming as expected that pages with longer download time yield to poor experience. Second, similar considerations hold for neutral (slightly above) and positive (slightly below) answers, although they are less visible – in part, this is due since positive grades represent the bulk of the answers $|\mathcal{A}^+|/|\mathcal{A}| = 84.8\%$, for which the PLT statistics of $\mathcal{A}^+$ and $\mathcal{A}$ are mechanically more similar (we will take care of class imbalance when appropriate later on in §4). Third, notice that a range of PLT values are present in the set of positive, neutral and negative answers, indicating as expected that the PLT alone cannot fully capture user perception.

4 USER FEEDBACK PREDICTION

Problem formulation: Disregarding the neutral scores, we now build data-driven models to forecast user answers. This allows to turn the problem into a binary classification one: this simple formulation enables immediate statements of performance objective, that we express in terms of the classic information retrieval metrics.

Clearly, from an operational standpoint a *conservative* estimation of user satisfaction is preferable. Indeed, the service operator wants to avoid that a malfunctioning service that is truly affecting user experience goes undetected, as when the ratio of dissatisfied users increases above a given level this can prompt alert to repair or ameliorate the service. In our settings, conservative prediction results translate into *maximizing the recall of negative scores*.

Reference classification results: Given the class imbalance, we have to preliminarily downsample the dataset[3]: indeed, given that after discarding neutral scores 92% of the users are satisfied, a naïve 0-R classifier that just learns the relative frequency of the scores and systematically answers with the majority class, would achieve 0.92 accuracy – but would entirely miss negative scores, having thus a null $\mathcal{A}^-$ recall. Hence, a more appropriate baseline for recall of unsatisfied users is that of a uniform random selection.

Fig. 3 reports a confusion matrix, additionally highlighting the average accuracy, precision and recall of the unsatisfied users. Results are gathered on all the 115 collected features with a 20-trees random forest [13] on a 10-fold validation using 80% of the samples for training. We obtain very similar results with XGBoost [17], with a slightly higher accuracy but lower $\mathcal{A}^-$ recall, which we do not report to avoid cluttering the pictures. Prediction outcome is clearly deceiving and only slightly better than the naïve baseline, despite the relatively large number of features collected: only 62%

[3]We prefer to avoid the diametrically opposite approach of synthetically generating users score, which is in stark contrast with the very same nature of our work.

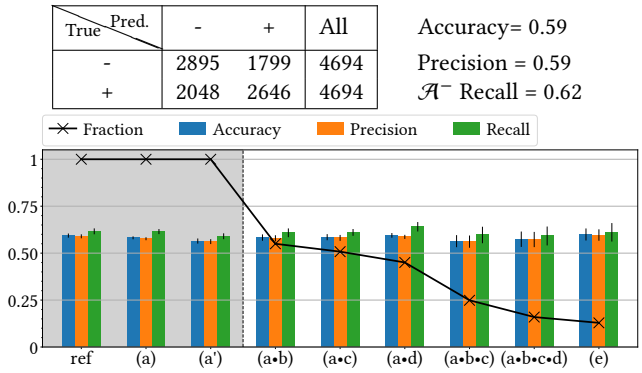

Figure 3: Classification results: Confusion matrix for all collected features as a reference (top) and performance obtained by limiting the (a) 61 available features, (a') 26 features of the performance class, and restricting the attention to (b) Chrome-only browser, (c) Russian population (d) Android OS and (e) top-1000 pages (and combinations thereof).

of the unsatisfied users are correctly captured, with a precision of 0.59. Interestingly, not shown in the picture, performance on the *remaining dataset*, i.e., the set of positive scores filtered out due to class imbalance, remains consistent with an accuracy of 0.65.

Feature subsampling: We next consider how the classification results change with respect to the above reference when considering only the 61/115 publicly available features, which is shown in Fig. 3-(a): as expected, since features in the available set are fewer but with better mutual information, classification results are practically unaffected. We reduce this set even further by only considering the 26 features of the performance class in (a'), which shows a slightly higher, but still very limited, reduction of classification performance: on the one hand, performance-related features consistently rank high in terms of Gini importance, though on the other hand they lack discriminative power for telling user answers apart.

Dataset subsampling: We finally spatially condition the dataset, investigating whether classification performance mechanically improves by reducing the heterogeneity in the dataset, in an attempt to recreate more homogeneous conditions as usually done in the lab studies. Particularly, (a·b) uses publicly available features and restrict the attention to the most popular browser, namely Chrome, considering both mobile and desktop flavors. In (a·c) we instead restrict to users of the prevalent country, and in (a·d) to Android users. We also combine these filters altogether (a·b·c) and (a·b·c·d), and finally consider (e) the top-1000 pages in our dataset. Clearly, conditioning the dataset implies that a smaller fraction of original dataset is available, which we also have to re-balance (solid black line in Fig. 3): in turn, confidence intervals for the metrics of interest increase for decreasing dataset fractions, which is expected. Yet, it is easy to gather that classification performances are only minimally affected in all the above cases, so that the state-of-the performance metrics we collect are apparently not enough to discriminate satisfied vs unsatisfied users.

5 DISCUSSION

In this paper we engineer, collect and (plan to) share at [7, 8] user survey scores pertaining to the quality of their Web browsing experience. Out of over 1.7 million queries, we gather over 62k answers corresponding to either positive (84.8%), neutral (7.7%) or negative (7.5%) experiences. We then develop data driven models to predict user scores: under this angle, the most important (and equally disturbing) takeaway is that it is surprisingly hard to predict even a very coarse-grained indication of user satisfaction. This can be tied in part to the lack of more informative indicators in our dataset, and also raises a number of interesting community-wide challenges, which we discuss next.

Collection and validation methodologies: We remark that this work is the first to collect user feedback from real users in real browsing activity, from an operational deployment. This is in stark contrast with most lab research, where volunteers or crowdworkers are exposed to a very limited heterogeneity (e.g., single device/browser), are not carrying on a browsing activity (e.g., A/B testing uses videos) and are not asked about their satisfaction but about other metrics as a proxy (e.g., which video finished first?). We argue that lab/crowdsourcing experiments and collection in the wild should *coexist*. Particularly, we argue that surveys such as those we are carrying on should be kept *running continuously*, as it is commonplace for VoIP applications that regularly poll their users for a QoE opinion. Operating continuously would lower barriers for further experiments [10], empower website operators with a very relevant performance indicator for their service, informing them in near-real time about impact of new features deployment, and ultimately helping to ameliorate data-driven models.

RSI: not needed, or not enough ?: Concerning Web user QoE metrics, this study seems to suggest a poor discriminative power of the RumSpeedIndex (RSI) so as to predict users scores, at least for Wikipedia users. In part, this may be due to the structure of Wikipedia pages (where, e.g., text may be more prevalent that in other pages in the Alexa top 100 typically considered in similar studies, see §2), which nevertheless raises the question so as to whether it is possible to design more specific metrics that are better fit to the spatial structure of any given page.

Per-device statistics: Given that "computation activities are the main bottleneck when loading a page on mobile browsers" [34], collecting per-device statistics [19] seems a mandatory step. Unfortunately, average per-device performance we considered in this work are not telling enough, as they merely report the resource *upper-bound* (i.e., CPU and RAM capacity) as opposite to the *actual state* of the device (i.e., free RAM and available CPU cycles) corresponding to the page view that the user answered about – which could hopefully ameliorate prediction performance.

ACKNOWLEDGEMENTS

We thank Tilman Bayer, Leila Zia and Nuria Ruiz from the Wikimedia Foundation and Saint Johann from the Russian Wikipedia community, whose input and help shaped this work.

Genre Differences of Song Lyrics and Artist Wikis: An Analysis of Popularity, Length, Repetitiveness, and Readability

markus.schedl@jku.at

ABSTRACT

Music is known to exhibit different characteristics, depending on genre and style. While most research that studies such differences takes a musicological perspective and analyzes acoustic properties of individual pieces or artists, we conduct a large-scale analysis using various web resources. Exploiting content information from *song lyrics*, contextual information reflected in *music artists' Wikipedia articles*, and listening information, we particularly study the aspects of *popularity*, *length*, *repetitiveness*, and *readability* of lyrics and Wikipedia articles. We measure popularity in terms of song play count (PC) and listener count (LC), length in terms of character and word count, repetitiveness in terms of text compression ratio, and readability in terms of the Simple Measure of Gobbledygook (SMOG). Extending datasets of music listening histories and genre annotations from Last.fm, we extract and analyze 424,476 song lyrics by 18,724 artists from LyricWiki.

We set out to answer whether there exist significant genre differences in song lyrics (RQ1) and artist Wikipedia articles (RQ2) in terms of repetitiveness and readability. We also assess whether we can find evidence to support the cliché that lyrics of very popular artists are particularly simple and repetitive (RQ3). We further investigate whether the characteristics of popularity, length, repetitiveness, and readability correlate within and between lyrics and Wikipedia articles (RQ4).

We identify substantial differences in repetitiveness and readability of lyrics between music genres. In contrast, no significant differences between genres are found for artists' Wikipedia pages. Also, we find that lyrics of highly popular artists are repetitive but not necessarily simple in terms of readability. Furthermore, we uncover weak correlations between length of lyrics and of Wikipedia pages of the same artist, weak correlations between lyrics' reading difficulty and their length, and moderate correlations between artists' popularity and length of their lyrics.

KEYWORDS

music listening behavior; song lyrics; repetitiveness; readability; Last.fm; Wikipedia; analysis

1 INTRODUCTION

The way music is created and consumed has substantially changed over time. Various music genres and styles have evolved, prospered, and disappeared again from public knowledge and appreciation. Existing research studying differences in genre and style commonly takes a musicological perspective and analyzes acoustic properties of individual pieces, such as rhythm, dynamics, melody, harmony, and timbre. While being a valid approach, it foregoes exploiting the abundance of web-based data sources that provide information on music pieces and artists.

In contrast, we conduct a large-scale analysis of almost half a million songs by artists of a variety of genres (given by a commercial genre taxonomy and a user-generated genre folksonomy). Extracting content information from lyrics, contextual information provided in artists' Wikipedia articles, and combining these with listening information, we set out to study the characteristics and interplay of *popularity*, *length*, *repetitiveness*, and *readability* of lyrics and Wikipedia articles.

More precisely, we formulate and investigate the following research questions:
RQ1: Can we observe (and if so describe) significant genre differences in song lyrics with regard to repetitiveness and readability?
RQ2: Can we observe (and if so describe) significant genre differences in artist Wikipedia pages with regard to repetitiveness and readability?
RQ3: Is there evidence to support the cliché that lyrics of very popular artists are particularly simple and repetitive?
RQ4: Can we observe (and if so describe) significant correlations between characteristics of lyrics and Wikipedia articles, notably popularity, length, repetitiveness, and readability?

The answers to these RQs will help gaining a better understanding of the role of genre and popularity when characterizing music by content (lyrics) and context (Wikis) information. The results will further allow to ameliorate user preference models by incorporating respective characteristics, and in turn improve personalized music access systems such as information retrieval or recommendation systems. For instance, together with sociodemographic information of music listeners, e.g., provided in the LFM-1b datasets [9, 10, 12], the findings of the study at hand could

Table 1: Statistical summaries of properties of song lyrics (L) and Wikipedia pages of music artist (W).

be used to create country-specific user models of lyrics preferences. Similar to previous work that showed superior performance of culture-aware music recommender systems that integrate descriptors of country-specific music mainstream [11], integrating user models of lyrics preferences could outperform methods that are unaware of this kind of information.

In the remainder of this article, we discuss related literature (Section 2), detail the data sources and data acquisition procedure we base our study upon (Section 3), describe the methodology we use to characterize lyrics and Wikipedia articles (Section 4), elaborate on our study to approach the RQs and discuss its results (Section 5), and conclude including further perspectives (Section 6).

2 RELATED WORK

Previous work on dynamics of music characteristics on a scale larger than individual pieces or artists has predominantly focused on the temporal evolution of music properties, investigating acoustic content features (e.g., rhythm, melody, harmony, and timbre). The analysis is commonly performed on datasets of several hundreds to thousands of music pieces only, and is often biased towards highly popular songs that appeared in the charts.

For instance, Schellenberg and von Scheve [13] investigate the evolution of tempo and key (major or minor) for about 1,000 top-40 songs in the charts, covering 25 years. They find a trend of increasing use of minor key (commonly perceived sadder than major key) and decrease in tempo. They also discover an increase in song duration and proportion of female artists over the years.

Mauch et al. [6] investigate 17,094 songs that appeared in the Billboard Hot 100 charts, covering the years 1960 to 2010. They compute harmonic and timbre features from the audio and apply a topic modeling approach (latent Dirichlet allocation), as a result of which each song is described as a mixture over eight chord progression clusters (topics) and eight timbral clusters. The authors report a strong and continuous decline over time of the topic reflecting dominant 7^{th} chords (often found in Jazz and Blues) and a tremendous increase of music with no clear chord structure in the early 1990s (corresponding to the rise of Hip-Hop and Rap music). This rise is also reflected in a timbral topic that characterizes music as "energetic", "speech", and "bright". Another timbral topic described as "guitar", "loud", and "energetic" reflects the predominance of Arena Rock bands in the 1980s, for instance, Kiss, Queen, and Bon Jovi.

Conducting a large-scale analysis, Serrà et al. [14] examine pitch, timbre, and loudness of 464,411 music pieces recorded between 1955 and 2010. The authors uncover a tendency of simpler pitch sequences (less complex melodies), increasing loudness levels during mastering (lower volume dynamics), and homogenization of timbre (fewer variety in sound color or texture) over the course of time.

Also song lyrics have been an object of study. They are investigated, for instance, by DeWall et al. [1]. The authors consider lyrics of the 10 most popular songs on the Billboard Hot 100 year-end charts, released between 1980 and 2007. They perform several linguistic analyses and find that the use of first person singular pronouns ("I", "me", etc.) increased over time, whereas the use of first person plural pronouns ("we", "our", etc.) decreased; concluding an increase in narcissism. Furthermore, the authors identify a decrease of words related to social interactions ("sharing", "talking", etc.), an increase of words expressing anger and antisocial behavior ("hate", "kill", etc.), and a decrease of words expressing positive emotions ("love", "happy", etc.) over time.

Morris [7] investigates lyrics of 15,000 songs from the Billboard Hot 100 between 1958 and 2017. Similar to our approach, the author measures repetitiveness in terms of how well lyrics can be compressed. He identifies Rihanna, Britney Spears, and Beyoncé as the artists with the most repetitive lyrics (they can be compressed by $\geq 60\%$), whereas lyrics by Frank Sinatra, Elvis Presley, and Brad Paisley can be compressed by the least amount ($\leq 38\%$).

A study of album reviews by Amazon customers on the large scale is conducted by Oramas et al. [8], who analyze 263,525 user reviews of 65,566 albums. They investigate the evolution of sentiments expressed in reviews between 2000 and 2014, using as features degree of affectivity, fraction of positive words among all words, and emotion strength. The authors do not find a clear temporal trend or pattern in reviews with regard to sentiment, except for a peak in 2008 which they try to explain with the election of Barack Obama as US president. Categorizing the reviews according to album release year (1960 to 2014) instead of review publication year, they further discuss the evolution of the two genres Pop and Reggae. While for the former review sentiments have been very stable over the years, positive sentiments in Reggae album reviews peaked between the late 1970s and the mid 1980s.

In contrast to existing work, we take a larger variety and amount of music into account by not only focusing on popular music or chart songs, but considering songs listened to by a large web community of music aficionados, i.e., users of Last.fm. Furthermore, we jointly investigate characteristics of musical content (lyrics) and contextual information (Wikipedia articles). We also refrain from investigating the temporal evolution of these characteristics, instead we provide an analysis of their differences between music genres according to genre definitions of coarse and of fine granularity.

3 DATA ACQUISITION

We base our study on the LFM-1b dataset [9, 10], which contains roughly 1.09 billion listening events scrobbled[1] between 2005 and

[1]Among Last.fm users it is common to use the term "scrobble" to indicate that a music piece has been listened to and to share this information with other users.

2014 by more than 120,000 Last.fm users. Last.fm is one of the largest online music streaming platforms and provides various connectors to other services, including Spotify, Pandora, iTunes, and Youtube, through which users can share what they are listening to.[2]

To analyze genre differences, we obtain **genre** information about artists using the *LFM-1b User Genre Profile* (LFM-1b UGP) dataset [12], which describes each artist by one or several genre and style annotations. In this dataset, two different dictionaries of genres/styles are considered: 20 broad (expert-defined) genres from the commercial music guide Allmusic[3] and 1,998 fine-grained (user-defined) musical style descriptors from Freebase.[4]

3.1 Acquiring Song Lyrics

For the 585,095 artists in the LFM-1b dataset, we gather the top tracks (most frequently listened to by Last.fm users as of January 2017), using the Last.fm API.[5] We then fetch the corresponding song lyrics from LyricWiki.[6] To obtain reliable results for the subsequent readability scoring, which is tailored to the English language, we next perform automatic language detection of the lyrics, using Google's language detection library,[7] which is reported to reach almost 100% precision for English using a naïve Bayes classifier trained on Wikipedia abstracts. Furthermore, to obtain significant results on the artist level, we only consider artists for which we could acquire at least 10 different song lyrics. This filtering eventually yields a dataset of 424,476 song lyrics by 18,724 artists.

3.2 Acquiring Artist Wikipedia Articles

For the 18,724 artists for which we could acquire (English) lyrics of at least 10 songs, we fetch the textual content of English Wikipedia articles (as of October 2018), using the Python wrapper Wikipedia-API.[8] To alleviate disambiguation issues and increase precision when retrieving Wikipedia articles, we use several keyword-based heuristics, e.g., identifying disambiguation pages or requiring that the first sentence contains at least one music-related term.[9] Following this approach, we eventually obtain 11,363 Wikipedia articles.

To ensure reproducibility of our study, the used datasets can be shared upon request. Please contact the author of the paper on this matter.

4 CHARACTERIZING LYRICS AND WIKIPEDIA ARTICLES

We adopt the following scoring approaches to quantify popularity, length, repetitiveness, and readability of lyrics and Wikipedia articles.

[2]https://www.last.fm/about/trackmymusic
[3]https://www.allmusic.com
[4]https://developers.google.com/freebase
[5]https://www.last.fm/api/show/artist.gettoptracks
[6]http://lyrics.wikia.com/Lyrics_Wiki
[7]https://code.google.com/archive/p/language-detection
[8]https://pypi.org/project/Wikipedia-API
[9]After manual inspection of hundreds of Wikipedia pages about music artists, we identified a set of terms at least one of which is used in (almost) every music artist-related page. These words include *music*, *band*, *singer*, *songwriter*, *musician*, *entertainer*, *rapper*, and *DJ*.

4.1 Measuring Popularity

To quantify artist popularity, we aggregate all listening events in the LFM-1b dataset for each artist and compute **play count (PC)** and **listener count (LC)** values, the former referring to the total number of listening events the respective artist attracted, the latter to the number of unique users who listened to the respective artist (at least once).

4.2 Measuring Length

To characterize an artist a's lyrics in terms of length, we compute the arithmetic mean of the number of **characters** and **words** in all song lyrics gathered for a. To describe a's Wikipedia article, we use the same two measures.

4.3 Measuring Repetitiveness

In order to approximate how repetitive a song's lyrics are, we adopt the idea that repetitiveness can be approximated by how much one can compress a text, applied to song lyrics by Morris [7]. More precisely, we use the deflation variant of the LZ77 algorithm [16] provided by the zlib library.[10] For each song, we compute the compressed length in characters of its lyrics and relate it to the uncompressed length, i.e., we compute the lyrics' **compression ratio (CR)**. We then define the repetitiveness score of an artist as the arithmetic mean of the CR of the artist's songs' lyrics in the dataset.

4.4 Measuring Readability

To assess the readability of lyrics, we use the **Simple Measure of Gobbledygook (SMOG)** [5]. It estimates the years of education required to comprehend the text under consideration and has frequently been validated empirically for English documents [2, 15]. Similar to the CR score, we define readability on the artist level as arithmetic mean of the SMOG scores of the artist's lyrics.

5 ANALYSIS AND RESULTS

A general statistical summary of popularity, length, repetitiveness, and readability scores, for both lyrics and Wikipedia articles, computed over all artists, is provided in Table 1. We observe, not surprisingly, that repetitiveness of lyrics (L_CR) is considerably higher on average than that of Wikipedia articles (W_CR), respectively, 58% vs. 50%. However, lyrics are less stable in this regard (standard deviation of 7% vs. 4%). In terms of readability, lyrics (L_SMOG) are slightly more difficult to understand than Wikipedia articles (W_SMOG), cf. SMOG score of 13 vs. 11, observing again less stability for lyrics (standard deviation of 3 vs. 1).

5.1 Genre Differences

Detailing the approach and results of our investigations to answer the RQs, we first focus on the question of genre differences in lyrics (**RQ1**) and Wikipedia articles (**RQ2**), with respect to the repetitiveness and readability scores. To this end, we illustrate in Tables 2 and 3 the means and standard deviations of CR and SMOG scores, for lyrics and Wikipedia articles, respectively, using the coarse genre taxonomy of Allmusic and the fine-grained Freebase folksonomy.

[10]http://www.zlib.net

Table 2: Compression ratio (CR) and readability score (SMOG) of lyrics and Wikipedia pages per genre, using the Allmusic genre taxonomy. Higher values of means are depicted in darker shades of green; higher values of standard deviations in darker shades of blue.

		Lyrics				Wiki			
		CR		SMOG		CR		SMOG

Pop	5322	60.40	6.18	12.48	2.71	50.77	3.90	11.36	1.20
Electronic	2623	59.98	7.81	12.47	3.04	50.44	4.27	11.51	1.32
Folk	2372	57.89	5.94	12.33	2.56	50.56	3.58	11.57	1.20
Punk	2321	58.22	7.48	12.21	2.85	50.91	3.72	11.30	1.28
Jazz	1336	59.09	6.48	12.50	2.92	50.90	3.42	11.59	1.17
Blues	1318	59.16	5.24	12.11	2.56	51.33	3.26	11.60	1.11
RnB	1169	62.83	5.57	13.01	2.61	51.42	3.78	11.31	1.04
Rap	1057	58.36	6.76	13.65	3.20	50.61	4.36	11.27	1.23
Heavy Metal	968	57.13	7.37	12.86	3.31	51.02	4.17	11.59	1.26
Country	866	58.72	5.01	12.44	2.45	50.80	3.52	11.53	1.10
Easy Listening	769	60.59	5.01	12.53	2.50	51.21	3.42	11.44	1.04
Vocal	637	59.85	5.78	12.38	2.69	50.64	3.81	11.35	1.19
Mean		**59.30**		**12.56**		**50.85**		**11.45**	

Considering the *Allmusic* genres, Table 2 reveals that RnB lyrics show the highest repetitiveness (CR of 62.83%), and they do so consistently (one of the lowest standard deviations of 5.57%). On the other hand, Heavy Metal lyrics are found to be least repetitive (CR of 57.13%), however, not consistently between this genre's artists (high standard deviation of 7.37%). As for readability, understanding Rap lyrics by far requires the highest reading capabilities (SMOG of 13.65), whereas Punk and Blues lyrics are the easiest to comprehend (SMOG of ≈12). For Wikipedia articles, no substantial differences between music genres in terms of CR and SMOG are observable when using the Allmusic taxonomy.

Investigating the results obtained with the fine-grained *Freebase* genres (Table 3), we observe highest repetitiveness for lyrics in the genres Dance and Electropop (both CR of ≈63%). In contrast, lowest CR is observed for Death metal and Hardcore punk (both CR of ≈53%). The most consistent genres in terms of CR are Soft rock, Americana, and Rock and Roll (all standard deviation of CR <5%). The genres whose lyrics require the highest reading grades are Hip-Hop, Death metal, and Progressive metal (all SMOG >13). Easiest to understand are lyrics of the genres Post-rock, Psychedelic rock, and Dream pop (all SMOG <11.5). As for artist Wikipedia pages, analogous to the Allmusic taxonomy, both repetitiveness and readability scores occupy a quite narrow range: CR between 49.45 for Indie folk and 52.02 for Classic rock; SMOG between 10.99 for Pop punk and 12.25 for Avant-garde.

5.2 Differences for Popular Artists

To investigate the cliché that song lyrics of very popular artists are particularly simple and repetitive (**RQ3**), we compare the top 20 artists in the LFM-1b dataset (popularity measured in terms of LC) with all other artists in the set. Table 4 depicts the corresponding

Table 3: CR and SMOG using the Freebase genre folksonomy.

popularity, length, repetitiveness, and readability scores. It further shows the means of these scores computed over all artists in the dataset (in row "Overall mean").

We observe several pronounced differences between the top artists as well as between the top artists and all artists (overall means). To assess statistical significance of these differences, we conduct a t-test for equivalence of sample means, comparing the top artists with the other artists in terms of each property. The respective p-values are shown in the last row of Table 4, results significant ($p < 0.001$) highlighted. With respect to RQ3, indeed, the top artists' lyrics are significantly more repetitive (higher CR values) than others' lyrics. No significant difference can be observed, however, for readability nor length of lyrics. Differences for Wikipedia articles are highly significant for length, CR, and SMOG scores.

5.3 Correlations Between Characteristics

Concerning correlations between popularity, length, repetitiveness, and readability within and between lyrics and Wikipedia pages (**RQ4**), we compute over all artists in the dataset Spearman's rank-order correlation coefficient ρ to cope with the different value ranges of the respective measures. The correlation figures are reported in Table 5; statistically significant values at $p < 0.001$ are highlighted. We observe that, while significant, most non-obvious[11] correlations are only weak. In particular, we see that artist popularity does barely correlate with lyrics length ($0.02 < \rho < 0.09$), but does weakly to moderately correlate with Wikipedia article length ($0.33 < \rho < 0.37$). Supporting the findings from our analysis of top artists (RQ3; cf. Section 5.2 and Table 4), also over all artists in the dataset, popularity is (weakly, but significantly) positively correlated with repetitiveness; however, only when measuring popularity in terms of listener count ($\rho \approx 0.15$). Almost no correlation can be found for play count ($\rho \approx 0.05$). This might be because artists with more repetitive lyrics may appeal to a larger variety of listeners (reflected in the LC value) than those with less repetitive lyrics, whereas the latter are listened to more frequently by a smaller number of listeners (reflected in the PC value).

Readability difficulty of lyrics shows a tendency to slightly increase with their length ($0.29 < \rho < 0.32$); the same holds for Wikipedia readability and length ($0.34 < \rho < 0.36$). We exemplify this observation by considering the genres Rap and Hip-Hop, which are among those with highest SMOG scores (cf. Tables 2 and 3) and at the same time show highest lyrics length: the average length of a Rap song's lyrics is 2,099 characters or 414 words, that of a Hip-Hop song equals 1,921 characters or 381 words. In contrast, over all genres, the average lyrics length is 1,151 characters or 229 words.

Furthermore, weak cross-category correlations (between lyrics and Wikipedia pages) exist between length of lyrics and length of Wikipedia pages ($0.21 < \rho < 0.22$). It seems that artists whose songs have longer lyrics stimulate a slightly higher level of activity or dedication of Wikipedia authors than those with shorter lyrics.

[11] Not surprisingly, popularity measures (PC and LC) as well as length measures (characters and words) strongly correlate. Medium correlations exist between compression ratio and length of lyrics; strong to very strong between CR and length of Wikipedia pages.

6 CONCLUSIONS AND FUTURE WORK

We performed a large-scale analysis of more than 420,000 song lyrics and more than 10,000 Wikipedia pages about music artists, statistically investigating popularity, length, repetitiveness, readability, as well as their correlations. We identified substantial differences in repetitiveness and readability of lyrics between genres, most pronounced when using a fine-grained genre folksonomy. For artist Wikipedia pages, no substantial differences between genres were observable, regardless of the used genre taxonomy or folksonomy.

Evidence supporting the cliché that lyrics of very popular artists are particularly simple and repetitive could be found partially. On the one hand, compression rates of top artists' lyrics are indeed significantly higher than those of others, indicating a higher repetitiveness of those lyrics. On the other hand, this does not hold for readability. Therefore, our analysis showed that lyrics of top artists are repetitive but not necessarily simple in terms of readability.

As a matter of fact, there exist limitations of our study. In particular, community biases are likely to affect the distribution of data items (e.g., artist listening events on Last.fm or songs for which lyrics are available on LyricWiki). Last.fm users' artist and genre preferences which barely generalize to the population at large represent another form of community bias [4] our approach is prone to. Also the distribution of demographics of the involved web services' users is unlikely to correspond to that of the general population [3]. Being aware of these limitations (which we plan to reduce in future work), we nevertheless believe that our findings will enable a better understanding of the role of genre and popularity when characterizing music by content (lyrics) and context (Wikis) information. Integrated into user models, the investigated lyrics and Wiki characteristics may also improve personalized music retrieval and recommendation systems.

Future work will include investigating additional data sources such as artist fan pages or album reviews. Also, while we currently only use the (text) content of Wikipedia's artist pages, metadata about the pages could be included in the investigation, e.g., the number of revisions or contributors to the Wikipedia page. In addition, further features could be defined and analyzed, for instance related to emotion or sentiment expressed in lyrics, Wikis, reviews, etc. Another avenue for further studies is to consider user-specific characteristics, including age, gender, culture, education, knowledge, or personality, and to investigate to which extent the preference for certain categories of songs or artists (described by content and context features) is reflected in such user characteristics.

ABSTRACT

This paper proposes an attributed network growth model. Despite the knowledge that individuals use limited resources to form connections to similar others, we lack an understanding of how local and resource-constrained mechanisms explain the emergence of structural properties found in real-world networks. We make three contributions. First, we propose a simple and accurate model of attributed network growth that jointly explains the emergence of in-degree, local clustering, clustering-degree relationship and attribute mixing patterns. Second, we make use of biased random walks to develop a model that forms edges locally, without recourse to global information. Third, we account for multiple sociological phenomena: bounded rationality; structural constraints; triadic closure; attribute homophily; preferential attachment. Our experiments show that the proposed Attributed Random Walk (ARW) model accurately preserves network structure and attribute mixing patterns of real-world networks; it improves upon the performance of eight well-known models by a significant margin of 2.5–10×.

1 INTRODUCTION

We present a network growth model that explains how distinct structural properties of attributed networks can emerge from a local edge formation process. In real-world networks, individuals form edges with limited information and partial network access. Moreover, phenomena such as triadic closure and homophily simultaneously influence individuals' decisions to form connections. Over time, these decisions cumulatively shape real-world networks to exhibit rich structural properties: heavy-tailed in-degree distribution, skewed local clustering and diverse attribute mixing patterns. However, we lack an understanding of local, resource-constrained mechanisms that incorporate sociological factors to jointly explain the emergence of multiple structural properties. Additionally, accurate network growth models are useful for synthesizing networks and extrapolating existing real-world networks.

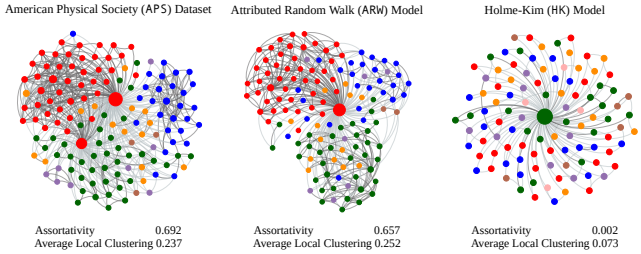

Figure 1: We contrast our proposed model, Attributed Random Walk (ARW), with a non-attributed growth model [20] to underscore the importance of using attributes for network growth.

Well-known models of network growth tend to make unrealistic assumptions about how individuals form edges. Consider a simple stylized example: the process of finding a set of papers to cite when writing an article. In preferential attachment [3] or fitness [5, 10, 43] based models, a node making m citations would pick papers from the *entire* network in proportion to their in-degree or fitness respectively. This process assumes that individuals possess complete knowledge of in-degree or fitness of every node in the network. An equivalent formulation—vertex copying [25]—induces preferential attachment: for every citation, a node would pick a paper uniformly at random from *all* papers, and either cite it or copy its citations. Notice that vertex copying assumes individuals have complete access to the network and form each edge independently. Although these models explain the emergence of power law degree distributions, they are unrealistic: preferential attachment and vertex copying require global node-level knowledge and complete network access respectively. Additionally, they do not account for the role of assortative mixing [35] via nodal attributes (e.g., venue of paper, political interests of Facebook users) in network formation.

Recent papers account for resource constraints [32, 44, 45] and nodal attributes [12, 17]. However, the former disregard attributes and the latter do not provide a realistic representation of edge formation under constraints. Furthermore, both sets of models do not jointly preserve multiple structural properties.

We aim to develop a growth model that accounts for resource constraints and sociological phenomena influencing edge formation in addition to preserving global network structure. We make three key contributions. First, we propose a simple and accurate model of attributed network growth. Second, our model is based on local processes to form edges, without recourse to global network information. Third, our model unifies multiple sociological phenomena—bounded rationality; structural constraints; triadic

closure; attribute homophily; preferential attachment—to jointly model global network structure and attribute mixing patterns.

The proposed model—Attributed Random Walk (ARW)—jointly explains the emergence of in-degree distribution, local clustering, clustering-degree relationship and attribute mixing patterns through a resource constrained mechanism based on random walks (see Figure 1). In particular, the model relies entirely on local information to grow the network, without access to information of all nodes. In ARW, incoming nodes select a seed node based on attribute similarity and initiate a biased random walk: at each step of the walk, the incoming node either jumps back to its seed or chooses an outgoing link or incoming link to visit another node; it links to each visited node with some probability and halts after it has exhausted its budget to form connections. Our experiments on six large-scale network datasets indicate that the proposed growth model outperforms eight state-of-the-art network growth models by a statistically significant margin of 2.5–10×.

The rest of the paper is organized as follows. We begin by defining the problem statement in Section 2. In Section 3, we outline six network datasets, describe key structural properties of real-world networks and discuss insights from sociological studies. Then, in Section 4, we describe the network growth model. Then, We present experiments in Section 5, discuss related work in Section 6 and conclude in Section 7.

2 PROBLEM STATEMENT

Consider an attributed directed network $G = (V, E, B)$, where V & E are sets of nodes & edges and each node has an attribute value $b \in B$. The goal is to develop a directed network growth model that preserves structural and attribute based properties observed in G. The growth model should be normative, accurate and parsimonious:

(1) **Normative**: The model should account for multiple sociological phenomena that influence how individuals form edges under constraints of limited global information and partial network access.
(2) **Accurate**: The model should preserve key structural and attribute based properties: degree distribution, local clustering, degree-clustering relationship and attribute mixing patterns.
(3) **Parsimonious**: The model should be able to generate networks with tunable structural properties, while having few parameters.

Next, we present empirical analysis on real-world datasets to motivate our attributed random walk model.

3 EMPIRICAL ANALYSIS

We first describe six large-scale network datasets. Then, we describe global network properties, insights from empirical studies and common assumptions in network modeling.

3.1 Datasets

We consider six citation networks of different scales (size, time) from diverse sources: research articles, utility patents and judicial cases. Table 1 lists their summary statistics and global network properties. Three of the six datasets are attributed networks; that is, each node has a categorical attribute value.

We focus on citation networks for two reasons. First, since nodes in citation networks form all outgoing edges to existing nodes at the time of joining the network, these datasets provide a clean basis to study edge formation in attributed networks. Second, the node-level, temporal information in datasets that span long time periods (e.g. USSC) enables us to study structural properties at different time stages via network snapshots. Next, we study the structural and attribute properties of these networks.

3.2 Global Network Properties

Statistical descriptors of network properties [33] such as degree distribution, local clustering, and attribute assortativity quantify the extent to which edge formation shapes global network structure.

Degree distribution: Real-world networks tend to exhibit heavy tailed degree distributions in which a small but significant fraction of the nodes turn into high-degree hubs. We observe that Log-normal fits, with parameters listed in Table 1, well describe the in-degree distributions, consistent with Broido and Clauset's [9] observation that scale-free, real-world networks are rare.

Local Clustering: Real-world networks exhibit high local clustering (LCC), as shown in Table 1. Local clustering can arise from triadic closure [34, 39], where nodes with common neighbor(s) have an increased likelihood of forming a connection. The coefficient of node i equals the probability with which two randomly chosen neighbors of the node i are connected. In directed networks, the neighborhood of a node i can refer to the nodes that link to i, nodes that i links to or both. We define the neighborhood to be the set of all nodes that link to node i. In Figure 2, we show that (a) average

Table 1: Summary statistics & global properties of six network datasets: $|V|$ nodes join the networks and form edges $|E|$ over time period T. In attributed networks, each node has a categorical attribute value that belongs to set A of size $|A|$. The networks exhibit lognormal (LN) in-degree distribution with mean μ and standard deviation σ, high average local clustering (LCC) & attribute assortativity (AA) coefficient and densify over time with densification power law (DPL) exponent α.

Network	Description	$\|V\|$	$\|E\|$	T	A, $\|A\|$	LN (μ, σ)	DPL α	Avg. LCC	AA r
USSC [14]	U.S. Supreme Court cases	30,288	216,738	1754-2002	-	(1.19, 1.18)	2.32	0.12	-
HEP-PH [15]	ArXiv Physics manuscripts	34,546	421,533	1992-2002	-	(1.32, 1.41)	1.67	0.12	-
Semantic [2]	Academic Search Engine	7,706,506	59,079,055	1991-2016	-	(1.78, 0.96)	1.58	0.06	-
ACL [36]	NLP papers	18,665	115,311	1965-2016	VENUE, 50	(1.93, 1.38)	1.43	0.07	0.07
APS [1]	Physics journals	577,046	6,967,873	1893-2015	JOURNAL, 13	(1.62, 1.20)	1.26	0.11	0.44
Patents [27]	U.S. NBER patents	3,923,922	16,522,438	1975-1999	CATEGORY, 6	(1.10, 1.01)	1.94	0.04	0.72

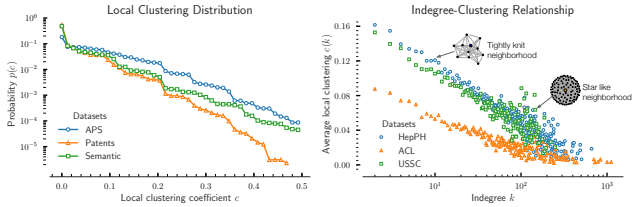

Figure 2: Real-world networks exhibit skewed local clustering distribution (left subplot) and a negatively correlated relationship between in-degree and average local clustering (right subplot).

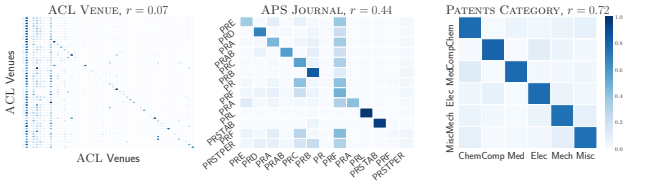

Figure 3: Attributed networks ACL, APS and Patents exhibit homophily w.r.t attributes Venue ($r = 0.07$), Journal ($r = 0.44$) and Category ($r = 0.72$) respectively.

local clustering is not a representative statistic of the skewed local clustering distributions and (b) real-world networks exhibit a negative correlation between in-degree and clustering. That is, low in-degree nodes have small, tightly knit neighborhoods and high in-degree nodes tend have large, star-shaped neighborhoods.

Homophily: Attributed networks tend to exhibit homophily [29], the phenomenon where similar nodes are more likely to be connected than dissimilar nodes. The assortativity coefficient [35] $r \in [-1, 1]$, quantifies the level of homophily in an attributed network. Intuitively, assortativity compares the observed fraction of edges between nodes with the same attribute value to the expected fraction of edges between nodes with same attribute value if the edges were rewired randomly. In Fgiure 3, we show that attributed networks ACL, APS and Patents exhibit varying level of homophily with assortativity coefficient ranging from 0.07 to 0.72.

Increasing Out-degree over Time: The out-degree of nodes that join real-world networks tends to increase as functions of network size and time. This phenomenon densifies networks and can shrink effective diameter over time. Densification tends to exhibit a power law relationship [27] between the number of edges $e(t)$ and nodes $n(t)$ at time t: $e(t) \propto n(t)^{\alpha}$. Table 1 lists the densification power law (DPL) exponent α of the network datasets.

To summarize, citation networks tend to be homophilic networks that undergo accelerated network growth and exhibit regularities in structural properties: heavy tailed in-degree distribution, skewed local clustering distribution, negatively correlated degree-clustering relationship, and varying attribute mixing patterns.

3.3 Insights from Sociological Studies

Sociological studies on network formation seek to explain how individuals form edges in real-world networks.

Interplay of Triadic Closure and Homophily: Empirical studies [6, 24] that analyze the interplay between triadic closure and homophily indicate that *both* structural proximity and homophily are statistically significant factors that simultaneously influence edge formation. Homophilic preferences [29] induce edges between similar nodes, whereas structural factors such as network distance limit edge formation to proximate nodes (e.g. friend of a friend).

Bounded Rationality: Extensive work [16, 28, 40] on decision making shows that individuals are boundedly rational actors; constraints such as limited information, cognitive capacity and time impact decision making. This suggests that resource-constrained individuals that join networks are likely to employ simple rules to form edges using limited information and partial network access.

Current preferential attachment and fitness-based models [3, 13, 41] make two assumptions that are at variance with these findings. First, by assuming that successive edge formations are independent, these models disregard the effect of triadic closure and structural proximity. Second, as discussed in section 1, these models require complete network access or knowledge of node-level properties.

Insights from sociological studies indicate that edge formation in real-world networks comprises biases towards nodes that are similar, well-connected or structurally proximate. Coupled with empirical analyses, it also motivates the need to model how resource-constrained edge formation processes collectively shape global network properties of large-scale networks over time.

4 ATTRIBUTED RANDOM WALK MODEL

We propose an Attributed Random Walk (ARW) model to explain the emergence of key structural properties of real-world networks through entirely local edge formation mechanisms.

Consider a stylized example of how a researcher might go about finding relevant papers to cite. First, the researcher broadly identifies one or more relevant papers, possibly with the help of external information (e.g. Google Scholar). These initial set of papers act as seed nodes. Then, acting under time and information constraints, she will examine papers cited by the seed and papers that cite the seed. Thus, she navigates a chain of backward and forward references to identify similar, relevant papers. Next, through careful analysis, she will cite a subset of these papers. Similarly, users in online social networks might form new friendships by navigating their social circle (e.g., friends of friends) to find similar others.

ARW grows a directed network as new nodes join the network. The mechanism is motivated by the stylized example: an incoming node selects a seed node and initiates a random walk to explore the network by navigating through neighborhoods of existing nodes. It halts the random walk after connecting to a few visited nodes.

In this section, we describe the edge formation mechanisms underlying ARW, explain how ARW unifies multiple sociological phenomena, and discuss methods required to fit ARW to network data.

4.1 Model Description

The Attributed Random Walk (ARW) model grows a directed network $\{\hat{G}_t\}_{t=1}^{T}$ in T time steps. At every discrete time step t, a new node u, with attribute value $B(u)$, joins the network $\hat{G}_t$. After joining the network, node u forms $m(t)$ edges to existing nodes.

The edge formation mechanism consists of two components: Select-Seed and Random-Walk. As shown in Figure 4, an incoming node u with attribute value $B(u)$ that joins the network at time t first selects a seed node using Select-Seed.

Select-Seed accounts for homophilic preferences of incoming nodes using parameters p_{same} and p_{diff} to tune attribute preferences.

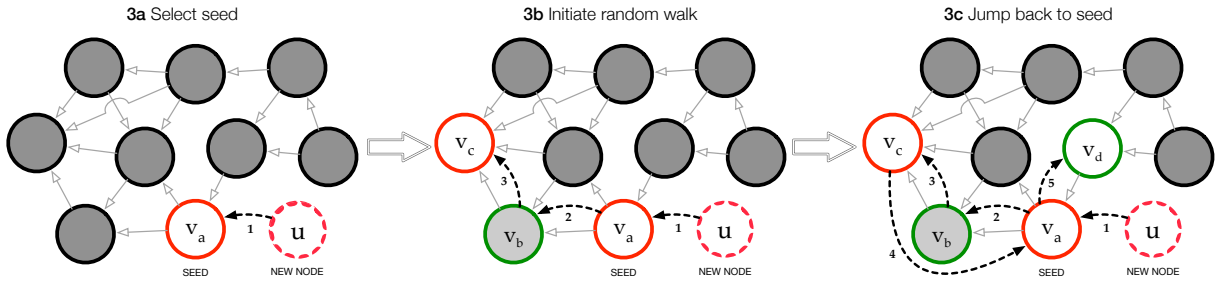

Figure 4: Edge formation in ARW: consider an incoming node u with outdegree $m = 3$ and attribute value $B(u) =$ RED $\in$ {RED, GREEN}. In fig. 3a, u joins the network and selects seed v_a via SELECT-SEED. Then, in fig. 3b, u initiates a RANDOM-WALK and traverses from v_a to v_b to v_c. Finally, u jumps back to its seed v_a and restarts the walk, as shown in fig. 3c. Node u halts the random walk after linking to v_a, v_c & v_d.

In Figure 4, node u selects a seed node and initiates a random walk using RANDOM-WALK to form $m(t)$ links.

> SELECT-SEED
>
> (1) With probability $p_{\text{same}}/p_{\text{same}}+p_{\text{diff}}$, randomly select a seed node from existing nodes that have the same attribute value, $B(u)$.
>
> (2) Otherwise, with probability $p_{\text{diff}}/p_{\text{same}}+p_{\text{diff}}$, randomly select a seed node from existing nodes that do *not* have the same attribute value, $B(u)$.

The RANDOM-WALK mechanism consists of four parameters: attribute-based parameters p_{same} & p_{diff} model edge formation decisions and the jump parameter p_{jump} & out-link parameter p_{out} characterize random walk traversals:

> RANDOM-WALK
>
> (1) At each step of the walk, new node u visits node v_i.
> - If $B(u) = B(v_i)$, u links to v_i with probability p_{same}
> - Otherwise, u links to v_i with probability p_{diff}
>
> (2) Then, with probability p_{jump}, u jumps back to seed s_u.
>
> (3) Otherwise, with probability $1 - p_{\text{jump}}$, u continues to walk. It picks an outgoing edge with prob. p_{out} *or* an incoming edge with prob. $1 - p_{\text{out}}$ to visit a neighbor of v_i.
>
> (4) Steps 1-3 are repeated until u links to $m(t)$ nodes.

When attribute data is absent, ARW simplifies further. A single link parameter p_{link} replaces both attribute parameters p_{same} & p_{diff}. SELECT-SEED reduces to uniform seed selection and in RANDOM-WALK, the probability of linking to visited nodes equals p_{link}.

Note that ARW has two exogenous parameters: the out-degree $m(t)$ and attribute $B(u)$ of incoming nodes. The attribute distribution varies with time as new attribute values (e.g., journals) crop up, necessitating an exogenous parameter. The parameter $m(t)$ is the mean-field value of out-degree m at time t in the observed network. While it is straightforward to model $m(t)$ endogenously by incorporating a densification power-law DPL exponent, exogenous factors (e.g., venue, topic) may influence node out-degree.

Next, we explain how each parameter is necessary to conform to normative behavior of individuals in evolving networks.

4.2 ARW and Normative Behavior

The Attributed Random Walk model unifies multiple sociological phenomena into its edge formation mechanisms.

Phenomenon 1. *(Limited Resources) Individuals are boundedly rational [16, 28, 40] actors that form edges under constraints of limited information and partial network access.*

As shown in Figure 4, RANDOM-WALK only requires information only about the 1-hop neighborhood of a few visited nodes, thereby accounting for the constraints of limited information and partial network access.

Phenomenon 2. *(Structural Constraints) Network distance act as a constraint that limits long-range connections. [24]*

We incorporate structural constraints using p_{jump}, the probability with which a new node jumps back to its seed node after every step of the random walk. This implies that the probability with which the new node is at most k steps from its seed node is $(1 - p_{\text{jump}})^k$; as a result, p_{jump} controls the extent to which nodes' random walks explore the network to form edges.

Phenomenon 3. *(Triadic Closure) Nodes with common neighbors have an increased likelihood of forming a connection. [39]*

When attribute data is absent, ARW controls the effect of triadic closure on link formation using p_{link} because with probability proportional to p_{link}^2, a new node u closes a triad through its random traversal by linking to both, a visited node and its neighbor,

Phenomenon 4. *(Attribute Homophily) Nodes that have similar attributes are more likely to form a connection. [29]*

The attribute parameters p_{same} and p_{diff} modulate attribute assortativity. When $p_{\text{same}} > p_{\text{diff}}$, nodes are more likely to connect if they share the same attribute value, thereby resulting in a homophilic network over time. Similarly, $p_{\text{same}} < p_{\text{diff}}$ and $p_{\text{same}} = p_{\text{diff}}$ make edge formation heterophilic and attribute agnostic respectively.

Phenomenon 5. *(Preferential Attachment) Nodes tend to link to high degree nodes that have more visibility. [3]*

ARW controls preferential attachment by adding structural bias to the random walk traversal using outlink parameter p_{out}, instead of relying on the global degree distribution. Random walks that traverse outgoing edges only (i.e., $p_{\text{out}} = 1$) eventually visit old nodes that tend to have high in-degree. Similarly, random walks that traverse incoming edges only (i.e., $p_{\text{out}} = 0$) visit recently joined nodes that tend to have low indegree. As a result, we use p_{out} to adjust bias towards node degree.

To summarize: ARW incorporates five well-known sociological phenomena—limited resources; structural constraints; triadic closure; attribute homophily; preferential attachment—into a single edge formation mechanism based on random walks.

4.3 Model Fitting

We now briefly describe methods to estimate model parameters, initialize $\hat{G}$, densify $\hat{G}$ over time and sample nodes' attribute values.

Parameter Estimation. We use grid search to estimate the four parameters using evaluation metrics and selection criterion described in Subsection 5.1.

Initialization. ARW is sensitive to a large number of weakly connected components (WCCs) in initial network $\hat{G}_0$ because incoming nodes only form edges to nodes in the same WCC. To ensure that $\hat{G}_0$ is weakly connected, we perform an undirected breadth-first search on the observed, to-be-fitted network G that starts from the oldest node and halts after visiting 0.1% of the nodes. The initial network $\hat{G}_0$ is the small WCC induced from the set of visited nodes.

Node Out-degree. Node out-degree increases non-linearly over time in real-world networks. We coarsely mirror the growth rate of observed network G as follows. Each incoming node u that joins $\hat{G}$ at time t corresponds to some node that joins the observed network G in year $y(t)$; the number of edges $m(t)$ that u forms is equal to the average out-degree of nodes that join G in year $y(t)$.

Sampling Attribute Values. The distribution over nodal attribute values $P_G(B)$ tends to change over time. The change in the attribute distribution over time is an exogenous factor and varies for every network. Therefore, we sample the attribute value $B(u)$ of node u, that joins $\hat{G}$ at time t, from $P_G(B \mid \text{year} = y(t))$, the observed attribute distribution conditioned on the year of arrival of node u.

To summarize, ARW uses four parameters —$p_{\text{same}}, p_{\text{diff}}, p_{\text{jump}}, p_{\text{out}}$— to incorporate resource-constrained individuals' biases towards similar, proximate and high degree nodes. Next, we discuss our experiments on the performance of ARW in preserving global properties of real networks.

5 MODELING NETWORK STRUCTURE

In this section, we evaluate ARW's efficacy in preserving observed network structure relative to well-known growth models.

5.1 Setup

In this subsection, we introduce eight representative growth models and describe evaluation metrics used to fit models to the datasets.

State-of-the-art Growth Models. We compare ARW to eight models representative of the key edge formation mechanisms: preferential attachment, fitness, triangle closing and random walks. Two of the eight models account for attribute homophily and preserve attribute mixing patterns, as listed in Table 2.

Ensuring Fair Comparison. To ensure fair comparison, we modify existing models in three ways. First, for DMS, SAN, KA do not have an explicitly defined initial graph, so we use initialization method used for ARW, described in subsection 4.3. Second, we extend models that use constant node outdegree m by increasing outdegree over time $m(t)$ using the method described in subsection 4.3. In the absence of model-specific parameter estimation methods, we use grid search to estimate the parameters of every network model, including ARW, using evaluation metrics and selection criterion described below.

Evaluation Metrics. We evaluate the model fit by comparing four properties of G & $\hat{G}$: degree distribution, local clustering distribution, degree-clustering relationship and attribute assortativity. We use Kolmogorov-Smirnov (KS) statistic to compare univariate distributions and Weighted Relative Error (WRE) for the degree-clustering relationship. WRE aggregates the relative error between the average local clustering $c(k)$ and $\hat{c}(k)$ of nodes with in-degree k in G and $\hat{G}$ weighted by the fraction of nodes with indegree k in G.

Jointly preserving multiple structural properties is a multi-objective optimization problem. Therefore, for each model, the selection criterion for the grid search parameter estimation method chooses the model parameters that minimizes the ℓ^2-norm of the aforementioned evaluation metrics. We normalize the metrics before computing the ℓ^2-norm to prevent unwanted bias towards any particular metric. We note that the parameter sensitivity of the Forest Fire (FF) model necessitates a manually guided grid search method.

Table 2: We evaluate the performance of our model ARW relative to three preferential attachment (PA) models, two pref. attachment & triangle closing (PA+TC) models and 3 random walk (RW) models.

5.2 Results

Now, we evaluate the performance of ARW relative to eight models on the datasets introduced in Subsection 3.1. For every pair of model and dataset, Figure 5 tabulates the evaluation metrics described in Subsection 5.1. These metrics are averaged over 100 runs and measure the accuracy with which the fitted models preserve key global network properties: degree distribution, local clustering distribution, degree-clustering relationship and attribute assortativity.

We use one-sided permutation tests [18] to evaluate the relative performance of ARW. If ARW performs better than a model on a dataset with significance level $\alpha = 0.01$ or $\alpha = 0.001$, the corresponding cells in Figure 5 are shaded gray ( ) or dark gray ( ) respectively. We also group models that have similar edge formation mechanisms by color-coding the corresponding rows in Figure 5. We use green ticks in Figure 5 to annotate models that preserve attribute assortativity up to two decimal places.

Existing models fail to *jointly* preserve multiple properties because they either do not account for triadic closure and homophily or are not flexible enough to generate networks with tunable structural properties. Preferential attachment models—DMS, RL, KA—preserve in-degree distributions (Figure 5A) but not clustering because they do not account for triadic closure (Figure 5B & Figure 5C). Models that use triangle closing mechanisms—HK, SAN—lead to considerable improvement over DMS and KA in modeling local clustering, but perform poorly w.r.t. degree-clustering relationship.

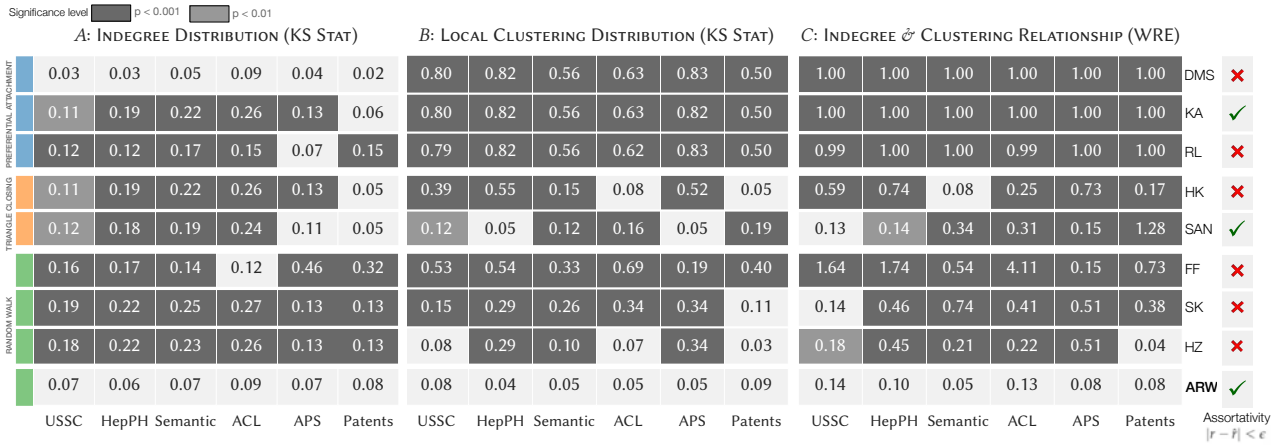

Figure 5: Modeling network structure. Tables 5A, 5B and 5C measure the accuracy of eight models in fitting key properties of real-world networks. Our model, ARW, jointly preserves all four properties accurately and often performs considerably better than existing models: the cells are shaded gray or dark gray if the proposed model ARW performs better at significance level $\alpha = 0.01$ ( ) or $\alpha = 0.001$ ( ) respectively.

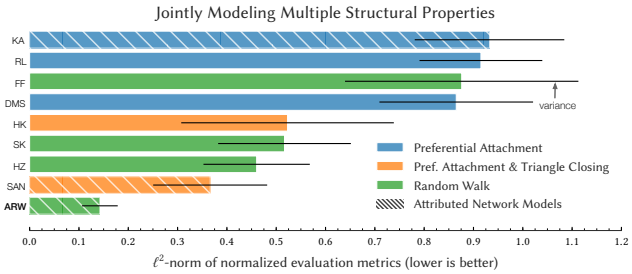

Figure 6: ARW outperforms existing models in jointly preserving key structural properties of node in-degree and local clustering by a significant margin of 2.5x-10x.

Existing random walk models—FF, SK, HZ— do not account for homophily and attribute mixing patterns. FF, in particular, considerably overestimates local clustering because of its recursive edge formation process.

Figure 5 clearly indicates the effectiveness of ARW in jointly preserving multiple global network properties. ARW preserves observed in-degree distributions by adjusting nodes' bias towards high degree nodes using p_{out}. ARW matches the local clustering distribution (Figure 5B) and in-degree & clustering relationship (Figure 5C) with high accuracy using p_{jump} and p_{link}. ARW also preserves attribute assortativity using the attribute parameters p_{same} and p_{diff}.

To summarize, ARW unifies sociological phenomena into a single mechanism to jointly preserve key network properties significantly better than existing models, as shown in Figure 6. Code pertinent to ARW is available online [1]. Please refer to the extended version of our paper [38] for more information.

6 RELATED WORK

Preferential attachment and fitness-based models [4, 5, 10, 30] can preserve heavy-tailed degree distribution, small diameter [8] and temporal dynamics [43] of real-world networks. Extensions of preferential attachment [32, 44, 45] that account for partial network access disregard properties such as clustering and mixing patterns. Models [20, 23, 26] couple preferential attachment with triangle closing to incorporate triadic closure. This increases average local clustering by forming edges between nodes with one or more common neighbors, as shown in Section 5.

Models [12, 17, 21, 46] that account for attribute mixing can be largely categorized as (a) fitness-based model that define fitness as a function of attribute similarity and (b) "microscopic" growth models that require complete temporal information about edge insertions & deletion. In Subsection 5.2, we show that attributed network models SAN and KA preserve mixing patterns but do not account for other structural properties of real-world networks.

First introduced by Vazquez [42], random walk models are inherently local. Models [7] in which new nodes only link to terminal nodes of short random walks generate networks with power law degree distributions [11] and small diameter [31] but do not preserve clustering. Models such as SK [37] and HZ [19], in which new nodes probabilistically link to each visited nodes incorporate triadic closure but are not flexible enough to preserve skewed local clustering, as shown in Subsection 5.2. Recursive random walk models such as FF [27] preserve temporal properties such as shrinking diameter but considerably overestimate local clustering. Furthermore, existing random walk models do not account for nodal attributes.

To summarize, existing models do not accurately explain how resource constrained processes shape well-defined global properties of attributed networks over time. Please refer to the extended version of the paper [38] for a detailed review of existing work.

7 CONCLUSION

In this paper, we proposed a simple, interpretable model of attributed network growth. ARW grows a directed network in the following manner: an incoming node selects a seed node based on attribute similarity, initiates a biased random walk to explore the network by navigating through neighborhoods of existing nodes, and halts the random walk after connecting to a few visited nodes. To the best of our knowledge, ARW is the first model that unifies multiple sociological phenomena—bounded rationality; structural constraints; triadic closure; attribute homophily; preferential attachment—into a single local process to model global network structure *and* attribute mixing patterns. We explored the parameter space of the model

[1] Code: https://github.com/CrowdDynamicsLab/ARW

to show how each parameter intuitively controls one or more key structural properties. Our experiments on six large-scale citation networks showed that ARW outperforms relevant and recent existing models by a statistically significant factor of 2.5–10×.

ABSTRACT

Microservice architectures and container technologies are broadly adopted by giant internet companies to support their web services, which typically have a strict service-level objective (SLO), tail latency, rather than average latency. However, diagnosing SLO violations, e.g., long tail latency problem, is non-trivial for large-scale web applications in shared microservice platforms due to million-level operational data and complex operational environments.

We identify a new type of tail latency problem for web services, *small-window long-tail latency* (SWLT), which is typically aggregated during a small statistical window (e.g., 1-minute or 1-second). We observe SWLT usually occurs in a small number of containers in microservice clusters and sharply shifts among different containers at different time points. To diagnose root-causes of SWLT, we propose an unsupervised and low-cost diagnosis algorithm– ϵ-Diagnosis, using two-sample test algorithm and ϵ-statistics for measuring similarity of time series to identify root-cause metrics from millions of metrics. We implement and deploy a real-time diagnosis system in our real-production microservice platforms. The evaluation using real web application datasets demonstrates that ϵ-Diagnosis can identify all the actual root-causes at runtime and significantly reduce the candidate problem space, outperforming other time-series distance based root-cause analysis algorithms.

1 INTRODUCTION

Tail latency [3, 7–9, 18, 19, 22, 25, 29, 29, 38, 44, 48, 49] becomes the main consideration as Service Level Objective (SLO) on performance [1, 30] for today's most of systems and applications, such as search engine [7, 25], key-value store [9, 21], datacenter network system [22, 48], shared networked storage [49], online data-intensive applications [44], big data system [8] etc. Strict SLO usually requires tail latency, rather than average latency. For example, Google requires the 99th percentile service time (written *TP*99) for its webSearch cluster within tens of milliseconds [25].

Some e-commerce companies try their best to provide the fastest user experience, they expect their web services can serve the requests within several milliseconds. Using a large statistical window to calculate the tail latency can not accurately identify the long-tail latency problem, thus they calculate the tail latency for their online shopping web services during 1-minute period, even during 1-second period. We call this type of tail latency as *small-window tail latency*. We study the small-window tail latency from the real-production web services in container-based microservice platforms (Section 2), finding that a new type of long-tail latency problem– *small-window long-tail latency* (SWLT), which usually occurs in a small number of containers in the microservice clusters, sharply shifts among different containers at different time points, and the tail latency of each container varies significantly.

Diagnosing root-causes of SWLT quickly is a challenging task. Firstly, as the business requirements increase, the number of web services dramatically increases. Figure 1 records the weekly number of web services from an internet company since July 2018, consequently the monitored performance metrics increase in million level [43]. Once SWLT occurs, identifying root-causes of SWLT seems like finding a needle from haystack. Secondly, current machine learn and deep learning based root-cause analysis approaches, heavily depend on training of massive data with highly computing cost, which is suitable for diagnosing daily [23] or seasonal anomaly [46], not fit for diagnosing the long-tail latency at extremely small timescales which have a heavy-tail, frequent-change

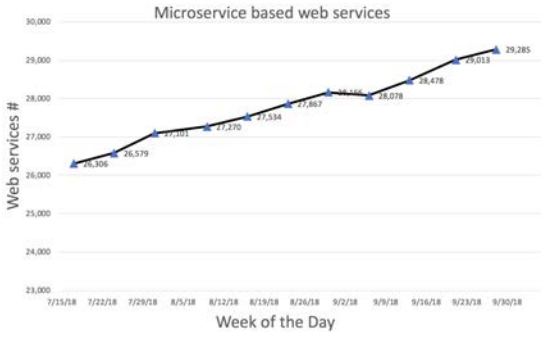

Figure 1: Number of web services in an internet company.

and high-variance feature. Diagnosing root-causes of SWLT requires the algorithm with low computation cost and high recall, and real-time delivery of analytical results.

In this paper, we present an unsupervised and low-cost root-cause analysis algorithm to diagnose root-causes of SWLT at runtime for web services in large-scale microservice platforms. In particular, we make the following contributions.

- We identify a new type of tail latency problem, *small-window long-tail latency* (e.g., in an 1-minute or 1-second period), which has a heavy-tail and high-variance characterization (Section 2). To the best of our knowledge, no current root-cause analysis algorithm can scale to such granularity.
- We propose an unsupervised and low-cost root-cause analysis algorithm–ϵ-Diagnosis (Section 3), using two-sample test algorithm and ϵ-statistics for measuring the similarity of time series, to identify root-causes of SWLT from millions of metrics for on-line web services at runtime. The ϵ-statistics is specially well-suited for the root-cause analysis for the heavy-tailed and highly-variant web applications.
- We implement a real-time diagnosis system in our real-production microservice platforms (Section 3). The evaluation using real-production datasets demonstrates the effectiveness and efficiency of the proposed root-cause analysis algorithm (Section 4). Our results show that ϵ-Diagnosis can identify all the root-cause metrics of SWLT with highest confidence level (lowest confidence threshold) compared to other time series distance based analysis algorithms, and reduce the candidate problem metrics to about 10%.

2 SMALL-WINDOW TAIL LATENCY

Long-tail phenomenons have been broadly observed in data-center [1, 7–10, 20, 22, 25, 37, 38, 44, 47–49], we focus on studying the tail latency at extremely small timescales (e.g., 1 minute, even 1 second) for web services deployed in container based microservice platforms.

Datasets. We have running tens of thousands of web services in our microservice platforms as shown in Figure 1, 90% applications are deployed in a cluster of less than 100 containers. So we select 4 types of representative applications with different cluster sizes, from small, medium, big, to super as shown in Table 1. We identify SWLT, and manually verify the problematic containers and root-cause metrics. We record 13 types of metrics for each container,

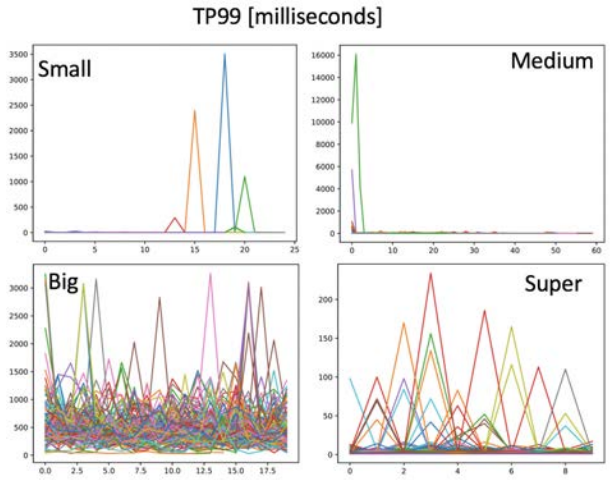
Table 1: Datasets from real-production web services.

DataSet	Small	Medium	Big	Super
Problematic Containers (#)	2	2	7	13
Total Containers (#)	15	55	99	260
Root-cause Metrics (#)	2	3	12	17
Total Metrics (#)	13*15	13*55	13*99	13*260
Alarm Windows (minutes)	15	30	10	5

such as CPU utilization, memory usage, Disk I/O utilization etc., all the metrics are observed with 1-minute resolution.

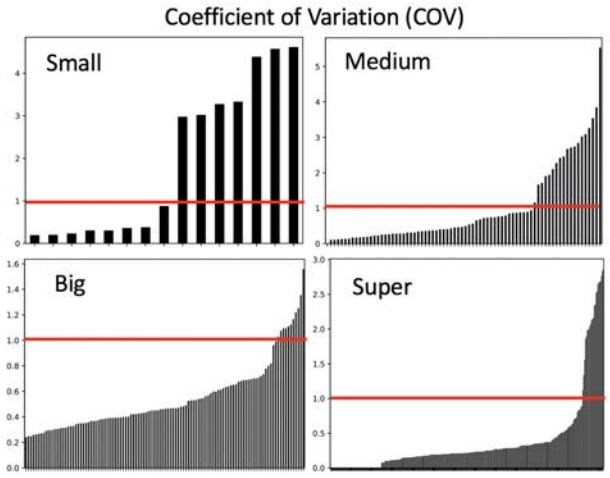
Observations. Figure 2 shows the 99th percentile response time (called *TP*99, which are calculated during 1 minute. Here, we use *TP*99 as an example of tail latency) and its variability of each container for the four application datasets.

From Figure 2a, we can see *only a very small number of containers are problematic when SWLT occurs*. For application Small, Medium, Big, there is only 1 container with problems most of the time. Application Super can have up to 5 problematic containers, which can have the problem at the same time. For all cases, the number of problematic containers is very small compared to the total number of containers. Figure 2a also shows that *the small-window tail latency of each container changes very sharply*. For example, the tail latency increases from several milliseconds to approximately 2.5 seconds during the 25-minute monitoring period at the time of 18 for application Small.



To analyze the variability of TP99 for each container, We calculate the coefficient of variation (COV) [45] for each container in the container clusters for the four applications. *COV* is the ratio of the standard deviation and the mean of the dataset, if $COV > 1$, it means high-variance distribution, otherwise, it's low-variance. In Figure 2b, y-axis is *COV* for each container. We can see *the small-window tail latency for all the applications is highly variant*. For application Super, there are 24 high-variance containers, Big is 12, Medium is 18, Small is 7.

Due to heavy-tail and high-variance characterization, identifying root-causes of SWLT seems like finding a needle from haystack. Developing an intelligent and real-time analysis system to automatically diagnose root-cause metrics of SWLT from the application cluster for large-scale web services has an important implication for application administrators to identify SLO violations.



Goals. To diagnose root-causes of SWLT with high-variance and frequent-shift in large-scale microservice platforms, the objectives of designing the diagnosis algorithm and system are two-fold: (1) the algorithm and the system can quickly diagnose root-causes at runtime with low computation cost, (2) the algorithm can significantly reduce the problem space (metrics) while guaranteeing not to miss any actual root-cause.

3 ϵ-DIAGNOSIS SWLT

We propose an unsupervised and low-cost root-cause analysis algorithm, ϵ-Diagnosis, which can diagnose root-causes of SWLT for large-scale web services at runtime.

(a) TP99 of 4 APPs. Each line represents the $TP99$ for a container.

(b) COV for 4 APPs. Each bar represents the COV for a container.

Figure 2: $TP99$ and COV for 4 application clusters.

We assume that once the long response time occurs, root-cause metrics in the problematic container might significantly change between the abnormal and normal periods. Such that, root-cause analysis is to identify the significantly-changed metrics. Therefore, in order to identify the significantly-changed metrics as the candidate root-cause metrics, we can use two-sample null hypothesis test (abnormal and normal samples) [26], which can use various time series similarity measurement algorithms [17]. Here, we adopt ϵ-statistics test (energy distance correlation) algorithms.

Detecting SWLT. To diagnose the root-cause of long-tail latency, the first task is to detect the long-tail latency. Threshold-based detection [12] is the simplest and widely-used anomaly detection approach. Our diagnosis system provides the alarm threshold interface (e.g., *TP99 threshold*) for the application administrators to detect SWLT for their web services. For example, the administrators can define a rule: if the 99th percentile response time during 1 minute for one service is bigger than 2000ms, it will trigger an alarm. Furthermore, the system provides *alarm window* interface to aggregate the alarm number for the same type of alarms during the alarm window. For example, if the alarm window is 15 minutes, the alarm system only reports the first alarm during the 15-minute time window. Once we detect a long-tail latency, it triggers ϵ-Diagnosis algorithm to analyze root-causes.

Selecting two samples from the snapshot. To identify the significantly-changed metrics as the root-cause, we store the context of web applications in the snapshot for comparison analysis when long-tail latency occurs. The snapshot includes various time-series metrics data, extracted from both the application layer and infrastructure layer cross millions of containers.

For application layer, we aggregate various performance metrics from the log files of various servers (e.g., Apache, Tomcat, MySQL), the metrics include throughput, QPS, concurrent loads, response time, number of error log, number of log, number of database connections etc. For infrastructure layer, we record all the metrics about CPU, memory, disk, network of each container. We formulate these time-series metrics as a time-series vector by

$$S_{(t)} = [x_1, x_2, \ldots, x_n]$$

where x_i is the aggregation value during the statistical/sampling period for each metric.

The system provides the alarm window interface to aggregate the alarm number for the same type of alarms during the alarm window. Thus we can guarantee there must exist some anomaly metrics during the alarm window leading to long tail latency. We use time-series metrics data during the alarm window as the *abnormal sample* (S_A). We choose time-series metrics data during the normal period from the snapshot as the *normal sample* (S_N).

Two-sample null hypothesis test. We would like to find the significantly-changed time series metrics as root-cause metrics. The two-sample test [36] is one of the most commonly used hypothesis tests when you want to compare two independent datasets to see if they are statistically similar or not. So we use two-sample test as the algorithm flow of ϵ-Diagnosis. The hypothesis of the two-sample test can be expressed by:

$$\begin{cases} H_0: & S_A = S_N. \\ H_a: & S_A \neq S_N. \end{cases} \tag{1}$$

if H_0 is true, it means that abnormal samples (S_A) and normal samples (S_N) are statistically equal. Otherwise, they are statistically different.

Further, we can use permutation test [31] or bootstrapping [40] to do hypothesis test, and calculate the p-value (P) using the sampling distribution of the test statistic under the null hypothesis. For different confidence level, we can get a confidence threshold to accept or reject the hypothesis. If the distribution of the test statistic of Hypothesis(1) is symmetric about 0, the test statistic is a two-sided test; otherwise it is a one-side test. For example, if the confidence level is 99% and it is a two-sided test, the confidence threshold (α) is 0.05,

$$\begin{cases} P < \alpha, S_A \neq S_N. \\ P \geqslant \alpha, S_A = S_N. \end{cases} \tag{2}$$

Here, if $P < \alpha$, we reject the hypothesis, which means that the anomaly sample and the normal sample are significantly different, so the corresponding metrics of the samples are potential root-causes. The overall ϵ-Diagnosis algorithm can be described in Algorithm 1.

Algorithm 1 Pseudo-code for the ϵ-Diagnosis algorithm

Input: small-window long-tail latency, M time-series metrics of N containers, confidence threshold α, alarm window
Output: candidate root-cause metrics, problematic containers

```
procedure ε-DIAGNOSIS
    for ContainerN ← 1 to N do
        S_A = getAnomalySample
        S_N = getNormalSample
        for MetricM ← 1 to M do
            ( ρ (S_A, S_N), P ) = Calculate Energy distance correlation coefficient of S_A and S_N using Equation (3) with P-value
            if P < α then
                /* Reject Hypothesis S_A != S_N */
                Add MetricM as a candidate root-cause metric
                Add ContainerN as a candidate problematic container
            else
                /* Accept Hypothesis S_A = S_N */
            end if
        end for
    end for
end procedure
```

The confidence threshold (α) plays a critical role in root-cause accuracy for our root-cause service. If α is too low, we might miss some true root-cause metrics, leading to higher false negative. If α is too high, we might consider more metrics as the potential root-cause, leading to higher false positive. So we have to make a trade-off between recall and precision. In the evaluation section, we empirically get the optimal confidence threshold α. We leave the auto-tuning of α as our future work.

ϵ-Statistics (Energy distance correlation). There are a lot of literature work on time series similarity measurement [17]. From observations in Figure 2) in Section 2, we note that the tail latency at extremely small timescale for web services is heavy-tailed and highly-variant. Energy distance based ϵ-statistics is specially well-suited for heavy-tailed and highly-variant datasets with a low computation cost [42]. Thus, we adopt ϵ-statistics test (energy distance correlation) to measure the similarity of two samples.

Energy distance is a variation of squared pairwise distance. The Energy correlation coefficient ($\rho(S_A, S_N)$) between anomaly samples (S_A) and normal samples (S_N) is defined as the square root of,

$$\rho^2(S_A, S_N) = \begin{cases} \frac{cov^2(S_A,S_N)}{\sqrt{\sigma^2(S_A)\sigma^2(S_N)}}, & \sigma^2(S_A)\sigma^2(S_N) > 0. \\ 0, & \sigma^2(S_A)\sigma^2(S_N) = 0. \end{cases} \quad (3)$$

where cov is the covariance of the two samples, σ is the standard deviation of each sample. The benefit and speciality of ϵ-statistics test is distribution-free, scale-equivariant and rotation-invariant. Therefore, it is suitable for diagnosing root-causes of long-tail latency for response time sensitive user-facing web services, in which case the tail latency is aggregated at small timescales, e.g., during 1 minute or 1 second.

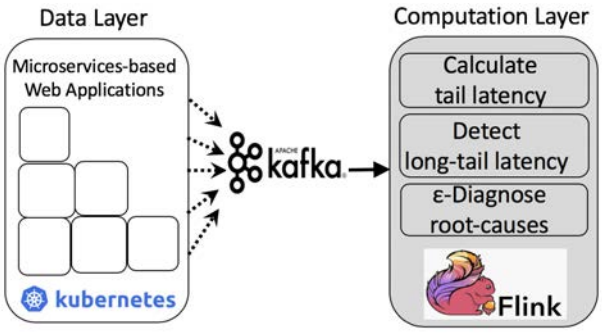


Figure 3: System architecture.

Real-time diagnosis system. We implement an automatic and intelligent diagnosis system at runtime using ϵ-Diagnosis algorithm to analyze root-causes of the long-tail latency at extremely small timescales (e.g., 1 minute or 1 second) for tens of thousands web applications deployed in our microservice platforms managed by Kubernetes [1] as shown in Figure 3. It consists of two main components: data layer and computing layer.

To support population-scale applications, enabling their SLO violation monitoring and delivering results as fast as possible (seconds) are non-trivial. One challenge is to transfer the large volume operation data from the distributed containers. To reduce the amount of data to transfer, we adopt Apache thrift [2] in the data collection agents. Thrift can work with plug in serialization protocols and data compression (e.g. gzip). We observe the compression ratio is around 1/23. The data is pipelined by kafka [3]. Kafka is able to be scaled quickly and easily without incurring any downtime, and handle many terabytes of data with consistent performance.

In computation layer, we calculate the small-window tail latency, detect SWLT by comparing the tail latency with the predefined alarm thresholds, and use ϵ-Diagnosis algorithm to identify the significantly-changed metrics as root-cause metrics. We adopt Apche flink [4] to implement these functions in computation layer, which can process the stream data with high performance and low latency. All the long-tail alarms are stored in event database (e.g., MySQL), all the time-series metrics are stored in time-series database (e.g., ClickHouse [5]), time-series database [33] can provide scalable performance for analytics and aggregation of time-series.

4 EVALUATIONS

4.1 Operational Data in Real-production

Our monitoring cluster consists of approximately 300 containers, which can monitor the small-window tail latency of approximately 30000 web services in our microservice platforms as shown in Figure 1. We deployed the root-cause analysis system in the monitoring cluster. Figure 4 shows the hourly amount of long-tail latency

[1] https://kubernetes.io/
[2] https://thrift.apache.org/
[3] https://kafka.apache.org/
[4] https://flink.apache.org/
[5] https://clickhouse.yandex/

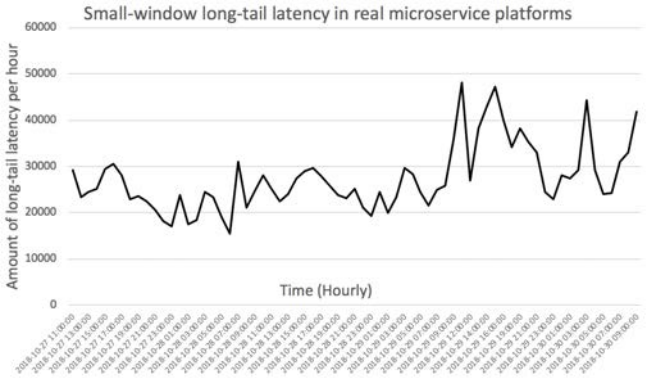

Figure 4: Service rate of ϵ-Diagnosis in a real-life production.

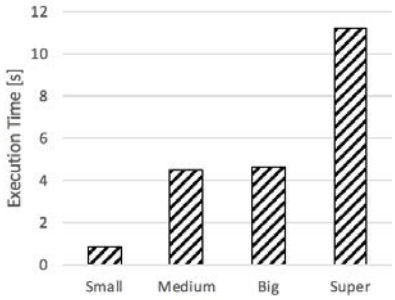

Figure 5: Execution time of ϵ-Diagnosis, in seconds.

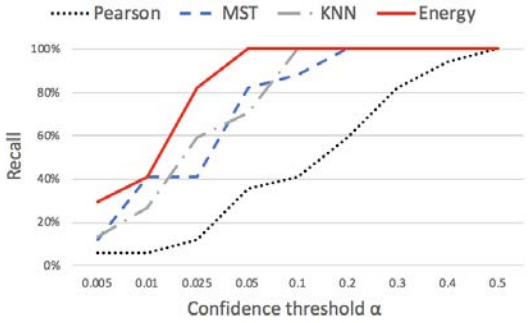

Figure 6: Energy can reach 100% recall quickly as α increases.

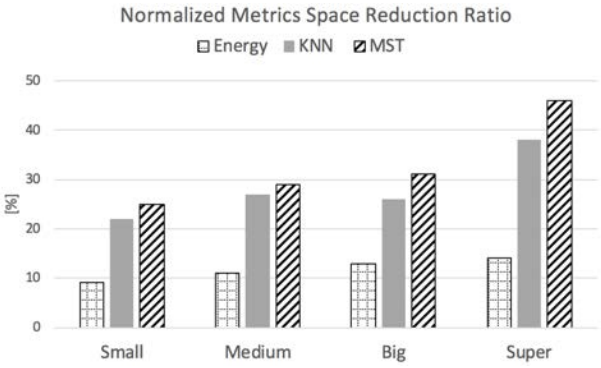

Figure 7: Energy can reduce metrics to approximately 10%.

alarms in three days for our web services. We detected approximately 30,000 long-tail latency with a peak of 50,000 in every hour. The request rate of root-cause diagnosis in total is 8.3 per second with a peak of 13.9 per second.

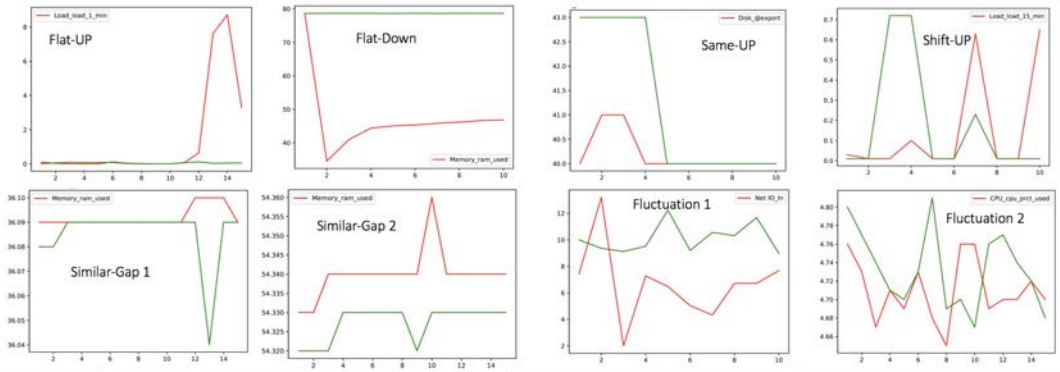
Execution time. One goal of designing the algorithm and the system is to provide an diagnosis service to identify root-causes of SWLT in mocroservice platforms at runtime. So we evaluate the computation cost for ϵ-Diagnosis.

We run the ϵ-Diagnosis system in a container equipped with a quad-core Intel Core i7 2.8 GHz CPU and 16 GB 2133 MHz LPDDR3 memory. Figure 5 shows the execution time for ϵ-Diagnosis algorithm for the datasets in Table 1. For Small application, the execution time of ϵ-Diagnosis is less than 1 second. As the number of the containers increases, the running time increases. Medium and Big are in the same level, since the sample size (alarm window) reduces from 30 to 10 as shown in Table 1, although the container amount increases from Medium to Big. In our microservice platforms, 80% applications are small web applications. ϵ-Diagnosis can finish the analysis within 1 second, so we use 10 containers to serve the requests of root-cause analysis as shown in Figure 4.

4.2 Performance of Algorithms

Next, we compare the performance of ϵ-Diagnosis with other time-series distance based root-cause analysis algorithms.

Experimental Methodology. We use an empirical approach in our experiments to define α. For example, we define α as a set of values [0.005, 0.01, 0.02, 0.05, 0.1, 0.2, 0.3, 0.4, 0.5], which are corresponding to the confidence level of two-sample test [99%, 98%, 96%, 90%, 80%, 60%, 40%, 20%, 0%] (two-sides test). In our experiments, we gradually increase α and evaluate the performance of the algorithms.



We compare the performance of the ϵ-Diagnosis algorithm (based on energy distance) with other three time-series similarity measurements. Pearson's distance is the simplest one, defined by,

$$\rho(S_A, S_N) = \frac{cov(S_A, S_N)}{\sigma(S_A)\sigma(S_N)} \tag{4}$$

where cov is the covariance of the two samples, σ is the standard deviation of each sample. K-NN [16, 26] and MST [15] algorithms both discretize the time-series samples, transform the distance of two time-series samples into inter-point distance, and use graph-theoretic algorithm to measure their similarity. KNN algorithm uses nearest neighbours to model the inter-point distance of two time series, meanwhile MST algorithm uses minimum spanning tree to represent their inter-point distance.

Results. We require that the algorithm can significantly reduce the problem space from million-level metrics while guaranteeing not missing any actual root-cause, namely guaranteeing 100% recall.

Figure 6 shows the recall of the four time-series measurement algorithms on all four datasets. As the confidence threshold α increases, the recall increases. We note that Energy can achieves 100% recall when α equals 0.05. The two graphic-theory based algorithm (MST and KNN) are 0.2 and 0.1, respectively. As α increases, Energy can identify all the root-causes at the fastest speed. Pearson can not find all the actual root-causes until α equals 0.5. So Pearson can

Algorithm	Flat-UP	Flat-Down	Same-UP	Shift-UP	Similar-Gap 1	Similar-Gap 2	Fluctuation 1	Fluctuation 2
Pearson	0.903	0.041	0.060	0.924	0.072	0.073	0.867	0.901
MST	0.568	0	0.774	0.582	0.430	0	0	0.737
KNN	0.063	0.011	0.033	0.296	0.103	0.106	0	0.712
Energy	0.043	0	0.061	0.047	0.031	0.001	0	0.211

Figure 8: Various two-sample patterns. Each line represents a sample. Smaller P, more significantly different time series.

Table 2: Precision of the algorithms for the four datasets.

DataSet	Small	Medium	Big	Super
MST (%)	62	59	67	66
KNN (%)	76	67	65	62
Energy (%)	79	72	76	72

not fit our case and operational environments, and we will omit the evaluation of Pearson.

Figure 7 shows that how much the time-series similarity measurement algorithms can narrow down the candidate problematic metrics from the total metrics under the condition of 100% recall (For Energy, KNN, MST, α is 0.05, 0.1, and 0.2). Energy can reduce metrics to approximately 10%, outperforming the other two, since it uses the smallest α, counting smaller metrics as the potential metrics. For the same reason, Energy can also get the best precision (e.g., 79% for the small application) as shown in Table 2.

To explain why Energy can outperform the other three algorithms, Figure 8 lists several representative time-series patterns from the infrastructure layer metrics and their corresponding p-value (P). Smaller P, more significantly different the two samples. We can note Energy is more sensitive than the other algorithms for all of the cases, specifically, it can identify more patterns as different samples, so it can achieve 100% recall with the smallest α. Meanwhile, there also exists false positive for Energy, since it might falsely identify some more metrics patterns as root-causes (e.g., "Fluctuation 2"). Pearson can not identify the the difference of "Flat-UP", which is disappointing, because several root-cause metrics have this type of peak pattern from our observations in our microservice platforms, it will miss this type of root-cause metrics.

5 RELATED WORK

Traditional rule (or signature) based performance diagnosis approaches for distributed systems, heavily depend on the operational fault knowledge base (such as Fingerprint [2, 6, 11]), and detect the anomaly and performance bottlenecks through tracing the request process flowing in large-scale distributed system (such as GoogleÃćâĈňâĎćs Dapper [39], Mace [24], Pinpoint [5], Pip [34], Stardust [35], X-Trace [14], Whodunit [4], Retro [27], Pivot Tracing [28], Quanto [13]). However, it is hard to build both operational fault knowledge base and call relationship in complex micro-service based applications with tens of thousands of invocation graphs [32]. Compared to rule based root-cause analysis, we do not need any operational knowledges and the training process.

Models and techniques for root-cause analysis are extensively summarized in the survey paper [41]. Luo et al. [26] model incident diagnosis as a two-sample problem and apply k-NN statistic based method to correlate event and time-series. Daily chronic problems [23] are statistically diagnosed, and seasonal KPIs alarms [46] are detected by an unsupervised anomaly detection algorithm based on VAE (Variational Auto-Encoder). Compared to statistical learning based root-cause analysis, our approach is an unsupervised approach with low computation cost. More importantly, our diagnosis target is more fine-grained long-tail latency problem at extremely small timescale (e.g., 1-minute or 1-second) for the large-scale on-line web services. To the best of our knowledge, no current root-cause analysis algorithm can scale to such granularity.

6 CONCLUSIONS

We identify a new type of SLO violation for web services, SWLT in large-scale microservice platforms, which has a heavy-tail and high-variance characterization. To diagnose root-causes of SWLT, we propose an unsupervised and low-cost algorithm–ϵ-Diagnosis,

using two samples test algorithm based on ϵ-statistics. We develop and deploy the root-cause diagnosis system in the microservice platforms to help identify the potential root-causes of SWLT from millions of metrics for tens of thousands of web services. Through evaluating with real-production datasets, we show that ϵ-Diagnosis can outperform other time-series distance based root-cause analysis algorithms in finding all the actual root-cause metrics of SWLT with highest confidence level.

ABSTRACT

Recommender systems are widely used to recommend the most appealing items to users. These recommendations can be generated by applying collaborative filtering methods. The low-rank matrix completion method is the state-of-the-art collaborative filtering method. In this work, we show that the skewed distribution of ratings in the user-item rating matrix of real-world datasets affects the accuracy of matrix-completion-based approaches. Also, we show that the number of ratings that an item or a user has positively correlates with the ability of low-rank matrix-completion-based approaches to predict the ratings for the item or the user accurately. Furthermore, we use these insights to develop four matrix completion-based approaches, i.e., Frequency Adaptive Rating Prediction (FARP), Truncated Matrix Factorization (TMF), Truncated Matrix Factorization with Dropout (TMF + Dropout) and Inverse Frequency Weighted Matrix Factorization (IFWMF), that outperforms traditional matrix-completion-based approaches for the users and the items with few ratings in the user-item rating matrix.

1 INTRODUCTION

Recommender systems are used in e-commerce, social networks, and web search to suggest the most relevant items to each user. Recommender systems commonly use methods based on Collaborative Filtering [15], which rely on historical preferences of users over items in order to generate recommendations. These methods predict the ratings for the items not rated by the user and then select the unrated items with the highest predicted ratings as recommendations to the user.

In practice, a user may not rate all the available items, and hence we observe only a subset of the user-item rating matrix. For the task of recommendations, we need to complete the matrix by predicting the missing ratings and select the unrated items with high predicted ratings as recommendations for a user. The matrix completion approach [3] assumes that the user-item rating matrix is low rank and estimates the missing ratings based on the observed ratings in the matrix. The state-of-the-art collaborative filtering methods, e.g., Matrix Factorization (MF) [10] are based on the matrix completion approach.

Assuming that the user-item rating matrix is low-rank, it was shown that in order to accurately recover the underlying low-rank model of a $n \times n$ matrix of rank r, at least $O(nr \log(n))$ entries in the matrix should be sampled uniformly at random [4]. However, most real-world rating matrices exhibit a skewed distribution of ratings as some users have provided ratings to few items and certain items have received few ratings from the users. This skewed distribution may result in insufficient ratings for certain users and items, and can negatively affect the accuracy of the matrix completion-based methods.

This paper investigates how the skewed distribution of ratings in the user-item rating matrix affects the accuracy of the matrix completion-based methods and shows by extensive experiments on different low-rank synthetic datasets and as well as on real datasets that the matrix completion-based methods tend to have poor accuracy for the items and the users with few ratings. Moreover, this work illustrates that as we increase the number of latent dimensions, the prediction performance for the items and the users with sufficiently many ratings continues to improve, whereas the accuracy of the items and the users with few ratings degrades. This suggests that because of over-fitting, the matrix completion-based methods for large number of latent dimensions do not generalize well for the items and the users with few ratings.

Building on this finding, we develop four matrix completion-based approaches that explicitly consider the number of ratings received by an item or provided by a user to estimate the rating of the user on the item. Specifically, we introduce (i) Frequency Adaptive Rating Prediction (FARP) method, which uses multiple low-rank models for different frequency of the users and the items; (ii) Truncated Matrix Factorization (TMF) method, which estimates a single low-rank model that adapts with the number of ratings a user and an item has; (iii) Truncated Matrix Factorization with Dropout (TMF + Dropout) method, which is similar to TMF but probabilistically select the ranks for the users and the items; and (iv) Inverse Frequency Weighted Matrix Factorization (IFWMF) method,

which weighs the infrequent users and items higher during low-rank model estimation. Extensive experiments on various datasets demonstrate the effectiveness of the proposed approaches over traditional MF-based methods by improving the accuracy for the items (up to 53% improvement in RMSE) and the users (up to 8% improvement in RMSE) with few ratings.

2 RELATED WORK

The current state-of-the-art methods for rating prediction are based on matrix completion, and most of them involve factorizing the user-item rating matrix [7, 9, 10]. In this work, our focus is on analyzing the performance of the matrix completion-based MF approach and use the derived insights to develop an approach that performs better for the users and the items with few ratings in the user-item rating matrix. These approaches estimate user-item rating matrix as a product of two low-rank matrices known as the user and the item latent factors. If for a user u, the vector $\boldsymbol{p}_u \in \mathbb{R}^r$ denotes the r dimensional user's latent factor and similarly for the item i, the vector $\boldsymbol{q}_i \in \mathbb{R}^r$ represents the r dimensional item's latent factor, then the predicted rating ($\hat{r}_{u,i}$) for user u on item i is given by

$$\hat{r}_{u,i} = \boldsymbol{p}_u \boldsymbol{q}_i^T. \tag{1}$$

The user and the item latent factors are estimated by minimizing a regularized square loss between the actual and predicted ratings

$$\underset{\boldsymbol{p}_u, \boldsymbol{q}_i}{\text{minimize}} \quad \frac{1}{2} \sum_{r_{ui} \in R} \left(r_{ui} - \boldsymbol{p}_u \boldsymbol{q}_i^T\right)^2 + \frac{\beta}{2} \left(||\boldsymbol{p}_u||_2^2 + ||\boldsymbol{q}_i||_2^2\right), \tag{2}$$

where R is the user-item rating matrix, r_{ui} is the observed rating of user u on item i, and parameter β controls the Frobenius norm regularization of the latent factors to prevent overfitting.

In another related work [21], it was shown that the lack of uniform distribution of ratings in the observed data could lead to folding, i.e., the unintentional affinity of dissimilar users and items in the low-rank space estimated by matrix completion-based methods. For example, the absence of an explicit rating between a child viewer and a horror movie could lead to an estimation of the corresponding latent factors such that both the child viewer and the horror movie are close in the low-rank space leading to the erratic recommendation of horror movies to the child viewer. We believe that the non-uniform distribution of the ratings is the reason behind this phenomenon.

The non-uniform distribution of ratings can also be viewed as an instance of rating data *missing not at random* (MNAR) [12]. The proposed solutions to MNAR model the missing data to improve the generated recommendations [13, 17, 19, 20]. However, in our work, we focus on the skewed distribution of ratings which often comes as a result of either new items or new users that are added to the system, or the items that are not popular to get many ratings. We use our analysis to develop a matrix completion-based approach to improve rating prediction for the users who have provided few ratings on items or for the items that have received few ratings from the users.

Table 1: Datasets used in experiments

Dataset	users	items	ratings	μ_u[a]	σ_u[b]	μ_i[a]	σ_i[b]	%[†]
Flixster (FX)	147K	48K	8.1M	55	226	168	934	1e-1
Movielens (ML)	229K	26K	21M	92	190	786	3269	3e-1
Yahoo Music (YM)	143K	136K	9.9M	69	199	73	141	5e-4
Netflix (NF)	354K	17K	9.5M	27	59	535	1693	1e-3

[a] Average ratings per user (μ_u) or per item (μ_i).

[b] Standard deviation of ratings per user (σ_u) or per item (σ_i).

[†] The percentage of observed ratings in the dataset.

3 IMPACT OF SKEWED DISTRIBUTION

As described in Section 1, the matrix completion-based methods can accurately recover the underlying low-rank model of a given low-rank matrix provided entries are observed uniformly at random from the matrix. However, the ratings in the user-item rating matrix in real-world datasets represent a skewed distribution of entries because some users have provided ratings to few items and certain items have received few ratings from the users.

In order to study how the skewed distribution of ratings in real datasets affects the ability of matrix completion to accurately complete the matrix (i.e., predict the missing entries) we performed a series of experiments using synthetically generated low-rank rating matrices. In order to generate a rating matrix $R \in \mathbb{R}^{n \times m}$ of rank r we followed the following protocol. We started by generating two matrices $A \in \mathbb{R}^{n \times r}$ and $B \in \mathbb{R}^{m \times r}$ whose values are uniformly distributed at random in $[0, 1]$. We then computed the singular value decomposition of these matrices to obtain $A = U_A \Sigma_A V_A^T$ and $B = U_B \Sigma_B V_B^T$. We then let $P = \alpha U_A$ and $Q = \alpha U_B$ and $R = PQ^T$. Thus, the final matrix R of rank r is obtained as the product of two randomly generated rank r matrices whose columns are orthogonal. The parameter α was determined empirically in order to produce ratings in the range of $[-10, 10]$.

We used the above approach to generate full rating matrices whose dimensions are those of the two real-world datasets, i.e., Flixster (FX) and Movielens (ML), shown in Table 1. For each of these matrices we select the entries that correspond to the actual user-item pairs that are present in the corresponding dataset and give it as input to the matrix completion algorithm. For each dataset we generated five different sets of matrices using different random seeds and we performed a series of experiments using synthetically generated low-rank matrices of rank 5 and 20. For each rank, we report the average of performance metrics in each set from the estimated low-rank models over all the synthetic matrices.

3.1 Results

3.1.1 Effect of item frequency in synthetic datasets. In order to investigate if the number of ratings an item has, i.e., item frequency, has any influence on the accuracy of the matrix completion-based methods for the item, we ordered all the items in decreasing order by their frequency in the rating matrix. Furthermore, we divided these ordered items into ten buckets and for a user computed the RMSE for items in each bucket based on the error between the predicted rating by the estimated low-rank model and the ground-truth rating. We repeated this for all the users and computed the average of the RMSE of the items in each bucket over all the users.

Figure 1 shows the RMSEs across the buckets along with the average frequency of the items in the buckets. As can be seen in

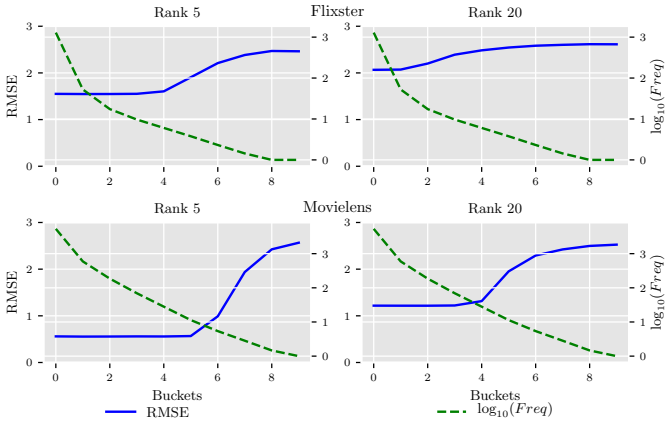

Figure 1: RMSE of the predicted ratings as the frequency of the items decreases.

the figure, the predicted ratings for the frequent items tend to have lower RMSE in contrast to infrequent items for all the datasets.

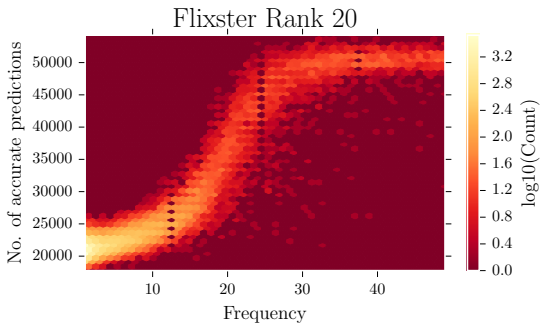

Figure 2: Scatter map of items having different frequency against their number of accurate predictions (Mean absolute error (MAE) $\leq$ 0.5) for low-rank model with rank 20.

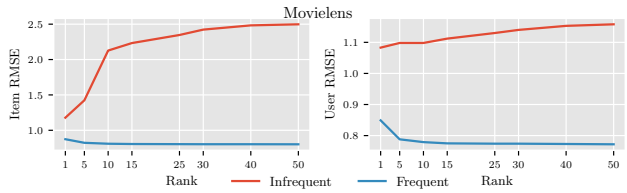

Figure 3: Variation in Test RMSE with increase in rank for the items and the users with different frequency.

Figure 2 shows the scatter map of items in FX having different frequency against the number of instances where the absolute difference between the original and the predicted rating, i.e., *Mean Absolute Error (MAE)*, is $\leq$ 0.5. As can be seen in the figure, the number of accurate predictions is significantly lower for items having fewer ratings ($\leq$ 20) compared to that of the items having a large number of ratings ($\geq$ 30). The lower error of the frequent items is because they have sufficient ratings to estimate their latent factors accurately. Hence for the real datasets, items appearing at the top in ordering by frequency and having high predicted scores will form a reliable set of recommendations to a user.

3.1.2 Effect of frequency on accuracy in real datasets. In order to assess the finding that the infrequent items are not estimated accurately by the matrix completion method, we evaluated matrix completion on a random held-out subset of the real datasets. We followed the standard procedure of cross-validation and exhaustive grid search for hyperparameters for model selection. We computed RMSE over the infrequent items in the test split, i.e., the items that have few ratings in the training split. For the analysis, we ordered the items in increasing order by the number of ratings in training splits. Next, we divided these ordered items into quartiles and identified the items in the first and the last quartile as the infrequent and the frequent items, respectively.

Figures 3 show the RMSE for the items and the users in the test for the Movielens (ML) dataset. We can see that the RMSE of the frequent items (or users) is lower than that of the infrequent items (or users). Furthermore, we observed similar trends in the remaining datasets (results not shown here due to space constraints). These results suggest that the matrix completion method fails to estimate the preferences for the infrequent items (or users) accurately in the real datasets. Also, the RMSE of the infrequent items increases with the increase in the rank while that of frequent items decreases with the increase in the rank. Similarly, the RMSE of the infrequent users increases with the increase in the rank. The increase in RMSE with the increase in ranks suggests that infrequent items or infrequent users may not have sufficient ratings to estimate all the ranks accurately thereby leading to the error in predictions for such users or items. The finding that infrequent items or infrequent users have better accuracy for fewer ranks follows from the result that $O(nr \log(n))$ entries are required to recover the underlying low-rank model of a $n \times n$ matrix of rank r [4], and therefore for fewer entries (e.g., infrequent users or infrequent items) we may recover only fewer ranks of the underlying low-rank model accurately.

4 METHODS

The analysis presented in the previous section showed that as the underlying rank of the low-rank model that describes the data increases, the error associated with estimating such a low-rank model from the skewed data increases for the infrequent users and the infrequent items. We use these observations to devise multiple approaches to improve the accuracy of the low-rank models for such users and items.

4.1 Frequency Adaptive Rating Prediction (FARP)

Since the error of the predictions from the estimated low-rank models increases for the infrequent users or items in skewed data, we propose to estimate lower dimensional latent factors for the infrequent users or items, and estimate higher dimensional latent factors for the frequent users or items. In this approach, we propose to learn multiple low-rank models with different ranks from all the available data and while predicting the rating of a user on an item we select the model that performed the best for the infrequent user or the item associated with the rating. Hence, the predicted rating

of user u on item i is given by

$$\hat{r}_{ui} = \boldsymbol{p}_{uk}\boldsymbol{q}_{ik}^T, \tag{3}$$

where $\boldsymbol{p}_{uk}$ and $\boldsymbol{q}_{ik}$ are the user and the item latent factors from the kth low-rank model. For example, if $f_u < f_i$ then we select the kth low-rank model for prediction such that it has the best performance for users having frequency f_u, and similarly if $f_i < f_u$ then we select the model with the best performance for items with frequency f_i.

The user and items can be assigned to different low rank models based on the number of ratings that exists for them in the dataset. One approach that we investigated is to order the users and the items by the number of ratings and divide them into equal quartiles and save the best performing model for each quartile.

4.2 Truncated Matrix Factorization (TMF)

An alternate approach we develop is to estimate only a subset of the ranks for these users or items. In this approach, the estimated rating for user u on item i is given by

$$\hat{r}_{u,i} = \boldsymbol{p_u}(\boldsymbol{q_i} \odot \boldsymbol{h_{u,i}})^T, \tag{4}$$

where $\boldsymbol{p_u}$ denotes the latent factor of user u, $\boldsymbol{q_i}$ represents the latent factor of item i, $\boldsymbol{h_{u,i}}$ is a vector containing 1s in the beginning followed by 0s, and $\odot$ represents the elementwise Hadamard product between the vectors. The vector $\boldsymbol{h_{u,i}}$ is used to select the ranks that are *active* for the (u, i) tuple. The 1s in $\boldsymbol{h_{u,i}}$ denote the active ranks for the (u, i) tuple.

4.2.1 Frequency adaptive truncation. One approach that we investigated for selecting the active ranks, i.e., $\boldsymbol{h_{u,i}}$, for a user-item rating is based on the frequency of the user and the item in the rating matrix. In this approach, for a given rating by a user on an item, first, we determine the number of ranks to be updated based on either the user or the item depending on the one having a lower number of ratings. In order to select the ranks, we normalize the frequency of the user and the item, and use a non-linear activation function, e.g., sigmoid function, to map this frequency of the user or the item in $[0, 1]$. Finally, we used this mapped value as the number of active ranks selected for the update of the user and the item latent factors. The number of active ranks to be selected is given by

$$k_{u,i} = \frac{r}{1 + e^{-k(f_{min} - z)}}, \tag{5}$$

where r is the dimension of the user and the item latent factors, $f_{min} = \min(f_u, f_i)$, f_u is the frequency of user u, f_i is the frequency of item i, k controls the steepness of the sigmoid function and z is the value of the sigmoid's midpoint. The use of such a function assists in identifying the users or the items that can not be estimated accurately using all the ranks and we can only estimate few ranks more accurately for such users or items. The active ranks for a user or an item can be chosen either from the beginning of all ranks or end of all ranks or can be chosen arbitrarily among all ranks until the same active ranks are used consistently for the user and the item. For ease of discussion and simplicity, we will assume that active ranks are chosen from the beginning of all ranks. Hence, the active ranks to be selected are given by

$$\boldsymbol{h_{u,i}}[j] = \begin{cases} 1, & \text{if } j \le k_{u,i} \\ 0, & \text{otherwise.} \end{cases} \tag{6}$$

We will refer to this method as Truncated Matrix Factorization (TMF).

4.2.2 Frequency adaptive probabilistic truncation. An alternative way to select the active ranks is to assume that the number of active ranks follows a Poisson distribution with parameter $k_{u,i}$. This method is similar to Dropout [18] technique in neural networks, where parameters are selected probabilistically for updates during learning of the model. Similar to regularization it provides a way of preventing overfitting in learning of the model. The active ranks to be selected are given by

$$\boldsymbol{h_{u,i}}[j] = \begin{cases} 1, & \text{if } j \le \theta_{u,i} \\ 0, & \text{otherwise,} \end{cases}$$

where $\theta_{u,i} \sim Poisson(k_{u,i})$. We will call this method as Truncated Matrix Factorization with Dropout (TMF + Dropout). Similar to Equation 2, the parameters of the model, i.e., the user and the item latent factors can be estimated by minimizing a regularized square loss between the actual and the predicted ratings.

4.2.3 Rating prediction. After learning the model the predicted rating for user u on item i for TMF model is given by

$$\hat{r}_{u,i} = \boldsymbol{p_u}(\boldsymbol{q_i} \odot \boldsymbol{h}_{u,i})^T, \tag{7}$$

where the active ranks, i.e., $\boldsymbol{h_{u,i}}$, is given by Equation 6. The predicted rating for the user and the item under TMF + Dropout model is given by the least number of ranks for whom the cumulative distribution function (CDF) for Poisson distribution with parameter k_{ui} obtains approximately the value of 1. The active ranks, i.e., $\boldsymbol{h_{u,i}}$, for prediction under TMF + Dropout are given by

$$\boldsymbol{h_{u,i}}[j] = \begin{cases} 1, & \text{if } j \le s \\ 0, & \text{otherwise,} \end{cases}$$

where s is the least number of ranks for whom the CDF, i.e, $P(x <= s) \approx 1$ and $x \sim Poisson(k_{u,i})$.

Unlike FARP, which requires us to estimate multiple models, TMF estimates a single model however it involves tuning of more hyperparameters in comparison to FARP.

4.3 Inverse Frequency Weighted Matrix Factorization (IFWMF)

In addition to the above approaches, we explored a weighted matrix factorization-based approach where we weigh the reconstruction error higher for the infrequent users and items. We propose to estimate the user and the item latent factors by minimizing a regularized weighted square error loss between the actual and the predicted ratings

$$\underset{\boldsymbol{p_u}, \boldsymbol{q_i}}{\text{minimize}} \quad \frac{1}{2}\sum_{r_{ui} \in R} w_{ui}\left(r_{ui} - \boldsymbol{p}_u\boldsymbol{q}_i^T\right)^2 + \frac{\beta}{2}\left(||\boldsymbol{p}_u||_2^2 + ||\boldsymbol{q}_i||_2^2\right), \tag{8}$$

where the the weight w_{ui} is given by

$$w_{ui} = \frac{1}{1.0 + \rho f_{\text{min}}}, \tag{9}$$

where ρ is a constant, $f_{\min} = \min(f_u, f_i)$, f_u and f_i are the normalized frequency of user u and item i, respectively. Essentially, we weigh the error in predictions more for the infrequent users and the infrequent items. This resembles the weighted matrix factorization [7, 8] where the weight of the reconstruction error is proportional to the confidence on the observed rating of user u on item i however in our method we weigh the error inversely proportional to the frequency of ratings observed for user u or item i. This is similar to the inverse propensity model-based approach [17], where the propensity is proportional to the frequency of the user or the item. The up-weighting of the reconstruction error associated with the infrequent users or the infrequent items may lead to over-fitting as we only have few ratings for these users and items.

5 EXPERIMENTAL EVALUATION

5.1 Comparison algorithms

We compared our proposed approaches against the the state-of-the-art Matrix Factorization [9] and LLORMA [11] method. LLORMA assumes that the different parts of the user-item rating matrix can be approximated by different low-rank models and the complete user-item rating matrix is approximated as a weighted sum of these individual low-rank models. We have used the LibRec [5] software package to compare the proposed methods against the LLORMA approach.

5.2 Model selection

We performed grid search to tune the dimensions of the latent factors, regularization hyper-parameters, constant (ρ), and sigmoid function's parameters, i.e., k and z. We searched for regularization weights (λ) in the range [0.001, 0.01, 0.1, 1, 10], dimension of latent factors (r) in the range [1, 5, 10, 15, 25, 50, 75, 100], constant (ρ) in the range [1, 10, 50], steepness constant (k) in the range [1 5, 10, 20, 40], and mid-point (z) in the range [-0.75, -0.50, -0.25, 0, 0.25, 0.50, 0.75]. The final parameters were selected based on the performance on the validation split. For LLORMA, we varied the number of local models (l_m) in the range [1, 5, 8, 15, 25, 50].

For FARP, we ordered the users in ascending order by frequency and divided them into equal quartiles. For each quartile, we saved the best performing model, i.e., the model having the lowest RMSE for all the users in that quartile in the validation split. Similarly, we ordered the items in ascending order by frequency and divided them into equal quartiles. Similar to users, we saved the best performing model for each quartile of items. At the time of prediction of rating for a user on an item, we choose the the model associated with the quartile of the user if the user is having lower number of ratings than the item, and if the item is having lower number of ratings than the user than we choose the model associated with the quartile of the item .

5.3 Datasets

In addition to Flixster (FX) [22] and Movielens 20M (ML) [6] datasets, we evaluated our proposed methods on subsets of the Yahoo Music (YM) [1, 16] and Netflix (NF) [2] datasets that we created in order to have a skewed distribution. These datasets were generated as follow. First, for each user we randomly selected the number of ratings that we want to sample from the user's ratings and randomly sampled these ratings for all users. Next, from the sampled ratings in previous step, for each item we randomly selected the number of ratings that an item has received from users in sampled ratings and randomly sampled these ratings for all the items. After following the above two steps, the sampled ratings from these datasets follows a skewed distribution and characteristics of all the datasets used in experiments are presented in Table 1.

5.4 Evaluation methodology

To evaluate the performance of the proposed methods we divided the available ratings in different datasets into training, validation and test splits by randomly selecting 20% of the ratings for each of the validation and the test splits. The validation split was used for model selection, and the model that was selected was used to predict ratings on the test split. We repeated this process three times and report the average RMSE across the runs.

In addition to computing RMSE obtained by different methods for the ratings in the test split, we also investigated the performance of the proposed approaches for the items and the users with a different number of ratings in the training split. To this end, we ordered the items and the users in increasing order by their number of ratings in training split and divided them equally into quartiles. We will report the RMSE achieved by different methods for ratings in the test split for the users and the items in these quartiles.

6 RESULTS AND DISCUSSION

6.1 Performance for rating prediction on entire dataset

Table 2 shows the results achieved by the proposed methods on the various datasets. As can be seen in the table for the task of rating predictions for all the ratings in the test splits the proposed approaches perform better than the MF method for FX, ML, YM and NF datasets. Interestingly, the proposed approaches have performed even better than the state-of-the-art LLORMA method and this suggests that LLORMA can be further improved by estimating local low-rank models that considers the skewed distribution of ratings in datasets. We found the difference between the predictions of different methods to be statistically significant (p-value ≤ 0.01 using two sample t-test). The performance is significantly better for FX in comparison to that of other datasets. Additionally, on FX dataset, the MF method outperforms the LLORMA method and a possible reason for this is that because of the skewed distribution LLORMA is not able to estimate a model that is as accurate as a global MF model. Moreover, LLORMA needs a significantly large number of local low-rank models in comparison to the proposed approaches. Also, by comparing the number of latent dimensions used by the models shown in Table 2 we can see that, for ML, TMF + Dropout and LLORMA needs significantly fewer ranks, i.e., 25, in comparison to that of MF, i.e., 100, to achieve the same performance and we believe that this could be because of MF overfitting the ML dataset for higher dimension of latent factors.

Table 2: Test RMSE of the proposed approaches for different datasets. The RMSE for the users and the items in different quartiles order by their frequency. Q1 refers to the quartile containing the least frequent users or items followed by remaining in Q2, Q3, and Q4. Table 4 shows the average number of test ratings in different quartiles for different datasets.

†Due to sampling, the test splits do not have ratings for users in Q1.

6.2 Performance for the users and the items with different number of ratings

Table 2 also shows the performance achieved by the different methods across the different quartiles of users and items. By comparing the performance of the different schemes we can see that the proposed methods significantly outperform the MF method and state-of-the-art LLORMA method for lower quartiles for majority of the datasets. This illustrates the effectiveness of the developed methods for the users and the items with few ratings. The better performance of the proposed methods for the users and the items with few ratings is because we can estimate accurately only a few ranks for them, and unlike MF and LLORMA the proposed approaches are effective in model estimation or predicting the ratings for these users and items.

Among the proposed approaches, the TMF-based approaches (TMF and TMF + Dropout), perform better in most of the quartiles in FX dataset. Surprisingly, FARP consistently performs better than the MF and LLORMA across most of the datasets, and this is promising as compared to TMF-based approaches FARP has fewer hyperparameters to tune. Specifically, in TMF-based approaches we have to tune regularization weights (λ), dimension of latent factors (r), steepness constant (k) and mid-point (z), while in FARP we have to tune only three parameters, i.e., number of low-rank models, regularization weights (λ) and dimension of latent factors (r). This might be of interest to practitioners because multiple low-rank models under FARP can be estimated in parallel using vanilla MF widely available in off-the-shelf packages, e.g., SPARK [23] and scikit-learn [14].

While the IFWMF method performs better than MF in lower quartiles, the other proposed approaches, i.e., FARP and TMF-based methods, outperform IFWMF for most of the quartiles in all the dataset thereby illustrating the effectiveness of FARP and TMF-based methods in preventing over-fitting and generating better predictions.

7 CONCLUSION

In this work, we have investigated the performance of the matrix completion-based low-rank models for estimating the missing ratings in real datasets and its impact on the item recommendations. We showed in Section 3 that the matrix completion-based methods because of skewed distribution of ratings fail to predict the missing entries accurately in the matrices thereby leading to an error in predictions and thus affecting item recommendations. Based on these insights we presented different methods in Section 4, which considers the frequency of both the user and the item to estimate the low-rank model or for predicting the ratings. The experiments on real datasets show that the proposed approaches significantly outperforms the state-of-the-art Matrix Factorization method for rating predictions for the users and the items having few ratings in the user-item rating matrix.

ABSTRACT

In the past, there have been several studies in analyzing password strength and structures. However, there are still many unknown questions to understand what really makes passwords both memorable and strong. In this work, we aim to answer some of these questions by analyzing password dataset through the lenses of data science and machine learning perspectives. We use memorable 3,260 password dataset collected from prior IRB-approved user studies over 3 years and classify passwords into three strength groups using online and offline attack limits. Then, we apply a *tensor decomposition* to analyze password dataset by constructing a 3rd-order tensor with passwords' syntactic and semantic features. In particular, we used PARAFAC2 tensor decomposition to uncover the main characteristics and features that affect password strength. We quantitatively identified the underlying factors that are more frequently observed in strong and memorable passwords. We hope that our finding can validate widely accepted advice for creating strong passwords and provide useful insights to design a better password suggestion system.

CCS CONCEPTS

• **Security and privacy → Authentication**; • **Computing methodologies → Factorization methods**.

1 INTRODUCTION

Although there have been several attempts to find strong alternatives to textual passwords, passwords are still widely used for many applications to authenticate users due to simplicity and convenience. However, textual passwords require two seemingly conflicting security and memorability requirements in order to serve today's user authentication needs. That is, users need to create both memorable and strong passwords. However, there is a clear tension between memorability and security. Strong passwords such as random strings are difficult to remember, while memorable passwords are easy to be guessed. Therefore, creating both strong and memorable passwords is a challenging task for a user. We, as security researchers, have to help users create both memorable and strong passwords, based on qualitative evidence and quantitative measurements.

To address these issues, several research [7, 9, 10, 19, 23, 25, 33, 34] have tackled the problems of analyzing and understanding the detailed structures of passwords and have shed lights on how people create memorable passwords. Also, Ur et al. [30] have uncovered some of users' misconception about strong passwords and users' detailed strategy to create strong passwords through small-scale lab study. However, prior research has heavily relied on leaked passwords dataset, which does not provide information on what passwords are memorable. Also, a small-scale qualitative study lacks on generalizing results based on quantitative measures. In addition, there are limited research in understanding the structures of passwords using the latest machine learning and data analysis techniques to identify latent factors that influence the creation of strong and memorable passwords.

In this research, we aim to understand syntactic and semantic features that strongly influence the creation of both strong and memorable passwords, using a *tensor decomposition*. A tensor decomposition is widely exploited and adopted in data mining, statistics, bioinformatics, psychology, physics, computer vision, and signal processing areas as a powerful tool to model a wide variety of heterogeneous, multiaspect, and higher-order data [24]. Especially, a tensor decomposition can effectively extract useful latent information out of multiaspect data tensors. In this work, in order to complement prior research, we consider passwords as multi-dimensional tensors and perform a tensor decomposition to uncover and validate the characteristics of both memorable and strong passwords. We leverage the memorable password dataset collected from prior IRB-approved user study by Woo et al. [36] as a baseline password dataset. Furthermore, we measure password strength in guess numbers using Monte-Carlo sampling method [13] and classify them to weak, medium, and strong strength group based on online (10^6 guesses) and offline guessing limit (10^{14} guesses) [14]. This allows us to analyze the characteristics of both memorable and

strong password structures using a tensor. Our key contributions are summarized as follows:

- We are the first to model passwords as tensors and apply a tensor decomposition to extract useful underlying features from passwords.
- We further provide the explainability on the syntactic and semantic features that predominately occur in strong and memorable passwords.
- Through distance analysis, we show and validate our results with findings from prior research.

Our quantitative finding supports that password length is the most dominating feature in explaining strong passwords. On the other hand, the predominant use of dictionary words are shown in weak memorable passwords. Our work provides the confirmation and validation of common advice in creating strong passwords, and can help guide users create both strong and memorable passwords.

2 RELATED WORK

Jakobsson and Dhiman [19] attempted to better understand the password structures. However, their research is limited in capturing diverse password patterns. Also, much research has investigated distribution of characters and types of mangling patterns [9, 10, 23, 34]. On the other hand, Ur et al. [30] conducted the small scale qualitative lab studies to uncover the rationale behind average users' misconception about weak and strong passwords. Although they provided very useful insights, their main focus is on the qualitative study. Rao et al. [25] found that people tend to use grammatical structures for long passwords and passphrases. They found that some Part-of-speech (POS) tags are more frequently used than others. In addition, Vera et al. [33] presented the first framework for automatically segmenting, classifying, and capturing the semantic essence of passwords. They employed the natural language processing techniques to effectively segment passwords into more meaningful semantic segments. However, their analysis is based on the leaked password datasets and cannot explain the specific factors influence the strength and memorability of passwords. From our understanding, no research efforts have made to systematically understand both syntactic and semantic latent factors that influence the construction of both strong and memorable passwords from a data science perspective. In this work, we employ a *tensor decomposition* to achieve these goals.

A tensor is a multi-dimensional array [24]. Due to its ability to express multimodal or multiaspect data, it is a very powerful tool in applications that inherently create such data. In mathematics, geometric vectors and scalars can be considered as the simplest tensors. A 1st-order tensor is a vector, a 2nd-order tensor is a matrix, and a 3rd-order tensor is a cube. In general, Nth-order tensor $\boldsymbol{X} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$ is represented by the outer product $\circ$ of N vector spaces as follows:

$$\boldsymbol{X} = a^1 \circ a^2 \circ \cdots \circ a^N, \tag{1}$$

where a^N is the vector in Nth dim. A rank (order) in a tensor indicates the number of components in the decomposed matrices and every tensor can be expressed as a sum of a rank-1 tensor [1, 22].

Expressing a tensor as a sum of a rank-1 tensor was first proposed by Hitchcock [17, 18]. Practical algorithms have begun to appear in the late 20th century. In 1970, Carroll and Chang [8] proposed a canonical decomposition (CANDECOMP) and Harshman [16] suggested parallel factor decomposition (PARAFAC), which is an extended version of 2-way factorization for higher-order data. Since CANDECOMP and PARAFAC have same concept, the CANDECOMP/PARAFAC decomposition formulated by Kiers [20] has been widely used. It decomposes Nth-order data into a linear sum of rank-1 tensor as described in Fig. 1.(a) and a 3rd-order tensor can be decomposed into three component matrices A, B, and C.

Harshman [16] suggested PARAFAC2 model to relax the limitation of CANDECOMP/PARAFAC model. Whereas CANDECOMP /PARAFAC decomposition requires the identical factors across a parallel set of matrices, PARAFAC2 requires only one identical factor mode (dimension) and relaxes the other factor matrices to vary. We use PARAFC2 for our password dataset analysis.

The Tucker decomposition is another commonly-used tensor decomposition, which was first introduced by Tucker [27] and refined later [28, 29]. It has a core tensor, which can be viewed as compression of original tenser $\boldsymbol{X}$. For a 3rd-order tensor, it decomposes a tensor into a core tensor and three matrices which have different ranks as shown in Fig. 1.(b).

Applellof and Davidson [6] pioneered the use of CANDECOMP/ PARAFAC model to extract information from a chemical system. Andersson and Bro [5] dedicated developing practical description and application of tensors. And Acar *et al.* [2, 3] was the first case to apply a tensor decomposition to data mining. They analyzed online chatroom data to understand how social groups evolved in cyberspace. They constructed a 3rd-order tensor with $user \times keyword \times time$ spaces. De Lathauwer and Vandewalle [12] applied the Tucker decomposition for dimensionality reduction in higher-order signal processing. Pioneers of the use of the Tucker decomposition in computer vision are Vasilescu and Terzopoulos [31]. They extended conventional Singular Values Decomposition (SVD) to N-mode SVD for a tensor. They also proved that it has significantly better performance than standard Principal Component Analysis (PCA) in image recognition [32].

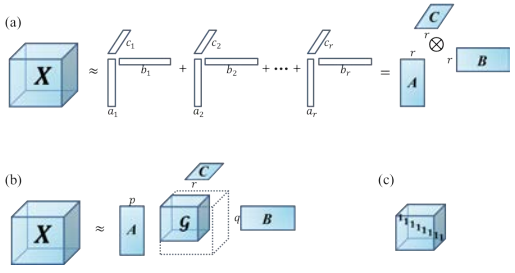

Figure 1: Examples of different tensor decomposition methods from a given 3rd-order tensor: (a) CANDECOMP/PARAFAC (CP) decomposition, where $\boldsymbol{X}$ is an approximated sum of r rank-1 tensors. (b) Tucker decomposition, where $\boldsymbol{X}$ is a rank-(p, q, r) tensor and g is a core tensor. (c) A super-diagonal core tensor with ones in all diagonal values. If the core tensor of Tucker decomposition is a super-diagonal and all of the ranks are same, it can be thought as same as CANDECOMP/PARAFAC decomposition.

3 TENSOR DECOMPOSITION OVERVIEW

Tensor decomposition is one of the most effective unsupervised methods to extract features and characteristics of Nth-dimensional

data and is capable of classifying data in the absence of training labels. Also, tensor decomposition can offer more accurate results by keeping the Nth-order structure of data without any feature mapping such as kernel trick as shown by other research [4, 11, 21].

Tucker decomposition: A given 3rd-order tensor $\boldsymbol{X} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$, the Tucker decomposition is described in Fig. 1.(b). and defined as follows:

$$\boldsymbol{X} \approx \sum_{p=1}^{P} \sum_{q=1}^{Q} \sum_{r=1}^{R} \mathbf{g}_{pqr} a_p \circ b_q \circ c_r = [\![\mathbf{g}; \mathbf{A}, \mathbf{B}, \mathbf{C}]\!], \tag{2}$$

where $a_p \in \mathbb{R}^{I_1}$ for p=1,. . ., P, $b_q \in \mathbb{R}^{I_2}$ for q=1,. . ., Q, and $c_r \in \mathbb{R}^{I_3}$ for r=1,. . ., R. g is a core tensor.

CANDECOMP / PARAFAC decomposition: As briefly discussed in Section 2, CANDECOMP/PARAFAC decomposition is a special case of the Tucker decomposition and can be constructed as follows:

$$\boldsymbol{X} \approx \sum_{r=1}^{R} \lambda_r a_r \circ b_r \circ c_r = [\![\lambda; \mathbf{A}, \mathbf{B}, \mathbf{C}]\!], \tag{3}$$

where R is rank, λ is weights $a_r \in \mathbb{R}^{I_1}$, $b_r \in \mathbb{R}^{I_2}$, and $c_r \in \mathbb{R}^{I_3}$, for r=1,. . .,R. For details of numerical tensor calculus, see Hackbusch's book [15]. CANDECOMP/PARAFAC decomposition can be considered as a special case of the Tucker decomposition where a core is super-diagonal and P = Q = R in Eq. 2. A super-diagonal is illustrated in Fig. 1.(c) [21].

PARAFAC2 decomposition: On the other hand, PARAFAC2 is a weak constraint version of PARAFAC. A given 3rd-order tensor, it is expressed by Acar and Yener [4] as below:

$$\boldsymbol{X}_k = \mathbf{A}\mathbf{D}_k\mathbf{B}^\top + \mathbf{E}_k, \tag{4}$$

where $\boldsymbol{X}_k$ represents a 3rd-order tensor, and $\mathbf{A}$ and $\mathbf{B}$ are the component matrices in the first and second modes, respectively. $\mathbf{D}_k$ is a diagonal matrix, whose diagonal elements are the kth row of the 3rd-component matrix $\mathbf{C}$. $\mathbf{E}_k$ contains residuals. Whereas PARAFAC must apply identical factors across the matrices, PARAFAC2 allows factors of matrices to be different but keeps only one factor invariance. Mathematically, it can be expressed by Acar and Yener [4] as following:

$$\begin{aligned} \boldsymbol{X}_k &= \mathbf{A}_k\mathbf{D}_k\mathbf{B}^\top + \mathbf{E}_k \\ \textit{subject to } &\mathbf{A}_k{}^\top\mathbf{A}_k = \Phi, k = 1, 2, \ldots, K, \end{aligned} \tag{5}$$

where $\mathbf{A}_k{}^\top\mathbf{A}_k = \Phi$ is orthonormal constraint and imposed to improve the uniqueness properties by Harshman [16] and all components are same as above.

4 DATASET

We leveraged the password data collected over three years from various authentication research by Woo et al. [35]. In the course of the study, these passwords were created and were successfully recalled after two days. The dataset includes more than 3,200 passwords. We used these successfully recalled passwords to understand features, which make passwords strong and memorable. First, we measured the strength of memorable passwords, using the Monte Carlo method by Dell'Amico, and Filippone [13]. We trained the guessing algorithm with a total of 21 million leaked passwords. Based on the estimated passwords' strength, we classified each password into the weak, medium or strong category, using the estimated number of guesses for online (10^6 guesses) and offline (10^{14} guesses) attack limits as boundaries between weak, medium, and strong password strength categories [14]. Number of passwords (%) in each strength group are summarized in Table 1. We found that majority of these collected passwords can withstand the online attacks, indicating these are fairly realistic passwords than now easily crackable leaked passwords from RockYou. After classifying memorable passwords into three different strength groups, we generated both *syntactic* and *semantic* features. Then, we applied the PARAFAC2 tensor decomposition to understand the latent syntactic and semantic features among different password strength groups.

Table 1: Memorable password dataset, categorized into three different strength groups

Strength Category	No. of Passwords (%)
Weak (guesses $< 10^6$)	109 (3.34%)
Medium ($10^6 \leq$ guesses $< 10^{14}$)	2,276 (69.82%)
Strong (guesses $\geq 10^{14}$)	875 (26.84%)
Total	3,260 (100%)

Syntactic Feature Generation: We generated 12 syntactic features for each password. First, we calculate the length of password (label: length) and the number of digits (label:D), special chars (label: S), and uppercase letter (label: UL). If there are more than three character classes among digits, special chars, uppercase, and lowercase letters, we define it as a 3class8, which is one of the widely used password composition policy. The number of class flips (change) is counted, when a character changes its class from one to another. Also, we counted the total number of flips (label: tFlips) as well as the following six sub flip cases: lowercase letter to special char (label: flipLS), lowercase letter to digit (label: flipLD), digit to special char (label: flipDS), digit to lowercase letter (label: flipDL), special char to lowercase letter (label: flipSL), and special char to digit (label: flipSD). We extract these features from each password.

Semantic Feature Generation: We used Vera et al.'s semantic segmentation parser [33] to segment the password and label each segment, which uses CLAWS7 tag set using Part-of-speech (POS) tagger by University Centre for Computer Corpus Research on Language (UCREL) [26]. In addition to CLAWS7 tag set, we have the following tags: "special$n$" and "char$m$", which represent the n consecutive special symbols and the m consequence characters. We extracted a total number of 114 different semantic features (tags). Through these initial tag generation process, we obtain a total of 67 features from 12 syntactic and 55 semantic features.

4.1 Pre-processing and Feature Refinement

Before actually constructing a tensor using the dataset with 67 features, we performed the following two pre-processing methods to make analysis much more reliable: 1) near zero variance removal and 2) normalization, which are popular pre-processing techniques.

1) Removing Near Zero Variance features: In one feature, if the majority of values do not vary much, then this feature cannot offer much useful information. And this would have an adverse effect on statistical analysis, since the variance is too small. These features with near zero variance values need to be eliminated prior to actual data analysis. In particular, we remove the near zero variance features for the following cases: the percentage of unique

values is less than 10% and the frequency ratio is greater than 19 (95/5). After removing near zero variance features using these two methods, we obtained a total of 31 features (12 syntactic and 19 semantic features) out of initial 67 features, where 12 syntactic tags are *length, D, S, UL, 3class8, filpLS, flipLD, flipDS, flipDL, flipSL, flipSD*, and *tFlip*. And 19 semantic tags include *article, verb, adjective, pronoun, nn, nn1, nn2, np1, npm, num, char1, char2, char3, special1, special2, number1, number2, number3*, and *number4*.

2) Feature Normalization: Since features are distributed in different ranges at different scale (i.e.: length, number of symbols), we should normalize each feature individually. We applied min-max normalization, which is one of the well-known feature scaling techniques as shown in Eq. 6. Min-max normalization changes all values into the range between 0 and 1, where the minimum value is mapped to 0 and the maximum value is mapped to 1.

$$Z = \frac{x - min(x)}{max(x) - min(x)}, \tag{6}$$

where *min* and *max* are the minimum and maximum value from the given x.

5 EXPERIMENTS

We have three pre-processed datasets for each weak, medium, and strong password group with its 31 features. Since we have 109, 2276, and 875 passwords in *weak, medium*, and *strong* strength group respectively, the size of the *weak* dataset is 109×31, the *medium* dataset is 2276×31, and the *strong* dataset is 875×31, where 31 is the number of features in each password group. Since our dataset has different size of rows across the strength and only one equivalent feature dimension, it cannot be a cube and we need to build up a 3rd-order tensor in different row size as shown in the left side of Fig. 2. The final dimension of our tensor becomes $I[3] \times J \times K = (109, 2276, 875) \times 31 \times 3$ and each dimension represents passwords (I[3]), syntactic and semantic features (J=31), and levels of password strength (K=3) from *weak, medium*, and *strong* as shown in Fig. 2.

Next, we decompose this 3rd-order password tensor into component matrices, **A**, **B**, and **C**, using PARAFAC2 algorithm including orthogonal constraint. After decomposition, we obtain component matrices **A**, **B** and **C** containing, where **A** consists of three password group-to-factor sub matrices ($(109,2276,875) \times r$) showing the factor dependency on each password across the strength matrices. And **B** represents the feature-to-factor matrix ($31 \times r$) indicating how much each feature (syntactic and semantic features) is affected by each factor. Final **C** captures strength-to-factor matrix ($3 \times r$) accounting for how much each factor affect passwords in each strength group.

Selecting an Optimal Rank *r*: When decomposing a tensor, it is critical to choose the optimal factor (rank) r, which is the number of factors to decompose a tensor. However, unlike 2-way factorization, there is no general straightforward algorithm to select the optimal r. Instead, a reconstruction error R_{error} is often used to find r, which is the difference between original tensor $\boldsymbol{X}$ and approximate tensor $\hat{\boldsymbol{X}}$ and it is calculated using the outer product of all matrices. It is defined as the Frobenius norm (Euclidean distance) $\|\boldsymbol{X} - \hat{\boldsymbol{X}}\|_{\mathbf{F}}$. In our case, from the 3rd-order tensor$\boldsymbol{X} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$, our goal is to find the following: $R_{error} = \min_{\hat{\mathbf{X}}} \|\boldsymbol{X} - \hat{\mathbf{X}}\|_{\mathbf{F}}$, where $\hat{\mathbf{X}}$ is generated in the same way in Eq. 5 and $\|\boldsymbol{X}\|$ is calculated as root-mean-square as follow:

$$\|\boldsymbol{X}\| = \sqrt{\sum_{i_1=1}^{I_1} \sum_{i_2=1}^{I_2} \sum_{i_3=1}^{I_3} X_{i_1 i_2 i_3}^2}. \tag{7}$$

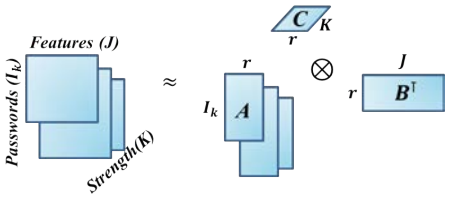

Figure 2: PARAFAC2 decomposition with password dataset, where the dim$(I[K] \times J \times K) = (I[3] \times 31 \times 3)$. $I[1] \times J$, $I[2] \times J$, and $I[3] \times J$ are the password-to-feature matrix in weak, medium, and strong password group.

In addition, we use the alternating least squares (ALS) algorithm to find an optimal value, and we must set the condition to stop the iteration for finding optimal solution. Otherwise, there is a possibility of falling into an infinite loop. We set 500 as the maximum iteration and 10^{-4} as the error tolerance, which is the gap of residuals between the present and previous iteration. Since the optimal r makes the reconstruction error the smallest, we trace Frobenius norm residuals and observe the percentage of variance to find an optimum.

A factor r and the residuals are mostly in inversely proportional to each other. It means that we can have a smaller residual as r increases. However, unfortunately, the ALS algorithm can perform poorly, if the number of factors r is too large. Therefore, we should choose a small r. And the Elbow method is one of the popular methods to achieve this goal, where the value at the sharp bending part of norm residual graph can be the optimal r. We present our optimum r in the following section.

6 RESULTS

Optimal Rank (r): We analyzed at the variance of the reconstruction ratio (R^2_{ratio}=$||\hat{\boldsymbol{X}}||^2/||\boldsymbol{X}||^2$) of the estimated tensor $||\hat{\boldsymbol{X}}||^2$ against the original $||\boldsymbol{X}||^2$ by changing the number of r from 2 to 10, as shown in Fig. 3. The Y-axis in Fig. 3 shows the percentage of variance between R_{error} as a red line and R^2_{ratio} values as a blue line, where R^2_{ratio} has an inverse relation from R_{error}. The sharp bending point shown in a dotted red circle is an elbow, which is the optimal r = 2. When r = 2, we further analyzed the reconstruction error R_{error} and found that R_{error} is less than 1% and the dropping rate is 73.80% showing drastic decrease compared to other neighboring points. The average dropping rate of other points between 3 and 10 were 18.48%. However, PARAFAC2 does not guarantee the uniqueness of decomposition solution. Hence, instead of relaxing the factor invariance constraint across the parallel set of matrices, we calculated the average R_{error} and R^2_{ratio} of each r by repeating 10 times.

With the factor value r = 2, our goal is to discover specifically which features have an dominating effect on the password memorability and strength from component matrices **B** and **C**. When we decomposed matrices, we applied the non-negativity constraints

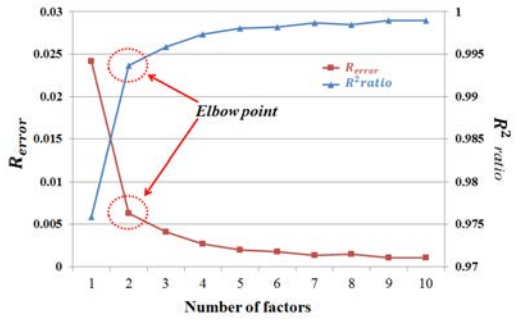

Figure 3: R_{error} (red line with the left Y-axis) and R^2_{ratio} by the number of factor (blue line with the right Y-axis). Each point is calculated as the average of 10 experiments. Red dotted circle indicates the elbow point.

to matrices **B** and **C**. Since non-negativity constraints not only mitigate the uniqueness problem but also provide positive values to component matrix after decomposition, it is more interpretable and practically used. Even though we mitigate the uniqueness issue by imposing non-negativity constraints, it does not eliminate the issue completely. Hence, we repeated the experiments 10 times and verified that all of them showed consistent patterns. Therefore, all results in this section are obtained from the one out of 10 representative experimental results.

Result 1. Syntactic + Semantic Features: We obtained the component matrices **B** and **C** from PARAFAC2 decomposition. To compute the decomposition, we use the alternating least square (ALS) method to select an optimal rank *r*. Specifically, a component matrix **C** captures the factors that directly influence password strength, as shown in Fig. 2. The detailed results of **C** are presented in Table 2, where passwords in *weak* strength group is affected by *factor1* with 0.7427 and *factor2* with 1.7622. On the other hand, passwords in *strong* strength group is impacted by *factor1* with 1.1229 and *factor2* with 2.8128. In addition, a component matrix **B** captures the relationship between two factors and each password feature. The detailed results of matrix **B** are presented in Table. 3. Note that, in tensor decomposition, it is not important to understand and interpret the actual value of factors. However, the relative effect and relationships among features are more important as shown in other research [2].

Table 2: A component matrix C, which reflects the relationship between two factors and strength group.

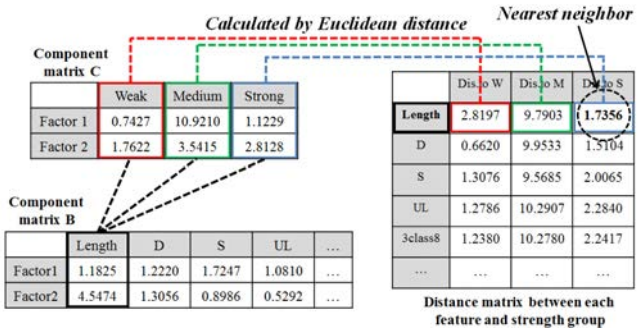

Figure 4: Illustration of finding the nearest neighbor of each feature from the component matrices B and C

Next, we need to identify features that have strong influence to each password strength group. We used the Euclidean distance (ED) algorithm to find the distance from each feature (i.e. length, D) to three password strength groups, where ED is computed as follows:

$$ED_{str} = \sqrt{(B^{str}_{f1} - C^{ft}_{f1})^2 + (B^{str}_{fr2} - C^{ft}_{f2})^2}, \quad (8)$$

where $str\ is\ strength \in \{weak, medium, strong\}$, $f\ is\ factor$, and $ft\ is\ feature$. B^{str}_{f1} is the $factor1$ value in Table 3 and C^{ft}_{f1} is the $factor1$ value from each feature in Table 2. The actual example of computing *ED* for length is illustrated in Fig. 4.

Each row in Table 4 is the Euclidean distance calculated using Eq. 8 and gray colored value in each row is the nearest neighbor (min.) distance. The smaller distance means the stronger impact to each password. As shown in Table. 4, only *length* is consistently computed as *strong*. This means that password length is the consistent and dominating feature that is related to strong passwords. In other words, a longer password triumphs over a more complex but shorter password, where similar results are found in other research [36].

Table 4: Distance matrix between 31 features and password strength. Length is the dominant contributor in making stronger passwords.

Result 2. Semantic features only: We found that the dominant contributor to strength is *length*. However, we still need to uncover what other semantic features can influence on both memorable and strong password creations. As we strongly hypothesize that semantic aspects would contribute in memorability, we conducted an additional experiment to examine semantic features other than length and syntactic features. In this experiment, we excluded syntactic features and only used 19 semantic features for a tensor decomposition.

Among 19 semantic features, *char1* was classified as *strong* most of the times. And *number4*, *nn1* (singular common noun, e.g. book), and *number2* (two consecutive digits: e.g. 37) was classified as *strong* 8 times. These four features can be considered as dominant contributors to generating strong passwords. Whereas *verb*, *adjective*, *nn2* (plural common noun, e.g. girls), *np* (proper noun and neutral for number, e.g. IBM), and *num* (every number, not digit, e.g. three) never appeared for *strong* strength group. Also, *np1* (singular proper noun, e.g. London) and *pronoun* were classified as *strong* only once.

From 19 semantic features, 10 features were based on dictionary word and 9 features non-dictionary word such as *char1*. Only one dictionary word feature (*nn1*) was shown to influence to strong password, as shown in Table. 5. It indicates dictionary words are rarely observed in strong passwords. It indirectly captures that users are making an effort to use non dictionary words to create strong passwords. If dictionary based words occur, they tended to be mostly *nn1* in strong passwords, which can be a crucial factor to improve the memorability of their passwords.

Table 5: Distance matrix between semantic features and password strength: dominant contributors are *number3, char1, nn1,* and *number2*. Most dictionary words features are not close to *strong* strength group. Only *nn1* is classified as *strong* among all dictionary word features.

7 DISCUSSION AND LIMITATION

In summary, the purpose of our research is to identify the features to make a password strong and memorable. Using syntactic and semantic features, we analyze password dataset and provide the insight to creating memorable and strong password. With 2-dim. password dataset, we constructed a 3rd-order tensor consisting of $(passwords \times features \times strength) = ((109, 2276, 875) \times 31 \times 3)$ and decomposed them using PARAFAC2. We discovered that password length is the dominant contributor in making a password stronger, compared to all other features. Among semantic features, most of them did not influence a strong password, except common nouns. Hence, we can conclude that creating a long password is the most powerful and practical way to strengthen memorable passwords. Although PARAFAC2 tensor decomposition provides a high degree of flexibility, it suffers from the uniqueness issue. Future research is needed in this area to further improve the performance of PARAFAC2. Also, we used more than 3,200 memorable passwords but more dataset would be helpful in more accurately identifying features. We also plan to perform our analysis with additional password datasets to verify our findings.

8 CONCLUSION

A tensor decomposition is the powerful method to quantitatively capture the importance and relationships among of underlying features in a dataset, providing the higher level of explainability. In this work, we applied the tensor decomposition for password data analysis and validate the features that strongly influence the creation of memorable and strong passwords. Our work complements the existing qualitative research and confirm the importance of creating a longer password using non dictionary words. Our work can be applied for better understanding the password structures for an unlabelled password dataset. Further, it can be integrated in generating password suggestions and advice for users to create memorable and strong passwords.

ABSTRACT

Rich engagement data can shed light on how people interact with online content and how such interactions may be determined by the content of the page. In this work, we investigate a specific type of interaction, *backtracking*, which refers to the action of scrolling back in a browser while reading an online news article. We leverage a dataset of close to 700K instances of more than 15K readers interacting with online news articles, in order to characterize and predict backtracking behavior. We first define different types of backtracking actions. We then show that "full" backtracks, where the readers eventually return to the spot at which they left the text, can be predicted by using features that were previously shown to relate to text readability. This finding highlights the relationship between backtracking and readability and suggests that backtracking could help assess readability of content at scale.

1 INTRODUCTION

Monitoring the interaction of users with Web pages at a large scale has contributed to a better understanding of reading behaviors [19] and to connecting patterns of readers' engagement to the textual content of articles [7]. At the same time, textual features have been used to model important aspects of writing, such as how readable [5] or engaging [21] a specific document may be. The latter, however, does not take into account the empirical behavior of readers, nor does it take into account specific attributes of the publication audience.

In this work, we use page instrumentation data[1] collected during reading sessions of online news articles in order to measure and study a reading behavior we refer to as *backtracking*. This under-explored signal of engagement occurs when readers scroll back or upward (see Figure 1) within an online article. A reader may backtrack, for instance, to re-read a previous section of the text. This definition of backtracking diverges from how backtracking was defined in lab studies of readability and text comprehension. For example, studies of *saccades* [31] — short, rapid eye movements between two close fixation points — refer to backtracking as regressive saccades, when the reader goes back a few words in the text. In contrast, our notion of online backtracking, while not as fine grained, presents multiple advantages. Such signals can be collected at scale by simple instrumentation of a Web page, allowing for regular observation of reading behavior in naturalistic settings over long periods of time.

Studying fine-grained signals of engagement such as backtracking at a large scale has the potential to greatly inform our understanding of reading and text. Recent work has examined similar signals to understand reading behavior in relation to textual content. In particular, Lagun and Lalmas [19] use within-page measurements of engagement, such as dwell time, to categorize reading sessions depending on the time spent in different areas of the page. Grusky et al. [8] use similar data to show that reading speeds (i.e., words-per-minute reading rates) are consistent with the ones observed in lab studies. Finally, recent work has begun to explore the modeling of user behavior using content-based features. Grinberg [7] has used accumulated information gain in the article to predict the farthest point read by users on the page.

In this work, we focus on backtracking behavior and its potential to reflect the qualities of the text. To this effect, we examine 1.4M sessions in which about 25K users read and engage with 8,000 online news articles across two major online publications. Because readers can backtrack for a variety of reasons, we define, explore, and measure the prevalence of three different forms of backtracking within articles. To better understand the connection between backtracking and article text, we develop text-based models that predict which articles experience high and low frequency of backtracking actions. We find that the signal we characterize as *full backtracking*– where a reader, after backtracking, eventually returns to the spot

at which they stopped reading–is related to properties of the text such as coreference and lexical features. Our results point towards the potential of backtracking as a new audience-driven approach to predict text comprehension at scale.

2 RELATED WORK

User engagement has been studied in depth since the early days of the Web. Signals have been gathered at page level (e.g. click-through rate [16]) or within pages, and in different settings, either transparently via instrumented pages or in controlled user studies. Such signals have then been leveraged for multiple tasks, such as understanding interaction with news articles [19], search satisfaction in browsers via mouse movements [14], or in mobile devices via touch actions [10]. Within the large body of work on this topic, we focus on work pertaining to reading behavior observed via eye-tracking devices, to readability, and to measuring the relationship between engagement and content.

Eye-tracking devices have been used in lab studies in order to examine readers' behavior. Most related to our work is the study of *saccades*, which are defined as a rapid movement of the eye between fixation points [31]. Saccades occur most often when scanning a text or trying to spot a specific piece of information while reading. Regressive saccades consist of going back by a few words, or a line at most, and represent about 10-15% of saccade events. They have also been referred to as backtracking, but differ from our definition of online backtracking as they operate at a much smaller scale. Eye tracking has also been used to explore the processing complexity of text when reading [17]. Other studies [22–24, 32] have incorporated eye-tracking and psychology in qualitative experiments and showed that good readers backtrack efficiently, while poor readers sometimes struggle to find the location that caused the difficulty, under the conjecture that comprehension failures are the cause of the regressive fixation. In contrast, our backtracking signal uses scrolling as a proxy for eye movement on the news article and is less granular, but requires no equipment and can be observed at scale.

Reading behavior has been studied extensively through the analysis and prediction of text readability. Traditional readability measures are typically derived from simple ratios of text properties, such as the average number of words per sentence, or the frequency of difficult words [3]. We take advantage of commonly used reading metrics, such as the Automated Readability Index (ARI) [34], which is defined as a function of the average character-per-word and word-per-sentence ratios. Other readability measures that we explore count the number of syllables per word [6, 26] or compute a ratio of multi-syllable words and the number of words and sentences [9, 18] to assess reading ease or grade level difficulty. Other reading indices include the Dale-Chall formula [4] that leverages a predefined list of "easy" words, with every other word being considered "difficult," or the nonlinear SMOG index [25], which uses syllable counting in order to identify challenging polysyllable words. Readability studies have also explored more complex language models [1, 29] considering grammatical structures [12, 13] and methods such as entity-grid representation [30, 33]. Feng et al. [5] have compared between different features for readability assessment, including coreferences, lexical and discourse features. These readability studies focus on assessing readability by grade level, using for instance manually-tagged datasets for grades 2-5 [28], or are targeted to non-native speakers, who are trying to learn a new language [29]. This makes these approaches not applicable to our domain of online news articles, for which most readers are past grade-level reading and are to the most part native speakers. For such an analysis, we lack large-scale manually tagged corpora, thus adopting the backtracking signal instead.

Similar to our work, which does not rely on manually-tagged corpora, other work has taken advantage of the textual content of Web pages to understand user behavior. In particular, Grusky et al. [8] and Lagun and Lalmas [19] have examined ways of measuring, validating, and modeling how users engage with online news articles. Similarly, Grinberg [7] has looked at semantic information gain and the development of ideas within the body of articles along with their topics in order to predict different types of engagement on news articles. We extend this existing line of work by focusing on a new signal of engagement, backtracking, which captures different aspects of reading behavior.

3 UNDERSTANDING BACKTRACKING

We first define backtracking events and identify the different types of backtracking seen in the data. We also describe backtracking patterns at page level, user level, and session level.

Backtracking takes place when readers break their sequential reading of an online document and scroll up, returning to a previous point in the text. One possible interpretation of such an event in the context of online news is that the user interrupted their sequential reading in order to re-read portions of the document, for example to find earlier references, to names, or to get additional clarity on content that may impact their understanding of the rest of the article [22–24]. Backtracking events may also involve other tasks the reader may perform on the page, such as, navigation or response to ad placement [36]. We explore several definitions that capture different aspects of backtracking.

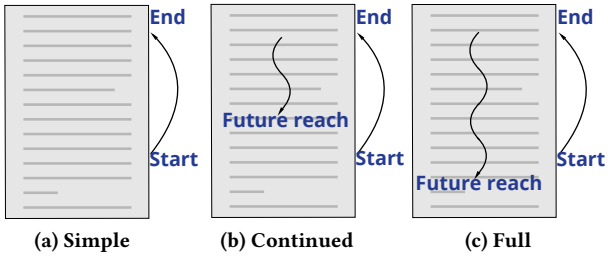

Figure 1: Different types of backtracking on Web pages

Defining backtracking (BT) events. A backtracking event occurs during a page-read event and is represented by an origin and target point defined as the tuple:

$$b = (start, end, reach)$$

Figure 1 presents the reading pattern for three different types of backtracking events. The first two values, *start* and *end*, represent the actual backtracking action and indicate a location in the article (hence, $start > end$). We also define *reach* as the furthest location

Table 1: P_{20} dataset size and number of backtracking events

	Users	Pages	Sessions	Simple BT	Continued BT	Full BT
LONG	15,949	3,968	694,728	57,897	28,840	246,787
SHRT	11,117	3,957	763,335	136,153	49,211	127,421

reached by the user following the current backtracking event. Capturing the *reach* value for each backtracking action helps interpret the context of the action by noting whether the user leaves the page, keeps scrolling or eventually returns to the *start* point. We define three types of backtracking events:

- Simple backtrack: Reader r scrolls back on page p but does not keep scrolling afterwards. Based on our previous definition, for the tuple $(start, end, reach)$, $reach \leq end$. This is the most basic backtracking signal.
- Continued backtrack: Reader r scrolls back, and proceeds to scroll forward afterwards but does not return to the *start* location ($start > reach > end$).
- Full backtrack: Reader r scrolls back, and eventually returns all the way to the backtrack starting point ($reach \geq start$).

In order to better capture intentional backtracks and meaningful movements of readers, we only consider backtracking of at least 100 pixels in range (consisting of about a dozen lines of text), where the user spends at least 15 seconds on the page after completing the backtrack.

Dataset description. Our dataset was provided by *Chartbeat* and includes data from two popular news websites from 2015. The first website is a popular news and entertainment magazine with long-form content, which we will refer to as LONG. The second, a popular short-format news website, will be referred to as SHRT. The raw data consists of "pings," which are defined as a record of viewport information [8] associated with a single user reading session on a single page. Pings are collected every 15 seconds, or at longer time intervals if a user is inactive. Every ping contains information about the visited page in the browser by a specific user, including height, width, length of the news article and the current position of the user on the page, all measured in pixels. We keep only data pertaining to English articles and originating from desktop (non-mobile) sessions. We consider only sessions that are longer than 30 seconds, as they are more likely to be indicative of actual reading behavior.

We refer to the session where a single reader r is reading a single page p as a *read event*. For most of the analysis below, we are using a subset of the dataset with pages p that have at least 20 reading sessions which we refer to as P_{20}. We chose to use P_{20} in order to ensure we have sufficient signal of behavior for each page, and reduce the effect of outliers (We perform sensitivity analysis in Section 4 to show how this choice effects performance in a prediction task.) The number of users, pages sessions and backtracking events performed in P_{20} are shown in Table 1.

Table 1 presents statistics on the different types of backtracking for pages that have passed the initial filtering P_{20}. We see that for roughly the same number of pages and reading sessions, LONG has almost twice as many full backtracking events, but less than half the number of simple backtracking events. There are two key factors that may explain this divergence. First, on the LONG site, pages are typically longer (5,000 pixels on average) than on SHRT (3,000 pixels on average). The longer the page, the more chances it will experience a backtracking action. In addition, we observed that on SHRT, a large proportion of simple backtracks end at the top of the page. This is likely a result of a static the navigation bar at the top of the page on SHRT website, causing the user to return to the top of the page in order to navigate to another area in the site.

As shown in Table 1, the P_{20} the dataset contains 1.4M reading sessions, but far fewer backtracking events. The majority of reading sessions have no backtracking event: 78% of the sessions in the LONG dataset, and 88% of the sessions on SHRT do not include any full backtracking event.

Backtracking patterns. Figure 2 shows the typical sizes of backtracking actions using a cumulative distribution function (CDF) of sizes for the three types of backtracking, measured in pixels. Given backtracking event $b \in B$, where B is the set of all backtracking events, let $\text{size}(b) = \text{start}(b) - \text{end}(b)$. Given any size x (x-axis), the CDF is $F(x) = P(\text{size}(b) \leq x)$ for all $b \in B$ (y-axis). As the figure shows, even though the pages on LONG are significantly longer than on SHRT, the typical size of full backtracking is smaller on LONG. For example, about 80% of the full backtracks (top curve in each figure) are under 550 pixels in size in LONG, while the same is true for only 75% of the backtracks on SHRT (top curve on both figures).

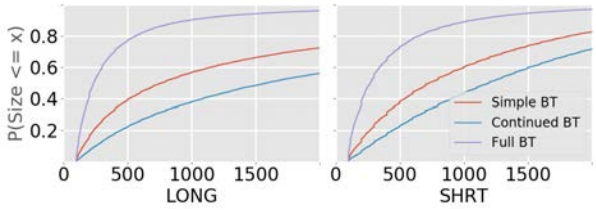

Figure 2: Backtracking sizes (in pixels) CDF

When readers backtrack, do they backtrack more than once? Figure 3 shows the number of backtrack events for sessions where there was at least one backtrack, for each type of backtracking event. For example, the right-most pane shows that 15% of LONG (red) sessions have exactly one full backtracking event. The rest of the sessions, that account for about 7% of the total number of sessions, contain two or more full backtracking events.

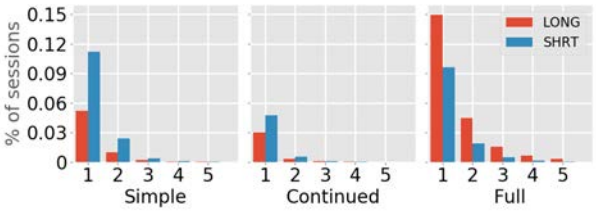

Figure 3: Number of backtracking events occurring across all sessions

We expect some pages to have more backtracking events than others, and we indeed verified that the variance of pages is much

greater than would have been be expected if the backtracking was a random event, e.g., modeled as a Bernoulli variable. We consider backtracking behavior to be close in nature to a Bernoulli, as we can see that backtracking more than once is rare and as such it is better to ask whether or not any backtracking event occurred. Figure 4 shows the page-level backtracking distribution for articles in P_{20}. The x-axis shows the backtracking-per-session average for each page, which is the number of backtracking events divided by number of reading sessions per page. The y-axis shows the number of pages with this average in each bin. For example, the right-most pane shows that, on LONG, very few pages have an average of more than 0.6 backtracking events per session. We see that for full backtracking, there is a significant difference in both variance and mean of the backtracking event distributions of the two domains.

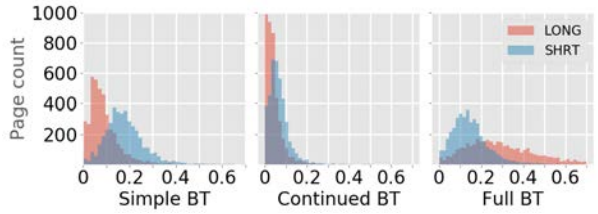

Figure 4: Are some pages more prone to backtracking? Pages' mean number of backtracking events per reading session

Are readers different in their tendency to perform backtracking? To answer this question we examine a slightly different subset of the data, U_{20}, comprised of reading sessions by users that have at least 20 reading sessions. Figure 5 shows the histogram of users' mean number of backtracks per session. Again, we see that the observed variance is much greater than if users backtracked at random, as a Bernoulli variable. The x-axis represents the average number of backtracking events per session, and the y-axis is the number of users within that bin. For example, half of LONG's readers (red) perform a full backtrack (right pane) once every three reading session on average. Compared to the page data (Figure 4), both the simple and full backtracking figures are more right-skewed, for both domains. For example, for the SHRT users (blue), there are many users that rarely perform any full backtracking.

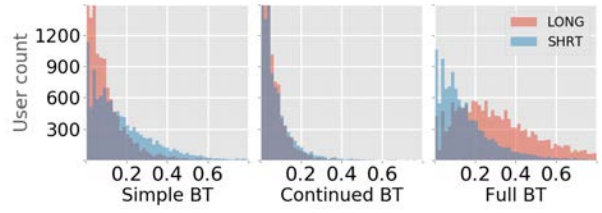

Figure 5: Do some users backtrack more frequently? Users' mean number of backtracking events per reading session

4 PREDICTING BACKTRACKING

How well can backtracking events be predicted, and what is the contributions of different features in predicting backtracking events? In this section we explore this question, also touching on the difference between types of backtracking events. The descriptive analysis suggests that LONG pages generate higher numbers of full backtracking events, which are more likely to relate to readability (as we also show below). Considering this finding, the analysis in this section is using only the LONG articles (line 1 in Table 1).

We define a binary classification task where we predict whether a page is likely to have a high or low number of backtracks per reading session. Based on the hypothesis that backtracking occurs when readers re-read a piece of text that they did not fully understand, we suggest that backtracking is an indicator of readability issues. We therefore examine several readability-related measures for texts as part of our prediction task, using a set of features inspired by previous work on readability by Feng et al. [5]. We consider four families of features at the article level:

Lexical features. These features have been shown to have strong predictive power in readability tasks, and can capture many different aspects of the text. The features include several established readability measures mentioned earlier, like the Dale-Chall score, and some simple text properties, such as average sentence length and the number of syllables per word. These features are computationally cheap to generate and do not require deep computational analysis.

Entity-density features. Entity-density features have been shown to be useful in readability prediction [5] mostly due to the fact that new concepts are often introduced in a narrative by entities (e.g. names, locations) and might impose additional burden on readers' working memory. In order to collect entities, we used spaCy[2] [15].

Part-of-speech (POS) density features. POS-based grammatical features are widely used for various tasks, including readability. In particular, [5] showed that noun-based POS features generate the highest classification accuracy in predicting correct readability grade level. In order to generate POS features, we use the spaCy POS tagger [15].

Coreference chain features. Coreference features were first studied in [5] for readability modeling, though they did not perform as well as two previous families of features in the earlier work. Our conjecture is that these features may help in representing the cognitive load on the user and should directly affect backtracking. We extract these features using the *End-to-end Neural Coreference Resolution* library[3] based on work by Lee et al. [20].

Table 2 provides more details about the features used for each family.

4.1 Defining the backtracking prediction task

Since our goal is to predict whether or not an article will have a high or low number of backtracking per reading session, we divide the training data into three equally sized sections, representing *high backtracking*, *medium backtracking*, and *low backtracking* based on the distribution shown in Figure 4. By excluding the third of the pages with *medium backtracking* and focusing on the equally sized *high backtracking* and *low backtracking* pages, we end up with

[2]https://spacy.io/
[3]https://github.com/kentonl/e2e-coref

Table 2: List of features computed for every article.

	Lexical Features
Dale-Chall score	Readability formula based on frequency of difficult words
ARI	Readability formula based on the relative length of words and sentences
Avg. syllables	Average syllables per word
SMOG grade	Readability formula based on the number of polysyllables (3 or more syllables)
Flesch-Kincaid score	Readability formula based on the ratio between sentences, words and syllables
Images	Number of images in article
Words	Number of words in article
Sentences	Number of sentences in article
	Entity-density Features
Entities	Number of named entities in article
Unique entities	Number of unique entities in article
	Coreference Features
Coreference chains	Number of coreference chains in article
Avg. coreference chain span	Average distance (in words) between words in the same chain
Avg. coreference chain size	Average number of words per chain
	POS Density Features (Nouns)
Percentage of nouns	Percentage of nouns in article (including entities) out of all tokens
Percentage of unique nouns	Percentage of unique nouns in article (including entities) out of all tokens.

balanced classes and a binary class label $y \in \{0, 1\}$, for two thirds of our training examples. We perform the same procedure for the development and test sets. We tested in preliminary experiments a set of classifiers such as SVM, logistic regression, and decision trees, we found that random forests performed best across all sets of features. Therefore, we use random forests for our analysis.

4.2 Prediction based on textual features

We examine how well the prediction performs with the full set of features, and assess the importance of the different types of features. From the P_{20} dataset, we keep only articles from LONG and split the samples into training, development and held out test sets with $75\% - 10\% - 15\%$ proportions. After filtering the *medium backtracking* pages, this dataset consists of 1,991-256-404 pages and 324,708-38,927-71,364 user sessions for training, development, and test sets. The allocation of pages to training, development and test set was determined by a random hash of the page URL. With a similar setup, but on a different subject, we perform an analysis akin to [2], including feature ablation. As mentioned before, the data for the prediction task is balanced and thus the expectation for a random prediction model is 50%. However, if we consider using the length (in pixels) of the page as the only prediction feature, the baseline to surpass is roughly 75%, in terms of accuracy.

The results, achieved on the held-out test set (and thus only computed after the work was complete) are shown in Table 3. The best performance was achieved using a random forest model[4] for full backtracking events, with an accuracy of 83.8%. We performed feature ablation by choosing a subset of features for the prediction task based on Table 2. For the feature ablation procedure, we associate each feature type with the length of the page, our control variable. We use length because, as mentioned above, longer pages provide more opportunity for backtracking, and length alone been shown to have significant predictive power for backtracking.

[4]hyper-parameters: maximum depth:10, minimum sample split:4

Table 3: Feature ablation for full backtracking prediction

Features	Accuracy	F1	AUC
All features	0.838	0.839	0.901
Lexical + length	0.824	0.826	0.889
Coreferences + length	0.802	0.806	0.861
Nouns + length	0.786	0.786	0.856
Entities + length	0.785	0.788	0.841
Length only	0.747	0.739	0.809

We notice that the lexical features hold the most predictive power, followed by coreference features. The strong performance of the coreference features, which characterize the average length and span of coreference chains in the text, is especially illuminating. These features represent a single facet of the textual context, compared to the set of different features included in the "lexical" set

When applied to the other two forms of backtracking, the complete model with all features can predict simple and continued backtracking with accuracy of 55% and 60% respectively, compared to the 85% accuracy of full backtracking prediction, the reduced performance of these models suggests that textual features are less useful in predicting simple and continued backtracking events. This follows our hypothesis that these two forms of backtracking are driven to other aspects of user actions, such as scrolling for inter-page navigation purposes.

Another aspect of the prediction task is the amount of information we have on every page. As mentioned earlier, pages with fewer than 20 views were discarded from our prediction task. We wish to know if requiring more information (a larger number of sessions) per page could improve the prediction task. We performed the training, test and prediction task on different subsets P_i of the full dataset, using a different minimum session count i for pages ($i = 1, 5, 10, 15, \ldots, 50$). The results are shown in Figure 6. The x-axis represents the minimum number of sessions per page (i), and the y-axis represents the average prediction accuracy, calculated in the same manner as defined earlier. For example, the prediction accuracy in P_{10} with the full model (red line, full circle markers) is over 80% (close to P_{20} performance), while length-only prediction on the same dataset (green line, empty circles) is 73.7%. We see that there is an increase in performance with a higher threshold for the minimum number of sessions per page, despite using fewer data points as i grows. Looking at the different sets of features, we see that all sets of features increase with a higher threshold of minimum views, but the improvement curve flattens out after $i = 20$. While we expect larger thresholds to yield better performance when more data is available, Figure 6 shows that it is sufficient to use 20 sessions per page to get enough signal for a prediction task.

4.3 Controlling for Users and Topics

We show above that the textual features of an article could help predict pages with high versus low levels of full backtracking. However,

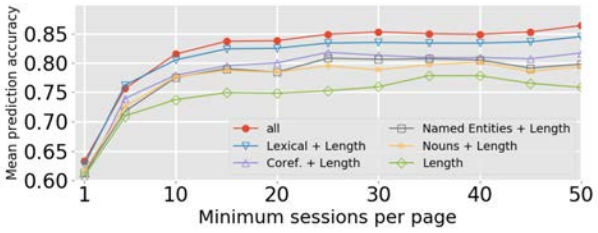

Figure 6: Prediction accuracy of different minimum sessions

we do not rule out the possibility that the text-based features are a function of the topic of the article (e.g., "health" or "sports"), or that the reader's choice of topics and articles to read is the one causing the observed differences in backtracking. For example, it could be that sports articles are easier to read or that users who choose to read sports articles tend to backtrack more often. In this section, we extend the analysis above to control for topics and users.

Topic vector. Article topics have been shown to have an effect on a user's reading behavior [7, 19]. Do topics have an effect on backtracking as well, and do they explain away the impact of any of the textual features? To examine this question, we used the set topics associated with every article as provided by LONG. We use the 35 most representative topics by removing from the dataset those that are either too rare or too frequent. From the selected set of topics, we produce a binary topic vector $T_i \in \{0,1\}^{35}$ for every page. We then add this vector as a new feature to our previously described backtracking prediction model. We do not observe any significant changes in the results, reaching +-1% in terms of accuracy, F1, and AUC compared to the results of the original model, as shown in Table 3. We also verified that the topic vector on its own is not a strong predictor of backtracking. Using the length of a page as control, a length + topic vector prediction task reaches 0.755, 0.747, 0.815 in terms accuracy, F1, and AUC — i.e. does not performs any better than a prediction based on length alone (as shown in Table 3).

Types of users. To effectively account for the effect of users choice of articles on backtracking we perform a similar prediction model to the one above, this time using the reduced-dimensionality user-page matrix as a feature in the prediction. Kallus et al [27] have shown that the use of matrix factorization to infer confounders can reduce the bias caused by measurement noise. Assuming specific users visit specific pages, we wish to learn the latent factors capturing different types of users, and further explore their significance on backtracking behavior. To this effect, we have built a binary page-user matrix $X \in \mathbb{R}^{mxn}$, where m, n represent the number of pages and users respectively from Table 1 and where X_{ij} is assigned the value 1 if user j visited page i and the value 0 otherwise.

In order to discover latent factors or low-dimensional embedding, we performed the matrix factorization $X \approx \hat{X} = UV$ or $\hat{X}_{ij} = U_i^T V_i$. Matrix $U \in \mathbb{R}^{mxk}$ holds the pages latent factors, while $V \in \mathbb{R}^{kxn}$ holds the users' latent factors. We take as a simplifying assumption that the difference between X and $\hat{X}$ is normally distributed, which allows us to use the mean-square error as our loss function.

We note as Ω the set of all observed (i, j) sessions. In the current settings, all sessions are observed, and we know for a fact whether or not a user has visited a given page. However, in order to better generalize our latent factors and account for the noise in our observed matrix, we hold out part of the of indices and perform cross-validation. This method is commonly used in collaborative filtering methods [35] in order to avoid overfitting. We add normally distributed regularization parameters to our model. This results into a new loss function, as stated below:

$$J = \sum_{(i,j)\in\Omega} (X_{ij} - U_i^T V_j)^2 + \lambda(\|U\|_F + \|V\|_F) \tag{1}$$

We use the alternative least squares [11] algorithm to minimize our loss function in an iterative way. This algorithm alternatively sets one matrix (U or V), and estimates the other by minimizing the loss function via derivation. This step is followed by adding the factor below to the latent factors' U, V matrices, iteratively until convergence:

$$\begin{cases} U_i = \left(\sum\limits_{j\in\Omega_i} v_j v_j^T + \lambda I \right)^{-1} \sum\limits_{j\in\Omega_i} (X_{ij} - \mu)\, v_j \\ V_j = \left(\sum\limits_{i\in\Omega_j} u_i u_i^T + \lambda I \right)^{-1} \sum\limits_{i\in\Omega_j} (X_{ij} - \mu)\, u_i \end{cases} \tag{2}$$

where Ω_i is the set of all users that visited page i, and Ω_j is the set of all pages that user j visited.

Similarly to the topics vector, adding the latent factors of pages to the prediction model showed a slight degradation in the prediction result on the held-out set, reaching 81.2%, 81.3%, 86.7% for accuracy, F1 score and AUC. In addition, the low-dimensional factors (with length of page as control) perform similar to our length-only baseline and reach 75.3%, 75.2%, 79.2% for accuracy, F1 score and AUC respectively.

5 CONCLUSION AND FUTURE WORK

This paper examines an under-explored signal, backtracking, and what it can teach us about the content of online news articles. We define and explore different types of backtracking actions on Web-based articles, showing that different news sites exhibit different backtracking patterns. We also demonstrate that full backtracking events can be accurately predicted with textual features related to readability assessment. By controlling for readers and topics, we discover that backtracking behavior is driven primarily by the textual content of an article. Our findings open a promising opportunity towards revisiting readability using large-scale web signals.

Our work has several limitations, related to data size and scope. Future work can extend the current work by analyzing a larger news corpora, or different content types, such as e-books. While our work only examined content from desktop interactions, understanding backtracking behavior across both desktop and mobile devices could expose different types of behaviors and perhaps more detailed understanding of backtracking. Finally, future work can leverage the insights about language's impact on readability and backtracking behavior. Such lines of work include supporting authors and editors in crafting content and helping struggling readers navigate text with language features known to hinder reading, such as coreferences. In both cases, the impact of these interventions could be measured at scale using the backtracking signal.

Unnecessarily Identifiable: Quantifying the fingerprintability of browser extensions due to bloat

†Stony Brook University
‡North Carolina State University

ABSTRACT

In this paper, we investigate to what extent the page modifications that make browser extensions fingerprintable are necessary for their operation. We characterize page modifications that are completely unnecessary for the extension's functionality as *extension bloat*. By analyzing 58,034 extensions from the Google Chrome store, we discovered that 5.7% of them were unnecessarily identifiable because of extension bloat. To protect users against unnecessary extension fingerprinting due to bloat, we describe the design and implementation of an in-browser mechanism that provides coarse-grained access control for extensions on all websites. The proposed mechanism and its built-in policies, does not only protect users from fingerprinting, but also offers additional protection against malicious extensions exfiltrating user data from sensitive websites.

1 INTRODUCTION

The past two decades have witnessed the web expanding and evolving at a tremendous rate with a similar expansion of the devices that users utilize to browse the web. However, this booming diversity of devices brought with it a new tracking technique called browser fingerprinting [8, 10–13, 16, 17]. Browser extensions are a recent addition to the fingerprinting domain [14, 18, 20, 23]. In order to provide added functionality, many extensions require full access to the pages that users visit. Some extensions modify existing elements from the Document Object Model (DOM) of webpages while others create new ones. Interacting with the DOM has the unfortunate consequence of causing side-effects which can later be detected and attributed back to installed extensions. In previous work, we showed that the presence of many browser extensions can be inferred just by looking at the modifications that they perform to the DOM [23]. Any malicious script running on the same webpage can then try to fingerprint the list of extensions installed in the browser. This poses a serious privacy risk as extension fingerprintability can lead to the identification of a user.

Fixing the problem of fingerprintable browser extensions is not straightforward. Browser extensions are intended to access and modify webpages that users are visiting and, in many cases, this is their main and desired functionality (e.g., hiding ads, highlighting search results, or enlarging photo thumbnails). At the same time, the question remains whether such functional side effects need to manifest on all pages unconditionally. For example, if a webpage does not contain ads, search results, photos, or other triggering content, it is completely unnecessary for an extension to disclose its presence since it will be hurting the privacy of the user while delivering no useful functionality.

In this paper, we investigate whether the page modifications that make extensions fingerprintable are necessary for their operation. We define the notion of *bloat* in the implementation logic of browser extensions as the unnecessary side effects that offer no functionality to users and can be abused for extension identification. By analyzing 58,034 extensions from the Google Chrome store, we identify the behaviors characteristic of bloat and quantify its prevalence in the wild. We study the origin of fingerprintable bloat and discover cases of shared libraries and common coding practices, which contribute to it. Moreover, we show that bloat is responsible for a large fraction of all fingerprintable on-page changes from extensions.

Orthogonally to our measurement and characterization of extension bloat, we argue that it is important for users to have client-side control over the reach of browser extensions and their interactions with the DOM of webpages. We provide the design and implementation details of a client-side access control mechanism that mitigates the aforementioned privacy risks that derive from bloat by empowering users to selectively enable/disable extensions on arbitrary websites. Moreover, we discuss how the same client-side access-control mechanism protects against general privacy risks of untrustworthy browser extensions, i.e., limiting or altogether stopping the leakage of browsing history and other sensitive on-page information by buggy and malicious extensions.

2 BLOAT-RELATED FINGERPRINTABILITY OF BROWSER EXTENSIONS

Software bloat refers to software including unnecessary code and libraries while the process of *debloating* denotes the removal of the excess components. For this paper, we focus on software bloat in terms of unnecessary implementation logic inside browser extensions, which results in them being unnecessarily fingerprintable. We use the following definition:

Definition. *Bloat-related side effects of browser extensions are artifacts on a web page which do not deliver functionality that is desired by users, yet reveal the extension's presence to trackers and fingerprinting scripts.*

2.1 Types of bloat

When the user visits a page with an installed extension, both the extension and the page have access to the same Document Object Model (DOM), which provides a programmatic interface of the page to JavaScript code. The extension can add or remove elements from the DOM of the visited page by injecting JavaScript. The core observation of our definition with regard to extension bloat, is that an extension should not modify the DOM of the visited page, unless it is absolutely necessary for its functionality. Unnecessary DOM modifications by the extension disclose its presence to visited pages and therefore to trackers situated on those pages.

Some extensions will perform changes on the visited page that are part of their intended functionality. For example, static panels filled with information (e.g., showing website statistics), toolbars with URL-independent tools (e.g., CSS inspectors), and modified text (e.g., extensions to correct the spelling of words) are all intentional. One may notice that the common feature of all of these examples is the presence of useful functionality, even if that functionality manifests on all pages.

To identify cases of true extension bloat, i.e., modifications that are unnecessary since they do not provide any useful function, we manually analyzed the types of changes that extensions perform on an empty page and their purpose. Our intuition was that an empty webpage has no existing content to trigger the logic of browser extensions. As such, any DOM modifications are potentially the result of bloat and should be investigated. Through this manual experiment we identify the following extension-independent categories of unnecessary DOM modifications:

•**Injected empty placeholders**. We discovered that it is a common practice among many extensions to include empty or invisible DOM elements first, which will be filled with data later based on a trigger (e.g., when specific content appears on a page, or when a user clicks the extension's icon) (Figure 1). The direct consequence of this preemptive DOM modification is that these placeholders unnecessarily increase the fingerprintability of extensions especially in the cases where the extension remains otherwise inactive.

•**Injected script tags**. Some extensions add script tags to the page's DOM, which are visible to any other script executing on the page. However, extensions have the ability to add and hide script tags, before any original code is executed on the page, by properly registering content scripts (i.e. scripts running together with webpages with access to a shared DOM).

•**Injected style tags**. Many extensions inject CSS tags into the page's DOM, which are visible to any script on the page. This behavior is unnecessary because there exist special APIs for extensions to inject CSS stylesheets in a page (e.g. `chrome.tabs.insertCSS`). When an extension uses this API, the added styles are not visible via standard CSS-querying APIs, such as, `document.styleSheets`. Using these methods, the injection does not modify the DOM tree.

•**Attributes for body/head/html tags**. Bloat also occurs when an extension sets attributes to parent DOM nodes, such as the `body`, `head` or `html` tag. We discovered many cases of custom attributes with words "installed" or "injected", which do nothing except disclose the extension's presence. Even if these attributes are used in CSS selectors, given that they target well-defined tags, they are unnecessary and can be removed from the corresponding CSS rules.

```
// Unnecessary and invisible placeholders
<div class="plugin-body" style="display:none;">
</div>
<div id="addManualImageDiv" style="display: none;">
</div>
<div id="mystickies"></div>
// Unnecessary top-level attributes
<html style="visibility: visible;">
<body screen_capture_injected ="true">
<body style="">
```

Figure 1: Examples of bloat-related DOM modifications of browser extensions.

Similarly to empty placeholders, attributes with empty values are signs of bloat in the extension's logic. The bottom half of Figure 1 illustrates several real examples of such behavior.

•**Window messages**. The browser provides a programmatic way for different JavaScript execution contexts to communicate via messages. Extensions can send a message to the visited page using `window.postMessage`, but that message can be received by any script running on the page that has registered the appropriate callback function. Since these messages reveal the presence of the extension to the visited page, we consider the presence of such messages on an empty webpage as extension bloat.

2.2 Quantification of extension bloat

To measure the fingerprintability due to browser-extension bloat, we collected 58,034 extensions from the Chrome Store in October 2017. These include 25,779 extensions with permissions to modify web pages on any URL. We evaluated each extension according to the necessary condition of our bloat definition. Namely, we retrieved all the fingerprintable DOM modifications that an extension introduces on any domain and filtered out ubiquitous side effects which were part of an extension's desirable functionality.

In order to automate the testing of extensions, we modified and used the source code of XHound [23]. Given the more narrow definition of the bloat-related DOM modifications (compared to *all* modifications that XHound can uncover), we simplified XHound by taking each extension to a custom domain only once, simulating the visiting of an arbitrary website. Moreover, we served an empty HTML page to extensions in order to eliminate the possibility of any specific content triggers, and we disabled the usage of the XHound's OnTheFlyDOM library as we are not interested in DOM modifications in response to specific content or user actions. As such, we collected only those fingerprintable side-effects that occur on an arbitrary webpage without any triggering content and without user actions. To further minimize the probability of false positives, we filtered out any cases of discovered "bloat" which do not conform to our definition, therefore calculating a lower bound of bloat-related fingerprintability.

Overall, we discovered 3,320 extensions, or 5.7% of all the extensions in Chrome's webstore, which have at least one fingerprintable side effect because of bloat. Out of those, 2,189 inject unnecessary nodes into the DOM (e.g., div, span, script, style), and 1,526 set unnecessary attributes to the body, head or HTML nodes. Moreover, 65% out of 3,320 extensions had *all* their changes categorized as bloat. In other words, these 2,145 extensions should have been completely invisible on our test pages. Figure 2 shows that both popular and less popular extensions are affected by this type of

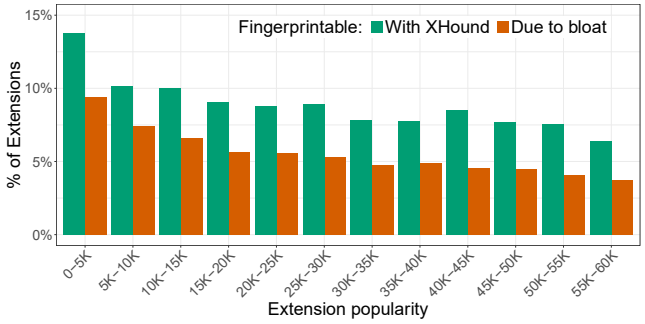

Figure 2: Percentage of fingerprintable extensions, and extensions with fingerprintable bloat, shown by extension popularity. High-ranked extensions tend to be more fingerprintable, and bloat-related side effects contribute to a stable large fraction of fingerprints.

bloat with more than 9% of the top 5K extensions containing bloat, and approximately 4% of the less popular extensions.

Apart from bloat-related DOM modifications, we discovered that 213 extensions reveal their presence by posting disclosing messages to web pages upon installation. We were surprised to find such a large number of extensions since Chrome APIs provide the ability to set up communication channels with only selected web pages with the `externally_connectable` permission. Moreover, we discovered 637 extensions listening to messages from any web page. This means that a tracker can potentially craft and send expected messages and wait for visible side effects from extensions in response. For example, as shown on Figure 3, Crypto-Plugin, a banking extension with 304,730 active users, responds to a specially-crafted message if there is an input element with id `CryptoPluginInstance` and a value containing a JSON-formatted command. Note that this behavior of taking arbitrary content and treating it as command can, in addition to make extensions unnecessarily identifiable, lead to severe security issues.

2.3 Impact on extension fingerprintability

In this section, we compare our results to the unmodified XHound prototype, which deploys additional techniques for triggering the functionality of browser extensions and can thus discover more fingerprintable side-effects. We find that a large fraction of fingerprintable extensions are actually fingerprintable due to bloat and could thus become invisible to trackers, if their bloat-related DOM modifications are removed.

Overall, using XHound, we could identify 5,323 fingerprintable extensions. Given our earlier finding of 3,320 extensions introducing bloat-related fingerprintable side effects, approximately 62% of all the fingerprintable extensions have at least one bloat-related side effect, which adds to their fingerprint. Moreover, even when using XHound's on-the-fly triggering content, 1,073 extensions remain with bloat only, suggesting that this bloat can be safely removed to make extensions invisible from prying webpages.

The bloat-related side effects of 3,320 Chrome extensions resulted in 2,032 extensions sharing their bloat-related fingerprint with no other extension (i.e. their bloat-related DOM modifications are unique to them and could be used to uniquely identify them). In terms of anonymity set sizes: 61.2% had totally distinct fingerprints, 8.8% shared their fingerprint with up to 10 other extensions, 7.2%

```
window.addEventListener("message", function(event) {
  if (event.data.sender == "crypto.plugin.native") {
    console.log(JSON.stringify(event.data));
  }
}, false);

var dummy_input = document.createElement("input");
dummy_input.setAttribute("value", "{}");
dummy_input.id = "CryptoPluginInstance";
document.body.append(dummy_input);

window.postMessage({sender: "crypto.plugin.js"}, "*")

// CONSOLE OUTPUT:
{"answer":{"errorCode":1,"errorText":"Wrong function"},
"type":"error", "sender":"crypto.plugin.native"}
```

Figure 3: Detecting the Crypto-Plugin extension by sending an appropriately-crafted message, simulating a triggering DOM content, and listening to the response.

shared with up to 100 extensions, while 22.8% shared their fingerprint with more than 100 extensions because of similar bloating changes related to jQuery (we discuss this in the next section). As a result, unnecessary bloat-related fingerprintability is, in and of itself, a clearly dangerous extension-fingerprinting vector.

2.4 Origin of bloat in browser extensions

According to our manual analysis of extension bloat (Section 2.1), poorly-designed internal logic is the most common reason for extension bloat. First, we discovered 1,070 extensions with the design flaw of adding placeholders before filling them with useful content. Second, we witnessed several cases of implementation bugs when a DOM modification appears because of poor coding practices. For example, the code in Figure 4 adds an empty class attribute to the body node even if `eod_disabled` was not set initially.

Next to extensions having their custom logic leading to unique cases of bloat, we discovered several libraries that perform unnecessary modifications in the DOM. For example, the jQuery library, when included as a content script, injects an empty style to the body of web pages (discovered on more than 980 extensions). Moreover, particular versions of jQuery have other hardcoded side effects like an injected div tag with id `pg_hgfkj4kj32mda` (version 1.7.2), or the added style `zoom: 1;` to the body of web pages (version 1.9.0). We also discovered the FancyBox JavaScript library on 65 extensions, which adds custom styles to web pages. Additionally, the CrossriderAPI, a cloud-based extension development tool, adds its own attribute to a page's body, namely `crossrider_data_store_temp`, on at least 45 extensions. In addition to the aforementioned cases of bloat, we discovered other cases of the same bloat modifications manifesting across tens of extensions but we could not attribute them to a particular library. These types of modifications could be due to reused code across related extensions or extensions developed by the same developers.

In summary, we discovered that a large number of browser extensions introduce fingerprintable modifications that could have been avoided and which are not necessary for the proper operation of the extension. On the one hand, this is a positive development since this finding suggests that the more careful design and implementation of browser extensions would allow users to be less fingerprintable, without the need to avoid using these extensions. On the other hand, solely relying on extension developers to voluntarily make their

```
document.documentElement.className =
  document.documentElement.className.replace(
    /eod_disabled/g, "")
```

Figure 4: An example of implementation bug in browser extension, which results in unnecessarily fingerprintable DOM modification

extensions more robust against browser fingerprinting, is likely not going to lead to drastic improvements with regard to user privacy. As such, we argue that there is a need to protect users, even when extension authors are not committed to change the logic of their extensions. We discuss such a solution in Section 3.

By comparing the set of fingerprintable/undetectable extensions throughout the years, we discovered that most extensions retain their original status. That is, if the first version of an analyzed extension was fingerprintable, the extension remains fingerprintable through subsequent updates. Overall, only 258 extensions from the initial 1,000 fingerprintable set were not fingerprintable in their first version. Similarly, most extensions that were originally undetectable, remain undetectable. This finding suggests that the fingerprintable bloat of extensions remains stable over time and thus requires an explicit attempt to remove it (i.e. will not disappear in future versions of extensions).

In the following, we present a few case studies of extensions which migrated from undetectable to fingerprintable and vice-versa. One example of an extension which became fingerprintable is Extended JS Console. It was undetectable for two years until the developer used the Crossrider framework to make development across different browsers easier. This framework injects a `crossrider_data_store_temp` attribute to the list of body tags that makes the framework easily detectable. Another example is the Dayboard extension which, after 18 undetectable versions, started to inject a `db-visibility-check` empty div on all visited page. Fortunately, there are also 72 extensions which were once fingerprintable but later became undetectable, e.g., the Web PKI, which, since February 2018, has stopped injecting empty div placeholders.

3 COUNTERMEASURES

Since extension authors cannot be trusted to appropriately limit the access of their own extensions (either due to the inability to specify a finite whitelist that works for all users, a lack of motive, or outright maliciousness), the limiting of those extensions must happen at the client-side.

This means that, in addition to extension authors specifying on which websites a given extension should run, there should be a second layer of access-control which empowers users to limit the access of extensions according to their needs. For example, users may want to disable ad-blockers on specific websites which they want to support with ad-revenue, even if the ad-blockers do not support per-website whitelisting. Similarly, users may want to disable all extensions on their banking website, to limit their exposure, in case of accidental information leakage [22] or malicious data exfiltration [7, 9, 15].

Instead of relying on users to whitelist/blacklist each of their installed extensions on every domain that they visit, we argue that we can build higher-level access-control primitives which can be intuitively utilized by users with limited technical expertise. Specifically, we propose primitives that take the form of the following access-control modes:

```
{   "ExtensionSettings":{
      #UBlock Origin
      "cjpalhdlnbpafiamejdnhcphjbkeiagm":{
         "runtime_blocked_hosts":[
            "*://*.bankofamerica.com"
         ]
      },
      #Dark Mode
      "dmghijelimhndkbmpgbldicpogfkceaj":{
         "runtime_blocked_hosts":[
            "*://*.google.com",
            "*://*.bankofamerica.com"
         ]
}}}
```

Figure 5: Example of an ExtensionSettings policy for two separate extensions.

•**Blocking extensions by default**. The goal of this mode is to stop "drive-by fingerprinting", i.e., the complete fingerprinting of a user's extensions just because a user visited an untrusted website.

•**Automatic disabling of extensions on sensitive domains**. We argue that there is often no need for extensions to be able to run in any and all websites that the users visit. As such, given a list of sensitive URLs (such as banking websites, social networks, dating websites, and healthcare-related websites), the browser can automatically disable all extensions on these domains and allow users to re-enable only the ones that they absolutely need.

•**Content-based automated blocking**. Next to maintaining lists of sensitive websites, we argue that a user's exposure can be further reduced if a browser disables extensions when a webpage allows users to input content. For example, disabling extensions on login pages could help reduce the likelihood of an extension exfiltrating user credentials.

Given the HTTPS issues of client-side proxies and the lack of APIs that a browser extension can use to block other browser extensions, a client-side access control mechanism for browser extensions *has* to include some level of browser modifications. By inspecting the source code of Chromium (our browser of choice given the availability of its source code and its market share) and discussing with developers of Chromium, we discovered the presence of an *Enterprise* mechanism built in the browser. Enterprise mechanisms are typically utilized in corporate environments where system administrators wish to limit the features that are available to individual deployments of powerful software, such as, a web browser. Even though these features are completely invisible to regular users, we discovered that the Enterprise features of Chromium were introduced in 2012 and are still part of the code base of the regular browser that users download.

Chromium's enterprise mechanisms are driven by an enterprise policy written in a platform-dependent format (e.g. JSON on Linux) which allows administrators to manage the browser's configuration and behavior. These policies cover a wide range of browser settings, from power management and proxy configurations, to printers, startup pages, and the default search engine. For our purposes, the `ExtensionSetting` policy allows administrators to disable specific extensions, and stop users from installing any extension that requests specific permissions [2]. The following two directives that control which websites can be accessed by extensions, are of particular interest for our client-side access control mechanism:

•`runtime_blocked_hosts`: List of strings representing hosts whose webpages the extension will be blocked from modifying.

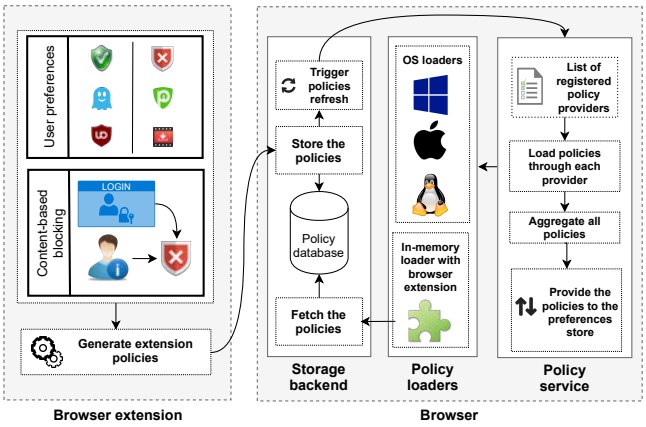

Figure 6: Implementation overview of the client-side access control mechanism for browser extensions.

•`runtime_allowed_hosts`: List of strings representing hosts that an extension can interact with, regardless of whether they are listed in `runtime_blocked_hosts`.

Figure 5 shows an example of an *ExtensionSettings* policy. The first ID refers to the ad blocker "uBlock Origin" and the second to the "Dark Mode" extension (an extension that changes the background color of a website and which we will use in a later demonstration). This policy instructs the browser to block both extensions from accessing any webpages from Bank of America but only the ad blocker is allowed to operate on `google.com`.

The files containing the Enterprise policies, are expected to be present in predefined filesystem paths, according to the operating system of the user. If such a file is discovered during the startup of the browser, it is loaded and enforced by Chromium.

By retrofitting the already available enterprise mechanism and exposing it to regular users through a dedicated UI that converts user choices to JSON policies, we can enable client-side access control of extensions with minimal changes to the browser's code. In addition to modifying as little as possible of the browser's existing code (therefore increasing our chances of adoption), we also rely on a proven mechanism that provides comprehensive extension blocking in a way that is not possible by combining blocking directives available to extension authors (such as the `exclude_matches` directive which allows extension authors to opt-out of running on specific domains and URLs).

The source code of our modified Chromium browser along with a fully compiled version can be found on GitHub: `https://github.com/plaperdr/extension-access-control`.

3.1 Interfacing with the user

Since Enterprise policies are fully controlled by JSON-formatted files available in obscure file paths, we cannot reasonably expect users to directly interact with them. To bridge the Enterprise policy mechanism with the interfaces that users are already familiar with, we developed a browser extension that creates policies based on user choices. Next to allowing users to individually disable extensions on websites through our extension's UI, we provide support for the following three blocking strategies, which map to the access-control primitives described in Section 3:

•**Flexible mode (default mode)**: All extensions are allowed on all webpages and the user can disable (or re-enable) at any time an extension on a specific website. Note that this mode does not interfere with the selective exclusion that extension authors may request using the `exclude_matches` directive in their manifest files. As such, extensions that were previously active only on selected URLs (e.g. a video-downloading extension being active only on `youtube.com`) remain active only on the same URLs.

•**Sensitive mode**: This mode is similar to the *Flexible mode* but comes preloaded with a list of sensitive websites where all extensions are automatically blocked. For our proof-of-concept implementation, this list consists of 50 popular banking websites. This mode also supports content-based blocking where extensions can be disabled if our mechanism detects the presence of sensitive content on a website that is not part of our predefined lists. Specifically, our current implementation blocks extensions whenever a password input field is detected in a webpage's HTML code.

•**Strict mode**: In this mode, all extensions are by default blocked on all websites. Users can selectively enable extensions wherever they require them.

Given a desired policy of blocking and enabling browser extensions on specific websites, this policy needs to be communicated to the enterprise policy-parsing mechanisms of the browser. Chromium has a relatively complex policy-loading system that spans dozens of files and thousands of lines of code. Figure 6 provides an overview of our modifications. First, our user-facing extension transforms all user choices and all rules derived from content-based blocking into an *ExtensionSettings* policy readable by the browser, indicating for each installed extension which hosts are blocked and which are allowed. This policy is then stored in a database that is available to our extension.

As mentioned earlier, the Enterprise mechanism expects policies to be available on different filesystem paths depending on the user's operating system. Specifically, Chrome's policy loader uses GPO (Group Policy Object) on Windows, XML files on MacOS, and JSON files on Linux. All of these locations are encoded as different "providers" in one combined mechanism called a *Policy Service*. For our implementation, we modified the Policy Service and added a new policy provider which pulls new policies directly from the database of our user-facing extension. Whenever a policy changes (e.g. because the user whitelisted/blacklisted an extension, or switched modes), our service triggers a "refresh" which causes Chromium's Policy Service to pull a new copy of the policy. The policies from all policy providers are then combined into a unique policy and transmitted to Chromium's *Preferences Store* that will parse it and apply it.

3.2 Evaluation

Performance Overhead. To test the overhead of our client-side access control mechanism, we visited the Alexa Top 50 websites with the original (i.e. unmodified) version of the Google Chromium browser (v.71) and our modified copy of the same version of the same browser. For each visited page, we recorded the time it takes for the browser to completely render every element. Specifically, we collected the timestamps corresponding to the following three events from the *window.performance.timing* object:

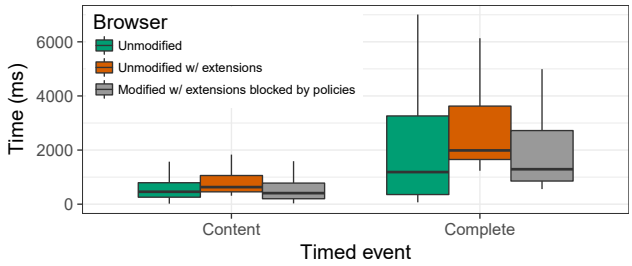

Figure 7: Performance measurements of unmodified Chromium version 71 with and without installed extensions, against our modified Chromium browser.

• the *DOMLoading* event is fired when the parser starts parsing the received webpage.

• the *DOMContentLoaded* event marks the point when both the DOM is ready and there are no stylesheets that are blocking JavaScript execution.This means that the browser can start combining the DOM and CSSOM into a render tree.

• the *DOMComplete* event is fired when the page and all of its subresources are ready.

We tested three different configurations: unmodified Chromium with no running extensions, unmodified Chromium with extensions, and our custom Chromium in "Strict" mode with extensions (i.e. all extensions are present but blocked by our custom policy). For our tests, we utilized five popular extensions: AdBlock [1], Google Keep [3], Grammarly [4], Honey [5], and LastPass [6]. The number of extensions was chosen to match the average number of extensions that regular users install, according to Starov et al. [23].

We repeated the measurements ten times and averaged the results, which are shown in Figure 7. The "Content" category corresponds to the time between the *DOMLoading* event and the *DOMContentLoaded* one. The "Complete" one is the time between *DOMLoading* and *DOMComplete*.

For both categories, we observe that the timings of our modified browser with all extensions disabled by the applied "Strict" policy closely match the timings of the unmodified browser without any extensions installed. Given that our mechanism makes use of existing Chromium code which we retrofit to give users the ability to make client-side access-control decisions, the obtained performance results make intuitive sense. Overall, our findings demonstrate that client-side access control of extensions not only will not slow down a user's browser but will, in fact, increase its performance by disabling extensions when they are not necessary.

Blocking Coverage. To test whether the extensions disabled through our access-control mechanism are completely disabled, we performed the following experiment. We selected 1,000 extensions which were introducing bloat-related fingerprintable DOM side effects and installed them, one by one, on our modified Chromium browser. We then used that browser together with the XHound tool [23] and attempted to extract fingerprints from each extension.

For the 985 extensions that we could install in our modified browser (15 out of the 1K sample would not properly execute on Chromium version 71), XHound was unable to extract fingerprintable DOM modifications, when these extensions were blocked through the "Strict" policy of our client-side access control mechanism. Given that XHound searches for any and all DOM modifications that can be attributed to an extension, this gives us confidence that our modified browser successfully disabled all extensions.

4 RELATED WORK

In the last few years, the privacy implications of browsers extensions have received significant attention [9, 14, 18, 19, 21–23, 25]. To the best of our knowledge, this is the first paper that i) quantifies to what extent the fingerprintable DOM modifications performed by extensions are necessary, ii) points out the resulting issue of *bloat* in the context of browser extensions, and iii) proposes a client-side access control mechanism for reducing the footprint of extensions in a user's browser which can counter many of the attacks described in the aforementioned papers. In concurrent work, Sjösten et al. described the privacy issues of unique extension identifiers and also proposed a client-side access control system for extensions [19]. While the two systems are conceptually similar, our work utilizes existing code within the Chromium browser thereby avoiding the disabling of security checks of browser extensions and the need for extension rewriting.

On October 1, 2018 and in parallel with our work, Google announced that future versions of their Chrome browser will allow users to selectively enable and disable extensions on different websites [24]. We find this a welcoming development and a confirmation of the need of client-side access control for browser extensions. The current instantiation of that mechanism allows users to whitelist extensions on a site-by-site basis, or only enable them when the user interacts with them through the browser's UI. We argue that our proposed policies strike a better balance between security and usability (e.g. extensions enabled everywhere *except* on sensitive sites) and we therefore hope that Google, as well as other browser vendors, will follow our proposed design.

5 CONCLUSION

In this paper, we investigated the fingerprintability of browser extensions due to bloat, i.e., the unnecessary side-effects caused by faulty application logic that reveal an extension's presence without providing any useful functionality. Bloated extensions represent a risk to online privacy as they facilitate the fingerprinting of installed extensions. We analyzed 58,034 extensions from the Google Chrome store and found that 5.7% of them contained fingerprintable bloat. For 61% of these extensions, their bloat was unique which can be abused for their direct identification. Finally, we presented the design and implementation of a client-side access control mechanism for Google Chromium which enables users to control the reach of extensions, either on a one-by-one basis, or via access modes (e.g. automatically blocking all extensions on sensitive websites). Overall, our paper highlights the problems associated with bloat for both users and developers. We hope that this work will motivate the more careful implementation of extensions by their developers and the adoption of client-side access control by all modern browsers.

Embarrassingly Shallow Autoencoders for Sparse Data

Harald Steck

hsteck@netflix.com

ABSTRACT

Combining simple elements from the literature, we define a linear model that is geared toward sparse data, in particular implicit feedback data for recommender systems. We show that its training objective has a closed-form solution, and discuss the resulting conceptual insights. Surprisingly, this simple model achieves better ranking accuracy than various state-of-the-art collaborative-filtering approaches, including deep non-linear models, on most of the publicly available data-sets used in our experiments.

1 INTRODUCTION

Many recent improvements in collaborative filtering can be attributed to deep learning approaches, e.g, [6, 10–12, 17, 25, 30, 31]. Unlike in areas like computer vision, however, it was found that a *small* number of hidden layers achieved the best recommendation accuracy. In this paper, we take this to the extreme, and define a linear model *without* a hidden layer (see Figure 1). The (binary) input vector indicates which items a user has interacted with, and the model's objective (in its output layer) is to predict the best items to recommend to the user. This is done by reproducing the input as its output, as is typical for *auto*encoders.[1] We hence named it Embarrassingly Shallow AutoEncoder (in Reverse order: EASE$^{\text{R}}$).

This paper is organized as follows: we define EASE$^{\text{R}}$ in the next section, using simple elements from the literature. In Section 3.1, we derive the closed-form solution of its convex training objective. This has several implications: (1) it reveals that the neighborhood-based approaches used in collaborative filtering are based on conceptually incorrect item-item similarity-matrices, while EASE$^{\text{R}}$ may be considered a principled neighborhood model, see Sections 3.2 and 4.3; (2) the code for training EASE$^{\text{R}}$ is comprised of only a few lines, see Section 3.3 and Algorithm 1; (3) if the model fits into memory, the wall-clock time for training EASE$^{\text{R}}$ can be several orders of magnitude less than for training a SLIM [20] model (see Section 3.4), which is the most similar model to EASE$^{\text{R}}$. Apart from that, we surprisingly found that EASE$^{\text{R}}$ achieved competitive ranking accuracy, and even outperformed various deep, non-linear, or probabilistic models as well as neighborhood-based approaches on most of the publicly available data-sets used in our experiments (see Section 5).

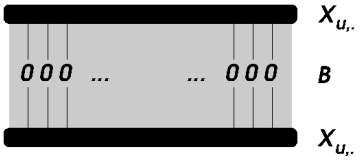

Figure 1: The self-similarity of each item is constrained to zero between the input and output layers.

2 MODEL DEFINITION

Like in many recommender papers that use implicit feedback data, we assume that the data are given in terms of a sparse (typically binary[2]) matrix $X \in \mathbb{R}^{|\mathcal{U}|\times|\mathcal{I}|}$, regarding the sets of users $\mathcal{U}$ and items $\mathcal{I}$, where $|\cdot|$ denotes the size of a set. A positive value (typically 1) in X indicates that the user interacted with an item, while a value of 0 indicates that no interaction has been observed.

The parameters of the EASE$^{\text{R}}$ model are given by the item-item weight-matrix $B \in \mathbb{R}^{|\mathcal{I}|\times|\mathcal{I}|}$. Note that this is also similar to neighborhood-based approaches, see Section 4.3. In this weight matrix, self-similarity of an item in the input-layer with itself in the output layer is forbidden as to force the model to generalize when reproducing the input as its output (see Figure 1): hence the diagonal of the weight-matrix is constrained to zero, $\text{diag}(B) = 0$. This constraint is crucial, and is discussed in detail in the remainder of this paper. This constraint was first introduced in the SLIM model [20].

The predicted score $S_{u,j}$ for an item $j \in \mathcal{I}$ given a user $u \in \mathcal{U}$ is defined by the dot product

$$S_{uj} = X_{u,\cdot} \cdot B_{\cdot,j}, \tag{1}$$

where $X_{u,\cdot}$ refers to row u, and $B_{\cdot,j}$ to column j.

3 MODEL TRAINING

We use the following convex objective for learning the weights B:

$$\min_{B} \quad ||X - XB||_F^2 + \lambda \cdot ||B||_F^2 \tag{2}$$

$$\text{s.t.} \quad \text{diag}(B) = 0 \tag{3}$$

[1] Note, however, that the proposed model does not follow the typical architecture of autoencoders, being comprised of an encoder and a decoder: one may introduce an implicit hidden layer, however, by a (full-rank) decomposition of the learned weight-matrix of this model.

[2] Non-binary matrices may also be used.

Several comments are in order:

- We choose the square loss ($||\cdot||_F$ denotes the Frobenius norm) between the data X and the predicted scores $S = XB$ over other loss functions because it allows for a closed-form solution (see next section). Training with other loss functions, however, might result in improved ranking-accuracy: in [17], it was observed that the multinomial likelihood resulted in better ranking-accuracy than training with the logistic likelihood (log loss) or the Gaussian likelihood (square loss). Directly optimizing a (surrogate) ranking loss might result in further accuracy gains–however, at possibly increased computational costs.
- We use L2-norm regularization of the weights B to be learned. The training objective hence has a single hyperparameter λ, to be optimized on a validation set.
- The constraint of a zero diagonal, $\text{diag}(B) = 0$, is crucial as to avoid the trivial solution $B = I$ (self-similarity of items), where I is the identity matrix. It was introduced in SLIM [20].

3.1 Closed-Form Solution

In this section, we show that the constrained convex optimization problem for learning the weight matrix B in Eqs. 2 and 3 can be solved in closed form.

We start by including the equality constraint in Eq. 3 into the objective function in Eq. 2 by forming the Lagrangian

$$L = ||X - XB||_F^2 + \lambda \cdot ||B||_F^2 + 2 \cdot \gamma^\top \cdot \text{diag}(B),$$

where $\gamma = (\gamma_1, ..., \gamma_{|\mathcal{I}|})^\top$ is the vector of Lagrangian multipliers. Its values will be chosen in Eq. 6 such that the constraint in Eq. 3 is fulfilled.

The constrained optimization problem in Eqs. 2 and 3 is solved by minimizing this Lagrangian. As a necessary condition, we hence set its derivative to zero, which yields the estimate $\hat{B}$ of the weight matrix after re-arranging terms:

$$\hat{B} = (X^\top X + \lambda I)^{-1} \cdot (X^\top X - \text{diagMat}(\gamma)),$$

where $\text{diagMat}(\cdot)$ denotes the diagonal matrix and I the identity matrix. Defining (for sufficiently large λ)

$$\hat{P} \triangleq (X^\top X + \lambda I)^{-1}, \tag{4}$$

this can be substituted into the previous equation:

$$\begin{aligned} \hat{B} &= (X^\top X + \lambda I)^{-1} \cdot (X^\top X - \text{diagMat}(\gamma)) \\ &= \hat{P} \cdot (\hat{P}^{-1} - \lambda I - \text{diagMat}(\gamma)) \\ &= I - \hat{P} \cdot (\lambda I + \text{diagMat}(\gamma)) \\ &= I - \hat{P} \cdot \text{diagMat}(\tilde{\gamma}) \end{aligned} \tag{5}$$

where we defined the vector $\tilde{\gamma} \triangleq \lambda \vec{1} + \gamma$ in the last line, with $\vec{1}$ denoting a vector of ones. The values of the Lagrangian multipliers γ, and hence $\tilde{\gamma}$, are determined by the constraint $\text{diag}(\hat{B}) = 0$. It follows from Eq. 5:

$$0 = \text{diag}(\hat{B}) = \vec{1} - \text{diag}(\hat{P}) \odot \tilde{\gamma} \tag{6}$$

where $\odot$ denotes the elementwise product, and hence:

$$\tilde{\gamma} = \vec{1} \oslash \text{diag}(\hat{P}),$$

where $\oslash$ denotes the elementwise division (which is well-defined given that $\hat{P}$ is invertible). Substituting this into Eq. 5 immediately results in the closed-form solution:

$$\hat{B} = I - \hat{P} \cdot \text{diagMat}\left(\vec{1} \oslash \text{diag}(\hat{P})\right). \tag{7}$$

In other words, the learned weights are given by:

$$\hat{B}_{i,j} = \begin{cases} 0 & \text{if } i = j \\ -\frac{\hat{P}_{ij}}{\hat{P}_{jj}} & \text{otherwise.} \end{cases} \tag{8}$$

This solution obviously obeys the constraint of a zero diagonal. The off-diagonal elements are determined by the matrix $\hat{P}$ (see Eq. 4), where the j^{th} column is divided by its diagonal element $\hat{P}_{jj}$. Note that $\hat{B}$ is an asymmetric matrix in general, while $\hat{P}$ is symmetric (see Eq. 4).

Eqs. 4 and 8 show that the sufficient statistics for estimating B is given by the data Gram-matrix $G \triangleq X^\top X$, which is an item-item matrix. This is a consequence of using the square loss in Eq. 2, and is helpful for estimating B from sparse data X: if X is a sparse binary matrix, then $G = X^\top X$ is a co-occurrence matrix. The uncertainty of a co-occurrence count G_{ij} is (approximately) determined by the standard deviation of the Poisson distribution, which is $\sqrt{G_{ij}}$. As long as the co-occurrence counts G_{ij} are 'sufficiently large', G and hence B can be estimated with small error. An interesting fact is that the entries of $G = X^\top X$ can be increased by two different mechanisms: (1) a denser X (due to users with increased activity), or (2) an increased number of users in X. The latter is particularly useful, as an increased sparsity of X can be compensated by an increased number of users. In other words, the problem that there possibly is only a small amount of data available for *each* user (i.e., data sparsity), does not affect the uncertainty in estimating B if the number of users in the data matrix X is sufficiently large.

3.2 Interpretation

In this section, we outline that the closed-form solution in Eq. 8 does not come as a complete surprise. To this end, let us consider the following special case throughout this section: let the training data X be an i.i.d. sample of $|\mathcal{U}|$ data points regarding a vector of $|\mathcal{I}|$ random variables $x \sim \mathcal{N}(0, \Sigma)$ that follows a Gaussian distribution with zero mean and covariance matrix $\Sigma \in \mathbb{R}^{|\mathcal{I}| \times |\mathcal{I}|}$.

Then the estimate of the covariance matrix is $\hat{\Sigma} = X^\top X / |\mathcal{U}|$. If we further drop the L2-norm regularization in Eq. 4 and assume invertibility, then $\hat{P} = \hat{\Sigma}^{-1}$ is the estimate of the so-called precision (or concentration) matrix. Estimating the precision matrix from given data is a main objective in the area of graphical models (e.g., see [15]).

It is well known [5, 15] that the (univariate) *conditional distribution* of the random variable x_j given the vector of *all* the other variables, denoted by $x_{-j} \triangleq (x_k)_{k \in \mathcal{I} \setminus \{j\}}$, is a Gaussian distribution with variance $\text{var}(x_j | x_{-j}) = 1/P_{j,j}$ and mean

$$\begin{aligned} \mu_{j|-j} \triangleq \mathbb{E}[x_j | x_{-j}] &= -x_{-j} \cdot P_{-j,j} / P_{j,j} \\ &= x_{-j} \cdot B_{-j,j} \\ &= x \cdot B_{.,j} \end{aligned}$$

where the dot in the first line denotes the dot-product between the (row) vector x_{-j} and the j^{th} column of the precision matrix

$P = \Sigma^{-1}$, omitting the j^{th} element. The second line follows from Eq. 8, and the last line from $B_{jj} = 0$. Note that this is identical to the prediction rule of the EASE$^{\text{R}}$ model in Eq. 1. This shows that EASE$^{\text{R}}$ makes a principled point-prediction that user u will like item j *conditional* on the fact that the user's past interactions with *all* items are given by $X_{u,.} = x$.

A more well-known fact (e.g., see [19]) is that the absence of an edge between the random variables x_i and x_j in a Markov network corresponds to the *conditional independence* of the random variables x_i and x_j given the vector of *all* the other variables $(x_k)_{k \in \mathcal{I} \setminus \{i,j\}}$, which is also equivalent to a zero entry in the precision matrix. Note that this is different from a zero entry in the covariance matrix Σ, which signifies *marginal independence* of x_i and x_j. This shows that the precision matrix is the conceptually correct similarity-matrix to be used, rather than the covariance matrix, which (or some rescaled variant thereof) is typically used in state-of-the-art neighborhood-based approaches (see Section 4.3).

Learning the graph structure in Markov networks corresponds to learning a sparse precision matrix from data. Approaches developed in that field (e.g., see [2, 7, 8, 13, 19, 23, 26, 29]) might be useful for improved learning of a *sparse* matrix $\hat{B}$. This is beyond the scope of this short paper.

While the interpretation we outlined in this section is limited to the special case of normally distributed variables with *zero mean*, note that the derivation of Eq. 8 does not require that each column of the data matrix X has zero mean. In other words, in EASE$^{\text{R}}$ any definition of the Gram matrix $G \triangleq X^\top X$ may be used, e.g., G may be the co-occurrence matrix (if X is a binary matrix), proportional to the covariance matrix (if X is pre-processed to have zero mean in each column), or the correlation matrix (if each column of X is pre-processed to have zero mean and unit variance). After training EASE$^{\text{R}}$ on these transformed matrices X and then transforming the predicted scores back to the original space (as defined by the binary matrix X), we found in our experiments that the differences in the obtained ranking accuracies were of the order of the standard error, and we hence do not separately report these results in Section 5.

3.3 Algorithm

The Python code of the resulting learning algorithm is given in Algorithm 1. Note that the training of EASE$^{\text{R}}$ requires only the item-item matrix $G = X^\top X$ as input, instead of the user-item matrix X, and hence is particularly efficient if the size of G (i.e., $|\mathcal{I}| \times |\mathcal{I}|$) is smaller than the number of user-item-interactions in X. In this case, the expensive computation of $G = X^\top X$ can be done on a big-data pre-processing system, prior to the actual model training.

3.4 Computational Cost

The computational complexity of Algorithm 1 is determined by the matrix inversion of the data Gram-matrix $G \triangleq X^\top X \in \mathbb{R}^{|\mathcal{I}| \times |\mathcal{I}|}$, which is $O(|\mathcal{I}|^3)$ when using a basic approach, and about $O(|\mathcal{I}|^{2.376})$ when using the Coppersmith-Winograd algorithm. Note that this is independent of the number of users as well as the number of user-item-interactions, as G can be computed in the pre-processing step.

This computational complexity is orders of magnitude lower than the cost of training a SLIM model and its variants [16, 20, 24]:

ALGORITHM 1: Training in Python 2 using numpy

Input: data Gram-matrix $G := X^\top X \in \mathbb{R}^{|\mathcal{I}| \times |\mathcal{I}|}$,
L2-norm regularization-parameter $\lambda \in \mathbb{R}^+$.
Output: weight-matrix B with zero diagonal (see Eq. 8).

```
diagIndices = numpy.diag_indices(G.shape[0])
G[diagIndices] += λ
P = numpy.linalg.inv(G)
B = P / (-numpy.diag(P))
B[diagIndices] = 0
```

those approaches take advantage of the fact that the optimization problem regarding $|\mathcal{I}|$ items can be decomposed into $|\mathcal{I}|$ independent (and hence embarrassingly parallel) optimization problems involving $|\mathcal{I}| - 1$ items each, due to the identity $||X - XB||_F^2 = \sum_{j \in \mathcal{I}} |X_{.,j} - XB_{.,j}|_2^2$. If each of the $|\mathcal{I}|$ independent problems is solved based on an item-item matrix, the total computational cost is hence $O(|\mathcal{I}|(|\mathcal{I}| - 1)^{2.376})$. Note that the computational cost of solving those $|\mathcal{I}|$ problems is larger by almost a factor of $|\mathcal{I}|$ than training EASE$^{\text{R}}$, which requires only a *single* regression problem to be solved. In practice, however, SLIM and its variants are trained on the user-item-interactions in X, which may incur additional computational cost. This explains the vastly reduced training-times of EASE$^{\text{R}}$ observed in our experiments in Section 5.

In practice, the wall-clock time depends crucially on the fact if the number of items $|\mathcal{I}|$ is sufficiently small such that the weight matrix fits into memory, so that the matrix inversion can be computed in memory. This was the case in our experiments in Section 5.

4 RELATED WORK

EASE$^{\text{R}}$ can be viewed as an autoencoder, as a modified version of SLIM, and a neighborhood-based approach. We discuss each of the three related approaches in the following.

4.1 Deep Learning and Autoencoders

While the area of collaborative filtering has long been dominated by matrix factorization approaches, recent years have witnessed a surge in deep learning approaches [6, 10–12, 17, 25, 30, 31], spurred by their great successes in other fields. Autoencoders provide the model architecture that fits exactly the (plain-vanilla) collaborative filtering problem. While various network architectures have been explored, it was found that deep models with a large number of hidden layers typically do not obtain a notable improvement in ranking accuracy in collaborative filtering, compared to 'deep' models with only one, two or three hidden layers, e.g., [10, 17, 25, 31], which is in stark contrast to other areas, like computer vision. A combination of deep and shallow elements in a single model was proposed in [6].

In contrast, EASE$^{\text{R}}$ has no hidden layer. Instead, the self-similarity of each item in the input and output layer is constrained to zero, see also Figure 1. As a consequence, the model is forced to learn the similarity of an item in the output layer in terms of the *other* items in the input layer. The surprisingly good empirical results of EASE$^{\text{R}}$ in Section 5 suggest that this constraint might be more effective than using hidden layers with limited capacity as to force the model to generalize well to unseen data.

4.2 SLIM and Variants

While the SLIM model [20] has shown competitive empirical results in numerous papers, it is computationally expensive to train, e.g., see [17, 20] and Section 3.4. This has sparked follow-up work proposing various modifications. In [16], both constraints on the weight matrix (non-negativity and zero diagonal) were dropped, resulting in a regression problem with an elastic-net regularization. While competitive ranking results were obtained in [16], in the experiments in [17] it was found that its performance was considerably below par. The square loss in SLIM was replaced by the logistic loss in [24], which entailed that both constraints on the weight matrix could be dropped, as argued by the authors. Moreover, the L1-norm regularization was dropped, and a user-user weight-matrix was learned instead of an item-item matrix.

All these approaches take advantage of the fact that the optimization problem decomposes into independent and embarrassingly parallel problems. As discussed in the previous section, however, this is several orders of magnitudes more costly than training EASE^R if the weight matrix fits into memory.

Most importantly, while those modifications of SLIM dropped the constraint of a zero diagonal in the weight matrix, it is retained in EASE^R. In fact, we found it to be the most crucial property for achieving improved ranking accuracy (see Section 5). As we showed in Section 3.1, this constraint can be easily included into the training objective via the method of Lagrangian multipliers, allowing for a closed-form solution.

Compared to SLIM [20], we dropped the constraint of non-negative weights, which we found to greatly improve ranking accuracy in our experiments (see Table 1 and Figure 2). Moreover, we did not use L1-norm regularization for computational efficiency. We also did not find sparsity to noticeably improve ranking accuracy (see Section 5). The learned weight matrix $\hat{B}$ of EASE^R is dense.

Also note that extensions to SLIM like cSLIM [21], can be turned into an analogous extension of EASE^R.

4.3 Neighborhood-based Approaches

Numerous neighborhood-based approaches have been proposed in the literature (e.g., see [27, 28] and references therein). While model-based approaches were found to achieve better ranking accuracy on some data sets, neighborhood-based approaches dominated on others, e.g., the Million Song Data Competition on Kaggle [1, 18]. Essentially, the co-occurrence matrix (or some modified variant) is typically used as item-item or user-user similarity matrix in neighborhood-based methods. These approaches are usually heuristics, as the similarity matrix is not learned by optimizing an objective function (loss function or likelihood). More importantly, the closed-form solution derived in Eqs. 4 and 8 reveals that the *inverse* of the data Gram matrix is the conceptually correct similarity matrix,[3] see Section 3.2 for more details. This is in contrast to the typical neighborhood-based approaches, which use the data Gram-matrix without inversion. The use of the conceptually correct, inverse matrix in EASE^R may explain the improvement observed in Table 2 compared to the heuristics used by state-of-the-art neighborhood approaches.

[3]In fact, inverse matrices are used in many areas, for instance, the inverse covariance matrix in the Gaussian density function or in the Mahalanobis distance.

5 EXPERIMENTS

In this section, the proposed EASE^R model is empirically compared to several state-of-the-art approaches, based on two papers that provided publicly available code for reproducibility of results [17, 28]. Both papers together cover linear, non-linear, deep and probabilistic models, as well as neighborhood-based approaches.

5.1 Experimental Set-up

We will only summarize the experimental set-ups used in these papers, and refer the reader to these papers for details.

Summary of Set-up in [17]: This paper considers the following models:

- Sparse Linear Method (SLIM) [20]. Besides the original model, also a computationally faster approximation (which drops the constraints on the weights) [16] was considered, but its results were not found to be on par with the other models in the experiments in [17].
- Weighted Matrix Factorization (WMF) [14, 22], a linear model with a latent representation of users and items.
- Collaborative Denoising Autoencoder (CDAE) [30], a non-linear model with one hidden layer.
- denoising autoencoder (MULT-DAE) and variational autoencoder (MULT-VAE^{PR}) [17], both trained using the multinomial likelihood, which was found to outperform the Gaussian and logistic likelihoods. Best results were obtained in [17] for the MULT-VAE^{PR} and MULT-DAE models that were rather shallow 'deep models', namely with a 200-dimensional latent representation, as well as a 600-dimensional hidden layer in both the encoder and decoder. Both models are non-linear, and MULT-VAE^{PR} is also probabilistic.

Three data sets were used in the experiments in [17], and were preprocessed and filtered for items and users with a certain activity level, resulting in the following data-set sizes, see [17] for details:[4]

- MovieLens 20 Million (*ML-20M*) data [9]: 136,677 users and 20,108 movies with about 10 million interactions,
- Netflix Prize (*Netflix*) data [3]: 463,435 users and 17,769 movies with about 57 million interactions,
- Million Song Data (*MSD*) [4]: 571,355 users and 41,140 songs with about 34 million interactions.

The evaluation in [17] was conducted in terms of *strong generalization*, i.e., the training, validation and test sets are disjoint in terms of users. This is in contrast to *weak generalization*, where the training and test sets are disjoint in terms of the user-item interaction-pairs, but not in terms of users. Concerning evaluation in terms of ranking metrics, Recall@k for $k \in \{20, 50\}$ as well as Normalized Discounted Cumulative Gain, NDCG@100 were used in [17].

Summary of Set-up in [28]: Their paper focuses on neighborhood-based approaches, and the authors publicly shared code[5] regarding the experiments in their table 2 in [28], albeit only for the data-split where the training data was comprised of (at most) 30% of each user's interactions (and the remainder was assigned to the test data), which restricted our experimental comparison to this single

[4]The code regarding *ML-20M* in [17] is publicly available at `https://github.com/dawenl/vae_cf`. The authors kindly provided the code for the other two data sets upon request.

[5]`http://www.cs.toronto.edu/~mvolkovs/SVD_CF.zip`

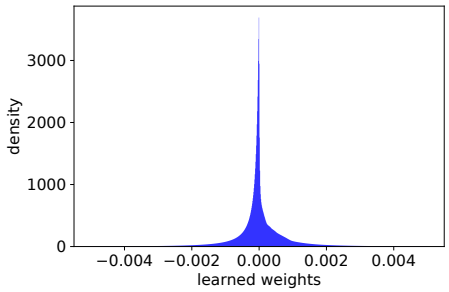

Figure 2: Histogram of the weights learned on *Netflix* data.

split in Table 2. They used the MovieLens 10 Million (*ML-10M*) data [9], which was binarized in [28] and is comprised of 69,878 users and 10,677 movies with 10 million interactions. Their evaluation was done in terms of *weak generalization*, and NDCG@10 was used as ranking metric for evaluation in [28].

5.2 Results

Despite the simplicity of EASE^R, we observed that EASE^R obtained considerably better ranking accuracy than any of the competing models on most of the data sets. This remarkable empirical result is discussed in detail in the following.

Comparison to SLIM: Table 1 shows that EASE^R achieved notably increased accuracy compared to SLIM on all the data sets. This suggests that dropping the L1-norm regularization as well as the non-negativity constraint on the learned weights is beneficial. Our analysis indicates that the latter is especially important: as illustrated in Figure 2 on the *Netflix* data (the histograms for *ML-20M* and *MSD* data look almost identical up to re-scaling, and are omitted), the learned weights in EASE^R are distributed around 0. Interestingly, it turns out that about 60% of the learned weights are negative on all the data sets in our experiments (regarding both papers [17, 28]). This indicates that it is crucial to learn also the dissimilarity (negative weights) between items besides their similarity (positive weights). Moreover, when we simply set the negative weights to zero (see EASE$^R\geq 0$ in Table 1), which obviously is not the optimal non-negative solution, the resulting accuracy drops and is very close to the one of SLIM. Apart from that, note that EASE$^R\geq 0$ is still quite dense (40% positive weights) compared to SLIM, which indirectly indicates that the sparsity of SLIM (due to L_1-norm regularization) did not noticeably improve the ranking accuracy of SLIM in our experiments.

Regarding regularization, the optimal L2-norm regularization parameter (λ) for EASE^R is about 500 on *ML-20M*, 1,000 on *Netflix*, and 200 on *MSD*. These values are much larger than the typical values used for SLIM, which often are of the order of 1, see [20]. Note that SLIM additionally uses L1-norm regularization, and hence has much fewer (non-zero) parameters than EASE^R.

As expected based on Section 3.4, we also found the (wall-clock) training-time of EASE^R to be smaller by several orders of magnitude compared to SLIM : [17] reports that parallelized grid search for SLIM took about two weeks on the *Netflix* data, and the *MSD* data was 'too large for it to finish in a reasonable amount of time' [17]. In contrast,

Table 1: Ranking accuracy (with standard errors of about 0.002, 0.001, and 0.001 on the *ML-20M*, *Netflix*, and *MSD* data, respectively), following the experimental set-up in [17].

(a) *ML-20M*	Recall@20	Recall@50	NDCG@100

MULT-DAE	0.266	0.363	0.313

training EASE^R on the *Netflix* data took less than two minutes, and on the *MSD* data less than 20 minutes on an AWS instance with 64 GB RAM and 16 vCPUs in our experiments. These times have to be multiplied by the number of different hyperparameter-values to be grid-searched. Note, however, that EASE^R only has a single hyperparameter (regarding L2-norm regularization), while SLIM has two hyperparameters (concerning L1 and L2 norms) to be jointly optimized.

Comparison to linear and deep non-linear models in [17]: Table 1 shows that EASE^R was consistently outperformed on only the *ML-20M* data, and only by a small margin by the best competing model (MULT-VAE^{PR}). On the *Netflix* and *MSD* data, EASE^R obtained significantly better ranking results than any of the competing linear, non-linear, deep or probabilistic models evaluated in [17]. On the *MSD* data, EASE^R even improved over the best competing model by 25%, 17% and 23% regarding Recall@20, Recall@50, and NDCG@100, respectively. This is consistent with the results of the Million Song Data Challenge on Kaggle [18], where neighborhood-based approaches were found to vastly outperform model-based

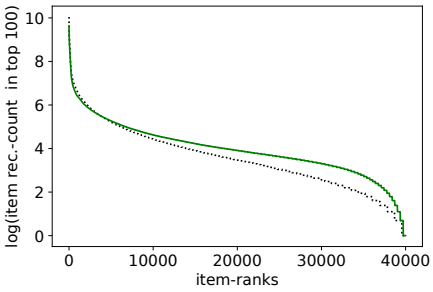

Figure 3: EASE^R (green) recommends long-tail items more often in the top-100, compared to MULT-VAE ^{PR} (dotted), on *MSD* data.

approaches [1]. As discussed in Section 4.3, EASE^R may also be viewed as a principled neighborhood approach.

As to explain EASE^R's relative improvements from *ML-20M* via *Netflix* to *MSD* data, various properties of the data sets may be considered. As shown by table 1 in [17], the number of user-item interactions, and the sparsity of the data sets do not appear well correlated with EASE^R's relative performance in Table 1. Only the number of users correlates well with the improvements of EASE^R over the competing models, which, however, appears to be spurious.

The explanation can be understood in terms of the tradeoff between recommending generally popular items vs. personally relevant items to each user, which is supported by two empirical findings: (1) we evaluated the popularity model in Table 1 as an additional baseline, where the items are ranked by their popularities (i.e., the number of users who interacted with an item). These unpersonalized recommendations obviously ignore the personalized relevance to a user. Table 1 shows that this popularity model obtains better accuracy on the *ML-20M* data than it does on the *Netflix* data, while its accuracy is considerably reduced on the *MSD* data. This suggests that good recommendations on the *MSD* data have to focus much more on personally relevant items rather than on generally popular items, compared to the *ML-20M* and *Netflix* data. (2) When counting how often an item was recommended in the top-100 across all test-users, and then ranking the items by their counts, we obtained Figure 3 for the *MSD* data: it shows that EASE^R recommended long-tail items more often than MULT-VAE ^{PR} did. In contrast, there was almost no difference between the two approaches on either of the data sets *ML-20M* and *Netflix* (figures omitted due to page limit).

The notable improvement of EASE^R over the other models on the *MSD* data suggests that it is able to better recommend personally relevant items on this data set. On the other hand, EASE^R's results on the *ML-20M* and *Netflix* data suggest that it is also able to make recommendations with an increased focus on popular items. We suspect that EASE^R's large number of parameters, combined with its constraint regarding self-similarity of items, provides it with sufficient flexibility to adapt to the various data sets. In contrast, the model architectures based on hidden layers with limited capacity seem to be unable to adapt well to the increased degree of personalized relevance in the *MSD* data.

Table 2: Comparison to the neighborhood-approaches in [28]: EASE^R considerably improves over 'ii-SVD-500' [28].

	EASE^R	EASE^R ≥ 0	reproduced from [28]: ii-SVD-500	item-item	WMF
NDCG@10	0.6258	0.6199	0.6113	0.5957	0.5969

Comparison to neighborhood-based approaches in [28]: Considerable improvements were obtained in [28] by first predicting the scores for all user-item interactions with a neighborhood-based approach ('item-item' in Table 2) that was followed by a low-rank singular value decomposition of the predicted user-item score-matrix ('ii-SVD-500' in Table 2): an increase in NDCG@10 by 0.0156 and 0.0144 compared to the baseline models 'item-item' and WMF, respectively, as reproduced in Table 2. In comparison, EASE^R obtained increases of 0.0301 and 0.0289 over the baseline models 'item-item' and WMF, respectively, see Table 2. This is about twice as large an improvement as was obtained by the approach 'ii-SVD-500' proposed in [28].

Given the small size of this training data-set, a large L2-norm regularization was required ($\lambda = 3000$) for EASE^R. Like in the previous experiments, also here about 60% of the learned weights were negative in EASE^R, and setting them to zero (EASE$^R \geq 0$ in Table 2) resulted in a small decrease in NDCG@10, as expected. In terms of wall-clock time, we found that training EASE^R was about three times faster than computing merely the factorization step in the ii-SVD-500 approach.

6 CONCLUSIONS

We presented a simple yet effective linear model for collaborative filtering, which combines the strengths of autoencoders and neighborhood-based approaches. Besides enabling efficient training (with savings of up to several orders of magnitude if the model fits into memory), the derived closed-form solution also shows that the conceptually correct similarity-matrix to be used in neighborhood approaches is based on the *inverse* of the given data Gram-matrix. In contrast, state-of-the-art neighborhood approaches typically use the data Gram-matrix directly. In our experiments, we found that allowing the learned weights to also take on negative values (and hence learn dissimilarities between items, besides similarities), was essential for the obtained ranking accuracy. Interestingly, the achieved ranking accuracy in our experiments was on par or even (notably) better than those of various state-of-the-art approaches, including deep non-linear models as well as neighborhood-based approaches. This suggests that models where the self-similarity of items is constrained to zero may be more effective on sparse data than model architectures based on hidden layers with limited capacity. We presented a basic version as to illustrate the essence of the idea, and leave various modifications and extensions for future work.

ABSTRACT

The degree to which Mexican immigrants in the U.S. are assimilating culturally has been widely debated. To examine this question, we focus on musical taste, a key symbolic resource that signals the social positions of individuals. We adapt an assimilation metric from earlier work to analyze self-reported musical interests among immigrants in Facebook. We use the relative levels of interest in musical genres, where a similarity to the host population in musical preferences is treated as evidence of cultural assimilation. Contrary to skeptics of Mexican assimilation, we find significant cultural convergence even among first-generation immigrants, which problematizes their use as assimilative "benchmarks" in the literature. Further, 2nd generation Mexican Americans show high cultural convergence vis-à-vis both Anglos and African-Americans, with the exception of those who speak Spanish. Rather than conforming to a single assimilation path, our findings reveal how Mexican immigrants defy simple unilinear theoretical expectations and illuminate their uniquely heterogeneous character.

1 INTRODUCTION

Are immigrants assimilating to U.S. culture? According to the "straight-line" assimilation hypothesis, developed by 20^{th}-century Chicago sociologists, the more time immigrants spend in the host society, the more culturally similar to natives they become [17, 25]. Early European immigrants seemingly conformed to this expectation. By the third generation, most European immigrant groups became largely culturally indistinguishable from Anglo-American natives [29]. Nevertheless, post-1965 immigrants from Latin America and Asia do not appear to be following a single, "linear" assimilative path. Instead, their assimilation appears "segmented" [30, 34]. While advantaged immigrants are still assimilating "linearly," disadvantaged groups are taking a less expected route. As they concentrate in poor neighborhoods, their children come in close contact with "downtrodden" native minorities like African-Americans and often adopt their cultural norms and styles [18].

What path are Mexican immigrants taking? Critics have questioned their willingness and/or capacity to assimilate to mainstream U.S. culture. Empirical evidence of their assimilation has been mixed [1, 23]. We focus on a key dimension of culture, musical taste, to assess the assimilation trajectories of Mexican Americans. Patterns of artistic consumption like musical taste can illuminate important aspects of the assimilation process [24]. Musical tastes both reflect and reproduce ethnic divides [27]. Hence, shrinking differences in musical tastes across generations would imply that cultural assimilation is taking place and that ethnic boundaries between groups are blurring.

We analyze the musical preferences of Mexican immigrants, Mexican Americans, non-Hispanic Whites (henceforth "Anglos"), and African-Americans on Facebook.[1] We find that 1st generation Mexican immigrants have relatively high levels of cultural assimilation. Further, rather than converging with the musical tastes of *either* Anglos or African-Americans, the 2nd generation Mexican-Americans have substantial cultural similarities with *both* groups, which highlights the manifold character of Mexican assimilation. Finally, assimilation varies significantly based on demographics including age, language preference, and education level.[2]

2 RELATED WORK

Sociologists of culture have identified musical tastes as key symbolic resources individuals draw on to negotiate and express their social positions [31]. According to Bourdieu [5], taste "classifies." It marks identity and social status. While taste for high-status musical genres like classical music or opera may signal a privileged class background, lower-status genres suggest a lower class position [8]. Cultural differences like musical taste may be the building blocks that reinforce and preserve ethnic boundaries [3, 32]. According to Telles and Ortiz, "the extent to which such cultural markers [of ethnicity] persist over generations may signify the extent to which ethnic groups remain viable."

However, few studies have examined the musical taste of Mexican immigrants. Using inter-generational survey data, Telles and Ortiz find that Mexican Americans express a taste for U.S. Latino music as well as for what they term "American, black" genres. Thomas [24] also uses survey data and finds that Mexican immigrants in the U.S. exhibit a wide array of differences in musical taste vis-à-vis Anglos, but these differences diminish among the U.S. born second-generation (particularly after adjusting for class). Though insightful, this nascent literature has limitations. Some of these studies only capture a few locales rather than national trends [23]. Further, first-generation immigrants are normally used as an "assimilative benchmark" to which later generation immigrants are compared [10], which ignores the fact that first-generation immigrants may themselves acculturate. Last, prior studies rely on immigrants' self reports of cultural taste on surveys, which may not capture their everyday preferences.

By relying on Facebook data, we are able to address these limitations. First, Facebook provides rich, nation-wide data on the expressed cultural preferences of its users, which allow researchers to obtain a broader sample than what is available through surveys. Second, Facebook's worldwide popularity allows us to compare Mexican immigrants' cultural preferences directly with those in the source-country: Mexicans living in Mexico. Third, on Facebook, immigrants spontaneously report the music styles that they prefer, which advertisers can then access to target specific subgroups. These data provide a more natural, bottom-up window on immigrant interests than a survey. While much of Facebook's data is private, researchers can use the advertising platform to obtain aggregate estimates for customized demographics, which can then be validated with ground-truth data [2, 19]. Using the advertising platform, Dubois et al. [9] proposed a method to measure immigrant assimilation via cultural interests on Facebook, which we apply to examine musical interests of Mexican immigrants.

3 DATA COLLECTION

3.1 Audience data

Facebook's advertising platform allows users to compute an estimated audience size for a proposed advertisement [14]. The audience can be defined by demographic attributes provided by Facebook, including gender, age, home location, ethnic affinity, and interests. Some attributes such as gender are self-reported, while others such as ethnic affinity (e.g. "Hispanic (US - All)") are inferred. Facebook users can report their preferences over multiple domains such as music, food, and sports [9]. In this paper we focus on musical genres as a marker of assimilation [24].[1]

3.2 Identification of second-generation Mexican immigrants

Sociologists typically assess immigrant assimilation by comparing the traits and life outcomes of immigrants across generations. The expectation is that the U.S. born children of first-generation immigrants will be significantly more acculturated [12] [24]. In this study, the key demographic dimension of interest is generational status. Unfortunately, Facebook's advertising platform does not permit this kind of targeting. We therefore use different Facebook user targets as proxies for the second or later Mexican-American generation:

(1) Hispanic American non-expats with interest in Mexico, i.e. "Mexican Americans (Mexico)";
(2) Hispanic Spanish-speaking American non-expats, i.e. "Mexican Americans (Spanish)"; and
(3) Hispanic Americans non-expat located in cities with a high concentration of Mexican-Americans, according to 2010 American Communities Survey, i.e. "Mexican Americans (communities)."

These methods are validated by comparing the estimated distribution of the population across different demographics (age, education, gender, marital status, and region) against known demographic distributions for second-generation Mexican Americans [11]. The sample mean and standard deviation for each demographic distribution are computed from the 2016 Public Use Microdata Sample (PUMS), following the sampling procedure outlined by Torrieri [26]. We compute the proportion of the population that falls into a given category $c \in C$ within each demographic group d as follows:

$$demo_{c,d} = \frac{count(c,d)}{\sum_{c' \in C} count(c',d)} \quad (1)$$

The demographic proportions are computed over the Mexican Americans in the PUMS data, and the three proxy populations described above (Mexico, Spanish, communities).

The demographic distributions in Figure 1 of the supplementary material show that most of the estimates are close to the survey estimates. The distributions of marital status, age, and education are slightly different from the ground-truth distributions, due to underlying differences in the Facebook user base as compared to the overall population [20]. This bias cannot be ignored, and we therefore caution readers to view our analysis as exploratory rather than definitive. Nonetheless, the overall distributions align well: the Kullback-Leibler divergence values [15] between the estimated and ground-truth populations are significantly lower than the values expected by chance ($KL = 0.240, 0.218, 0.236$ for Spanish-speaking, interest and communities as compared to $KL = 0.858, 0.936, 1.29$ by chance based on $N = 1000$ random samples from uniform distribution). We use all three audience estimates as proxies for 2+ generation Mexican Americans in the rest of the study.

3.2.1 Population statistics. We are interested in comparing the rate of assimilation among first and later generations of Mexican immigrants, with respect to the majority racial group (Anglos) and a minority racial group (African Americans). Our study focuses on

Population name	Facebook estimate	Population estimate
Anglos	112,000,000 (59%)	189,591,066
African Americans	29,000,000 (78%)	37,014,326
U.S. Hispanics	14,000,000 (57%)	24,695,129
Mexican-Americans (communities)	4,100,000 (18%)	23,407,709
Mexican-Americans (Spanish)	1,700,000 (9%)	19,380,816
Mexican-Americans (Mexico)	2,900,000	n/a
Mexican immigrants	9,400,000 (82%)	11,508,371
Mexicans in Mexico	62,000,000 (56%)	111,375,417

Table 1: Summary of all populations relevant to the study.

five main populations: (i) non-Hispanic white Americans ("Anglos"), (ii) African Americans, (iii) Mexican immigrants to the United States, (iv) Mexican-Americans, and (v) Mexican people living in Mexico. As mentioned above, we define the Mexican-American population in three different ways: interest in Mexico, speaking Spanish, and living in a predominantly Mexican American community. Note that the populations are not mutually exclusive: for instance, someone may have both an interest in Mexico and may live in a Mexican-American neighborhood. These ethnic groups are targeted with Facebook's "ethnic affinities" demographics, which has been shown to be reasonably accurate in prior work [21].

We provide a summary of all populations of interest in the study in Table 1. As expected, the Facebook estimates are generally smaller than the survey estimates in part because of incomplete penetration [20]. In addition to independent counts, it is worth noting that the Mexican American populations show relatively low overlap: 36.2% between what we define 'communities' and 'interest'; 27.2% between 'interest' and 'Spanish'; 32.2% between 'Spanish' and 'communities'; and 11.7% between all three. This provides further justification for treating the Mexican American populations separately throughout the rest of the study.

3.3 Collect musical interests

The study focuses on music as a marker of cultural identity, which requires identifying specific musical interests to use in data collection. An important advantage of using Facebook as data source is that the interests are defined by users, which provides a bottom-up perspective on cultural interests that is often missed by other data sources such as surveys. It is important to note that because the interests are user-selected, the cultural preferences expressed may be seen as more of an identity "performance" [6] rather than true preference.

We began with a initial set of Facebook musical genres collected in 2016 [4], expanded the list manually for Latin American-specific genres from Wikipedia, expanded the list with suggestions from Facebook's advertising platform (manually filtered for musical genre), then filtered to 741 genres with a worldwide audience size above 100,000 (smaller genres are unreliable for comparing sub-populations). We provide the complete set of genres $\mathbb{I}$ in the supplementary material.

These interests provide the basis for computing differences and similarities across sub-populations. Following the approach of Dubois et al. (2018) our analysis starts by computing *interest ratios*, which represent the proportion of a given population p that is interested in genre i:

$$I_{p,i} = \frac{count(p,i)}{\sum_{i' \in \mathbb{I}} count(p,i')} \tag{2}$$

For example, if 10 users from population p show interest in hip-hop music, 60 in rock music and 30 in rap music, then the interest ratio for hip-hop would be $I_{p,hip-hop} = \frac{10}{100} = 0.10$. This quantity measures the share of interest in a given genre. Note that there is potential for overlap between populations. The interest ratio does not account for that, as we have no way of knowing how many users like both hip-hop and rock music, so we treat them as separate populations.

3.4 Quantify assimilation

The intuition behind the measure of assimilation that we propose is that a population of migrants is considered more assimilated if their interests are similar to the interests of the population at the destination, and dissimilar from the interests of the population at the origin. If the destination population is highly interested in hip-hop music, the origin population shows little interest in hip-hop, but the expat population from origin to destination is highly interested in hip-hop, we would say that the expat population is highly assimilated to the destination population with respect to hip-hop, meaning that expats match the taste of natives for the specific genre.

To quantify the level of assimilation following Dubois et al. [9], we compute for each genre the assimilation ratio (*AR*) of ex-pat interest proportion and destination interest proportion:

$$AR_i = \frac{I_{expat,i}}{I_{dest,i}} \tag{3}$$

where $I_{expat,i}$ and $I_{dest,i}$ are the proportions of the ex-pat and destination populations that have indicated an interest in musical genre i (Equation 2). A higher *AR* score indicates that the ex-pat population is more assimilated to the source population's interest in genre i.

Before computing *AR*, we identify a subset of musical genres $\hat{\mathbb{I}}$ that are strongly identified with the destination population. The interests in genres are filtered as follows:

(1) Remove all interests $\mathbb{I}'$ that are more associated with the source population than with the destination population:
$\mathbb{I}' = \{i \in \mathbb{I}; I_{dest,i} < I_{source,i}\}; \hat{\mathbb{I}} = \mathbb{I} \setminus \mathbb{I}'$.
(2) Compute the difference Δ between destination and source interest proportions, and remove all interests $\mathbb{I}''$ for which the difference falls below the p^{th} percentile ($p = 50$ following [9]):
$\Delta = I_{dest} - I_{source}; \mathbb{I}'' = \{i \in \mathbb{I}; \Delta_i \leq P_p(\Delta)\}; \hat{\mathbb{I}} = \hat{\mathbb{I}} \setminus \mathbb{I}''$

This produces a set of interests $\hat{\mathbb{I}}$ that are distinctly more associated with the destination population than with the source population (i.e. more "American" than "Mexican"), which we use to evaluate assimilation. Note that this process is repeated for each separate destination population.

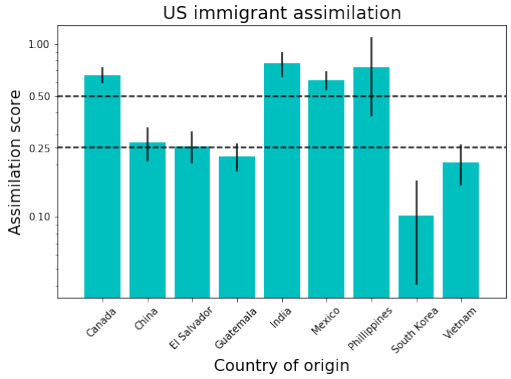

Figure 1: Median assimilation scores for selected immigrant groups. Error bars indicate 95% confidence intervals for the median.

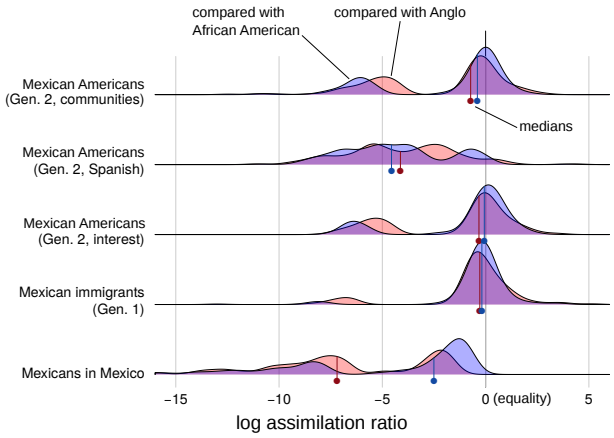

Figure 2: Assimilation scores for first- and second-generation Mexican immigrants, separated by target ethnic group (Anglo=red, African-American=blue) and log-transformed. Dotted line marks the expected assimilation value $AR = 0$, which implies an equal amount of interest for the expat and ethnic group.

4 RESULTS

4.1 Verifying cultural assimilation

In this study, we assume that the musical interests expressed on Facebook can measure cultural assimilation. To validate that assumption, we compute the assimilation ratio for several immigrant groups and validate against results from the literature [28]. We query Facebook for the audience counts for the top 100 U.S. music interests for all immigrants and natives from the following countries: Canada, China, El Salvador, Guatemala, India, Mexico, Philippines, South Korea, and Vietnam (following Vigdor [28]). We then compute all assimilation scores for each immigrant population using the top 50% of interests in the target country as compared with the source country.

The median assimilation scores and standard errors are shown in Figure 1. We see a clear divide between the high-assimilation immigrant groups (Canada, India, Mexico, and the Philippines) and the low-assimilation immigrant groups (China, El Salvador, Guatemala, South Korea, and Vietnam). This general trend mirrors the findings of Vigdor [28] (cf. Figure 6) who found that assimilation for Canadian and Filipino immigrants were higher than for immigrants from China, El Salvador, Guatemala, South Korea, and Vietnam.

While not exhaustive, this test provides some evidence that the behavior of the assimilation scores is consistent with prior work.

4.2 Comparing assimilation across ethnicity and generations

Are Mexican immigrants and their descendants becoming culturally assimilated in the U.S.? Prior work has typically measured assimilation with respect to the majority U.S. group ("Anglos"). However, some scholars have argued that Mexican Americans may be acquiring the tastes of marginalized native minorities, such as African Americans [7, 24]. Therefore, we compare the rate of assimilation across generations with respect to two reference populations: U.S.-born Anglos and African Americans.

Figure 2 shows the smoothed kernel estimate of assimilation scores between the different Mexican-origin groups and Anglos (in red) and between these groups and the musical tastes of African Americans (in blue). It shows that Mexicans in Mexico have the least similar musical tastes relative to Anglos. Also, their tastes are more similar to those of African Americans, which may be driven by the growing popularity of rap and hip-hop in Mexico. Nevertheless, such greater cultural proximity to African Americans' musical tastes cannot be found among 1st generation Mexican immigrants, who show great convergence with *both* Anglos and Blacks. This suggests that Mexican immigrants are a select group and/or that 1st generation immigrants have already acquired U.S. musical tastes during their time in the U.S.

The 2nd generation results are mixed. When we measure the Mexican-American 2nd generation by their interests ("interest") or by their residence ("communities"), we find a high degree of convergence with the musical preferences of *both* Anglos and Blacks, which calls into question unilinear expectations of cultural adaptation. In contrast, when we define the 2nd generation based on the ability to speak Spanish, we find greater cultural differences vis-à-vis both Anglos and Blacks perhaps because Spanish knowledge is a marker of "thick" ethnicity. Further, individuals in this group who are not of Mexican origin may be different from their Mexican counterparts.

These results call into question the use of 1st generation immigrants as an "assimilation benchmark" since these immigrants already show substantial cultural assimilation. They also show the sensitivity of assimilation measures to using different definitions of the 2nd generation in Facebook.

4.3 Comparing assimilation rates across demographics

Our next analysis investigates patterns of assimilation across different immigrant sub-populations. We compute the assimilation

ratios for the following demographic sub-populations of the Hispanic Mexican ex-pats living in the U.S.: age, education, gender[3], dominant language, and geographic region. These variables are known to modulate the distribution of musical taste among immigrants [24] and immigrant assimilation in general [22]. With respect to Equation 3, we set the destination population (for I_{dest}) to U.S.-born Anglo people and the source population (for I_{source}) to Mexico-born people.

The distributions in Figure 3 show substantial differentiation among subpopulations (top plot). There are significant differences for the ages and language demographics (according to Kruskal test, test statistic=21.6, ($p < 0.001$) for age, ($17.6, p < 0.001$) for language):

(1) Younger (13-18) immigrants and Mexican Americans have lower assimilation scores than the older age groups (all groups 29+).
(2) English-speaking immigrants and Mexican Americans have higher assimilation scores than Spanish-speaking and Bilingual groups.

The finding about language is more intuitive: English-speaking Facebook users are more likely to understand typical American music (mostly in English). The age finding is unusual, considering that younger immigrants are more likely to be willing to change their musical interests to align with their peers. However, analyzing the top-k interests for the youngest age group reveals why they show greater cultural dissimilarity: the top interests for 13-18 Mexican immigrants are highly concentrated under hip-hop and rap genres ("Southern hip hop", "Midwest hip hop", "Gangsta rap") and tend to miss the majority of typical Anglo interests ("Alternative rock", "Progressive rock", "Rock and roll").

In addition, subgroups of Mexican Americans, especially those defined by educational level, show notable differentiation: Mexican Americans with a Bachelor's degree or more tend to have higher assimilation scores than those with less than a high school degree. Musical taste is not necessarily inaccessible to those with a lower education, so this finding is unanticipated. In addition, female Mexican Americans have a slight tendency toward higher assimilation than male Mexican Americans, which may be related to different gender socialization among Mexican Americans versus Mexican immigrants.

4.3.1 Regression analysis. It is important to note that the prior demographic patterns may be complicated by cross-variable correlations. For instance, younger Hispanic Facebook users tend to speak more English than older Hispanic Facebook users. We therefore recompute the assimilation ratios across all cross-sections of the above demographics for all immigrant groups.[4] We run a linear regression to predict the level of assimilation from the demographic variables:

$$AR_i = \beta^T D_i + \epsilon \tag{4}$$

[3]Facebook only allows audience estimates for binary gender, so we restrict our analysis to male versus female while acknowledging that gender is a spectrum.
[4]The set of interests $\mathbb{I}$ is restricted to the top 20 music interests to reduce the number of queries.

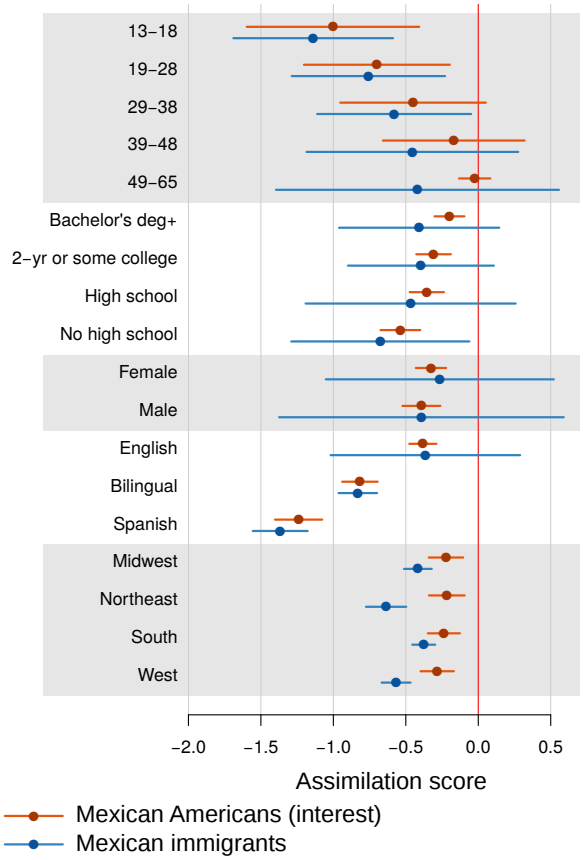

Figure 3: Median assimilation scores for Mexican immigrants and Mexican Americans (interest; i.e. all Hispanic Americans with a declared interest in Mexico), compared to Anglo interests and subdivided by demographic. The x axis shows log assimilation ratios.

where β is a vector of coefficients for all possible demographic values (male, female, etc.) and D_i is a binary vector to indicate the relevant demographic values for group i (male=1, female=0, etc.). We treat all demographics as categorical even though some may be ordinal (e.g. age, education) to account for possible nonlinear effects. We run this regression twice, using Anglo and African American Facebook users as the target populations.

The regression results for the Anglo assimilation scores are shown in Table 2. Some of the earlier results about demographic trends are corroborated here: younger, less educated and English-speaking populations have higher assimilation scores. We confirm the gender effect outlined earlier, which lends support to the notion of women as leaders of change rather than being culturally conservative. Lastly, another surprising finding shows a negative correlation with generation: later generations are expected to assimilate more, but after controlling for other variables, all definitions of the later generation have a negative correlation with assimilation. This may be due to different distributions of demographics across generations, such as the tendency of the later generation to be younger, which are controlled for in the following regression.

	$\beta(S.E.)$	p
Intercept	-0.791 (0.054)	***
Gender		
Male	-0.272 (0.027)	***
Education		
High school graduate	-0.001 (0.037)	
Less than high school graduate	-0.381 (0.038)	***
Two-year degree, Some college	-0.190 (0.038)	***
Age		
19-28	1.168 (0.042)	***
29-38	0.996 (0.043)	***
39-48	0.878 (0.043)	***
49-65	0.730 (0.043)	***
Language		
English	0.464 (0.033)	***
Spanish	-1.045 (0.035)	***
Region		
Northeast	-0.336 (0.042)	***
South	0.506 (0.036)	***
West	0.367 (0.037)	***
Gen. 2+ population		
Mexican American (Spanish)	-1.547 (0.052)	***
Mexican American (communities)	-1.203 (0.036)	***
Mexican American (interest)	-0.922 (0.033)	***

Table 2: Regression on log assimilation score with Anglo Americans as the destination population. $N = 20,145, R^2 = 0.217, F = 399.6 (p < 0.001)$**.** $^{***}\ p < 0.001$**, otherwise** $p > 0.05$**.**

The regression results for the African American assimilation scores are shown in the supplementary material. The general patterns remain the same as in the Anglo regression, albeit with some weakened effects ("West" and "female" have lower coefficients).

To test interactions among variables, we re-run the Anglo assimilation score regressions using three separate models:

(1) Model 1: interaction between age and education
(2) Model 2: interaction between age and language use
(3) Model 3: interaction between age and generation

We omit the table for space (see supplementary material) but summarize the main effects as follows. In Model 1, higher education correlates with lower assimilation but the effect is less strong for younger ("19-28") and somewhat older ("39-48") populations. In Model 2, older age has no effect on assimilation by itself but older populations that are English-speaking or Bilingual ("39-48 * English") tend to have higher assimilation scores. In Model 3, the later generation still tends to have lower assimilation, but younger members of the later generation ("19-28 * Gen. 2") have higher assimilation.

Across all analyses, we find that several high-level patterns are consistent for Mexican immigrants and Mexican Americans. We also find that there are important sources of heterogeneity such as different language effects and interactions between age and other demographics.

4.4 Summary of findings

(1) The musical tastes of Mexicans in Mexico are more similar to African Americans' tastes than to Anglos'.
(2) 1st generation Mexican immigrants exhibit high assimilation to Anglos and African Americans.
(3) 2nd generation Mexican Americans also exhibit significant assimilation to both Anglos and African Americans with the exception of those that predominantly use Spanish as their main language.
(4) In aggregate, higher-educated, older, and English-speaking populations show more assimilation to Anglo musical tastes. When controlling for cross-demographic effects, female, younger and 1st generation show more assimilation.

5 DISCUSSION

Critics have questioned the capacity and/or willingness of Mexican immigrants to assimilate culturally to the U.S. Nevertheless, we find evidence of substantial cultural assimilation even among 1st generation Mexican immigrants, which calls into question their use as a benchmark population. Further, we find that 2+ generation Mexican Americans also show high levels of cultural convergence with regards to Anglos and African Americans, with the exception of Spanish-speaking Mexican Americans. This could be evidence that Spanish maintenance is a marker of "thick" ethnicity [13].

Rather than conforming to a single assimilative path, our findings highlight how Mexicans immigrants defy simple unilinear theoretical expectations. Indeed, their remarkable convergence with both Anglo and Black musical tastes, along with the preservation of some ethnic musical genres, reflect Mexican-Americans' heterogeneous character [1]. Last, the greater similarity in musical preferences of Mexicans in Mexico vis-à-vis African Americans complicates interpreting a preference for "black" genres as a straightforward indicator of downward assimilation among immigrants.

The primary limitation of the study comes from Facebook's "black box" algorithms for inferring attributes such as ethnic affinity. Though we cannot validate the classifier outputs on a per-user level, previous work has used data on stocks of migrants [33] and voter registration data [21] to show that, by and large, the inference for country of origin and ethnic affinity are quite reliable. However, such errors are likely non-random, so we cannot rule out potential for bias. Replicating our findings with other music-related data sources, such as 'Last.fm' [16], could be worth pursuing.

Finally, it is important to consider privacy implications of our work. Whereas Cambridge Analytica and similar companies (1) use individual level data, and (2) actively try to change user behavior, we do neither in our work. We only work with anonymous, aggregate data that in terms of content is similar to census-level data.

6 ACKNOWLEDGMENTS

The authors would like to thank the researchers at the Max Planck Institute for Demographic Research for their feedback on an early version of this work in summer 2018; Matheus Araujo and Antoine Dubois for their help with accessing Facebook data; and the anonymous reviewers for their thoughtful feedback. This work received support from the guest program of the Max Planck Institute for Demographic Research.

Learning Intent to Book Metrics for Airbnb Search

ABSTRACT

Airbnb is a two-sided rental marketplace offering a variety of unique and more traditional accommodation options. Similar to other online marketplaces we invest in optimizing the content surfaced on the search UI and ranking relevance to improve the guest online search experience. The unique Airbnb inventory, however, surfaces some major data challenges. Given the high stakes of booking less traditional accommodations, users can spend many days to weeks searching and scanning the description page of many accommodation "listings" before making a decision to book. Moreover, much of the information about a listing is unstructured and can only be found by the user after they go through the details on the listing page. As a result, we have found traditional search metrics do not work well in the context of our platform. Basic metrics of single user actions, such as click-through-rates, number of listings viewed, or dwell time, are not consistently directionally correlated with our downstream business metrics. To address these issues we leverage machine learning to isolate signals of intent from rich behavioral data. These signals have key applications including analytical insights, ranking modeling inputs, and experimentation velocity. In this paper, we describe the development of a model-based user intent metric, "intentful listing view", which combines the signals of a variety of user micro-actions on the listing description page. We demonstrate this learned metric is directionally correlated with downstream conversion metrics and sensitive across a variety of historical search experiments.

1 INTRODUCTION

Airbnb[1] is a two-sided rental marketplace where users can book unique as well as more traditional accommodations. The guest booking "funnel" is generally defined in three stages:

Search - A user executes searches, likely specifying a location, dates, and guest count. The user may also apply filters to their search to express specific preferences, such as price maximum and/or minimum. Available accommodation listings from our inventory are retrieved, ranked via our relevance models, and presented to the user. A user will explore the results by clicking listings to open the details page, with information such as checkin and checkout times, available amenities, sleeping arrangements, reviews, and more.

Contact - Once a user finds a listing they are interested in, they send a message to the host requesting to book their place. Note that guests can also send messages to hosts asking for clarification of listing details or special requests without sending a formal request to book.

Book - Once the host approves the request, the guest receives a notification and can then finalize the booking. Some hosts opt-in to a program, called "instant book", where booking requests are automatically accepted. It is also possible that the host will reject the booking request, at which point the guest will have to contact other listings to find accommodations.

The search team at Airbnb focuses on optimizing the guest experience from search to booking. We analyze the efficiency at which guests move through the different stages of the conversion funnel to inform product and model improvements, and measure their success in online experiments. We generally observe contacts and bookings almost simultaneously. Therefore, relying primarily on contacts and bookings signals poses two major challenges:

1. **Sparsity** - very few visitors and searchers end up contacting or booking,
2. **Signal Time Lag** - searchers can spend days to weeks searching before contacting or booking, so it can take a similarly long time for lifts or drops in booking signals to manifest within experiments.

Consequently, we are strongly motivated to develop upper-funnel metrics which are less sparse, meaning observed for non-bookers as well, and can be realized faster than downstream business metrics. This is a classical challenge in product optimization shared by many online platforms[2].

Our challenges and contributions are unique in that clicks, view duration, and traditional search metrics are not good leading indicators for bookings on our platform. Movements in click metrics are not consistently correlated with downstream business metrics,

[1] Airbnb.com
[2] https://www.slideshare.net/bonbonsuperbonbon/defining-true-north-metrics-to-quantify-engagement-at-linkedin

making it difficult to draw conclusions from their increases or decreases. We, therefore, develop a new metric based on a machine learning model, screening signals of friction from signals of intent. This metric captures a new stage in the booking funnel between Search and Contact, the searcher found a listing which is a good match for them. We can use this metric for a range of applications: drive more analytics insights of our booking funnel, increase experimentation velocity, and feed less sparse signals to our ranking models.

This paper outlines the challenges of using traditional search engagement metrics within the complex Airbnb booking funnel. However, by sacrificing some simplicity and turning towards a machine learning derived user intent metric, "intentful listing view", we were able to overcome these challenges. We demonstrate the machine learning based metric is directionally correlated with downstream business metrics and sensitive across a variety of historical search experiments. The contributions of our work are two-fold:

1. Developing a simple yet effective approach to capture intent from page engagement signals.
2. Creating a new conversion leading indicator for increased experimentation velocity and less sparse ranking optimization.

2 ENGAGEMENT SIGNALS IN AIRBNB SEARCH

The use of observable user behaviors, such as clicks, is a popular approach to evaluate the quality of online search retrieval and ranking systems [2]. These signals are inexpensive to obtain, especially compared to expert judgments, and can be gathered in large quantities. Given these attractive features, user behavior metrics are relatively well-adopted in the field of Web Search [4]. However, given the signal is naturally noisy and user behavior is multi-faceted, deriving metrics which truly reflect the relevance of results can be challenging [6].

The direct application of user behavior metrics to Airbnb search poses a few challenges. In the context of Web Search, the time it takes a user to complete a "search task" can be measured in minutes and at most a few query reformulations [8]. For Airbnb search we are not afforded such a luxury. Even the most eager to book user can spend 3 days searching, execute 12 unique searches, and view the description page of 11 listings before booking.

Motivated by click-through-rate we implemented a similar concept at Airbnb, number of listing views per user [5]. We evaluated the quality of this metric as a leading indicator of booking, via a meta-analysis of historical experiments. We ideally want to observe a strong correlation and directional agreement between movements in the leading indicator metric and booking conversion. Figure 1 shows there is very mild correlation between the listing view metric and booking conversion for 20 search experiments; confidence intervals are omitted as all results are statistically significant. In 40% of the experiments, represented by green dots, the number of listing views decreases yet booking conversion improves, or the inverse. There is also only a 0.06 Kendall's tau correlation between the metrics. The contradictions and lack of correlation make it difficult to utilize this click-based metric with confidence. At Airbnb clicks and views are not a strong signal of intent. Much of the information

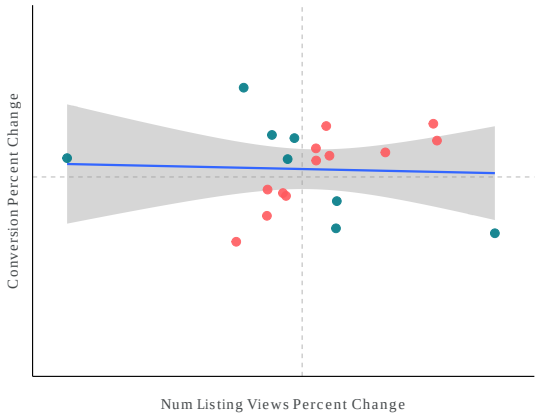

Figure 1: Correlation of Num Listing Views Metric with Booking Conversion Metric

about a listing is unstructured and can only be found after viewing the details on the listing page. Therefore, it is not clear if increases in number of listing views is a signal of consideration or increased friction.

In an effort to remove quickly abandoned listing views, we explored restricting to only long dwell-time views [9, 10]. Across a variety of duration thresholds and transformations as suggested by [11] and [12], we were unable to achieve reasonable correlation with business metrics. Listings have varying numbers of photos, description lengths, and number of reviews; this can cause unwanted bias and variation in comparing view duration across listings. We also explored Airbnb product specific engagement information such as clicking into the price details module on the listing page as well as searching for specific dates. Efforts produced metrics which either did not correlate with business metrics, or were too focussed on a specific path of engagement, and did not generalize well to all searchers. For example, some searchers without specific dates in mind will execute searches without entering dates, and determine their travel dates based on the availability of listings they like. Therefore, a metric related to searching for specific dates would not extend to that user segment.

Taking a step-back, we invested analytical resources in mapping out users' specific product surface touch-points on the path to booking. We identified that viewing the listing description page is a touch point which every guest passes through on their way to booking, and is a step which is relatively high-up in the funnel. We also identified that users perform a range of actions on the listing description page: clicking photos, paginating reviews, etc. The list of actions is extensive and performed in varying sequences, such that it is difficult to comprehend globally positive and negative actions from basic summary statistics. Note that users will also sometimes abandon a listing description page, only to return to it a day later.

Zhou et al. [13] successfully improved e-commerce recommendations using micro-actions between users and items, not solely relying on purchase signals. In addition, Kim et al. [7] trained a machine learning classification model using search query attributes, page attributes, and dwell-time, to predict if a web search result

click is associated with user satisfaction. Motivated by these successes, we attempt to build a machine learning model which can combine the rich collection of user micro-actions on the listing description page to produce a more reliable engagement signal.

3 INTENTFUL VIEW MODEL

Our objective is to build a model which can identify guest listing views which signal that a user is considering booking a listing, versus those which the user has dismissed from consideration. We formalize this objective as a classification task.

3.1 Problem Formulation

Given our focus is on the searching to contacting stage of the funnel, we utilize the action of contacting a listing as our target outcome variable. Therefore, for a given user, u_i, and listing, l_k, we model the probability a user's view of the listing, v_{u_i,l_k}, will result in a listing contact, i.e.

$$Pr\left(u_i \text{ contacts } l_k \mid v_{u_i,l_k}\right).$$

The above classification formulation is straightforward, but there is the added complexity that some users contact a listing and some do not. We include all users in our training data, contacters and non-contacters, so as to avoid the selection-bias of only including users who contact. We emphasize learning the delineation between a contacter and non-contacter while still focussing on user-listing level predictions. This is achieved by applying some filtering in terms of positive and negative examples in our training data:

> **Positives** - listing views of users which lead to contact of the viewed listing,
> **Negatives** - listing views which did not lead to a contact, and the searcher did not contact any other listings for the given trip.

Note that it is possible for a user to contact multiple listings for a trip, and all such examples are included in the data as positives.

It can be seen that a contacter's only contribution are the listings he or she contacted, and listings that were viewed but not contacted for the given trip are omitted. While this can be viewed as over simplifying the problem, it helps reinforce the objective of separating the actions of guests which have reached the stage to contact, versus those who will not contact. Previous analyses at Airbnb have shown that most users who contact a listing will view and strongly consider a set of listings. But since he or she can only stay in one place for a given location and dates, most users choose to contact only one of the listings they were considering. Therefore, including negatives from users who contact crosses into the territory of learning preferences, and less so a threshold of intent. Their omission improves our signal to noise ratio for modeling general intent to contact.

Figure 2 illustrates which user listing views are included in the training data (opaque), and their associated label, versus those which are excluded (transparent). The "thumbs up" denotes that a user was implicitly interested in a listing. Note that the first and second user "liked" multiple listings, but only the contacted listings' views are included in the training data, while all the listing views from the non-contacting user are included.

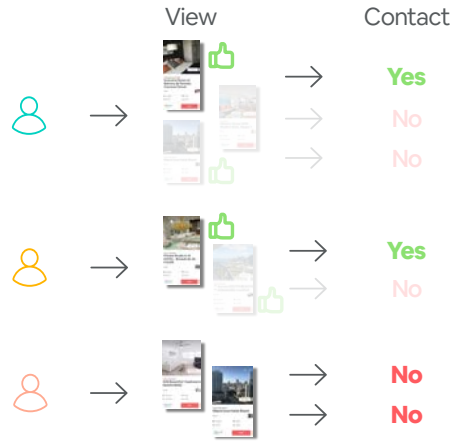

Figure 2: Illustration of Training Data Construction

Many guests view a listing multiple times before booking, this is a valuable signal of intent. We, therefore, update the probability of contact with each view, incorporating information about the current view as well as past views, up to a reasonable look-back time threshold. This updates our objective as follows:

$$Pr\left(u_i \text{ contacts } l_k \mid v_{u_i,l_k,t_1},\ldots,v_{u_i,l_k,t_m}\right),$$

where m denotes the rank number of the current view of listing l_k by user u_i at time t_j.

3.2 Feature Engineering

We implement granular logging of user micro-actions on the listing description page, which enables us to build a rich feature set. Motivated by Zhou et al. [13] we log dwell time on the entire listing page as well as page scroll depth. We also log number of clicks, dwell time, expand/collapse, and pagination for each individual section of the listing page, e.g. photo carousel, description text, reviews, etc. From this logging we generate four classes of features:

1. **Actions on Most Recent View** - This includes features of user actions for the most recent view of the listing.
2. **Actions from Previous Views** - We predict contact with respect to the current view as well as all previous views of the listing by the user. We therefore include a class of features which are aggregated summary statistics of the user actions from previous views of the listing. We use the same numeric features from the "Recent View" class, calculating the min, max, and mean value across all previous views. We also found it improved model performance to include as their own individual class the feature values for the very first view of the listing, in addition to the aggregates.
3. **Time Gap Info of Previous Views** - Information about the timing pattern of a user's multiple views of a listing also impacts model performance. We include features with basic time information: number of previous views of the listing, time since last view of the listing, and min, max, and average

time between views of the listing. For cases when a user has no previous views of the listing, these values are all set to null.

4. **Trip Information** - User behavior which signals intent can be different depending on how far out the trip is (lead time), the length of the trip, and/or how many guests are attending. We include features with this information, as well as how many unique checkin and checkout dates a user enters on the listing's availability module. Users with a strong affinity for a listing will sometimes modify their travel dates to fit the availability constraints of the listing.

3.3 Model Training

We train on user logs from a fixed time period and evaluate on an independent test set from a future time period; care is taken to ensure no user is represented in both sets. We perform some basic filtering by removing examples from users with a single view of a listing with duration less than 5 seconds; this threshold is chosen because it removes very low-intent negative examples without affecting the coverage of positive examples. In order to avoid overfitting to users with many views, we weight training examples by the reciprocal of the total number of examples per user. All continuous and count features are log-transformed. We train our model using the XGboost[3] library with a log-loss objective function. Tuning parameters are selected by evaluating performance on a separate validation set.

3.4 Evaluation of Model Performance

We evaluate the AUC performance of our XGboost classification model compared to a variety of alternative models:

(1) Total View Duration - We score the intent level of listing views by the sum total view duration of the current view and previous views of the listing; this is equivalent to the traditional dwell-time weighting of clicks.
(2) Number of Repeat Views - We score views by total number of previous views of the listing by the user
(3) Decision Tree Depth 2, 3, and 4 - Using the same features as in the full XGboost model, we train a few simple decision trees of varying depth with Gini impurity as the split criterion [1].

Figure 3 shows the ROC curve and AUC performance of each model on the test set. The XGboost model out performs all other models. This is not surprising given the increased complexity of the model, but the dramatic improvement in performance lends a strong argument to continue with the more complex model in lieu of something simpler.

3.5 Evaluation of Model Robustness

The listing description page is a product surface which is still under development. We test product changes attempting to improve booking conversion which can re-order sections, collapse/expand sections, alter the content within a section, or delete a section altogether. Our model includes features related to user actions on the listing description page UI, so we want to be sure the model is for the most part robust to UI changes.

[3]https://xgboost.readthedocs.io/en/latest/

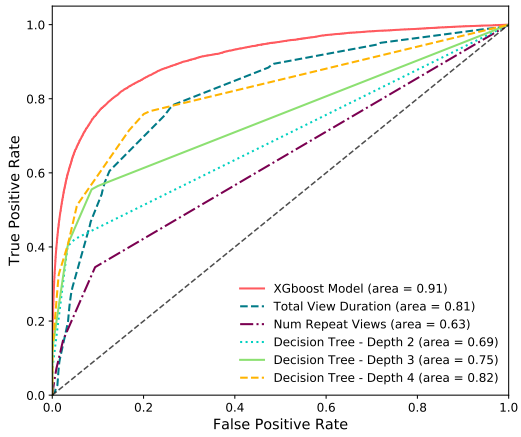

Figure 3: Model Performance Evaluation

Table 1: Model Evaluation on Different Listing Page Design

	Current Listing Page	Previous Listing Page
AUC	0.91	0.89

We compare the AUC performance of our model on the current listing page UI, on which it was trained, versus a previous version. The previous UI version differs fairly drastically from the current version in that there are additional sections and all sections are expanded by default, so the listing description page is longer. Table 1 shows that while there is an expected slight decline in model performance on the different design, the change is not too dramatic with an AUC drop of only 2%.

Since the model performance can be slightly influenced by UI changes, we invest in monitoring metrics related to model performance. Via Airflow[4], we calculate and report daily the model's predictive performance (AUC), as well as descriptive statistics and distributional characteristics of the prediction output of the model and feature inputs. In the future we intend to explore semi-regular automatic retraining of the model via a similar process.

4 APPLICATION TO EXPERIMENTATION

Similar to other online marketplaces, A/B experimentation is a vital component of optimizing the Airbnb search experience. As previously outlined, the long booking conversion funnel can pose challenges in terms of experimentation velocity. Leading indicator metrics help us more quickly determine which product changes are tracking towards improved booking conversion and those which are likely hurting conversion. It also enables us to understand how experiments are affecting different subsets of users, especially those with less traffic. In this section we demonstrate how we use the output from the intentful view model to build a strong leading indicator metric for search experiments, "intentful viewer".

An effective leading indicator metric is consistently correlated with downstream business metrics and ideally more sensitive, i.e.

[4]http://airbnb.io/projects/airflow

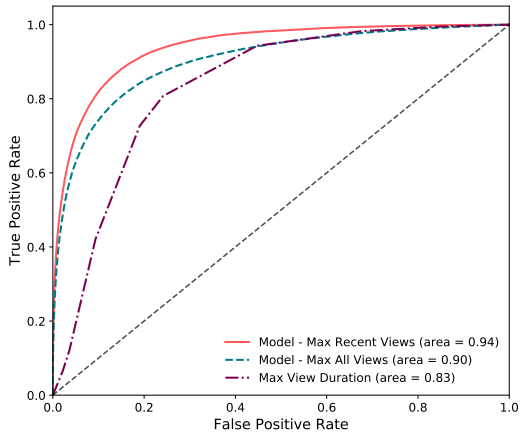

Figure 4: User-Level Prediction of Contacter Evaluation

reaches statistical significance before downstream metrics [3]. Depending on the product change there are cases in which the correlation will not hold, but the goal is for those cases to be rare and easily explainable. We therefore evaluate the quality of our proposed leading indicator metric based on those two factors.

4.1 User Level Prediction

Doing a view which signals intent to contact can be considered a milestone for a user in the search to book funnel. We, therefore, convert the output of our model from user-listing level to simply user level. We do not modify the model, but instead aggregate the model predictions across all listings viewed by the user. We make the reasonable assumption that a users overall intent to contact any listing is bounded from below by their maximum intent to contact an individual listing. More formally, for a user, u_i, with views across listings $\mathcal{L}_i = l_1, \ldots, l_r$, then

$$Pr\left(u_i \text{ contacts any listing}\right) >= \max_{l_k \in \mathcal{L}_i} Pr(u_i \text{ contacts } l_k)\,. \quad (1)$$

This formulation is likely a conservative probability of contacting, but enables us to generate a user level metric which is easier to interpret within the setting of an online experiment.

Figure 4 shows the ROC performance of the user-level prediction with target variable of contacter vs non-contacter. For users with multiple views of a listing, we find it improves predictions to only use the probability of contact from the most recent view of each listing in equation 1. We also include the comparison to an alternative model where user intent is ranked by maximum view duration on an individual listing. The intentful view model user-level prediction, based on most recent view, has a 13% better AUC than dwell time.

4.2 Metric Definition

We attempt to establish a probability threshold such that any user with a predicted probability above the threshold is declared "intentful". Therefore, within a given experiment we can compare the share of users in control and treatment who have reached this stage, with the conclusion that a product change which drives more users into an intentful state will lead to an increase in booking conversion.

Based on our previously outlined goals, we ideally want the selected threshold to result in a metric which is both:

1. Directionally correlated with our downstream booking conversion metrics, and
2. more sensitive than downstream metrics.

Quantifying if two metrics are directionally correlated is straightforward. The directional correlation of the relative lift of two metrics, m_1 and m_2, between branches A and B within an experiment, E_k, can be expressed as

$$D\left(m_1, m_2, E_k\right) = I\Big(\text{sgn}\Big(\,L(m_1, E_k)\,\Big) = \text{sgn}\Big(\,L(m_2, E_k)\,\Big)\Big), \quad (2)$$

where $L(m_j, E_k)$ denotes the lift of metric m_j, and $I(\cdot)$ and $\text{sgn}(\cdot)$ are the indicator function and sign operator respectively. We drop the references to branches A and B for simplicity.

Similar to Kharitonov et al. [6], we measure the sensitivity of a metric, m_j, on a given experiment using the z-score statistic, defined as

$$Z\left(m_j, E_k\right) = \frac{\bar{m}_{j_B} - \bar{m}_{j_A}}{\sqrt{\text{Var}\left(\bar{m}_{j_B} - \bar{m}_{j_A}\right)}},$$

where $\bar{m}_{j_A}$ and $\bar{m}_{j_B}$ are the samples means of metric m_j for experiment branches A and B respectively, in experiment E_k. A higher absolute value of the z-score implies higher confidence in the difference of the metric means between control A and treatment B.

When comparing sensitivity, we focus on the inequality comparison of sensitivity (e.g. greater-than) as opposed to the raw magnitude. For a given experiment, we therefore compare if the z-score of our derived metric is larger than that of our downstream metric. Based on the direction of the downstream metric z-score we transpose the scores such that an increase is always desired, i.e. branch B > A.

We present our downstream booking conversion metric as m_C, and derived intentful viewer metric as $m_I(\tau)$, which depends on a probability threshold τ. Using our previously defined expressions, for a set of experiments $\mathcal{E} = \{E_1, \ldots, E_N\}$, we wish to optimize two expressions:

$$\frac{1}{N}\sum_{E_k \in \mathcal{E}} D(\; m_I(\tau),\, m_C,\, E_k\;)\,, \quad (3)$$

$$\frac{1}{N}\sum_{E_k \in \mathcal{E}} I(\; Z\left(m_I(\tau), E_k\right) > Z\left(m_C, E_k\right)\;)\,. \quad (4)$$

We evaluate the above expressions over a range of τ values for a set of historical search experiments. Ideally, we would only use ground-truth experiments for which the booking conversion metrics are statistically significant. We, however, only have 20 such experiments with the required logging to score our intentful view model. In order to increase our sample size we include experiments which did not meet the traditional 0.05 significance level, expanding to experiments with a booking conversion metric p-value up to 0.3. This doubles our sample size of experiments, increasing it to 42.

Since we have stronger confidence in the results of some experiments versus others, we weight the observations by $\omega = (1 - \text{p-value})$, using the booking conversion metric p-value for the experiment. The intuition behind this weighting comes from the notion that

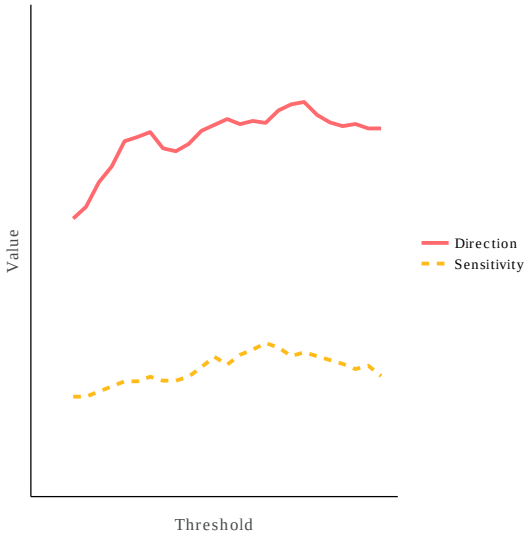

Figure 5: Intentful Viewer Directionality Agreement and Sensitivity for Range of τ Values

the p-value reflects the evidence against the null hypothesis. So the smaller the p-value, the more confidence we have in the experiment results, and therefore the experiment receives more weight. We modify expressions 3 and 4 as follows,

$$\frac{1}{\sum \omega_{m_C,E_k}} \sum_{E_k \in \mathcal{E}} \omega_{m_C,E_k} \, D(\, m_I(\tau),\, m_C,\, E_k \,), \tag{5}$$

$$\frac{1}{\sum \omega_{m_C,E_k}} \sum_{E_k \in \mathcal{E}} \omega_{m_C,E_k} \, I(\, Z\,(m_I(\tau), E_k) > Z\,(m_C, E_k) \,). \tag{6}$$

Figure 5 shows the evaluation of expressions 5 and 6 across the 42 experiments for a range of values of τ. There is a general concave shape for both directionality and sensitivity. Given the somewhat flat trend of sensitivity after a certain threshold, we select τ such that it maximizes directionality, we refer to this selected threshold as τ^*.

4.3 Results

For our selected τ^*, we plot in Figure 6 the correlation of the percent change in the intentful viewer metric versus the downstream booking metric across 20 statistically significant experiments. It can be seen our new metric achieves a strong correlation and directional agreement with the conversion metric, especially when compared to the number of listing views metric from Figure 1. In Table 2 we show a comparison of summary statistics of the two metrics. Our intentful viewer metric is able to achieve a directional agreement for 95% of the experiments, whereas the listing view count metric is only 60%. We also see that our new metric is more sensitive than the conversion metric 35% of the time. This shows there are still improvements to be made in terms of increasing the sensitivity, perhaps incorporating the magnitude of the difference of the z-score in the optimizing expression can help. We leave that for future work at this moment.

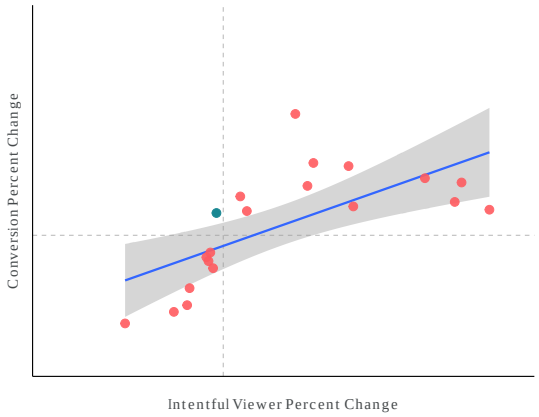

Figure 6: Correlation of Intentful Viewer Metric with Booking Conversion Metric

Table 2: Intentful Viewer vs Num Listing Views Metric

	Intentful Viewer	Num Listing Views
Direction Agreement	0.95	0.60
Kendall's Tau Cor	0.62	0.06
Greater Sensitivity	0.35	0.20

5 CONCLUSIONS AND FUTURE WORK

We present an effective approach, using a machine learning classification model, to capture user intent via user engagement signals. The predictive performance and robustness of the model are evaluated extensively. We use the output of the model to build a user intent metric, "intentful viewer". We demonstrate via a meta-analysis of historical experiments that this metric is strongly correlated with business output metrics.

In the future, as more historical experiments are available, we will explore alternative methods for determining the optimal probability threshold for our "intentful viewer" metric. We also currently predict at the listing-level and then aggregate model predictions up to the user-level. It is possible to jointly model, via a conditional probability representation, a user's overall intent and how that intent disperses to individual listings. We can also iterate on improving model predictive performance by transitioning to neural network sequence models. This would provide a more advanced method for incorporating a user's historical actions on a listing, as the user history can be fed as a raw sequence to the model as opposed to a set of summary statistics as we currently employ. Finally, we will explore the use of the intentful view predictions as a more reliable implicit feedback signal in our search ranking models.

ACKNOWLEDGMENTS

We would like to thank Claire Lebarz, Thomas Legrand, Navin Sivanandam, Richard Dear, and the entire Airbnb Search Team for their feedback and suggestions throughout the development of this work.

ABSTRACT

Online users engage in self-disclosure - revealing personal information to others - in pursuit of social rewards. However, there are associated costs of disclosure to users' privacy. User profiling techniques support the use of contributed content for a number of purposes, e.g., micro-targeting advertisements. In this paper, we study self-disclosure as it occurs in newspaper comment forums. We explore a longitudinal dataset of about 60,000 comments on 2202 news articles from four major English news websites. We start with detection of language indicative of various types of self-disclosure, leveraging both syntactic and semantic information present in texts. Specifically, we use dependency parsing for subject, verb, and object extraction from sentences, in conjunction with named entity recognition to extract linguistic indicators of self-disclosure. We then use these indicators to examine the effects of anonymity and topic of discussion on self-disclosure. We find that anonymous users are more likely to self-disclose than identifiable users, and that self-disclosure varies across topics of discussion. Finally, we discuss the implications of our findings for user privacy.

1 INTRODUCTION

Public discourse has been emboldened by the ubiquitous use of social media, including social networking websites, blogs, and online newspaper comment forums. Users can now share information, express opinions, and discuss various topics of interest with a wide audience through these platforms. This engagement often includes *self-disclosure*— the communication of personal information to others [10]. Online social networks and comment forums thrive on user-generated content and, therefore, encourage self-disclosure [33].

Self-disclosure is generally considered conscious behavior, in which users engage in pursuit of strategic goals including social connectedness, validation, self-expression, relational development, identity clarification, and social control [1, 6, 11]. However, there are associated costs of this behavior to users' privacy. Personal information posted online becomes shared knowledge and may be retained or shared downstream, in ways or by parties unintended by its original owner. Understanding self-disclosure is paramount to devising ways of mitigating these risks and achieving data parsimony [23]. We note that while work on self-disclosure in seemingly bounded environments (e.g. social networks [6, 23]) has shed light on users' motivations for and practices of self-disclosure, less is known about user disclosures in public commentaries. In this work, we address these gaps.

Following, we present in-depth analyses of self-disclosure in a longitudinal dataset of about 60,000 comments on 2202 news articles from four major English news websites [5]. Inspired by prior work on online disclosure and anonymity, we focus on two contextual features that we suspect are related to self-disclosure in public forums, namely anonymity and topic of a commentary.

Our contribution is two-fold. First, we provide an automated method for detecting language indicative of various types of self-disclosure, leveraging both syntactic and semantic information present in texts. We identified 9 categories of self-disclosure, ranging from users' personal attributes (e.g. location, sexual orientation) to subjective categories, such as opinions. Second, we use these results to examine the effects of anonymity and topic of discussion on self-disclosure. Our results indicate that users who have greater anonymity are more likely to self-disclose online, and that self-disclosure varies for different topics of discussion. Finally, we discuss the implications of our results on online self-disclosure for privacy. To the best of our knowledge, this is the first study which uses an automated detection method to analyze triggers of oversharing and personal information disclosure outside the classic boundaries of social network domains.

The remainder of the paper is organized as follows. In the next section, we present related work in this area. Next, we provide background and discuss our hypotheses. We then discuss a novel method that we used to detect self-disclosure in online public platforms, followed by validation of the method. The remainder of this paper is dedicated to hypotheses testing and discussion of findings.

2 RELATED WORKS

People engage in self-disclosing behavior consciously for various intrinsic and extrinsic benefits. As disclosing personal information

online has privacy risks, users try to maintain a balance between self-disclosure costs and benefits. They utilize different media affordances such as anonymity, audience representations, etc. in this pursuit. Users' self-disclosure decisions are therefore dependent on these media affordances. Previous studies have used survey-based functional models incorporating social media affordances to examine self-disclosure characteristics in social networking sites (SNS). A recent study [9] highlighted the differences in disclosures between private SNS and public SNS. The authors showed the roles of audience representations (bounded vs unbounded), and network characteristics (size and diversity) in describing self-disclosure. However, they noted the need for extending studies of self-disclosure to online platforms other than Facebook and Twitter.

Anonymity, as a social media affordance contributing to self-disclosure, has been extensively studied under the term online disinhibition [31]. Multiple studies have noted the positive relationships between anonymity and self-disclosure in computer mediated communication [16, 21]. However, the findings are not consistent for all types of online platforms. For instance, Qian and Scott [27] reported no association between increased visual anonymity with greater self-disclosure. Similarly, Chen et al. [8] showed negative effect of network anonymity on self-disclosure on Sina Weibo platform but reported positive effect of perceived anonymity. These mixed findings suggest that different online media have different affordances of anonymity and therefore, the relationship between anonymity and self-disclosure is dependent on media characteristics. In this work, we study the effect of anonymity on self-disclosure in online news commentaries which afford different levels of anonymity as described in in Section 3.

Studies on self-disclosure have mostly relied on manual coding and analysis of users' contents primarily into broad categories of personal information, personal thoughts and opinions, and personal feelings and emotions [4, 14]. Personal information is related to facts about a person while textual contents that convey thoughts, opinions, feelings and emotions are subjective in nature. Each of these broad categories may include several sub-categories such as biographic information, property, location, family details, etc [7, 14]. In line with existing literature, we adopt similar terminologies and consider two broader categories of self-disclosure namely: objective and subjective (See Table 1). Objective categorization include factual information about a person: birthday/age, race, sexual orientation, affiliation, money, relationships and experiences. Subjective categorization includes categories related to internal states of an individual: interests, opinions and feelings.

Automated detection of self-disclosure has been tackled by recent studies [7, 33]. Caliskan et al. [7] created a supervised machine learning method to detect private information in tweets through the use of privacy ontology, named entity recognition, topic modeling and sentiment analysis. They assigned privacy scores to each user based on the percentage of the userâĂŹs tweets annotated. We used a different approach as we rely on an unsupervised method to detect individual self-disclosure categories in texts. Bak et al. [3] created a supervised method with topic models and SVM to detect personally identifiable information (PII) and personally embarrassing information (PEI). Precision and recall for their supervised method of PII detection were 0.23 and 0.21 while for PEI precision and recall were 0.30 and 0.23 respectively. In comparison, our unsupervised method achieved greater precision and recall across most categories of self-disclosure. Further, Bak et al. [2] applied modified latent Dirichlet allocation (LDA) topic models for semi-supervised classification of Twitter conversations into three self-disclosure levels. They did not categorize texts into individual categories of self-disclosure as we do.

3 BACKGROUND AND HYPOTHESES

We study self-disclosure as it correlates to a few critical contextual dimensions. Here, we discuss our hypotheses, and ground them in relevant literature. The first dimension we consider is *anonymity*.

H1: Anonymous users are more likely to self-disclose than identifiable users in online public commentaries.

Other authors have found that anonymity contributes to increased self-disclosure both on- and offline [21, 25, 29]. In particular, previous studies have suggested that, emboldened by the cover of anonymity, people may feel less restrained and express fewer inhibitions [31]. Many online platforms offer some degree of anonymity to users in service to freedom of expression [30], where the nature of that anonymity varies across platforms. To comment within article commentaries, in most cases, users either need to sign in to a commenting platform (e.g., Disqus [12]), provide an email address (medium/high anonymity if a throw-away account is used [19]) or provide links to an existing social network account (high identifiability), e.g. Facebook.

Recent work indicates [32] there is a predictive relationship between anonymity state and perceived anonymity. Users intuit that they are more identifiable when linking social network accounts than they are when using pseudonyms. Our analyses consider two anonymity states among users, representing pseudonym vs. social-media-linked accounts. *Following, we refer to users logged into Disqus as "anonymous" and users logged in through existing social media accounts as "identifiable".* Our first hypothesis considers differences in self-disclosure between anonymous and identifiable users.

H2: Users' self-disclosure varies across topics.

A second contextual dimension that we suspect is relevant to self-disclosure is the *topic* of a discussion. Public discourse in news websites and opinion forums is topic-oriented. The news article or the opinion column usually determines the initial topic of discussion. Because individuals relate to content based on prior experiences and feelings, they respond differently to different topics [33] where self-disclosure is a subset of that response. Hence, we hypothesize that users self-disclose differently across topics.

4 DETECTION OF SELF-DISCLOSURE

We anchor our approach for detection of traces of self-disclosure in an opinion extraction technique [17], wherein opinion, opinion-holder and the opinion topic are extracted. However, our goal is not limited to detection of subjective language (opinion). We intend to detect objective language pertaining to self-disclosure as well. To do so, we leverage both the semantic and the syntactic resources in a sentence. The intuition is that a self-disclosing sentence has self-reference[1] as a subject or the object of reference is the self.

[1]We do not consider any indirect forms of self-disclosure with no explicit self-reference in the text and we do not detect the degree of self-disclosure

Table 1: Description of categories of self-disclosure used as instructions for labelling survey

Language	Categories	Description
Objective	Birthday/Age	Sharing one's own birthday information or references to own age.
	Race	Sharing one's own race such as being black, white, Hispanic, etc
	Sexual Orientation	Sharing one's sexual orientation and identity such as being straight or LGBT. Includes marital status
	Location	Sharing one's own location such as town, city, states, proximity to a landmark, etc
	Affiliation	Sharing one's nationality, religion, political affiliation, loyalties to groups and brands of a certain nationality, etc
	Money	Sharing one's own financial worth, monetary values of property, plans/goals related to money, etc
	Relationships	Sharing information about the family composition such as having children, brothers, sisters, etc
	Experience	Sharing past experiences of events, habits, work-life, etc. Includes positive or negative experiences and recollections of any past events or memories
Subjective	Interests	Sharing one's own hobbies and interests, including pastimes, favorites, tastes in music, movies, and books. Includes disclosures about pets, as well.
	Feelings	Expressions of deep personal feelings, including humiliation, desires, anxiety, depression, fears, pain, and beliefs which most people would likely disclose only to a friend or family
	Opinion	Discussing one's own opinions, attitudes, and beliefs about current and/or historical events that one is NOT relating to personal experience. Includes views on government, trends, specific events in entertainment/sports, religion, etc.
-	Other	Personal information about the author is revealed but can't be categorized in any categories
-	None	No information about the author revealed

Presence of first person pronouns is generally considered as linguistic markers for self-disclosing texts [15]. Moreover, several studies have used presence of first person pronouns as a prominent feature in determining self-disclosure in online contents [2, 11, 33].

The categories of self-disclosure as shown in Table 1 are distinguished based on related named entities present in the sentence in the vicinity of related verbs. For instance, anyone disclosing where he/she lives uses sentences with verbs related to location like live, stay, etc together with the place where they live. A typical example would be the sentence "I live in Pennsylvania". In this scenario, the author of this text includes the place of living (a location entity) and the verb "live" (related to location) with reference to the self (use of "I"). Hence, our method identifies self-disclosure categories in text through the knowledge of subject, verb, object and named entities. The overall method of detection and categorization of self-disclosure consists of four phases: (1) dictionary construction, (2) subject-verb-object triplet detection, (3) named entity recognition and (4) rule based matching.

4.1 Category Specific Dictionary Construction

We constructed a vocabulary of verbs often associated with the different categories of self-disclosure. The dictionary consists of verbs used in a labeled dataset from a study of self-disclosure in Airbnb profiles [22]. The dataset consisted of 5248 annotated sentences from 1234 user profiles. Each sentence was categorized into one or many of the eight categories. We extracted the frequent root verbs from sentences categorized into categories of work or education, origin or residence, travel, interests and tastes, and relationships to construct dictionaries of verbs associated with our categories. The dictionaries also consist of additional verbs manually added to aid in the categorization. We constructed multiple dictionaries of verbs: subjective (36), location (21), affiliation (20), , money (12), birthday/age (3), and race and sexual orientation (1). We also created additional dictionaries of attributes for categories of relationships, race, and sexual orientation. Specifically, names of different racial groups, types of sexual orientation and types of social and family relationships were compiled to create these individual dictionaries. We used these dictionaries as entities for the aforementioned three categories.

4.2 Subject, Verb and Object Extraction

We used the Python package Spacy based subject verb object extraction[2]. The implementation was adapted and modified to suit our goals. The subject, verb and object extractor takes text as input, pre-processes the text, splits it into individual sentences and further splits a sentence into individual clauses if present. Text pre-processing includes expanding the contractions such as "I'm" to "I am". Each clause in a sentence passes into the dependency parser and all the verbs are extracted. The dependencies or the syntactic relationships between other tokens in the clause with the verbs is used to determine the subject and objects in the text. Our method was aware of the passive voice and negation in sentences.

4.3 Named Entity Recognition

We attribute the presence of "real-world object" called a named entity like a location, nationality, etc in a sentence as a distinguishing feature among different categories of self-disclosure. We used a model[3] trained on OneNotes corpus, which can detect about 18 different types of entities[4]. Entities of DATE and CARDINAL (number) were used for birthday/age category. Location related entities such

[2]https://github.com/NSchrading/intro-spacy-nlp/blob/master/subject_object_extraction.py
[3]https://github.com/explosion/spacy-models/releases//tag/en_core_web_lg-2.0.0
[4]Details about entities: https://spacy.io/api/annotation

as GPE, FAC and LOC served as distinguishing entities for location category while NORP (Nationalities or religious or political groups) distinguished affiliation category in our categorization scheme.

4.4 Rule Based Matching

Overall, the self-disclosure categorization scheme remained similar for all the objective categories. Self-reference with presence of specific category related verb and appropriate named entities signaled self-disclosure in text. As the proximity of named entities in the sentences vary according to sentence construction, we added a proximity window of up to five words on either side of verb to effectively detect specific categories. It is useful in removing false positives as in case of sentence like *I have countless arguments with seemingly educated people in many countries on why Singapore works.* Here, all the attributes for location disclosure such as matched verb "have" with location entity "Singapore" and subject "I" are present but the proximity check prevents it's categorization into location category. Similarly, we added a proximity window of three words between subject and verb. It should also be noted that we do not include any named entities in the categorization scheme for subjective categories like personal interests, opinions and feelings. Such categories are solely based on presence of first person pronouns and verbs often used in expression of subjectivity.

5 VALIDATION OF METHOD

In this section, we describe process we used to validate our method of detecting and categorizing self-disclosure from user comments.

5.1 Dataset

Our work uses a dataset of user comments on news websites obtained from authors of the paper [5]. It consists of 309319 comments on 52260 news articles crawled from 10 selected news websites over a three month period. We constructed a smaller subset of the data by considering four news websites from majority native English speaking nations: ABC News, CNBC, The Huffington Post and Techcrunch. The time period of the contents was between March and August 2015. We cleaned the data by removing duplicates and comments with no readable text. In total, there are about 59249 comments from 22132 users (14219 identifiable and 7913 anonymous). As described in the earlier section, we differentiate anonymity states based on the account people use to comment on news websites. Commentors on The Huffington Post and Techcrunch used Facebook profile as their identity on these news websites. The users of CNBC and ABC News used Disqus accounts. Accordingly, we consider the users who commented on The Huffington Post and Techcrunch as identifiable and the rest as anonymous. The data consisted of 2202 news articles: The Huffington Post (1136), Techcrunch (119), CNBC (421) and ABC News (526). The anonymous users had higher average number of comments (4, SD = 10.85) than identifiable users (1.94, SD = 2.82).

In order to validate our method, we categorized all the comments using the method described earlier in the paper. Because the data consisted of numerous comments with incomplete sentences and imperative sentences (with no subject), we sampled the dataset after categorization. If we sampled before categorization, the sample size required to include samples of all the relevant categories of self-disclosure would be large. Hence, we performed stratified random sampling only after categorization.

The categorization scheme used here generated multi-label classification for each comment as any comment may contain different types of self-disclosure (including no self-disclosure category). We converted multi-label data into multi-class before sampling. We sampled 200 comments from each class and any class with number of samples less than 200 included all the examples of that class in the overall sample. In this way, we represented all types of examples in the final sample of 3516 comments.

5.2 Labeling

We used the crowd-sourced platform Amazon Mechanical Turk to obtain labels for our sample data. The labeling task was conducted under IRB protocol "STUDY00010405" approved by the Penssylvania State University's Institutional Review Board (IRB). Detailed instructions were given to the labelers about different categories of self-disclosure. Moreover, we included an example of categorization. Each comment was labeled by three different workers into atleast one of the categories in Table 1. To ensure the quality of labels and to ensure that the recruited workers read instructions carefully, the workers were required to answer an attention check question similar to the instructional manipulation check in the paper [26]. We rejected about 8.2% of the responses from the crowd-sourced workers failing the attention check.

We used Gwet's AC1 [13] as a reliability metric for the labeled data. Categorization scheme that classifies a comment into one or many categories of self-disclosure was treated as a group of binary classifiers: one binary classifier for presence/absence of a particular category of self-disclosure. We dropped the category of "organization" because of poor reliability. This category was related to the disclosures of one's workplace, school, membership in any organization, following of sports teams and ownership of properties of a certain brand. Overall, we observed good agreement among labelers: birthday/age (96.5%), race (97.7%), sexual orientation (97.7%), location (85.8%), affiliation (83.5%), money (89.3%), relationships (89.2%), experience (62.9%), interests (93.6%), feelings (81.4%), other (74.1%) and none (70.5%). Also, considering a single label for self-disclosure presence or absence in the text, the reliability score was 70.5%. For each comment, final labels (one or many) were obtained through majority voting. 9.76% of total number of comments did not have a consensus among the labelers.

5.3 Performance of Method

We evaluated the categorization scheme by comparing the crowd-sourced labels against the labels from the algorithm. Performance metrics were calculated only for 3174 comments which had final labels obtained through consensus among multiple labelers. We consider a comment to be self-disclosing in nature if it contains any one of the categories of self-disclosure (except Other) and if None, it is considered as not self-disclosing in nature. Overall, the precision, recall and F1 scores were 98, 89 and 93 respectively. Individual categories' classification performance metrics are summarized in Table 2 with a combined subjective category. We merged the categories of interests, opinions and feelings as a combined subjective category

because unlike objective facts about a person, the subjectivity in interests, opinion and feelings are difficult to distinguish and detect. As pointed out in [24, 34], "because subjectivity is a feature of a person's mind, it is not open to objective observation or verification". Hence, distinguishing between individual categories of subjective language is a task not in purview of our work.

Table 2: Performance metrics for categorization

Category (Support)	Precision	Recall	F1-Score
Birthday/Age (37)	19	43	26
Race (21)	46	62	53
Sexual Orientation (13)	50	62	55
Location (188)	26	70	38
Affiliation (106)	27	42	33
Money (150)	50	23	31
Relationships (206)	36	82	50
Experience (464)	29	50	37
None (97)	15	28	19
Subjective: interests, opinions and feelings (2383)	76	73	74
Overall self-disclosure	98	89	93

6 RESULTS ON HYPOTHESIS TESTING

We performed multiple tests to examine two specific hypotheses as described in detail in section 3. In this section, we present the statistical results of our hypotheses tests.

6.1 H1: Anonymity and Self-Disclosure

We tested our first hypothesis, namely, that anonymous users are more likely to self-disclose than identifiable users. We considered only those comments in a commentary which did not have any self-disclosing comments within five[5] preceding comments, in order to remove any peer effects (peer influence). We aggregated comments by user, obtaining histories of comments for 12,936 users—5218 anonymous and 7718 identifiable. We labeled users who self-disclosed in at least one comment *self-disclosing*. A Chi-squared test revealed that self-disclosure was significantly associated with anonymity [$\chi^2(1) = 59.538$, $p < 0.001$]. Binary logistic regression showed that anonymous users were more likely (1.366 times, $p < 0.001$) to self-disclose than identifiable users, adding support to H1.

Beyond absolute presence/absence of self-disclosure, we were also interested to see if there was a difference in frequency of self-disclosure between users of different anonymity states. Because users with higher number of comments have higher opportunities of self-disclosure, we suspected to see a difference in proportion of self-disclosure between two groups. Hence, we balanced the dataset for the average number of comments (2.91) for both user groups of different anonymity states. Specifically, we created a subset with total of 9468 users and comprising of 4734 identifiable and 4734 anonymous users. Stratified random sampling across strata of different number of comments was done to create this balanced data. We conducted a Mann-Whitney U test to test the differences between the two independent groups of anonymity states in terms of proportion of self-disclosure. The mean rank of proportion of self-disclosure was higher for anonymous users than identifiable users [U=11632245, $p < 0.001$], confirming our hypothesis.

In the next section, we further explore these findings on the effects of anonymity on self-disclosure by accounting for topic of conversation.

[5]We used five comments only because users are more likely to read only few preceding comments either the most popular ones or the most recent ones [20]

Table 3: Top five topics from topic model with frequent keywords

Topic	Keywords
Crime & Police Shootings	police, cop, people, kill, officer, shoot, death
Economy & Finance	money, tax, pay, people, government, wage, year
Security & Terrorism	people, war, kill, american, isis, fight, country
Technology	apple, watch, good, phone, time, car, people
Politics	people, time, hillary, country, vote, good, party

6.2 H2: Topics and Self-Disclosure

In order to validate our hypothesis about the effect of topics on self-disclosure, we first pre-processed our dataset for topical extraction. We performed topical modeling of users' comments using a Python wrapper[6] for LDA mallet. To get an optimal number of topics, multiple topic models were created with number of topics varying from 1 to 200. We used coherence score [28] as a measure of quality and interpretability of the topic models. Subsequent analysis revealed the best topic model with 20 topics and coherence score of 0.358. In this topic model, topics on related discussions were merged. For instance, two topics related to politics were merged into one. In this way, we merged similar topics to obtain 15 clear and distinct topics. Examples of some topics are shown in Table 3. Each news article with the associated comments were assigned the most dominant topic from topic model.

We used Kruskal-Wallis H test [18] to examine if users disclose about themselves differently for different topics. Kruskal Wallis H test is a non-parametric version of one way ANOVA and therefore, it is applicable to test our data (non-normal) for differences in proportion of self-disclosing users across 15 topics. Results showed that there was a statistically significant difference in proportion of self-disclosing users between the different topics of discussion [$\chi^2(16) = 29.928$, $p < 0.05$], confirming our hypothesis. Statistical significant differences were also observed for topics in proportion of users disclosing birthday/age, location, affiliation, relationships, money and experiences categories (each $p < 0.001$). We discuss the implications of these results in section 7. We refined the analysis to examine the effect of topic of discussion on the relationship between anonymity state and disclosure behavior. Multiple Mann-Whitney U tests were performed to test if the proportion of self-disclosure

[6]https://radimrehurek.com/gensim/models/wrappers/ldamallet.html

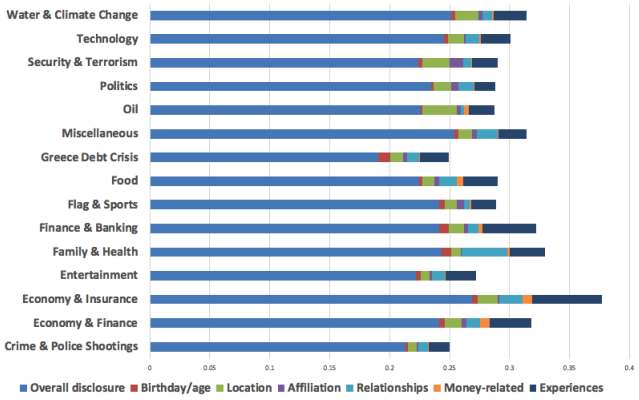

Figure 1: Average proportions of self-disclosing users per category across topics

for users differs within topics for different anonymity states. No significant differences were found after Bonferroni correction. Hence, the results show that the topic of discussion has no effect on the relationship between anonymity states and self-disclosing behavior.

7 DISCUSSION

In this study, we were able to detect language patterns of self-disclosure with differentiation into pertinent categories at reasonable accuracy levels. Because past studies on automatic detection of self-disclosure focused on supervised classification of levels of disclosure rather than unsupervised categorization of self-disclosure language [2, 7, 33], we cannot make like to like comparisons of our method's performance. Inherently, the task of detecting nuances of self-disclosure language is complex, even for humans as revealed by the agreement statistics between human annotators (See Section 5.2).

We used our categorization scheme to label users' comments in the experimental dataset. In general, *our findings confirmed our first hypothesis: users who have higher anonymity state are more likely to self-disclose than identifiable users.* The effect of anonymity as such to encourage or increase self-disclosure has been observed in social networking sites [8, 21] and our results show it is consistent even in online news commentaries.

Regarding the second contextual factor, topic of discussion, we found that proportion of self-disclosing users varied for different topics. Self-disclosing users' proportions across many individual categories also varied across topics (See Figure 1). Specifically, we observed discussions related to economy and insurance had the highest proportion of self-disclosing users. The two most relevant articles, as assigned by topic model to this topic, were centered around health-care policy. We observed many users shared their experiences and financial information, e.g. regarding health insurance, and note that this is reflected in the high proportion of users disclosing experiences and money-related information. Disclosures of specific categories in the context of certain topics are intuitive. For instance, highest proportion of users disclosed their relationships in the context of discussions about family and health. While we did not pursue specific hypotheses related to patterns of disclosure across topics, the findings here warrant further research in this regard. These results suggest the importance of context provided by the topic of discussion [33] of self-disclosure in SNS.

Our study on self-disclosure behavior has several implications. First, the results show that the online dis-inhibition actively drives responses from users on online news commentaries. Users utilize the affordances of anonymity provided by the online platform to exercise self-expression, especially subjective opinions and feelings. Hence, there are design implications for platforms to afford some levels of anonymity to maintain users' intimate participation in expression of opinions and feelings.

Second, the use of automated methods like ours to detect personal information in public comments highlights potentially hidden privacy threats. Users may be aware of the risks of disclosing too much in single comments (even with relative anonymity) and yet may be oblivious to the use of longitudinal aggregation of disclosed information. With close to 60,000 public comments over about 22k users, aggregated disclosures for each user revealed multiple categories of personal information. The ratio of number of anonymous users to number of identifiable users disclosing personal information increased with increase in number of categories disclosed. We found that higher number of users (48) disclosed four or more categories of personal information as compared to identifiable users (34). For example, multiple users disclose information about birthday/age and location. This can lead to unique identification, even if the users sign themselves with a truly random id. If such detection methods are carried out at larger scales in publicly available data (like public comments), we believe user profiles with sensitive information can be created and even anonymous users may be identified. Beyond loss of anonymity, aggregated personal information can be used by adversaries for malicious purposes.

8 CONCLUSIONS

In this study, we presented a novel method of detecting self-disclosure within commenting platforms online. We then examined two contextual factors contributing towards self-disclosure in online news commentaries: anonymity and topic of discussion. Using a dataset of user comments on online news commentaries, we tested and confirmed our hypotheses regarding these contextual factors. Specifically, our findings showed that anonymity elicits self-disclosure in online public comments. Additionally, context as specified by topic of discussion results in more likelihood of self-disclosure. Lastly, we provide implications of our results on online privacy. Self-disclosure behavior exhibited over time is perilous to user's privacy.

We see this work as a first step toward a more comprehensive study on online self-disclosure and the context within which it occurs. Our approach on automated self-disclosure detection is limited by the category-specific dictionaries. Also, albeit comprehensive, our taxonomy on self-disclosure categories is not exhaustive; there are several other categories of personal information revealed by online users. Further research is warranted in these areas.

ACKNOWLEDGEMENTS

We thank J. Barua, D. Patel and V. Goyal for the data used in this study. This work was supported by the National Science Foundation under grant 1453080.

ABSTRACT

The visual appearance of a webpage carries valuable information about the page's quality and can be used to improve the performance of learning to rank (LTR). We introduce the *Visual learning TO Rank* (ViTOR) model that integrates state-of-the-art visual features extraction methods: (i) transfer learning from a pre-trained image classification model, and (ii) synthetic saliency heat maps generated from webpage snapshots. Since there is currently no public dataset for the task of LTR with visual features, we also introduce and release the ViTOR dataset, containing visually rich and diverse webpages. The ViTOR dataset consists of visual snapshots, non-visual features and relevance judgments for ClueWeb12 webpages and TREC Web Track queries. We experiment with the proposed ViTOR model on the ViTOR dataset and show that it significantly improves the performance of LTR with visual features.

1 INTRODUCTION

The design and appearance of a webpage are determining factors for a user to examine the page or to divert to another page [8, 9, 11, 17]. However, relatively little is known about the potential of visual appearance to help determine the perceived relevance of a webpage. Recently, visual features, extracted from snapshots of webpages and search engine results pages (SERPs), have been introduced into learning to rank (LTR) and have been shown to significantly improve the LTR performance [4, 18].

In this paper we continue studying LTR with visual features and propose the *Visual learning TO Rank* (ViTOR) model that integrates state-of-the-art visual features extraction methods. We present two implementations of the ViTOR model. First, we extract visual features from webpage snapshots using transfer learning and, in particular, by adopting the VGG-16 [16] and ResNet-152 [5] models pre-trained on ImageNet. Second, we introduce a novel set of visual features extracted from synthetic saliency heatmaps, which explicitly model how users view webpages [14].

Currently, there is no dataset available to support research on LTR with visual features. Fan et al. [4] experimented with webpages from the GOV2 collection.[1] However, GOV2 solely contains webpages within the .gov domain, i.e., pages with a relatively narrow scope, and, more importantly, these webpages do not contain their original images and styles. Hence, the GOV2 collection cannot fully support research on LTR with visual features, as it does not reflect visually rich and diverse webpages found on the internet today.

To overcome this issue, we release the ViTOR dataset that contains webpages from the ClueWeb12 collection[2] and queries from the TREC Web Tracks 2013 & 2014 [1, 2]. For each webpage of ClueWeb12 that also appears in the web tracks, the ViTOR dataset contains a snapshot and a set of content features, such as BM25 and PageRank. The introduced dataset is made publicly available.[3]

To assess the performance of the proposed ViTOR model, we run experiments on the introduced ViTOR dataset. Our experiments confirm that visual features significantly improve the LTR performance, which is inline with previous findings [4]. We also show that both implementations of the ViTOR model, namely transfer learning (with VGG-16 and ResNet-152) and synthetic saliency heatmaps, significantly outperform other LTR methods with visual features.

In summary, the main contributions of this work are: (i) We introduce transfer learning to extract visual features for LTR. (ii) We introduce synthetic saliency heatmaps as a novel set of LTR features. (iii) We introduce and publish ViTOR, an out-of-the-box dataset for LTR with visual features.

2 RELATED WORK

In this section, we discuss related research on the usage of visual information in LTR and the relation between visual appearance and user perception of webpages.

Using eye-tracking, Nielsen [9] and Pernice [11] demonstrate that webpage design and content placement influences the ability of users to find information they are looking for. Both studies show that by organizing the content in certain shapes (e.g., an F-shape), information can be navigated more efficiently. Wang et al. [17] show that the size of the fixation areas measured using eye-tracking is larger on webpages with more content, which increases the likelihood that the attention of a user is distracted. Such studies highlight the importance of the visual appearance of a webpage and its effect on how users perceive pages, demonstrating that visual information has to be taken into account when ranking webpages.

Zhang et al. [18] consider using visual features for LTR and, specifically, for learning to re-rank. The authors propose a multi-modal architecture for re-ranking snippets on a SERP by learning their visual patterns. This work demonstrates that combining both visual and non-visual features can improve re-ranking performance.

The closest work to ours is the study by Fan et al. [4], which uses visual information to rank webpages instead of re-ranking snippets within an existing ranking. The authors use snapshots of webpages to extract visual features for LTR and show that such visual features significantly improve retrieval performance. They feed snapshots through a neural network that attempts to model the previously mentioned F-shape. The output of this neural network is then concatenated with more traditional ranking signals, such as BM25 and PageRank. Finally, the proposed model (called ViP) is trained end-to-end using a pairwise loss. In our paper, we continue this line of research and propose the ViTOR model for LTR with visual features that makes use of the state-of-the-art visual feature extraction techniques and shows superior performance compared to ViP. Also, we develop and publish the ViTOR dataset that contains visually diverse webpages compared to the GOV2 dataset used in [4], which lacks visual diversity and, importantly, does not contain images and style information together with webpages.

3 ViTOR MODEL

In this section, we introduce the ViTOR model for LTR with visual features. The proposed model consists of three parts. First, we introduce the model architecture in Section 3.1. Then, in Section 3.2 we describe two visual feature extractors used by ViTOR: VGG-16 [16] and ResNet-152 [5], both pre-trained on ImageNet. Finally, in Section 3.3 we propose to enhance ViTOR by generating synthetic saliency heatmaps for each of the input images. The implementation of the proposed ViTOR model is available online.[4]

3.1 Architecture

The ViTOR architecture is visualized in Figure 1. The process starts by taking an image x_i (1) as an input to the visual feature extraction layer (2) in order to create a generic visual feature vector x_{vf}. These features are considered generic because they can be extracted using convolutional filters trained on a different dataset and task. In order to transform generic visual features into LTR specific visual features, we use x_{vf} as an input to the visual feature transformation layer (3). This visual feature transformation layer outputs a visual feature vector x_{vl} that can be used in combination with other LTR features.

Separating the visual feature extraction and transformation layers allows us to significantly reduce the computational requirements when using a pre-trained model for visual feature extraction. In Section 7.1 we further elaborate on how the computational requirements can be reduced. In Section 3.2 below, we demonstrate how transfer learning can be applied to use pre-trained visual feature extraction methods in combination with the ViTOR architecture.

The ViTOR architecture also makes use of content features x_c (4), e.g., BM25, PageRank, etc. The final feature vector x_l is constructed by concatenating the visual features x_{vl} with the content features x_c. This final feature vector is then used as an input to the scoring component (5), which transforms the features into a single score x_s for each query-document pair. The resulting model is trained end-to-end using a pairwise hinge loss with L_2 regularization similarly to [4]. The scoring component uses a single fully connected layer with a hidden size of 10 and dropout set to 10%, which showed good performance in preliminary experiments.

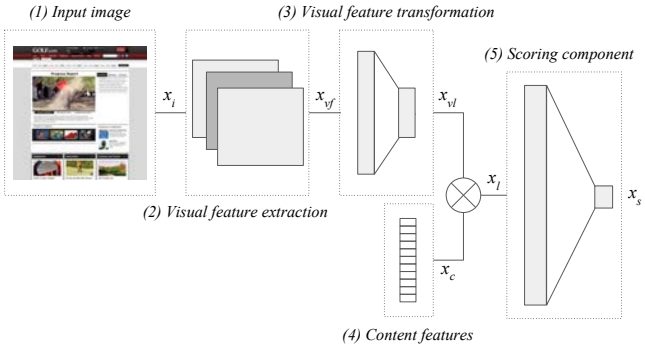

Figure 1: ViTOR architecture.

3.2 Visual feature extractors

In order to use webpage snapshots in LTR, the snapshots have to be converted to a vector representation that can then be used in combination with existing content features. Since preparing training data for LTR is costly and its amount is usually low, it is beneficial to use a visual feature extraction method that is already pre-trained. In this work we use the VGG-16 [16] and ResNet-152 [5] models, two well-explored image classification models which both have an implementation with ImageNet pre-trained parameters. Below, we describe how these two models are implemented within the ViTOR architecture.

VGG-16 [16] is commonly used for training transfer-learned models, because it provides a reasonable trade-off between effectiveness and simplicity [14]. Its architecture consists of a set of convolutional layers and fully connected layers. The convolutional layers extract features from an input image, which are then used by the fully connected layers to classify the image. The convolutional layers of VGG-16 are generic with respect to an input and task [3] and, thus, can be used as a visual feature extractor within the ViTOR architecture to create generic visual features x_{vf}. Hence, we use the convolutional layers as is, by freezing all the parameters during training. Because we do not alter any of the convolutional layers, the size of x_{vf} is determined by the output of the convolutional layers in the original VGG-16 model, being 1×25088.

The fully connected layers of VGG-16, instead, can be altered and retrained in order to be used with new inputs and tasks. Due to this, we utilize them as a visual feature transformation layer within the ViTOR architecture to produce LTR specific features x_{vl}. In particular, we replace the last fully connected layer of VGG-16 by a newly initialized fully connected layer. Then we optimize the parameters of all fully connected layers of VGG-16 during training. The size of x_{vl} is set to 30, as this size showed good performance in preliminary experiments.

The ResNet-152 [5] architecture was shown to outperform VGG-16 in ImageNet classification. The residual connections between convolutional layers of ResNet-152 allow for deeper networks to

be trained without suffering from vanishing gradients. Similarly to VGG-16, ResNet-152 has convolutional layers that extract features from an input image, which are in turn used by a fully connected layer to classify each image. We use these convolutional layers as the visual feature extraction layer, which transforms x_i to x_{vf}. All parameters of these convolutional layers are frozen during training. As with VGG-16, the size of x_{vf} is determined by the output size of the original convolutional layers in the ResNet-152 model, 1×2048.

Additionally, the original ResNet-152 architecture only has a single fully connected layer, which empirically showed to not be enough to successfully train the ViTOR model. Instead, we transform x_{vf} to x_{vl} by training a fully connected network from scratch. The transformation layer is constructed using three layers with each having 4096 hidden units and a final layer resulting in x_{vl} with a size of 30, which was empirically found to provide good performance in preliminary experiments.

3.3 Saliency heatmaps

In order to increase the ability to learn the visual quality of a webpage, we propose to explicitly model the user viewing pattern through synthetic saliency heatmaps. The use of saliency heatmaps could be advantageous compared to the use of raw snapshots for the following reasons. First, synthetic saliency heatmaps explicitly learn to predict how users perceive webpages by training an end-to-end model on actual eye-tracking data. We expect this information to better correlate with webpage relevance compared to raw snapshots. Second, saliency heatmaps reduce the average storage requirements by up to 90%, because they are gray-scale images and have large areas of the same color, which can be stored efficiently. This makes the use of saliency heatmaps attractive for practical applications. Figure 2 shows example snapshots with their corresponding heatmaps (first and third columns respectively).

Following [14], we use a two-stage transfer learning model that learns how to predict saliency heatmaps on webpages. Similarly to the visual feature extraction approaches above, [14] takes a pre-trained image recognition model and finetunes the output layers on the following two datasets in order respectively: (i) SALICON [6], a large dataset containing saliency heatmaps created with eye-tracking hardware on natural images, and (ii) the webpage saliency dataset from [15], a smaller dataset containing saliency heatmaps created with eye-tracking hardware on webpages.

The trained model is used to convert a raw snapshot into a synthetic saliency heatmap. This heatmap is then used as an input image x_i for the ViTOR model (see Figure 1).

4 ViTOR DATASET

In this section, we introduce the ViTOR dataset for LTR with visual features. Section 4.1 contains information about the underlying ClueWeb12 collection and TREC Web Track topics. Section 4.2 explains how the snapshots for ClueWeb12 are acquired. Section 4.3 discusses content features, such as BM25 and TF-IDF, included in the ViTOR dataset. Finally, Section 4.4 gives an overview of the structure in which the ViTOR dataset is presented and published.

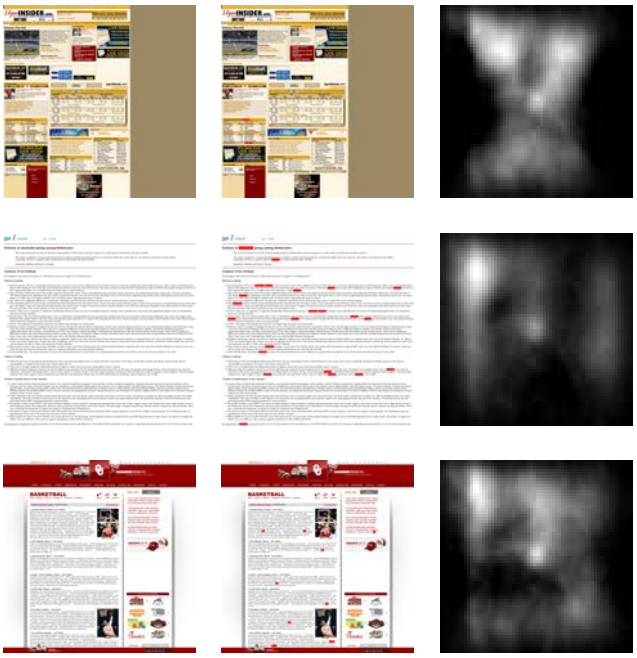

Figure 2: Examples of a vanilla snapshot, a red highlighted snapshot, and a saliency heatmap from left to right, respectively.

4.1 ClueWeb12 & TREC Web Track

For the ViTOR dataset we choose to use a combination of the ClueWeb12 document collection and the topics from the TREC Web Tracks 2013 & 2014 [1, 2], because this is currently the most recent combination of a large-scale webpage collection together with judged queries (with graded relevance).

ClueWeb12 is a highly diverse collection of webpages scraped in the first half of 2012. The total collection contains over 700 million webpages. We only use ClueWeb12 webpages that have judgements for any of the 100 queries in the TREC Web Tracks 2013 & 2014. In total, there are 28,906 judged webpages. Table 1 shows the breakdown of the total number of webpages and different relevance labels in the combined set of topics from 2013 and 2014.

Table 1: Number of webpages per source and the corresponding breakdown of TREC Web Track relevance grades.

Count/Label	TREC Web	Wayback	ClueWeb12	No image
Total	28,906	23,249	5,392	265
Nav grade (4)	40	36	4	0
Key grade (3)	409	347	62	0
Hrel grade (2)	2,534	2,222	295	17
Rel grade (1)	6,832	5,679	1,123	30
Non grade (0)	18,301	14,395	3,701	205
Junk grade (-2)	790	570	207	13

4.2 Snapshots

Although each entry in the ClueWeb12 collection contains the webpage's HTML source, many pages lack styling and images files

in order to render the full page. To overcome this issue, we use the Wayback Machine,[5] which offers various archived versions of webpages with styling and images since 2005. For each page in ClueWeb12, that is also judged in the TREC Web Tracks 2013 & 2014, we scrape an entry on the Wayback Machine that is closest to the original page scrape date as recorded in ClueWeb12. A snapshot is then taken using a headless instance of the Firefox browser. To reproduce [4], we also create a separate query-dependent dataset with the same snapshots where all query words are highlighted in red (HEX value: #ff0000). Examples of snapshots and snapshots with highlights are shown in Figure 2 (first two columns).

Since the Wayback Machine does not contain an archived or working version of each webpage in the ClueWeb12 collection, a filtering process is introduced to maximize the quality of each snapshot. Using the following criteria, a snapshot is selected for each available webpage: (1) Each webpage is requested from the Wayback Machine. (2) A webpage that is not on the Wayback Machine, times out, throws a JavaScript error, or results in a PNG snapshot smaller than 100KB is marked as broken. Such webpages are rendered again using the online rendering service provided by ClueWeb12.[6] (3) A manual selection is made between all webpages that are rendered from both sources. The Wayback version is used if it contains more styling elements and if the content is the same as in the rendering service. Otherwise, the rendering service version is used.

As a result, most of the 28,906 judged webpages have a corresponding snapshot from either the Wayback Machine or ClueWeb12 rendering service. Only 265 documents did not pass the filtering and were discarded. Table 1, row one, summarizes the results of the ViTOR dataset acquisition process. The table also shows the distribution of judgment scores among the snapshots that were taken from the Wayback Machine and ClueWeb12 rendering service.

4.3 Non-visual features

In LTR, documents are ranked based on various types of features, such as content features (e.g., BM25), quality indicators (e.g., PageRank) and behavioral features (e.g., CTR). In order to use the ViTOR dataset to measure the effect of visual features, we also add a set of content features and quality indicators, listed in Table 2. These 11 features are chosen so that they resemble most informative features of the most recent LETOR 4.0 dataset [12] and are easy to compute (see Section 7.2 for a detailed comparison of different feature sets). Also note that behavioral features, such as CTR, are not available for the TREC Web Tracks.

The content features, such as TF-IDF and BM25, are computed by doing a full pass over the complete ClueWeb12 collection. The PageRank scores are taken from the ClueWeb12 Related Data section.[7] The following modifications based on the feature transformations described in LETOR are made to stabilize training: (1) Free parameters k_1, k_3 and b for BM25 were set to 2.5, 0 and 0.8, respectively. (2) Since the PageRank scores are usually an order of magnitude smaller than all other scores, we multiply them by 10^5. (3) The log transformation is applied to each feature. (4) The log-transformed features are normalized per query.

Table 2: Non-visual features provided with the ViTOR dataset.

Id	Description	Id	Description	Id	Description
1	Pagerank	5	Content TF-IDF	9	Title IDF
2	Content length	6	Content BM25	10	Title TF-IDF
3	Content TF	7	Title length	11	Title BM25
4	Content IDF	8	Title TF		

4.4 Final collection

In summary, the ViTOR dataset contains: (i) a directory with webpage snapshots (Section 4.2), and (ii) a set of files with content features divided into folds (Section 4.3). Each snapshot is stored as a PNG file that can be identified by its corresponding ClueWeb12 document id. The non-visual features are stored in LETOR formatted files containing the raw, logged and query normalized values. The query normalized values are randomly split per query into five equal partitions. These partitions are then used to create five folds, where each fold contains three partitions for training and the remaining two partitions for validation and testing.

5 EXPERIMENTAL SETUP

In this section, we discuss the configurations of the ViTOR architecture, baselines and metrics used during our experiments.

ViTOR configurations.. We experiment with four configurations of the ViTOR architecture. ViTOR baseline refers to the ViTOR model with only content features. This configuration is trained by feeding content features into the scoring component directly, without adding any visual features. ViTOR snapshots and ViTOR highlights use visual features extracted from vanilla snapshots of webpages and from snapshots of webpages with highlighted query terms, respectively. Finally, ViTOR saliency uses visual features extracted from synthetic saliency heatmaps. The snapshots, highlights and saliency heatmaps for each model respectively are used as the input image (component (1) of Figure 1. For the ViTOR configurations with visual features, we experiment with both VGG-16 and ResNet-152 visual feature extraction methods. The learning rates for VGG-16 and ResNet-152 are set to and 0.0001 and 0.00005, respectively. Each experimental run is generated using the Adam optimizer [7] with a batch size of 100.

Baselines. We compare our proposed ViTOR model to the ViP model by Fan et al. [4], the only existing LTR method that uses visual features. We train ViP on both vanilla and highlighted snapshots with the resulting configurations being ViP snapshots and ViP highlights, respectively. Following [4], we also compare the ViTOR model to a number of content-based ranking methods, namely BM25 and state-of-the-art LTR techniques, such as RankBoost, AdaRank, and LambdaMart.[8]

Metrics. To measure the retrieval performance, we use precision and ndcg at $\{1, 10\}$ and MAP. Statistical significance is determined using a two-tailed paired t-test (p-value ≤ 0.05).

6 RESULTS

In this section, we present experiments that are set out to test the following: (1) the ViTOR model improves the LTR performance

[8] The LTR methods are taken from https://sourceforge.net/p/lemur/wiki/RankLib.

Table 3: Results for the ViTOR model using only content features (baseline), vanilla snapshots, highlighted snapshots, and saliency heatmaps. All results significantly improve over the ViTOR baseline. Best results are shown in bold.

	p@1	p@10	ndcg@1	ndcg@10	MAP
ViTOR baseline	0.338	0.370	0.189	0.233	0.415
VGG snapshots	0.514	0.484	0.292	0.324	0.442
ResNet snapshots	0.550	0.452	0.310	0.301	0.437
VGG highlights	**0.560**	**0.520**	0.323	**0.346**	**0.456**
ResNet highlights	0.530	0.463	0.305	0.312	0.440
VGG saliency	0.554	0.453	0.310	0.302	0.422
ResNet saliency	**0.560**	0.476	**0.333**	0.321	0.442

when introducing visual features, (2) synthetic saliency heatmaps improve the LTR performance when used as an input the ViTOR model, and (3) the ViTOR model improves both visual and non-visual state-of-the-art ranking methods.

6.1 ViTOR model with VGG-16 and ResNet-152

In Table 3, we compare the performance of the ViTOR model when used with and without visual features. The first row shows the ViTOR baseline, when using only the content features as an input to the scoring component. The second to fifth rows show the performance of using VGG-16 and ResNet-152 with both vanilla and highlighted snapshots. These results clearly show that both VGG-16 and ResNet-152 visual feature extraction methods significantly improve the performance compared to the ViTOR baseline.

When comparing the results of the ViTOR model with visual features, we observe the following: (i) The highest ranking performance is achieved by using VGG-16 on the highlighted snapshots. (ii) For VGG-16, the values of all metrics are consistently better for highlighted snapshots compared to vanilla snapshots, which is in line with the findings of [4] and is to be expected: highlighted snapshots carry more information compared to vanilla snapshots. Based on these results, we conclude that the use of visual features in LTR significantly improves performance and that highlighted snapshots should on average be preferred over vanilla snapshots.

6.2 ViTOR model with saliency heat maps

The last two rows of Table 3 show the performance of the ViTOR model when using synthetic saliency heat maps as an input. The visual features are learned using both VGG-16 and ResNet-152. In this case, ResNet-152 consistently outperforms VGG-16. Although the highlighted snapshots with VGG-16 still outperform ResNet-152 with saliency heat maps on p@10, ndcg@10 and MAP, the saliency heat maps with ResNet-152 match and outperform VGG-16 with highlighted snapshots when looking at p@1 and ndcg@1. Hence, saliency heat maps should be preferred in applications where early precision is important, while highlighted snapshots should be used when a high overall performance is needed.

6.3 Baseline comparison

Table 4 compares the performance of the ViTOR model to BM25, non-visual LTR methods and the ViP model by Fan et al. [4]. Specifically, the table shows the performance of VGG-16 with highlighted snapshots and of ResNet-152 with synthetic saliency heatmaps, as these are the best-performing variants of the ViTOR model according to Table 3. Both methods have a significant performance increase compared to BM25, almost doubling the metrics values in many cases.

Table 4: Results for the VGG-16 with highlighted snapshots, ResNet-152 with saliency heatmaps, and baselines. † indicates a significant decrease in performance compared to VGG highlights and ‡ indicates a significant decrease in performance compared to both ViTOR implementations. Best results are shown in bold.

	p@1	p@10	ndcg@1	ndcg@10	MAP
BM25	0.300‡	0.316‡	0.153‡	0.188‡	0.350‡
RankBoost	0.450	0.444	0.258	0.288†	0.427
AdaRank	0.290‡	0.357‡	0.149‡	0.227‡	0.398
LambdaMart	0.470	0.420†	0.256	0.275†	0.418
ViP snapshots	0.392‡	0.398‡	0.217‡	0.254‡	0.421‡
ViP highlights	0.418‡	0.416‡	0.239‡	0.269‡	0.422‡
VGG highlights	**0.560**	**0.520**	0.323	**0.346**	**0.456**
ResNet saliency	**0.560**	0.476	**0.333**	0.321	0.442

When comparing to non-visual LTR methods, both ViTOR implementations show consistently better performance. However, not all metrics are improved significantly. We attribute this to the fact that, similarly to [4], the LTR component of the ViTOR model is based on pairwise hinge loss, which is a relatively simple loss function.

Finally, we compare the ViTOR implementations to ViP, the only existing LTR method with visual features. Here, we clearly see that both our implementations significantly outperform ViP on all metrics. Also note, that ViP loses to two out of three non-visual LTR baselines, namely RankBoost and LambdaMart. We believe this is due to the reason discussed above: ViP uses pairwise hinge loss as the LTR component [4], which may be suboptimal.

The above results show that the proposed ViTOR model outperforms baselines, whether they are supervised or unsupervised, use visual features or not. However, to achieve consistent significant improvements compared to the state-of-the-art LTR methods, different loss functions within the ViTOR model have to be investigated.

7 DISCUSSION

In this section, we address two practical aspects of the proposed ViTOR model and dataset: (i) the number of parameters of the ViTOR model and corresponding optimizations, and (ii) the performance of content features included in the ViTOR dataset.

7.1 Training and inference optimization

Both training and inference using deep convolutional networks are generally computationally expensive. By separating the feature extraction and transformation layers in the proposed ViTOR architecture (see Figure 1) we allow powerful computational optimizations for both training and inference.

Training optimization. Although we freeze the parameters in the visual feature extraction layer (component (2) of Figure 1) when using a pre-trained model, we still need to compute the output

from all the frozen parameters during the forward propagation. We can avoid the computational cost associated with the forward propagation on the frozen layers by storing the output of the visual feature extraction layer to disk prior to training. By storing these vectors to disk, we leave only the parameters of the fully connected layers (component (3) of Figure 1) to be calculated and stored in memory during the forward propagation.

By applying the above procedure, we can reduce the number of parameters of the ViTOR model. When using VGG-16, the visual feature extraction layer consists of 14, 714, 688 parameters, which is 12.3% of the parameters in the ViTOR model. When using ResNet-152, the visual feature extraction layer consists of 58, 144, 239 parameters, which is 49.5% of the parameters in the ViTOR model.

By using the stored output of the visual feature extraction layer x_{vf} instead of an actual image x_i as the input of the ViTOR model, we reduce the size of each input by 84.7% and 98.6% for VGG-16 and ResNet-152 respectively. This reduction in input size further reduces the memory required for training the model.

Real-time inference optimization. When using LTR in a large-scale production environment, the impact of newly introduced LTR features (visual features, in our case) on real-time computational requirements is of major concern.

Since both the vanilla snapshots and synthetic saliency heatmaps are query independent, the output of the visual feature transformation layer (component (3) of Figure 1) does not change for different document/query pairs. This enables offline inference, leaving only the scoring component to be inferred in real-time. Since a visual feature vector is 1×30, using the offline inferred feature vector would result in a LTR model with $30 + 11 = 41$ features. This increase in parameters is negligible in terms of computational costs.

7.2 Benchmarking content features

In LTR research, both the amount and type of considered features vary widely per dataset and study. The most recent LETOR 4.0 dataset [12] contains 46 features extracted for webpages from the GOV2 dataset and queries from the million query tracks 2007 and 2008 (MQ2007 and MQ2008). In the ViTOR dataset, we use 11 features that are a subset of the 46 features of LETOR (see Table 2). These 11 features are chosen to be both informative and easy to compute. Here, we compare our subset of 11 features to the full set of 46 features. The experiments are run on the GOV2 dataset and MQ2007 queries. The LTR methods considered are the same as in Section 6, namely RankBoost, AdaRank, and LambdaMart.

The results of running the considered LTR methods using both 46 and 11 features are shown in Table 5. From these results, we see that the number of features has a significant effect on the performance of AdaRank. However, for the best-performing RankBoost and LambdaRank methods the drop in performance is minor when using 11 features instead of 46 features. This indicates that the chosen 11 features included in the ViTOR dataset form a reasonable trade-off between effectiveness and computation cost.

Table 5: Comparison of 46 LETOR features and 11 LETOR features that are also used in ViTOR.

	p@1	p@10	ndcg@1	ndcg@10	MAP

8 CONCLUSION

In this paper, we considered the problem of LTR with visual features. We proposed the ViTOR model that extracts visual features from webpage snapshots using transfer learning (specifically, pre-trained VGG-16 and ResNet-152 models) and synthetic saliency heatmaps. In both cases the extracted visual features significantly improved the LTR performance. We also showed that the proposed ViTOR model significantly outperformed the visual LTR baselines.

In addition to the model, we released the ViTOR dataset, containing visually rich and diverse webpages with corresponding snapshots. With the ViTOR dataset it is now possible to comprehensively study LTR with visual features.

One direction for future work is the study of state-of-the-art LTR methods, such as RankBoost and LambdaMart, within the scoring components of the ViTOR model. This could improve performance without changing the visual feature extraction and transformation components. Another promising direction is to combine multiple visual features, i.e., visual features extracted from vanilla snapshots, snapshots with highlights and saliency heatmaps. Other visual feature extractors, such as the CapsuleNet [13] model, which is able to learn spatial relations in images, might also provide additional performance. Other methods of combining visual and textual features might also be worth exploring. Future work could also investigate the robustness of this method when using various rendering variations, e.g., different browser, resolutions. Finally, performing a more qualitative analysis on which elements cause improvements in LTR with visual features would be interesting, e.g., by interpreting the filters in the feature extractor [10].

Code and data

Both the ViTOR dataset[9] and the code used to run the experiments in this paper[10] are available online.

ABSTRACT

Health literacy, i.e. the ability to read and understand medical text, is a relevant component of public health. Unfortunately, many medical texts are hard to grasp by the general population as they are targeted at highly-skilled professionals and use complex language and domain-specific terms. Here, automatic text simplification making text commonly understandable would be very beneficial. However, research and development into medical text simplification is hindered by the lack of openly available training and test corpora which contain complex medical sentences and their aligned simplified versions. In this paper, we introduce such a dataset to aid medical text simplification research. The dataset is created by filtering aligned health sentences using expert knowledge from an existing aligned corpus and a novel simple, language independent monolingual text alignment method. Furthermore, we use the dataset to train a state-of-the-art neural machine translation model, and compare it to a model trained on a general simplification dataset using an automatic evaluation, and an extensive human-expert evaluation.

1 INTRODUCTION

The rapid increase of health information on the internet has resulted in more patients turning to the Internet as their first source of health information. In a recent structural review, Tan and Goonawardene found that patients consult the internet primarily to be actively involved in the decision making related to their health [29]. While finding more evidence of positive impact on decision making and the patient-physician relation from online health information searches, Tan and Goonawardene warn that information found on the internet "has the potential to misguide patients and make them excessively anxious". Moreover, they observe that discrepancies between a physician's advice and a patient's conclusions from online information can erode the patient-physician relationship, which could limit timely access to care.

In a 2018 report [31] by the World Health Organization, contextualize these warnings, by concluding that a majority of European citizens has insufficient health literacy (the ability to read and understand healthcare information, make appropriate health decisions and follow health instructions). The report stipulates that one of the major causes of this low health literacy is that health information is often inaccessible to the general public because the literacy demands of health information and the literacy skills of average adults are mismatched, the information is often poorly written, poorly designed and/or geared to an highly sophisticated audience. One way to improve health literacy is by simplifying (online) medical text, to match the literacy level and vocabulary of average adults.

To illustrate this, we provide an example from Wikipedia, and its simplified version from Simple Wikipedia below.

- Pituitary adenomas represent from 10% to 25% of all intracranial neoplasms and the estimated prevalence rate in the general population is approximately 17%.
- Pituitary adenomas represent from 10% to 25% of all brain tumors and is thought to happen in about 17% to 25% of most people.

Observe that the Wikipedia editors simplify text on two levels: (1) complicated medical terminology (*intracranial neoplasms*) is replaced by simpler terms and (2) complicated non-medical sentence structures (*estimated prevalence rate in the general population*) are simplified. There is an rapidly increasing body of online medical texts, such as electronic health records, clinical trials, medical research, drug labels and patient information leaflets. This rapid increase makes manual simplification unfeasible.

Therefore, in this paper, we focus on the following research question:

> **RQ**: To what extent can we use automated methods to simplify expert level health text to laymen level?

Current work in automated medical text simplification is mostly limited to simplifying medical terminology, either by the generation of explanations (explanation generation), or by replacing these terms with laymen terms or definitions (lexical simplification) [1, 5–8, 24, 25]. This ignores complex non-medical terms and

complicated sentence structures, which also hamper readability [33]. The state-of-the-art in automated text simplification, Neural Machine Translation [22, 28], shows promise to solve this second problem, but requires large parallel corpora for training, which are lacking in the medical domain. Recent work by Adduru et al. focused on the creation of such a medical text simplification corpus [2]. Unfortunately, the resulting set is not publicly available.

Original Contribution As there are no publicly available medical text simplification corpora, we create a new aligned corpus by semi-automatically filtering a set of aligned health-related sentences from an existing parallel text simplification corpus. In addition, we introduce a language independent monolingual text alignment method and use it for aligning additional health sentences from Wikipedia and Simple Wikipedia disease articles. The resulting data set is made publicly available for future research[1]. Furthermore, we propose a method using state-of-the-art Neural Machine Translation for medical text simplification, which can both simplify general text but also learns to translate medical concepts into simpler terms. We perform experiments with that method on the filtered health sentences. We report results of quantitative evaluations, and a qualitative one.

2 RELATED WORK

In this section we discuss relevant work on text simplification in the medical domain. We first discuss lexical simplification, text simplification which focuses on the replacement of complex terms. Secondly, we discuss syntactic simplification: simplification which focuses on the replacement of complicated sentence structures and conclude with combined approaches: text simplification which targets both the replacement of complicated terms and the replacement of complicated structures.

Lexical simplification Most work on medical lexical simplification is focused on the usage of large vocabularies, most prominently the Unified Medical Language System (UMLS) [4] to replace expert medical terms with consumer oriented synonyms. The UMLS is a meta-thesaurus, which contains unified entities from a large number of medical vocabularies (such as SnomedCT [9], MeSH [18] and CHV [37]). In summary, the state-of-the-art in lexical simplification is recognizing UMLS concepts from text and replacing them with a consumer-oriented synonym from the Consumer Health Vocabulary [37], an open access collection of consumer oriented synonyms for medical concepts. Despite significant efforts to automatically enrich and correct the Consumer Health Vocabulary from user-generated data [11, 13, 30, 36], evaluation of the effect of using these terms on the perceived simplicity of medical text by the lay population is lacking and recent work by Xie et al. articulates that medical concept replacement alone is not sufficient for medical text simplification [33].

Syntactic simplification There is little work investigating medical syntactic simplification in isolation. Leroy et al. investigate the (manual) splitting of complex noun phrases to improve readability of long sentences. However, they conclude that this approach does not necessarily improve readability and recommend that sentences should only be split when the split phrases "feel more natural" [17]. Furthermore, negations in medical texts were investigated and it was shown that easier text contains less morphological negations than difficult text [21]. An easy text contains for example "not clear" instead of "unclear", which could effectively be solved by a lexical simplification tool based on frequency analysis.

Combined approaches Monolingual machine translation, i.e. machine translation algorithms trained on a parallel corpus in the same language, have shown great promise in recent years. Such systems learn how to translate complex language into simple language, when trained of a parallel corpus of complex and simple sentences. In theory, such a translation combines lexical and syntactic simplification. Most prominent is the progress in Neural Machine Translation [22], which has demonstrated to achieve state-of-the-art performance on text simplification tasks for common language. Neural Machine Translation relies on the availability of a large parallel corpus for training and evaluation purposes. For common language, publicly available corpora are available from aligned Wikipedia and Simple Wikipedia sentences, the Parallel Wikipedia Simplification (PWKP) corpus [38] and a more recent corpus presented Hwang et al. [12] and from news articles, the Newsela corpus [34].

Algorithms trained on these datasets perform well on general language simplification, but have been shown to perform poorly on medical text simplification [2, 16]. For instance, an (statistical) algorithm trained on the PWKP dataset for simplifying cancer and other health text produced output that was "imperfect and required a second manual step to be consistent and accurate" [16].

To successfully employ Neural Machine Translation on health text, we would need a health specific parallel corpus. Unfortunately such a corpus is not available and, a first attempt by Adduru et al. to creating one [2] showed that this is not as easy as it seems. Adduru et al. used an array of methods to automatically align sentences from the medical subset of Wikipedia and Simple Wikipedia, as well as https://www.webmd.com and https://www.medicinenet.com. The result is a -proprietary- medical text simplification corpus of 2,493 sentence pairs. Adduru et al. present an automated evaluation of a Neural Machine Translation algorithm on these data, but do not include an human evaluation.

3 DATA

In this section we present two datasets we created for text simplification in the medical domain. The first dataset (EXPERT) is an expert-evaluated medical subset filtered from the aligned wikipedia corpus presented by Hwang et al. [12]. It is focusing on reliable high-quality sentence alignments such that it can be used as a test set for benchmarking. The second dataset (AUTOMATED) is a novel dataset created by automatic collection of aligned sentences from the medical subset of Wikipedia. Here, the focus lies on having a large dataset which can serve as training data, but we accept smaller losses in quality resulting from the automatic alignment. In table 1, we provide a summary of the presented datasets, compared to the medical corpus presented by Adduru et al. [2].

3.1 EXPERT dataset

Our EXPERT dataset is created using the aligned corpus presented in [12] as a baseline, which aligns sentences between Wikipedia and SimpleWikipedia. As the corpus does not focus on a particular

[1] available at https://research.mytomorrows.com/

	Fully aligned	Partially aligned
EXPERT	2,267	3,148
AUTOMATED	3,797	-
Adduru et al. [2]	2,493	-

Table 1: An overview of the datasets

domain, only few medical sentences are covered which motivates the creation of our EXPERT dataset. This initial corpus consists of manually and automatically generated *good* and *good partial* aligned sentence pairs, the former defined as "the semantics of the simple and standard sentence completely match, possibly with small omissions (e.g., pronouns, dates, or numbers)" and the latter as "a sentence completely covers the other sentence, but contains an additional clause or phrase that has information which is not contained within the other sentence". In the remainder of the paper we will refer to the *good* sentence pairs as *fully aligned* and to the *good partial* as *partially aligned* sentence pairs.

To generate the EXPERT dataset, we use a state-of-the-art medical named entity recognition tool, QuickUMLS [26] to sentences which may contain a medical topic from the fully aligned and partially aligned datasets. QuickUMLS is an approximate dictionary matching algorithm which matches terms from text with synonyms in the UMLS. We used QuickUMLS with the default setting for similarity threshold (0.7) and limited the semantic types to *Disease or Syndrome* and *Clinical Drug*). We consider a sentence pair a candidate medical sentence pair, when QuickUMLS recognizes at least one medical concept in either the complex or the simple medical sentence. After QuickUMLS processing, we provided the resulting candidate medical sentence pairs to a domain expert for additional validation, i.e. to confirm whether the sentence pair is indeed health-related. Using this approach, we created a filtered corpus of 2,267 *fully aligned* medical sentences and 3,148 *partially aligned* sentences.

3.2 AUTOMATED dataset

In addition to the labour-intensive manual filtering, we created a pipeline to automatically create an aligned dataset from Wikipedia and Simple Wikipedia, which allows efficient creation of a much larger dataset, at the cost of a slight loss in quality. In principle, such a pipeline has 3 distinct steps: (1) Collection of relevant articles and their related simplified version, (2) Splitting the articles in sentences and (3) Aligning the sentences into pairs.

3.2.1 Finding relevant articles. Recent work, by Kajiwara and Komachi [14] and Adduru et al. [2] focused on the creation of an aligned corpus from Wikipedia and Simple Wikipedia. The former presented a methodology to create a general corpus, the latter a medical corpus. Kajiwara and Komachi used a full dump of Wikipedia and Simple Wikipedia and aligned the articles with matching titles. Given the goal of creating a general-purpose corpus, they did not attempt to select articles based on topic. In their work, they identify a total of 126,725 Wikipedia articles with a matching Simple Wikipedia article in the English language. In contrast, Adduru et al. present an approach to collect a specific subset of medical Wikipedia articles. They manually selected a set of 164 articles, which they match to Simple Wikipedia articles with a matching title. Manual collection of such a dataset seems unnecessarily cumbersome. We propose an approach using DBPedia [3] and select all articles that fall in the *dbo: Disease* class. After title matching to Simple Wikipedia, this gives us a set of 1,098 aligned articles.

3.2.2 Splitting. Analogous to Kajiwara and Komachi, we extract the text from the Wikipedia and Simple Wikipedia articles, using the python Wikipedia API [2] and the NLTK 3.3 sentence tokenizer [3]. This gives an average number of words per sentence of 26.1 for the normal articles and 19.5 for the simple articles. The average numbers of sentences per article are 123.4 and 20.3 respectively. In comparison, Kajiwara and Komachi report an average number of words per sentence of 25.1 for the normal articles and 16.9 for the simple articles and an average number of sentences per article of 57.7 and 7.65, respectively. Medical articles (simple and normal), seems to be longer and more complex (they contain more and longer sentences).

3.2.3 Aligning. To align sentences from Wikipedia to Simple Wikipedia, we employ a two step approach: first we generate *candidate pairs*, by combining each sentence from the Wikipedia articles which each sentence of the related Simple Wikipedia article. This gives us a total of 3,660,064 candidate pairs from the 1,098 articles. Adduru et al. report 818,520 candidate pairs from 164 articles, demonstrating that their manually collected set contains longer articles than ours (3333.4 candidate pairs per article in our set versus 4991 candidate pairs per article in their set). Secondly, we select the most similar pairs from the candidate pairs. Various methods have been reported to perform this task, Kajiwara and Komachi employ pre-trained Word2Vec word embeddings to determine sentence similarity. Similarly, Hwang et al. present a method that relies on Wiktionary [12]. When aligning sentences where the distinctive (medical) terms are arguably very infrequent, such dependencies may not be wanted, as also noted by Adduru et al. who use a classifier to identify matching sentences.

BLEU alignment. We propose a simple metric, the BLEU score [23] to align the AUTOMATED dataset. The BLEU score is used commonly to evaluate Machine Translation algorithms, by comparing the similarity between the output of a translation algorithm to references sentence. In short, BLEU does this by counting overlapping word n-grams. For the sake of brevity, we refer to Papineni et al.[23] for details on the method. To the best of our knowledge, we're the first to employ BLEU for a sentence alignment task. To evaluate the quality of the BLEU alignment for the sentence alignment task, we compare BLEU alignment to the Maximum alignment reported by Kajiwara and Komachi[14], using the manual alignment set from Hwang et al. [12] for evaluation. This evaluation set contains 67,853 candidate sentence pairs, judged by human annotators. 277 were considered fully aligned, 281 partially aligned and 67,295 considered either not good enough partial alignments or bad alignments.

We test both methods in two sentence alignment scenarios: (1) Full alignment: Fully aligned sentences versus the rest and (2) Partial alignment: Fully and partially aligned sentences versus the rest.

Table 2 reports maximum F1-score and AUC for both methods in both scenarios. We observe that BLEU alignment performs on

[2] https://pypi.org/project/wikipedia/
[3] http://www.nltk.org

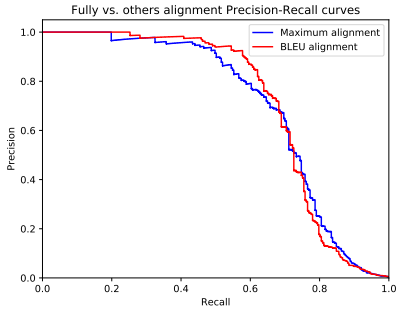

Figure 1: Precision-recall curves of Maximum alignment and BLEU alignment

Fully vs. rest	Max F1	AUC
BLEU alignment	0.717	0.714
Maximum alignment in [14]	0.717	0.730
Alignment used to align Wikipedia [12]	0.712	0.694
Fully and partially vs. rest		
BLEU alignment	0.534	0.484
Maximum alignment in [14]	0.638	0.618
Alignment used to align Wikipedia [12]	0.607	0.529

Table 2: Max F1 and AUC scores for identifying fully aligned and fully and partially aligned sentences

par with Maximum alignment for fully aligned sentences, but performance is worse on partially aligned sentences. In figure 1 we report the precision-recall curve for the fully aligned scenario.

We observe that BLUE alignment provides a useful method when performing sentence alignment on highly domain specific text. Despite the poorer performance on partial alignment, it does not depend on pretrained embeddings or external datasources to function. In addition, when aligning medical data, the vocabulary might contain a lot of words that are neither in the vocabulary of pretrained Word2Vec models nor in Wiktionary, which may deteriorate performance of approaches that use such sources. BLEU alignment only looks at overlapping n-grams, which makes it language independent.

In the AUTOMATED dataset, we only include fully aligned sentence pairs, given the poor performance BLEU alignment demonstrated on partial alignment. In presented dataset, we include sentence pairs with a BLEU score >0.29, which led to a maximum F1 score during evaluation. After filtering out sentences with MediaWiki mathematical formulas, the final set consists of 3,797 fully aligned medical sentences. In table 3 we present example aligned sentences from this set.

4 NEURAL TEXT SIMPLIFICATION

Most current research on text simplification in the medical domain focuses on simplifying medical concepts only. However, monolingual NMT has shown great potential in text simplification research but has not been applied to the medical domain yet. Therefore, we replicate the state-of-the-art NMT text simplification system of [22] as a baseline, and evaluate it on our expert-curated

Wikipedia	Simple Wikipedia	BLEU
Spinal tumors are neoplasms located in the spinal cord.	Spinal tumors is a form of tumor that grows in the spinal cord.	0.39
Aspirin is an appropriate immediate treatment for a suspected MI.	Aspirin is an early and important treatment for a heart attack.	0.33

Table 3: Example alignments using BLEU alignment

dataset. This system outperformed phrase-based [32] and syntax-based statistical machine translation [35] approaches, as well as an unsupervised lexical simplification approach [10]. Furthermore, we design a second NMT model which uses a combination of our AUTOMATED and other datasets, and replacing medical concepts with identifiers.

4.1 Training and Evaluation sets

For the setup of our experiments, we rely on the general dataset presented by Hwang et al.[12] and combine this with the EXPERT and AUTOMATED datasets described in the previous section. This gives us 4 datasets:

- **Fully aligned health sentences** f_{health} - Filtered and expert evaluated fully aligned health sentences from f_{wiki}: 2,267 sentences.
- **Partially aligned health sentences** p_{health} - Filtered and expert evaluated partially aligned health sentences from p_{wiki}: 3,148 sentences.
- **Fully aligned general domain sentences** $f_{\text{general}} = f_{\text{wiki}} - f_{\text{health}}$: 152.538 sentences.
- **Partially aligned general domain sentences** $p_{\text{general}} = p_{\text{wiki}} - p_{\text{health}}$: 126.785 sentences.

4.2 Baseline

We implemented the baseline system in OpenNMT[4], an open source framework for NMT. The architecture consists of two LSTM layers, states of size 500 and 500 hidden units and a 0.3 dropout probability. The vocabulary size is pruned to 50,000 in both the source and target language. Word embedding size is set to 500. We used pretrained Word2Vec embeddings from the Google News corpus [20] of size 300. The remaining part is learned during training of the NMT (while the pre-trained part remains fixed). Lastly, the decoder uses global attention with input feeding [19]. The system is trained for 15 epochs, using a SGD optimizer and an initial learning rate of 1.0. After epoch 9, the learning rate decay is 0.7, i.e. learning_rate = learning_rate * learning_rate_decay.

At translation time beam search is used to find the best prediction given the input. Beam search is an approximation of the best possible translation. At each step of the translation the k most likely words are generated given the input sentence. Here, k is called the beam size. Then, the most likely sequence (i.e. translation) is called hypothesis 1, the next hypothesis 2, etc. We will evaluate both hypothesis setting in the next section. The system that performed most changes and highest percentage of correct ones in [22] used a

[4]http://opennmt.net/

beam size of 12. This system is trained on general domain corpus, i.e. $f_{\text{general}} + p_{\text{general}}$.

4.3 Medical+CHV Replacement

Our second NMT system (MED-CHV) we evaluate in this paper follows a similar architecture as the baseline, but is trained on a combination of the general corpus and our health-related corpora (minus the corpus which is used as a test set): $f_{\text{general}} + p_{\text{general}} + f_{\text{health}} + p_{\text{health}} + f_{\text{BLEU-health}}$

In addition, we replace each medical concept encountered in the complex text with a Concept Unique Identifier (CUI) from UMLS. This approach reduces the (medical) vocabulary (and medical concept sparsity), since any textual variation of a concept is mapped (or normalized) to a single CUI, aggregating the references for each concept. For example, *atherosclerotic heart disease* and *coronary heart disease*, which are synonyms, are both replaced with C0010054. Furthermore, it enables us the replace CUIs with their CHV-preferred term if the CUI is not part of the source vocabulary of the NMT (i.e. rare medical concepts / CUIs). We used QuickUMLS [26] with a similarity threshold of 0.7, a value for which highest F1-scores were achieved in [26], to detect medical concepts and link them to a CUI. For the decoder we use pre-trained Word2Vec embeddings of size 200, trained on 10,876,004 English abstracts of biomedical articles from PubMed [15].

Note that we include the 50,000 most frequent words in the source and target vocabulary (so we have enough reference translations for each word in the vocabulary). This may cause that some CUIs are not in the source vocabulary and are therefore not translated. To overcome this, we replace CUIs that are out of vocabulary with their CHV-preferred term, if it exists, or copy the original source token. To do this, we make use of a phrase table, which can be pre-constructed before translation. Each entry in the phrase-table contains a CUI with its CHV-preferred term or its original source token. Instead of substituting out of vocabulary words with source words that have the highest attention weight, a possible translation in the phrase-table is looked up. This way the output does not contain any raw CUI.

5 EVALUATION

In this evaluation, we focus on the question of how well does NMT-based text simplification work in the medical domain. For our first experiment, we rely on an automated evaluation approach based on a reference test-set drawn from our EXPERT dataset. The second evaluation relies on human evaluators, and focuses on simplicity, understandability, and correctness of simplified sentences.

We randomly select 500 and 350 sentences as validation set and test set respectively from f_{health}. Automatic evaluation is done on the test set of size 350. Human evaluation is done in the first 70 sentences of the test set (since human evaluation is rather costly).

Automatic Evaluation: Text simplification is typically automatically evaluated using a traditional machine translation metric BLEU [23] and a text simplification specific metric SARI [35].

BLEU compares the output against references and produces a score between 0 and 1, with 1 representing a perfect translation (i.e. identical to one of the references). In our evaluation we use word n-grams up to 4. However, when used for simplification, it has to be handled with care as it is not uncommon that the source sentences (from Wikipedia) and the reference sentences (from Simple Wikipedia) are identical or very similar as Wikipedia editors just copied them over without or only with minor modifications. Therefore, a machine simplification which just keeps the source sentence as-is often has high BLEU scores, but is not simpler.

Hence, a specific text simplification metric was introduced in [35], called SARI, which compares **S**ystem output **A**gainst **R**eferences and against the **I**nput sentence. It focuses on lexical simplification, i.e. replacing complex words and phrases with simpler alternatives. "It explicitly measures the goodness of words that are *added*, *deleted* and *kept* by the systems" [35], by comparing the output with the source and the reference or multiple. SARI combines several aspects of adding and deleting words into a single numeric measure: the terms added by the simplification algorithm with respect to if they are also added in the reference simplification; and the terms removed by the simplification algorithm also with respect to if they are removed in the reference, and the terms which are kept stable between the reference and a simplification.

For this experiment, we evaluate the baseline system and the MED-CHV system, both with hypothesis 1 and 2 selection strategies (i.e., choose the most likely simplification and the second most likely one.) Furthermore, we consider an "Identity" simplification which just copies the source sentences without modifying.

Human Evaluation: As both metrics used in the automatic evaluation are insufficient to fully describe the capabilities of machine simplification, such evaluation need to be accompanied by a human evaluation. To this end, we obtain feedback on simplified sentences focusing on grammar, meaning preservation (both measured on a 1-5 Likert scale), and simplicity (on a scale of -2 to 2, with negative values representing that the text has become more complex). This follows the setup outlined in [22]. An evaluator is presented with a sentence pair (complex, simple) and asked to give the scores. We base our annotation guidelines on [27]. We slightly edited the guidelines, since their focus was on splitting (and deleting parts of) sentences, while our system mainly replaces words and deletes parts of sentences.

6 RESULTS AND DISCUSSION

In this section we report results of automatic and human evaluation.

Automatic Evaluation: In table 5, SARI, along with its three components, and BLEU scores are reported. The scores represent if the system is actually modifying the text, and how it relates to the test set reference sentences. "Identity" does not perform any text simplification, but simply uses the source sentence. This tells us how similar the source is to the reference. It serves as calibration scores for SARI and BLEU; e.g., not simplifying anything results in a BLEU score of 0.53 and a SARI score of 21.56. Both hypothesis 1 and 2 of the baseline (i.e. choosing the most likely or second likely simplification) are able to improve SARI scores. The main difference between them is that hypothesis 2 deletes with higher precision than hypothesis 1. Both hypotheses of the MED-CHV show comparable numbers for keeping and deleting terms, but a slightly higher number for adding terms. This may be because of the additional terms (medical concepts) the medical NMT is translating. BLEU scores of the identity and the baseline's

Source	Sentence
Wikipedia	Coronary artery disease (CAD) also known as atherosclerotic heart disease , coronary heart disease , or ischemic heart disease (IHD) , is the most common type of heart disease and cause of heart attacks .
Simple Wikipedia	Atherosclerosis is a form of heart disease .
Baseline, h-1	Coronary artery is the most common type of heart disease .
Baseline, h-2	Coronary artery is a type of disease .
Medical input	C1956346 (CAD) also known as C0010054 , C0010054 , or C0151744 (C0151744) , is the most common type of C0018799 and cause of C0027051 .
MED-CHV, h-1	$\{\text{coronary artery disease}\}_{\text{copied}}$ is the most common type of $\{\text{heart disease}\}_{\text{NMT}}$.
MED-CHV, h-2	$\{\text{coronary artery disease}\}_{\text{copied}}$ is the most common type of $\{\text{heart disease}\}_{\text{NMT}}$ and cause of $\{\text{heart attack}\}_{\text{NMT}}$.

Table 4: Example translations from different systems, medical concepts in MED-CHV are replaced with their CUI.

Approach	SARI	F_{add}	F_{keep}	P_{del}	BLEU
Identity	21.56	0.00	64.68	0.00	53.07
Baseline, h-1	28.14	1.91	60.37	22.15	54.78
Baseline, h-2	32.73	2.03	55.82	40.34	44.51
MED-CHV, h-1	32.27	2.24	57.10	37.47	47.48
MED-CHV, h-2	33.92	2.96	54.93	43.88	44.37

Table 5: Evaluations with automatic metrics

hypothesis 1 are highest. This may be due to that in hypothesis 1 the baseline is often producing the exact same sentence. The others are less conservative, i.e. perform more changes, which reduces BLEU. We showed that the NMT systems indeed improve SARI scores and therefore we expect that the output is simpler than the input. The medical NMT slightly increased SARI over the baseline (due to its F_{add} component). Therefore, we expect that simplicity scores will be at least similar to the baseline.

Manual Evaluation: Three laymen provided feedback on the first 70 sentences of the test set with respect to grammar, meaning preservation, and simplicity.

Table 6 shows that the baseline produces decent grammar and meaning preservation scores and indeed simplifies the text. However, MED-CHV scores show that grammar, meaning preservation and simplicity scores are all lower than the baseline. We assume that this is due to MED-CHV replacing out of vocabulary concepts with their CHV-preferred terms (which are expert curated simplified terms) instead of substituting them with source words that have the highest attention weight. While we assumed that using these expert term simplifications should perform well, also previous research concluded that "some CHV-preferred terms can be above the level of consumers' comprehension" [24].

Example translations are given in table 4. Note that the input of medical NMT is the Wikipedia sentence with medical concepts replaced with their CUI. Common medical concepts, such as heart disease (C0018799) and heart attack (C0027051), are part of the vocabulary and correctly translated by the NMT. Coronary artery disease (C1956346) is neither part of the vocabulary, nor a CHV-preferred term exists for it. Therefore, the source term is copied.

7 CONCLUSION AND FUTURE WORK

Automated Medical Text Simplification can be a cornerstone technology to address insufficient health literacy. However, research into this domain is hampered by the lack of open training and test corpora. Therefore, in this paper we introduced such an open corpus which is based on the widely available Wikipedia-Simple Wikipedia text simplification corpus, and expanded with additional aligned sentences focusing on the medical domain. This corpus was created based on filtering with a medical expert from an existing aligned dataset, and by a novel simple, language independent monolingual text alignment method.

We used this corpus to evaluate two Neural Machine Translation models: one was trained on the aligned Wikipedia corpus (baseline), the other one was in addition trained on our corpus, but with medical terms replaced by their UMLS Concept Unique Identifiers. We assumed that the replacement would further boost performance. Both models were evaluated automatically and manually focusing only on the medical subset of the test data set we created. During automatic evaluation, it could be shown that the baseline performs fewer changes to sentences when simplifying. However, in the manual human-driven evaluation, it became clear that changing too many parts of the sentence can be detrimental, and that the baseline sentences were judged to be more understandable and simpler. We assume that this can be attributed to the act of replacing out of vocabulary medical concepts with their CHV-preferred terms. We therefore assume that training only with our extended dataset without additional replacements should yield superior performance. Due to the extreme costs of manually evaluating simplification results, this experiment will be covered in our future work. While this result was disappointing, it shows that automatic text simplification is a difficult task which demands future research.

In summary, we contributed a novel and open test and training dataset of aligned sentences focused on medical text simplifications, which easily allows such future research. Furthermore, we could show that even training a Neural Machine Translation model on a non-specialized corpus can still yield acceptable results in a complex domain like medical texts, clearly hinting at the potential of future endeavours.

ABSTRACT

Capturing the meaning of sentences has long been a challenging task. Current models tend to apply linear combinations of word features to conduct semantic composition for bigger-granularity units e.g. phrases, sentences, and documents. However, the semantic linearity does not always hold in human language. For instance, the meaning of the phrase "ivory tower" cannot be deduced by linearly combining the meanings of "ivory" and "tower". To address this issue, we propose a new framework that models different levels of semantic units (e.g. sememe, word, sentence, and semantic abstraction) on a single *Semantic Hilbert Space*, which naturally admits a non-linear semantic composition by means of a complex-valued vector word representation. An end-to-end neural network [1] is proposed to implement the framework in the text classification task, and evaluation results on six benchmarking text classification datasets demonstrate the effectiveness, robustness and self-explanation power of the proposed model. Furthermore, intuitive case studies are conducted to help end users to understand how the framework works.

1 INTRODUCTION

In natural language understanding, it is crucial, yet challenging, to model sentences and capture their meanings. Essentially, most statistical machine learning models [3, 9, 15, 20, 23] are built within a linear bottom-up framework, where words are the basic features adopting a low-dimensional vector representation, and a sentence is modeled as a linear combination of individual word vectors. Such linear semantic composition is efficient, but does not always hold in human language. For example, the phrase "ivory tower", which means "a state of privileged seclusion or separation from the facts and practicalities of the real world", is not a linear combination of the individual meanings of "ivory" and "tower". Instead, it carries a new meaning. We are therefore motivated to investigate a new language modeling paradigm to account for such intricate non-linear combination of word meanings.

Drawing inspiration from the recent findings in the emerging research area of quantum cognition, which suggest that human cognition [1, 2, 8] especially language understanding [6, 7, 29] exhibit certain non-classical phenomena (i.e. quantum-like phenomena), we propose a theoretical framework, named *Semantic Hilbert Space*, to formulate quantum-like phenomena in language understanding and to model different levels of semantic units in a unified space.

In Semantic Hilbert Space, we assume that words can be modeled as microscopic particles in superposition states, over the basic sememes (i.e. minimum semantic units in linguistics), while a combination of word meanings can be viewed as a mixed system of particles. The Semantic Hilbert Space represents different levels of semantic units, ranging from basic sememes, words and sentences, on a unified complex-valued vector space. This is fundamentally different from existing quantum-inspired neural networks for question answering [31, 32] which are based on a real vector space. In addition, we introduce a new semantic abstraction, named as *Semantic Measurements*, which are also embedded in the same vector space and trainable to extract high-level features from the mixed system.

As shown in Fig. 1, the Semantic Hilbert Space is built on the basis of quantum probability (QP), which is the probability theory for explaining the uncertainty of quantum superposition. As quantum superposition requires the use of the complex field, Semantic Hilbert Space has complex

values and operators. In particular, the probability function is implemented by a unique (complex) density operator.

Semantic Hilbert Space adopts a complex-valued vector representation of unit length, where each component adopts an amplitude-phase form $z = re^{i\phi}$. We hereby hypothesize that the amplitude r and complex phase ϕ can be used to encode different levels of semantics such as lexical-level co-occurrence, hidden sentiment polarity or topic-level semantics. When word vectors are combined, even in a simple complex-valued addition form, the resulting expression will entail a non-linear composition of amplitudes and phases, thus indicating a complicated fusion of different levels of semantics. A more detailed explanation is given in Sec. 3. In this way, the complex-valued word embedding is fundamentally different from existing real-valued word embedding. A series of ablation tests indicate that the complex-valued word embedding can increase performance.

The Semantic Hilbert Space is an abstract representation of our approach to modeling language through QP. At the level of implementation, an efficient and effective computational framework is needed to cope with large text collections. To do so, we propose an end-to-end neural network architecture, which provides means for training of the network components. Each component corresponds to a physical meaning of quantum probability with well-defined mathematical constraints. Moreover, each component is easier to understand than the kernels in convolutional neural network and cells in recurrent neural networks.

The network proposed in this paper is evaluated on six benchmarking datasets for text classification and achieves a steady increase over existing models. Moreover, it is shown that the proposed network is advantageous due to its high robustness and self-explanation capability.

2 SEMANTIC HILBERT SPACE

The mathematical foundation of Quantum Theory is established on a Hilbert Space over the complex field. In order to borrow the underlying mathematical formalism of quantum theory for language understanding, it is necessary to build such a Hilbert Space for language representation. In this study, we build a *Semantic Hilbert Space* $\mathcal{H}$ over the complex field. As is illustrated in Fig. 1, multiple levels of semantic units are modeled on this common Semantic Hilbert Space. In the rest of this section, the semantic units under modeling are introduced separately.

We follow the standard *Dirac Notation* for Quantum Theory. A unit vector and its transpose are denoted as a ket $|\mu\rangle$ and a bra $\langle\mu|$, respectively. The inner product and outer product of two unit vectors $\vec{u}$ and $\vec{v}$ are denoted as $\langle u|v\rangle$ and $|u\rangle\langle v|$ respectively.

2.1 Sememes

Sememes are the minimal non-separable semantic units of word meanings in language universals [13]. For example, the word "blacksmith" is composed of sememes "human", "occupation", "metal" and "industrial". We assume that the Semantic Hilbert Space $\mathcal{H}$ is spanned by a set of orthogonal basis $\{|e_j\rangle\}_{j=1}^n$ corresponding to a finite closed set of sememes $\{e_j\}_{j=1}^n$. In the quantum language, the set of sememes are modeled as *basis states*, which is the basis for representing any quantum state. In Fig. 1, the axes of the Semantic Hilbert Space correspond to the set of sememe states, and semantic units with larger granularity are represented based on quantum probability.

2.2 Words

The meaning of a word is a combination of sememes. We adopt the concept of *superposition* to formulate this combination. Essentially, a word w is modeled as a quantum particle in *superposition state*, represented by a unit-length vector in the Semantic Hilbert Space $\mathcal{H}$, as can be seen in Fig. 1. It can be written as a linear combination of the basis states for sememes:

$$|w\rangle = \sum_{j=1}^{n} r_j e^{i\phi_j} |e_j\rangle \tag{1}$$

where the complex-valued weight $r_j e^{i\phi_j}$ denotes how much the meaning of word w is associated with the sememe e_j. Here $\{r_j\}_{j=1}^n$ are non-negative real-valued amplitudes satisfying $\sum_{j=1}^n {r_j}^2 = 1$ and $\phi_j \in [-\pi, \pi]$ are the corresponding complex phases. We could also transfer the complex number in a complex plane as $re^{i\phi} = r\cos\phi + ir\sin\phi$.

It is worth noting that the complex phases $\{\phi_j\}$ are crucial as they implicitly entail the *quantum interference* between words. Suppose two words w_1 and w_2 are associated to weights $r_j^{(1)} e^{i\phi_j^{(1)}}$ and $r_j^{(2)} e^{i\phi_j^{(2)}}$ for the sememe e_j. The two words in combination are therefore at the state e_j with a probability of

$$\left| r_j^{(1)} e^{i\phi_j^{(1)}} + r_j^{(2)} e^{i\phi_j^{(2)}} \right|^2 = \left| r_j^{(1)} \right|^2 + \left| r_j^{(2)} \right|^2 + 2 r_j^{(1)} r_j^{(2)} \cos\left(\phi_j^{(1)} - \phi_j^{(2)}\right) \tag{2}$$

where the term $2r_j^{(1)} r_j^{(2)} \cos(\phi_j^{(1)} - \phi_j^{(2)})$ reflects the interference between the two words, where as the classical case corresponds to a particular case $\phi_j^{(1)} = \phi_j^{(2)} = 0$.

2.3 Semantic Compositions

As is illustrated in Fig. 1, we view a word composition (e.g. a sentence) as a bag of words [14], each of which is modeled as a particle in superposition state on the Semantic Hilbert Space $\mathcal{H}$. To obtain the semantic composition of words, we leverage the concept of *quantum mixture* and formulate the word composition as a mixed system composed of the word

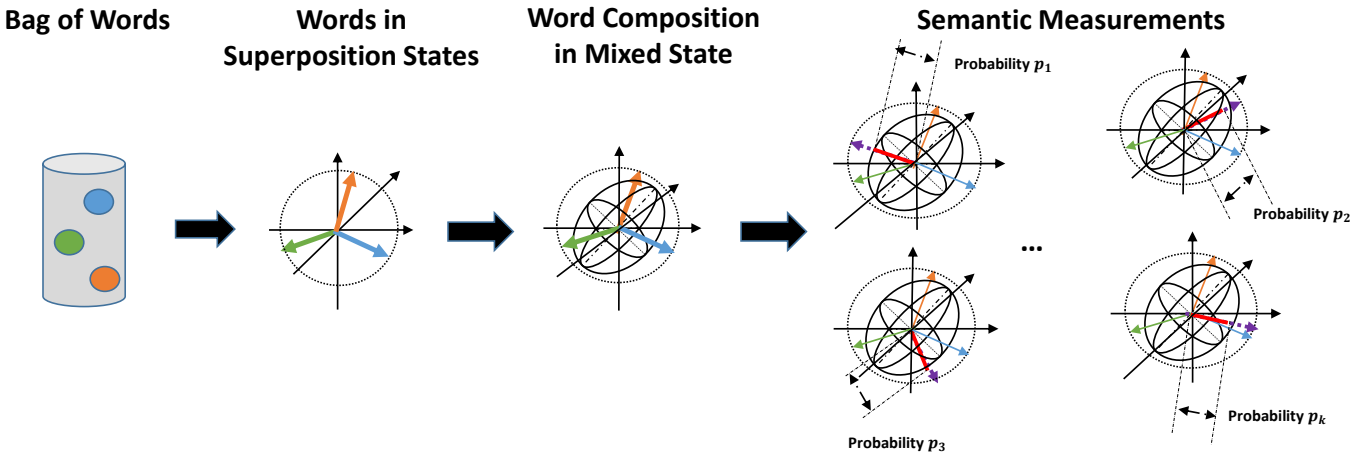

Figure 1: Illustration of Semantic Hilbert Space. The green, blue and orange colors correspond to three different words modeled as quantum particles. The black dotted circle represents the unit ball in the Semantic Hilbert Space. The ellipsoid in solid line refers to the quantum probability distribution defined by the density matrix of the word composition. The purple lines are semantic measurements. The intersections of the ellipsoids and semantic measurements are in thick red lines, the lengths of which correspond to measurement probabilities.

superposition states. The system is in a *mixed state* represented by a n-by-n density matrix ρ on $\mathcal{H}$, which is positive semi-definite with trace 1. It is computed as follows:

$$\rho = \sum_i p(i) \, |w_i\rangle \langle w_i|, \tag{3}$$

where $|w_i\rangle$ denotes the superposition state of the i-th word and $p(i)$ is the classical probability of the state $|w_i\rangle$ with $\sum_i p(i) = 1$. It determines the contribution of the word w_i to the overall semantics.

The complex-valued density matrix ρ can be seen non-classical distribution of sememes in $\mathcal{H}$. Its diagonal elements are real and form a classical distribution of sememes, while its complex-valued off–diagonal entries encode the interplay between sememes, which in turn gives rise to the interference between words. A density matrix assigns a probability value for any state on $\mathcal{H}$ such that the values for any set of orthogonal states sum up to 1 [12]. Hence it is visualized as an ellipsoid in Fig. 1, assigning a quantum probability to a unit vector with the intersection length.

2.4 Semantic Measurements

As a non-classical probability distribution, a sentence density matrix carries rich information and in particular it contains all the information about a quantum system. In order to extract the relevant information to a concrete task from the semantic composition, we build a set of measurements and compute the probability that the mixed system falls onto each of the measurements as a high-level abstraction of the semantic composition.

Suppose our proposed *semantic measurements* are associated with a set of measurement projectors $\{P_i\}_{i=1}^k$. According to the Born's rule [5], applying the measurement projector P_i onto the sentence density matrix ρ yields the following result:

$$p_i = tr(P_i \rho) \tag{4}$$

Here, we only consider pure states as measurement states, i.e. $P_i = |v_i\rangle \langle v_i|$. Moreover, we ignore the constraints of the measurements states $\{|v_i\rangle\}_{i=1}^k$ (i.e. orthogonality or completeness), but keep them trainable, so that the most suitable measurements can be determined automatically by the data in a concrete task, such as classification or regression. In this way, the trainable semantic measurements can be understood as a similar approach to supervised dimensionality reduction [11], but in a quantum probability framework with complex values.

3 QUANTUM PROBABILITY DRIVEN NETWORK

In order to implement the proposed framework, we further propose an end-to-end neural network based on quantum probability. Fig. 2 shows the architecture of the proposed Quantum Probability Driven Network (QPDN). The embedding layer, which is composed of a unit complex-valued embedding and a term-weight lookup table, captures the basic lexical features. The mixture layer is designed to combine the low-level bag-of-word features with an additive complex-valued outer product operation. The measurement layer adopts a set of trainable semantic measurements to extract the higher-level features for the final linear classifier.

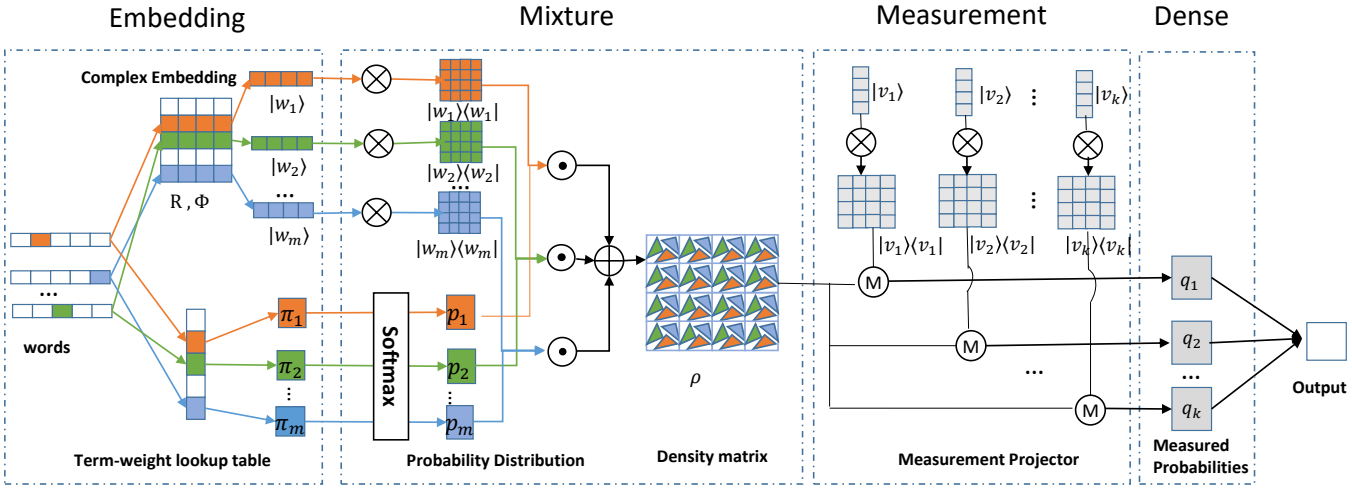

Figure 2: Architecture of Quantum probability-driven Neural Network. $\odot$ means that a matrix multiplies a number with each elements. $\oplus$ refers to a element-wise addition. $\otimes$ denotes a outer production to a vector, $\mathfrak{M}$ means a measurement operation according to Eq. 4.

In the following we will introduce the architecture layer by layer.

3.1 Embedding Layer

The parameters of the embedding layer are $\{R, \Phi, \Pi\}$, respectively, denoting the amplitude embedding, the phase embedding, and the term-weight lookup table. Eq. 1 expresses a quantum representation as a unit-length, complex-valued vector representation for a word w, i.e. $|w\rangle = [r_1 e^{i\phi_1}, r_2 e^{i\phi_2} ... r_n e^{i\phi_n}]^T$. The term-weight lookup table is used to weight words for semantic combinations, which will be described in the next subsection. During training, word embeddings need to be normalized to unit length after each batch.

This representation allows for a non-linear composition of amplitudes and phases in its mathematical form. Suppose two words w_1 and w_2 are of weights $r_j^{(1)} e^{i\phi_j^{(1)}}$ and $r_j^{(2)} e^{i\phi_j^{(2)}}$ for the j^{th} dimension (corresponding to the j^{th} sememe). The combination of w_1 and w_2 gives rise to a weight $r_j e^{i\phi_j}$ for the j^{th} dimension computed as

$$\begin{aligned} r_j e^{i\phi_j} &= r_j^{(1)} e^{i\phi_j^{(1)}} + r_j^{(2)} e^{i\phi_j^{(2)}} \\ &= \sqrt{|r_j^{(1)}|^2 + |r_j^{(2)}|^2 + 2 r_j^{(1)} r_j^{(2)} cos(\phi_j^{(1)} - \phi_j^{(2)})} \\ &\times e^{i \arctan\left(\frac{r_j^{(1)} \sin(\phi_j^{(1)}) + r_j^{(2)} \sin(\phi_j^{(2)})}{r_j^{(1)} \cos(\phi_j^{(1)}) + r_j^{(2)} \cos(\phi_j^{(2)})}\right)} \end{aligned} \quad (5)$$

Where both r_j and ϕ_j is a non-linear combination of $r_j^{(1)}$,$r_j^{(2)}$,$\phi_j^{(1)}$ and $\phi_j^{(2)}$. If the amplitudes and phases are associated to different levels of information, the amplitude-phase representation then naturally gives rise to a non-linear fusion of information.

3.2 Mixture Layer

A sentence is modeled as a density matrix, which is constructed in Sec. 2.3. Instead of using uniform weights in Eq. 3, word-sensitive weights are used for each word, which is commonly used in IR, e.g. inverse document frequency (IDF) as a word-dependent weight in TF-IDF scheme [28].

In order to guarantee the unit trace length for density matrix, the word weights which are from the lookup table in a sentence are normalized to a probability value through a softmax operation: $p(i) = e^{\pi(w_i)} / \sum_j^m e^{\pi(w_j)}$. Compared to the IDF weight, the normalized weight for a specific word in our approach is not static but updated adaptively in the training phase. Even in the inference/test phase, the real term weight i.e. $p(w_i)$ is also not static, but highly depends on the neighbor context words through nonlinear softmax function.

3.3 Measurement Layer

The measurement layer adopts a set of one-rank measurement projectors $\{|v_i\rangle\langle v_i|\}_{i=1}^k$ where $|v_i\rangle\langle v_i|$ is the outer product of its corresponding state in Semantic Hilbert Space $|v_i\rangle$. After each measurement, we can obtain one probability for each measurement state like $q_j = tr(\rho\, |v_j\rangle\langle v_j|)$. Finally, we can obtain a vector $\vec{q} = [q_1, q_2, ...q_k]$. Similarly to the word vectors, the states $|v_i\rangle$ are represented as unit states and normalized after several batches.

Dataset	train	test	vocab.	task	Classes
CR	4K	CV	6K	product reviews	2
MPQA	11k	CV	6K	opinion polarity	2
SUBJ	10k	CV	21k	subjectivity	2
MR	11.9k	CV	20k	movie reviews	2
SST	67k	2.2k	18k	movie reviews	2
TREC	5.4k	0.5k	10k	Question	6

Table 1: Dataset Statistics. (CV means 10-fold cross validation for testing performance.)

3.4 Dense Layer

The vector $\vec{q}$ in the measurement layer consists of k positive scalar numbers and it is used to infer the label for a given sentence. A dense layer with softmax activation is adopted after the measurement layer to get a classification probability distribution, i.e. $\widehat{\vec{y}} = \text{softmax}(\vec{q} \cdot W)$. The loss is designed as a cross-entropy loss between $\widehat{\vec{y}}$ and the one-hot label $\vec{y}$.

4 EXPERIMENTS

Our model was evaluated on six datasets for text classification: CR customer review [17], MPQA opinion polarity [30], SUBJ sentence subjectivity [25], MR movie review [25], SST binary sentiment classification [27], and TREC question classification [21]. The statistics of them are shown in Tab. 1.

We compared the proposed QPDN with various models, including Uni-TFIDF, Word2vec, FastText [18] and Sent2Vec [24] as unsupervised representation learning baselines, CaptionRep [15] and DictRep [16] as supervised representation learning baselines, as well as CNN [19] and BiLSTM [10] for advanced deep neural networks. In Tab. 2, we reported the classification accuracy values of these models from the original papers.

We used Glove word vectors [26] with 50,100,200 and 300 dimensions respectively. The amplitude embedding values are initialized by L2-norm, while the phases in complex-valued embedding are randomly initialized in $-\pi$ to π. We searched for the best performance in a parameter pool, which contains a learning rate in {1E-3, 1E-4, 1E-5, 1E-6}, an L2-regularization ratio in {1E-5, 1E-6, 1E-7, 1E-8}, a batch size in $\{8, 16, 32, 64, 128\}$, and the number of measurements in $\{5, 10, 20, 50, 100, 200\}$.

The main parameters in our model are R and Φ. Since both of them are $n \times |V|$ in shape, the number of parameters is roughly two times that of FastText [22]. For the other parameters, Π is $|V| \times 1$, $\{|v_i\rangle\}_{i=1}^{k}$ is $k \times 2n$, while W is $k \times |L|$ with L being the label set. Apart from word embeddings, the model is robust with limited scale at $k \times 2n + n \times |V| + k \times |L|$ for the number of parameters.

The results in Tab. 2 demonstrate the effectiveness of our model and an improvement of classification accuracies over some strong baseline supervised and unsupervised representation models on most of the datasets except MPQA. In comparison with more advanced models including BiLSTM and CNN, our model generally performed better than BiLSTM with increased accuracy values on the multi-class classification dataset (TREC) and three binary text classification datasets (MR, SST & SUBJ). However, it under-performed CNN on all 6 datasets with a difference of over 2% on 3 of them (MPQA, SST & TREC), probably because that it uses fewer parameters and simpler structures.

Table 2: Experimental Results in percentage (%). The best performed value (except for CNN/LSTM) for each dataset is in bold. where † means a significant improvement over FasText.

Model	CR	MPQA	MR	SST	SUBJ	TREC
Uni-TFIDF	79.2	82.4	73.7	-	90.3	85.0
Word2vec	79.8	**88.3**	77.7	79.7	90.9	83.6
FastText [18]	78.9	87.4	76.5	78.8	91.6	81.8
Sent2Vec [24]	79.1	87.2	76.3	80.2	91.2	85.8
CaptionRep [15]	69.3	70.8	61.9	-	77.4	72.2
DictRep [16]	78.7	87.2	76.7	-	90.7	81.0
Ours: QPDN	**81.0**†	87.0	**80.1**†	**83.9**†	**92.7**†	**88.2**†
CNN [19]	81.5	89.4	81.1	88.1	93.6	92.4
BiLSTM [10]	81.3	88.7	77.5	80.7	89.6	85.2

We argue that QPDN achieved a good balance between effectiveness and efficiency, due to the fact that it outperforms BiLSTM.

5 DISCUSSIONS

This section discusses the power of self-explanation and conducts an ablation test to examine the usefulness of important components of the network, especially the complex-valued word embedding.

Self-explanation Components. As is shown in Tab. 3, all components in our model have a clear physical meaning corresponding to quantum probability, where classical Deep Neural Network (DNN) can not well explain the role each component plays in the network. Essentially, we constructed a bottom-up framework to represent each level of semantic units on a uniform Semantic Hilbert Space, from the minimum semantic unit, i.e. sememe, to the sentence representation. The framework was operationalized through superposition, mixture and semantic measurements.

Ablation Test. An ablation test was conducted to examine how each component influences the final performance of QPDN. In particular, a double-length real word embedding network was implemented to examine the use of complex-valued word embedding, while mean weights and IDF weights were compared with our proposed trainable weights. A set of non-trainable orthogonal projectors and a dense layer on top of the sentence density matrix were

Table 3: Physical meanings and constraints

Components	DNN	QPDN
Sememe	-	basis vector / **basis state** $\{w \mid w \in C^n, \|\|w\|\|_2 = 1, \}$ complete &orthogonal
Word	real vector $(-\infty, \infty)$	unit complex vector / **superposition state** $\{w \mid w \in C^n, \|\|w\|\|_2 = 1\}$

replace projectors with dense layer	0.8221	-0.0170
QPDN	**0.8391**	-

implemented to analyze the effect of trainable semantic measurements.

Due to limited space, we only reported the ablation test result for SST, which is the largest and hence the most representative dataset. We used 100-dimensional real-valued word vectors and 50-dimensional complex-valued vectors for the models in the ablation test. All models under ablation were comparable in terms of time cost. Tab. 4 showed that each component plays an important role in the QPDN model. In particular, replacing complex embedding with double-dimension real word embedding led to a 5% drop in performance, which indicates that the complex-valued word embedding was not merely doubling the number of parameters.

The comparison with IDF and mean weights showed that the data-driven scheme gave rise to high-quality word weights. The comparison with non-trainable projectors and directly applying a dense layer on the density matrix showed that trainable measurements bring benefits to the network.

Discriminative Semantic Directions. In order to better understand the well-trained measurement projectors, we obtained the top 10 nearest words in the complex-valued vector space for each trained measurement state (like $|v_i\rangle$), using KD tree [4]. Due to limited space, we selected five measurements from the trained model for the MR dataset, and selected words from the top 10 nearest words to each measurement. As can be seen in Tab. 5, the first measurement was roughly about time, the second one was related to verb words which mainly mean 'motivating others'. The third measurement grouped uncommon non-English words together. The last two measurements also grouped words sharing similar meanings. It is therefore interesting to see that relevant words can somehow be grouped together into certain topics during the training process, which may be discriminative for the given task.

Table 5: The learned measurement for dataset MR. They are selected according to nearest words for a measurement vector in Semantic Hibert Space

Measurement	Selected neighborhood words
1	change, months, upscale, recently, aftermath
2	compelled, promised, conspire, convince, trusting
3	goo, vez, errol, esperanza, ana
4	ice, heal, blessedly, sustains, make
5	continue, warned, preposterousness, adding, falseness

6 CONCLUSIONS

In order to better model the non-linearity of word semantic composition, we have developed a quantum-inspired framework that models different granularities of semantic units on the same Semantic Hilbert Space, and implement this framework into an end-to-end text classification network. The network showed a promising performance on six benchmarking text datasets, in terms of effectiveness, robustness and self-explanation ability. Moreover, the complex-valued word embedding, which inherently achieved non-linear combination of word meanings, brought benefits to the classification accuracy in a comprehensive ablation study.

This work is among the first step to apply the quantum probabilistic framework to text modeling. We believe it is a promising direction. In the future, we would like to further extend this work by considering deeper and more complicated structures such as attention or memory mechanism in language, in order to investigate related quantum-like phenomena on textual data to provide more intuitive insights. Additionally, Semantic Hilbert Space in a tensor space is also worthy to be explored like [32], which may provide more interesting insights for current communities.

ABSTRACT

The proliferation of publicly accessible urban data provide new insights on various urban tasks. A frequently used approach is to treat each region as a data sample and build a model over all the regions to observe the correlations between urban features (e.g., demographics) and the target variable (e.g., crime count). To define regions, most existing studies use fixed grids or pre-defined administrative boundaries (e.g., census tracts or community areas). In reality, however, definitions of regions should be different depending on tasks (e.g., regional crime count prediction vs. real estate prices estimation). In this paper, we propose a new problem of task-specific city region partitioning, aiming to find the best partition in a city w.r.t. a given task. We prove this is an NP-hard search problem with no trivial solution. To learn the partition, we first study two variants of Markov Chain Monte Carlo (MCMC). We further propose a reinforcement learning scheme for effective sampling the search space. We conduct experiments on two real datasets in Chicago (i.e., crime count and real estate price) to demonstrate the effectiveness of our proposed method.

1 INTRODUCTION

Given the growing amount of urban data, a number of data-driven models have been developed to provide insights for urban problems. A common approach is to treat each region as a data sample, take the region properties as features, and build a model to learn the correlation between region features and a target variable. Crime prediction is a good example. Criminologists are interested in knowing the correlation between demographics and crime [17, 21]. Each region i is taken as a data sample, with X_i as its demographic feature and Y_i as its crime count. A model (e.g., linear regression or negative binomial model) is built to estimate crime count vector Y using the feature matrix X. If some features (e.g., disadvantage index) show a significant correlation with crime count, researchers could relate this empirical result with criminology theory [8] and policy makers could further propose corresponding policies to address crime issues.

(a) Prediction errors (b) Community #6

Figure 1: (a) Heatmap of crime prediction error at community level in Chicago. Darker color means higher prediction error. The community area #6 is an outlier with the largest error. (b) Community #6 consists of 34 tracts (top) and their pair-wise similarity (bottom). It is clear that 5 tracts (red) on the east side are different from others.

Existing studies often use pre-defined administrative boundaries (e.g., street block, census tract, or community area) to define a region [17, 24]. A plot of 77 administrative community areas of Chicago is shown in Figure 1. However, such administrative boundaries might be too rigid and do not reflect the true spatial regions with regards to the targeted urban issues. One can alternatively propose to study the problem at the point level or small grid cell level (e.g., 10 meters by 10 meters grids). However, this could lead to data sparsity issues and jeopardize the integrity of the statistical model. Consequently, any inference made from the model would be at risk of bias. These concerns have both theoretical and policy implications. We use the following example to further illustrate the issue of using pre-defined community areas to study crime.

Example 1.1. Following previous work [17], we replicate a negative binomial model to predict crime count using demographic features by treating each community area as a data sample. Figure 1 plots the crime prediction error for each community area of Chicago. Community area #6 (i.e., Lake View area) shows an abnormally high error. In order to explain this outlier, we further investigate the internal structure of this area. Community #6 consists of 34 census tracts as shown in the top of Figure 1(b). In the bottom of Figure 1(b), we visualize pair-wise Euclidean distance between tracts based on demographic features. There are five tracts

https://doi.org/10.1145/3308558.3313704

that are different from others, and they are all located on the east side of community #6. These five tracts, when mixed with other tracts in this community, lead to inferior performance of crime count prediction in that area.

The observation above motivates us to learn a better region partition for crime study. In this paper, we propose a new problem of *task-specific region partitioning*. Given spatial variables and a selected model (e.g., linear regression), we aim to partition the city into regions such that the model trained by taking regions as data samples achieves optimal results.

Task-specific city region partitioning is a challenging problem. The key challenge lies in that the region properties (both features and target variable) and the model coefficients change simultaneously when we change the region partition. We prove that this is an NP-hard problem. We adopt a stochastic sampling approach to tackle our NP-hard problem. We start from a pre-defined region partition (e.g., community areas), and generate a new partition sample by flipping the membership of a smaller area (e.g., a tract). First, two variants of MCMC methods are proposed to generate new samples. Finally, we employ reinforcement learning to automatically learn how to generate the next sample that is more likely to improve the prediction performance.

We evaluate our method on two real datasets, i.e. crime counts and real estate prices. The learned region partitions are shown to consistently outperform the administrative boundaries and spatial clustering method. For example, our methods, on average, outperform the administrative boundary by 67% in MAE for a crime count prediction task.

To summarize, the contributions of this paper are three fold. First, we propose a novel problem on task-specific region partitioning, which is motivated by real-world urban studies [17]. Second, we prove the problem is NP-hard and use MCMC and reinforcement learning sampling strategies to solve the problem. Finally, we validate our method through extensive experiments on two real datasets.

2 REGION PARTITION PROBLEM

The input of our problem is a set of minimum spatial units. Without loss of generality, we use tract as the unit of study in this paper, and the set of tracts is denoted as $\mathcal{T} = \{t_1, t_2, \cdots, t_n\}$. Within each tract t_i, the following information are available $\langle p_i, y_i, x_i \rangle$, where p_i is a sequence of GPS coordinates representing tract exterior boundary, y_i is the target variable of interest, such as crime count and average house price, and $x_i \in \mathcal{R}^d$ is a d-dimension contextual feature vector. Note that each tract is a polygon with one connected component.

A city is partitioned into different community areas. We use community area as the proper unit to study the correlation between y and x. Each community area consists of several adjacent tracts, denoted as $Z_j = \{t_1^j, t_2^j, \cdots\}$. We derive $\langle P_j, Y_j, X_j \rangle$ for each community area Z_j by aggregating $\{\langle p_i, y_i, x_i \rangle | t_i \in Z_j\}$, where P_j is the exterior boundary, Y_j is the prediction target, and X_j is the contextual features of Z_j.

Definition 2.1 (Partition). A partition over $\mathcal{T}$ consists of a set of m non-overlapping community areas, denoted as $\mathcal{Z} = \{Z_1, Z_2, \cdots, Z_m\}$, satisfying the following four conditions

(1) (subset) $\forall j, Z_j \subset \mathcal{T}$;
(2) (non-overlapping) $\forall p, q, Z_p \cap Z_q = \emptyset$;
(3) (completeness) $\bigcup_{j=1}^{m} Z_j = \mathcal{T}$;
(4) (spatial-continuity) $\forall j$, P_j defines a polygon with exact one connected component.

A task is to learn a model f that takes input X and predicts Y on a given partition $\mathcal{Z}$. In order to learn a good model f, task-specific region partition problem is defined as follows.

Definition 2.2 (Task-specific region partition). Given a set of tracts $\mathcal{T}$ and a task f, find a partition $\mathcal{Z}$ with m components, such that the task error is minimized. Formally, we have

$$\arg\min_{\mathcal{Z}, f} \sum_{j=1}^{m} \Big(||Y_j - f(X_j)||_2 + G(Z_j) \Big), \tag{1}$$

where $G(\mathcal{Z}) = \sum_{j=1}^{m} G(Z_j)$ is a constraint on partition. For simplicity, we use $\mathcal{F}(\mathcal{Z}, f) = \sum_{j=1}^{m} \mathcal{F}(Z_j, f)$ as the quality measure of a partition $\mathcal{Z}$, where $\mathcal{F}(Z_j, f) = ||Y_j - f(X_j)||_2 + G(Z_j)$. Hence, the objective becomes

$$\arg\min_{\mathcal{Z}, f} \mathcal{F}(\mathcal{Z}, f). \tag{2}$$

The constraint function G ensures the partition $\mathcal{Z}$ has desirable property, such as small variance in community populations or balanced size in terms of community area.

NP-Hardness. The problem in Definition 2.2 is a combinatorial optimization problem. The decision version of the problem is to find a partition $\mathcal{Z}$, such that $\mathcal{F}(\mathcal{Z}, f) \leq \epsilon$, where ϵ is a constant. Here we prove such decision problem is NP-complete, and therefore the optimization version is NP-hard.

In the NP-completeness proof, we first approximate the decision problem above with an easier problem. The fact, that X_i, Y_i, and f are dynamically changing according to $\mathcal{Z}$, complicates the original problem. Therefore, we replace the jointly learned optimal f with a fixed f_0. Since f minimizes Equation 2 while f_0 does not, we have $\mathcal{F}(\mathcal{Z}, f) < \mathcal{F}(\mathcal{Z}, f_0)$. Next, we use the largest task error on one community area $\sup\{\mathcal{F}(Z_j, f_0)\}$ to approximate the overall task error $\mathcal{F}(\mathcal{Z}, f_0)$, where sup calculates supremum of a set. Namely, $\mathcal{F}(\mathcal{Z}, f) < \mathcal{F}(\mathcal{Z}, f_0) < m \cdot \sup\{\mathcal{F}(Z_j, f_0)\}$, because there are m community areas. Therefore, if we prove $\exists \mathcal{Z}$, such that $m \cdot \sup\{\mathcal{F}(Z_j, f_0)\} \leq \epsilon$, then we have $\mathcal{F}(\mathcal{Z}, f) \leq \epsilon$.

Now we prove the approximated decision problem is NP-complete. First, such approximated decision problem is NP, because given a partition $\mathcal{Z}_0$, we are able to validate $m \cdot \sup\{\mathcal{F}(Z_j, f_0)\} \leq \epsilon$ in polynomial time. Next, we prove the NP-hardness of this problem by reducing the (k, v)-balanced partitioning problem to the approximated decision problem. The (k, v)-balanced partition problem [2] is a proved NP-complete problem, which partition graph into k disjoint components of size at most $v\frac{n}{k}$, while the capacity of edge cut is less than ϵ. We construct the adjacency graph of all tracts $\mathcal{T}$, with weight $\sup\{\mathcal{F}(Z_j, f_0)\}$ on each edge. A solution to (m, v)-balanced partition problem on such adjacency graph is a solution to the approximated decision problem. The balanced partition problem achieve $k \cdot \sup\{\mathcal{F}(Z_j, f_0)\} \leq \epsilon$, where k is the number of edges to cut the graph. It is clear that $k > m$, and therefore we find a partition satisfying $m \cdot \sup\{\mathcal{F}(Z_j, f_0)\} \leq \epsilon$.

3 METHODS

We employ a stochastic search process to find approximate solutions due to the NP-hard nature of our problem. First, we propose two variants of Markov Chain Monte Carlo (MCMC) method with different sample proposal strategy. Then, we use reinforcement learning to automatically learn the sample strategy.

3.1 Markov Chain Monte Carlo

The optimal task function f in Equation (2) can be easily learned, when a partition $\mathcal{Z}$ is given. Therefore, the challenge lies in searching through the partition space. Toward this goal, we first adopt the MCMC method, or more specifically the Metropolis-Hastings algorithm to optimize $\mathcal{Z}$.

Markov Chain Monte Carlo [3] is a stochastic algorithm that constructs a Markov chain that will ultimately converge to p through stochastic sampling [11]. In our case, the state space is all possible partitions $\mathcal{Z}$, and the distribution $p(\mathcal{Z})$ defines how likely that $\mathcal{Z}$ is optimal. Clearly, it is difficult to calculate $p(\mathcal{Z})$, but a partition $\mathcal{Z}$ with lower $\mathcal{F}(\mathcal{Z})$ value is more likely to be optimal.

In addition to the quality function $\mathcal{F}$, MCMC employs a proposal function $q(\mathcal{Z}'|\mathcal{Z})$, which defines the transition probability from state $\mathcal{Z}$ to $\mathcal{Z}'$. The Markov chain moves toward $\mathcal{Z}'$ with acceptance probability $\gamma = \min\left[1, \frac{p(\mathcal{Z}')q(\mathcal{Z}|\mathcal{Z}')}{p(\mathcal{Z})q(\mathcal{Z}'|\mathcal{Z})}\right]$. And $p(\mathcal{Z}) = \frac{e^{-\mathcal{F}(\mathcal{Z})/T}}{P}$ is the Boltzmann distribution, where P is the normalization constant, and T is the temperature parameter. The proposal function q is very flexible, if not limitless. In practice, the choice of q generally affects how quickly the algorithm converges.

The MCMC algorithm is described below. First, we initialize the partition with the existing administrative boundary, denoted as $\mathcal{Z}_0$. Within each step, we draw $u \in [0, 1]$ from uniform distribution $\mathcal{U}_{[0,1]}$, draw the next partition $\mathcal{Z}'$, and calculate acceptance probability γ. Only if u is smaller than γ, we accept the new partition $\mathcal{Z}'$. We repeat the process above, until $\mathcal{F}(\mathcal{Z})$ converges.

MCMC with Naive Proposal. We begin by establishing a baseline MCMC with the simplest q we can devise. Namely, we generate a new partition by *uniformly randomly* selecting one tract $t_i \in \mathcal{T}$ that is on the boundary of some community area Z_j, and then flip t_i to the adjacent community area. With naive proposal strategy, q is symmetric, because $q(\mathcal{Z}'|\mathcal{Z})$. Therefore, the acceptance probability $\gamma = \min[1, \frac{p(\mathcal{Z}')}{p(\mathcal{Z})}]$.

Guided MCMC with Softmax Proposal. We propose another MCMC approach with a more intelligent proposal strategy than uniformly random selection. This approach is a greedy strategy that we prefer to adjust the community area with the highest prediction error to improve current partition.

Given this intuition, we heuristically design our guided MCMC method to sample a community area with large error first. To achieve this, we apply the softmax function over the prediction errors on different community areas to derive the sample probability of each community area, i.e. $p(Z_j) = \frac{\exp(||Y_j - f(X_j)||_2)}{\sum_{k=1}^{m} \exp(||Y_k - f(X_k)||_2)}$. Note that under the softmax proposal approach, the proposal function q is not symmetric. Therefore, we have to explicitly calculate the values for q functions.

Discussion: we acknowledge that there are plenty of other strategies to build random walks for MCMC. However, there is always a trade-off between efficiency and effectiveness. The naive MCMC is the simplest approach to conduct MCMC, while being slow to converge. The guided MCMC employs human heuristics to improve the efficiency at the expense of potentially converging to a worse local optima, because the greedy strategy may prune the search space too aggressively.

3.2 Reinforcement Learning

There are two main drawbacks of the MCMC method. First, when drawing a new sample, the MCMC methods do not account for any information from previous samples. Namely, the naive MCMC could repeatedly reject the same sample. Intuitively, all the samples we observed so far should carry certain information to assist sampling in the future. Second, the Markov chain-based stochastic search strategy is more likely to get stuck on a local optima, because the nature of MCMC sampling follows a depth first search. It is very likely that another chain leads to a better local optima, but the algorithm is not able to explore the alternative outcome.

To address these two issues of MCMC method, we propose a reinforcement learning (RL) [15] scheme for generating new samples. RL differs from standard supervised learning in that the correct input/output pairs are not presented at the same time. Instead, RL is concerned with how agents ought to take actions in an environment so as to maximize cumulative gain.

In what follows, we map the RL components to our problem. The set of tracts consists of the environment, and their community area assignment is the state. An action is to re-assign some tract t_i from Z_j to Z_p, denoted as tuple $\langle t_i, Z_p \rangle$. The immediate reward of such transition is defined by $\Delta\mathcal{F} = e^{-\mathcal{F}(\mathcal{Z}')} - e^{-\mathcal{F}(\mathcal{Z})}$, where the exponential function coverts the loss into gain. We define the cumulative gain Q as a function of the current state $\mathcal{Z}$ and action $\langle t^k, Z^k \rangle$ at step k, and Q satisfies the following condition

$$Q(\mathcal{Z}, \langle t^k, Z^k \rangle) = \Delta\mathcal{F} + \delta \cdot \sum_{a \in \{\langle t^{k+1}, Z^{k+1} \rangle\}} Q(\mathcal{Z}', a), \tag{3}$$

where δ is the discount factor on future reward and $\{\langle t^{k+1}, Z^{k+1} \rangle\}$ is the set of all possible actions given $\mathcal{Z}'$. Given Q function, at each state $\mathcal{Z}$, we are able to find the best action with the highest cumulative gain through

$$\arg\max_{\langle t, Z \rangle} Q(\mathcal{Z}, \langle t, Z \rangle). \tag{4}$$

In our problem, a reinforcement learning scheme faces the following three challenges.

Huge state space. The state space is exponential to the number of tracts. Consequently, we cannot track the exact reward for each state and actions. Instead, we rely on Deep Q-learning (DQN) [16], where a deep neural network approximates the Q function.

Our neural network architecture is shown in Figure 2. The input of our DQN model includes the partition $\mathcal{Z}$ and an action tuple $\langle t, Z \rangle$. Since the input consists of either indexes of community area or index of a tract, we employ an embedding layer to encode these positive integers into dense vectors. We concatenate $\mathcal{Z}$ and Z and apply the CA embedding layer $embed_{CA}$ to obtain d_{CA}-dimension

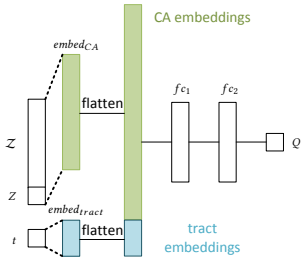

Figure 2: The Deep Q-learning neural network architecture. The input contains current partition $\mathcal{Z}$ and action $\langle t, Z\rangle$. We employ two embedding layers $embed_{CA}$ and $embed_{tract}$ for community area and tract respectively. The embeddings of all inputs are flattened and concatenated together as the intermediate representation of the partition and action. Multiple fully connected layers, $\{fc_1, fc_2, \cdots\}$, are used for predicting the final output Q.

vectors. The output from $embed_{CA}$ has a dimension of $(n+1)$-by-d_{CA}, where n is the number of tracts or the length of $\mathcal{Z}$. The index of target tract t is encoded into d_{tract}-dimension vector through tract embedding layer $embed_{tract}$. The output from $embed_{tract}$ has dimension of 1-by-d_{tract}. The embeddings of all inputs are flattened and concatenated together as the intermediate representation of the partition and action. Multiple fully connected layers, $\{fc_1, fc_2, \cdots\}$, are used for the prediction task. Finally, the output layer predicts the sigmoid of Q, which is the reward if the given action is taken on given partition. The detailed parameter setting of our DQN model is given later.

Large and dynamic action space. It is difficult to directly calculate the summation of future Q values in Equation (3), and to find the maximum over all actions in Equation (4). The reason is that for different partition states, the tracts on the boundaries are different, and thus the set of possible actions is also different. In this paper, we set the discount factor $\delta = 0$ to ease the calculation of Q. When searching for the best action with Equation (4), we sample a subset of $m = 32$ actions, and find the best action within such subset.

It is worthy to mention that when the discount factor is set to 0, the DQN only accounts for immediate reward instead of the total reward. Even so, the DQN method is still intuitively better than the MCMC method. The reason is that an MCMC approach cannot keep track of the information from rejected historical samples. The DQN method on the other hand can account for the similarity between partitions, and thus potentially avoid to repeatedly try the same action on similar partitions. The DQN is able to learn extra information from historical samples in the form of immediate reward, if not the total reward.

Training overhead is high. To train the Deep Q-learning model, we perform a sequence of random actions to generate a batch of training data. Such training overhead is significantly higher than the MCMC method. To improve the efficiency, we save our DQN model across different tasks and different rounds. The neural network is only updated when the found action cannot improve the cumulative reward.

4 EXPERIMENTS

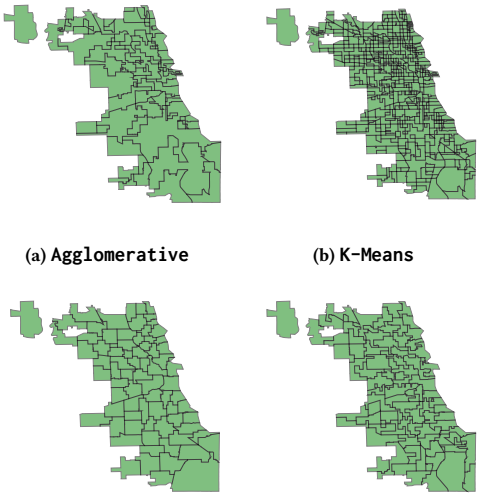
4.1 Experiment Setting

4.1.1 Data description. The fundamental geographic unit of study in this paper is a tract, which is a small area established by the U.S. Census Bureau. Analysis at the tract level is attractive because it offers the finest level of granularity where demographic data are available.

We collect the *demographic data* of 801 tracts in Chicago from the 2010 US census survey [1]. The demographic data provide the raw count of households over 100 different categories, include ethnicity, income, education, etc. The *geographic boundary information* for 801 tracts are available through the U.S. census survey [1] as well. Each boundary is defined by a polygon with a sequence of GPS coordinates. The Chicago Data Portal [12] makes the Chicago *crime data* publicly available online. Our study focuses on data from 2010 and 2011 in which over 700,000 incidents of crime were recorded. For each crime incident, the date, location, and incident type are reported. *House Price Data* in the Chicago metropolitan area are obtained from Zillow, a popular real estate website [29]. We collect the last sale price, floor size, latitude, and longitude information for over 44, 000 properties that were sold between January 2015 and December 2017.

4.1.2 Prediction Tasks. We employ a negative binomial regression model [17] as our prediction task, namely

$$\mathbf{E}(Y) = \exp(\alpha X),$$



where $\mathbf{E}$ calculates the expectation. The link function used in the regression is a negative binomial distribution. The reason to use negative binomial regression is that 1) it is suitable for non-negative value prediction, and 2) it solves the over-dispersion problem by allowing the variance to be larger than the mean.

The demographics features at the community level are pre-processed as contextual features, X_i, including total population, percentage of household in each income category, diversity of ethnicity, etc.

Two prediction tasks are used to evaluate our region partition methods in the experiments. Both tasks use the same processed demographic features, X. The first task is crime count prediction, where we aggregate the total number of crime in a community as Y. The crime count in year 2010 is used as training, and 2011 data are used as testing. The second task is house price prediction, where we use the average price per square foot in a community as Y. The houses that are sold before August 1st, 2016 are used as training, while the rest are used as testing. The split point makes the training and testing data have roughly equal number of samples.

4.1.3 Compared Methods. The existing administrative boundary is a clear baseline partition. Since our region partition problem is similar to clustering problem, we employ various conventional clustering methods to derive different clustering partitions as alternative baselines. More specifically, we compare the following region partition methods.

- Administrative boundary **(`Admin`)** uses the existing administrative boundary defined by US Bureau of Census [1]. A visual depiction of this partition can be seen in Figure 1.
- Various clustering methods. **`K-Means`** clustering separates tracts into n groups of equal variance. **`Agglomerative`** clustering performs a hierarchical clustering using a bottom up approach. The ward linkage function, along with a tract adjacency graph, are used to guarantee spatial continuity. **`Spectral`** clustering does a low-dimensional embedding of the affinity matrix between

(a) **Agglomerative** (b) **K-Means**

(c) **Spectral** (d) **DQN**

Figure 3: (a - c) The clustering results for three clustering baselines. (d) The learned partition from DQN method for crime prediction task. Note that K-means generate non-connected communities, and thus smaller regions. In all cases $m = 77$.

samples first, and then applies the K-means method. Note that Spectral also takes the tract adjacency graph as the affinity graph.

- Two variants of MCMC method. **Naive** MCMC with a straightforward uniform proposal. **Softmax** MCMC with softmax proposal is another variant, which uses human heuristics.
- Q-learning is our proposed reinforcement learning method to search for an optimal partition. In our **DQN** model, the embedding dimension of community area d_{CA} is 2, while d_{tract} is 4. We employ two fully connected layers for the prediction task, where fc_1 has 200 neurons and fc_2 has 100 neurons.

Since Naive, Softmax, and DQN all learn a region partition based on a supervised task, these methods utilize information from both the feature matrix, X, and the target vector, Y. To ensure a fair comparison between these methods and the conventional clustering methods (Agglomerative, K-means, and Spectral), we run the latter under three different settings: X only, Y only, and both X and Y. In each instance, we set the number of clusters as $m = 77$, which equals the number of community areas in Admin. Note that Agglomerative is a stable clustering method and produces the exact same clustering result each time it is run. Meanwhile, the K-Means and Spectral methods do not always converge to the same partition, and therefore we run each 10 times. Similar to K-means and Spectral, our proposed Naive, Softmax, and DQN may converge to different local optimal partitions, and thus we run our methods 10 times as well. Finally, we compute the mean and standard deviations of their corresponding error measures.

4.1.4 Evaluation Metrics. Given a partition $\mathcal{Z}$, we evaluate the quality of this partition on the testing data set. Mean Absolute Error (MAE) and standard deviations are used to measure the performance of prediction tasks. We compute MAE metric using Leave-one-out Cross-validation.

Table 1: MAE and corresponding standard deviation of various partition methods, averaged over 10 runs. For all deterministic methods, we did not report the standard deviation.

Method	Crime	House price
Admin	1,826.84	31.29
Agglomerative X only	60,126.28	51.28
Agglomerative Y only	14,069.28	41.87
Agglomerative X and Y	147,465.30	51.32
K-means X only	2,513.35 (433.74)	31.74 (1.17)
K-means Y only	1,048.59 (99.47)	32.75 (1.03)
K-means X and Y	2,779.78 (307.68)	32.98 (1.76)
Spectral X only	1,373.07 (36.82)	30.85 (1.36)
Spectral Y only	1,356.17 (48.73)	31.35 (2.09)
Spectral X and Y	1,407.57 (60.21)	32.30 (1.12)
Naive	697.40 (60.21)	33.21 (13.53)
Softmax	671.90 (62.91)	32.99 (4.48)
DQN	**602.93** (91.65)	**22.64** (2.24)

4.2 Quantitative Evaluations

4.2.1 Effectiveness Study. In Table 1, we report the evaluation results of the various partition methods. The partitions from different baselines are visualized in Figure 3(a-c). We run each method 10 times, and report the MAE and corresponding standard deviations in the table. We hold constant the number of MCMC iterations at approximately 1,500. Early stopping is allowed if a convergence criterion (discussed below) is met. The final partition of DQN is visualized in Figure 3(d). Overall, we have the following three observations.

Clustering methods overall perform poorly. This is likely due to the fact that the clustering methods do not fully consider the task information in a supervised way. Even when we consider both $\mathbf{X}$ and $\mathbf{y}$, the clustering methods are outperformed by the proposed methods. In general, Agglomerative results in the highest prediction errors for both crime prediction and house price prediction task. This is likely due to the fact that Agglomerative utilizes tract connectivity as a hard constraint. As a result, the generated communities have a large variance in their sizes, as shown in Figure 3(a). K-Means gives worse result than that of Admin in almost all cases. While the number of communities, m is held constant in all cases, the generated partition of K-Means appears to be greater than $m = 77$ in Figure 3(b) because K-Means does not incorporate spatial continuity constraint. Consequently, one community can consist of several disconnected components. Spectral tends to yield the best results in both tasks among these baselines because it accounts for the affinity of tracts and generates communities with similar sizes. However, it is worth mentioning that Spectral method cannot guarantee the spatial continuity of generated communities. From Figure 3(c), we can also see that Spectral results in a similar partition as the original administrative boundary, shown in Figure 1(a). That is also why it achieves similar prediction accuracy as Admin.

The proposed MCMC method outperforms the baselines. Both variants of MCMC methods significantly outperform Admin and Spectral baselines. Such observations validate the effectiveness

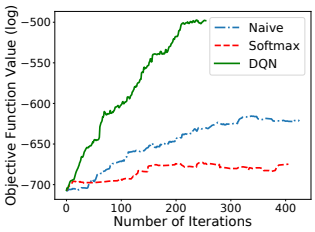


Figure 4: Convergence plots for proposed methods on house price prediction task.

of the MCMC strategy in searching for optimal solutions. On average, `Softmax` tends to outperform `Naive` on both tasks studied. However, it is inconclusive if this is a general result due to the incremental performance difference between the two in certain cases.

`DQN` *method performs the best among all.* It is clear that `DQN` finds a better local optimal solution than that of MCMC methods. On the crime prediction task, the average MAE is 602.93, which represents a 67% improvement over `Admin` baseline. On the house price prediction task, `DQN` consistently gives the best performance. The reason is that `DQN` explores over a subset of actions and picks the best one at each step, compared to the MCMC method, which searches the partition space in a depth first search fashion. Comparing the final partition of `DQN` and `Spectral`, we notice that `Spectral` partition is quite similar to the original administrative boundary in Figure 1. As a consequence, `Spectral` has similar MAE to `Admin`, but is much worse than `DQN`.

4.2.2 Convergence Study. In addition to discussing the proposed methods in the context of model accuracy, we also briefly investigate their performance in terms of convergence. In our method, we track the standard deviation of the $\mathcal{F}$ values from the last 50 iterations. When such standard deviation is less than a pre-defined threshold, we stop. In Figure 4 we visualize the log of quality measure, i.e. $-\mathcal{F}(\mathcal{Z})$, against the number of iterations for three proposed methods on the house price task.

We perform only one run of each method, which could result in slightly different results than what we observe on average. However, Figure 4 is common enough to understand typical convergence behavior. We observe that `DQN` finishes in a less than 300 iterations, while `Naive` and `Softmax` both take more than 400 iterations. Clearly, we observe that `DQN` converge to a better optimal solution with higher training gain. In this specific run, `Naive` is slower to converge than `Softmax`, but also finds a more optimal solution. There is more evidence that these methods may give very similar results, on average.

5 RELATED WORK

Urban Data Heterogeneity. As we collect more types of new urban data, we are able to solve a wide spectrum of urban problems. For example, recent studies use various urban data, such as POI and crowd mobility [19, 20], to estimate air quality [26], noise pollution [27], real estates values [7] and crime [17, 21].

These existing works focus on mining the subtle correlations across different domains of data. We generalize the urban problems above as a learning task, f, which maps some urban features to a target variable of interest. We study how to find a proper region partition as the domain of urban problem, f, so that the learned correlation is consistent and significant.

Traditional Region Partition Methods. There are mainly four types of region partition methods that are widely used in existing urban computing literature. 1) A fixed sized grid [18, 22, 26], 2) existing administrative boundaries [17], 3) clustering of point-wise urban data to get regions [10], and 4) other specifically designed partitions, such as road networks partition [24], cellular tower coverage partition [23], and fan-shaped partitions [28].

It is worthy mentioning that most existing partition methods are purely based on cartographic information, and do not make use of the urban data properties. In this paper, we try to partition the city with an explicit objective, so that the partition methods explicitly take the learning task f into consideration.

Partition Problem in Other Contexts. In the field of community detection problem [5, 6], the partition problem is well studied as well. While most of these works do not have an extra objective for partition, a few of them involves additional property as constraint. For example, the homophilic network decomposition [13] partitions the networks while characterize the degree of homophily of its nodes. The authors assign a dominant label within each group. Hence, the problem is essentially a classification problem, which is fundamentally different from ours.

Another general problem is to partition a set into k groups and fit a model within each group [25]. Such problem definition aims to show that the correlations between features and target vary over the space (e.g., in some area, disadvantage index correlates with crime; while in some other areas, it does not). A simplified version of such problem is segmented regression in 2D space, which could be solved efficiently with dynamic programming [4]. Compared to our problem, such problem formulation has different goal while being easier to solve.

Discrete Optimizations. Our problem is a discrete optimization problem. The objective is easy to derive but difficult to find an optimal solution for. MCMC sampling has been shown to be effective in optimizing discrete structures [14]. To improve the efficiency of MCMC, the learning to optimize technique [9] employs reinforcement learning framework to learn where to draw the next sample. Our solution is mostly inspired by this work.

6 CONCLUSION

In this paper, we proposed a new problem called task-specific region partition. The problem is motivated by the drawbacks of existing administrative boundaries. The task-specific region partition problem is NP-hard, and hence searching for a global optimum is difficult. Two variants of MCMC methods and a reinforcement learning method are proposed to efficiently search for an optimal solution. Our methods are evaluated on two prediction tasks using two evaluation metrics. The learned predictions consistently outperform the administrative boundaries in both tasks.

ABSTRACT

To alleviate sparsity and cold start problem of collaborative filtering based recommender systems, researchers and engineers usually collect attributes of users and items, and design delicate algorithms to exploit these additional information. In general, the attributes are not isolated but connected with each other, which forms a knowledge graph (KG). In this paper, we propose **K**nowledge **G**raph **C**onvolutional **N**etworks (KGCN), an end-to-end framework that captures inter-item relatedness effectively by mining their associated attributes on the KG. To automatically discover both high-order structure information and semantic information of the KG, we sample from the neighbors for each entity in the KG as their receptive field, then combine neighborhood information with bias when calculating the representation of a given entity. The receptive field can be extended to multiple hops away to model high-order proximity information and capture users' potential long-distance interests. Moreover, we implement the proposed KGCN in a minibatch fashion, which enables our model to operate on large datasets and KGs. We apply the proposed model to three datasets about movie, book, and music recommendation, and experiment results demonstrate that our approach outperforms strong recommender baselines.

1 INTRODUCTION

With the advance of Internet technology, people can access a vast amount of online content, such as news [25], movies [5], and commodities [26]. A notorious problem with online platforms is that the volume of items can be overwhelming to users. To alleviate the impact of information overloading, recommender systems (RS) is proposed to search for and recommend a small set of items to meet users' personalized interests.

A traditional recommendation technique is collaborative filtering (CF), which assigns users and items ID-based representation vectors, then models their interactions by specific operation such as inner product [16] or neural networks [8]. However, CF-based methods usually suffer from sparsity of user-item interactions and the cold start problem. To address these limitations, researchers usually turn to feature-rich scenarios, where attributes of users and items are used to compensate for the sparsity and improve the performance of recommendation [3, 17].

A few recent studies [9, 18, 19, 22–24] have gone a step further than simply using attributes: They point out that attributes are not isolated but linked up with each other, which forms a *knowledge graph* (KG). Typically, a KG is a directed heterogeneous graph in which nodes correspond to *entities* (items or item attributes) and edges correspond to *relations*. Compared with KG-free methods, incorporating KG into recommendation benefits the results in three ways [18]: (1) The rich semantic relatedness among items in a KG can help explore their latent connections and improve the *precision* of results; (2) The various types of relations in a KG are helpful for extending a user's interests reasonably and increasing the *diversity* of recommended items; (3) KG connects a user's historically-liked and recommended items, thereby bringing *explainability* to recommender systems.

Despite the above benefits, utilizing KG in RS is rather challenging due to its high dimensionality and heterogeneity. One feasible way is to preprocess the KG by *knowledge graph embedding* (KGE) methods [20], which map entities and relations to low-dimensional representation vectors [9, 19, 23]. However, commonly-used KGE methods focus on modeling rigorous semantic relatedness (e.g., TransE [1] and TransR [12] assume $head + relation = tail$), which are more suitable for in-graph applications such as KG completion and link prediction rather than recommendation. A more natural and intuitive way is to design a graph algorithm directly to

exploit the KG structure [18, 22, 24]. For example, PER [22] and FMG [24] treat KG as a heterogeneous information network, and extract meta-path/meta-graph based latent features to represent the connectivity between users and items along different types of relation paths/graphs. However, PER and FMG rely heavily on manually designed meta-paths or meta-graphs, which are hardly to be optimal in reality. RippleNet [18] is a memory-network-like model that propagates users' potential preferences in the KG and explores their hierarchical interests. But note that the importance of relations is weakly characterized in RippleNet, because the embedding matrix of a relation $\mathbf{R}$ can hardly be trained to capture the sense of importance in the quadratic form $\mathbf{v}^\top \mathbf{R}\mathbf{h}$ ($\mathbf{v}$ and $\mathbf{h}$ are embedding vectors of two entities). In addition, the size of ripple set may go unpredictably with the increase of the size of KG, which incurs heavy computation and storage overhead.

In this paper, we investigate the problem of KG-aware recommendation. Our design objective is to automatically capture both high-order structure and semantic information in the KG. Inspired by graph convolutional networks (GCN)[1] that try to generalize convolution to the graph domain, we propose **K**nowledge **G**raph **C**onvolutional **N**etworks (KGCN) for recommender systems. The key idea of KGCN is to aggregate and incorporate neighborhood information with bias when calculating the representation of a given entity in the KG. Such a design has two advantages: (1) Through the operation of neighborhood aggregation, the *local proximity structure* is successfully captured and stored in each entity. (2) Neighbors are weighted by scores dependent on the connecting relation and specific user, which characterizes both the *semantic information of KG* and *users' personalized interests in relations*. Note that the size of an entity's neighbors varies and may be prohibitively large in the worst case. Therefore, we sample a fixed-size neighborhood of each node as the receptive field, which makes the cost of KGCN predictable. The definition of neighborhood for a given entity can also be extended hierarchically to multiple hops away to model *high-order* entity dependencies and capture users' potential *long-distance* interests.

Empirically, we apply KGCN to three datasets: MovieLens-20M (movie), Book-Crossing (book), and Last.FM (music). The experiment results show that KGCN achieves average AUC gains of 4.4%, 8.1%, and 6.2% in movie, book, and music recommendations, respectively, compared with state-of-the-art baselines for recommendation.

Our contribution in this paper are summarized as follows:

- We propose knowledge graph convolutional networks, an end-to-end framework that explores users' preferences on the knowledge graph for recommender systems. By extending the receptive field of each entity in the KG, KGCN is able to capture users' high-order personalized interests.
- We conduct experiments on three real-world recommendation scenarios. The results demonstrate the efficacy of KGCN-LS over state-of-the-art baselines.
- We release the code of KGCN and datasets (knowledge graphs) to researchers for validating the reported results and conducting further research. The code and the data are available at https://github.com/hwwang55/KGCN.

[1]We will revisit GCN in related work.

2 RELATED WORK

Our method is conceptually inspired by GCN. In general, GCN can be categorized as spectral methods and non-spectral methods. Spectral methods represent graphs and perform convolution in the spectral space. For example, Bruna et al. [2] define the convolution in Fourier domain and calculates the eigendecomposition of the graph Laplacian, Defferrard et al. [4] approximate the convolutional filters by Chebyshev expansion of the graph Laplacian, and Kipf et al. [10] propose a convolutional architecture via a localized first-order approximation of spectral graph convolutions. In contrast, non-spectral methods operate on the original graph directly and define convolution for groups of nodes. To handle the neighborhoods with varying size and maintain the weight sharing property of CNN, researchers propose learning a weight matrix for each node degree [6], extracting locally connected regions from graphs [13], or sampling a fixed-size set of neighbors as the support size [7]. Our work can be seen as a non-spectral method for a special type of graphs (i.e., knowledge graph).

Our method also connects to PinSage [21] and GAT [15]. But note that both PinSage and GAT are designed for homogeneous graphs. The major difference between our work and the literature is that we offer a new perspective for recommender systems with the assistance of a heterogeneous knowledge graph.

3 KNOWLEDGE GRAPH CONVOLUTIONAL NETWORKS

In this section, we introduce the proposed KGCN model. We first formulate the knowledge-graph-aware recommendation problem. Then we present the design of a single layer of KGCN. At last, we introduce the complete learning algorithm for KGCN, as well as its minibatach implementation.

3.1 Problem Formulation

We formulate the knowledge-graph-aware recommendation problem as follows. In a typical recommendation scenario, we have a set of M users $\mathcal{U} = \{u_1, u_2, ..., u_M\}$ and a set of N items $\mathcal{V} = \{v_1, v_2, ..., v_N\}$. The user-item interaction matrix $\mathbf{Y} \in \mathbb{R}^{M \times N}$ is defined according to users' implicit feedback, where $y_{uv} = 1$ indicates that user u engages with item v, such as clicking, browsing, or purchasing; otherwise $y_{uv} = 0$. Additionally, we also have a knowledge graph $\mathcal{G}$, which is comprised of entity-relation-entity triples (h, r, t). Here $h \in \mathcal{E}$, $r \in \mathcal{R}$, and $t \in \mathcal{E}$ denote the head, relation, and tail of a knowledge triple, $\mathcal{E}$ and $\mathcal{R}$ are the set of entities and relations in the knowledge graph, respectively. For example, the triple (*A Song of Ice and Fire*, *book.book.author*, *George Martin*) states the fact that George Martin writes the book "A Song of Ice and Fire". In many recommendation scenarios, an item $v \in \mathcal{V}$ corresponds to one entity $e \in \mathcal{E}$. For example, in book recommendation, the item "A Song of Ice and Fire" also appears in the knowledge graph as an entity with the same name.

Given the user-item interaction matrix $\mathbf{Y}$ as well as the knowledge graph $\mathcal{G}$, we aim to predict whether user u has potential interest in item v with which he has had no interaction before. Our goal is to learn a prediction function $\hat{y}_{uv} = \mathcal{F}(u, v|\Theta, \mathbf{Y}, \mathcal{G})$, where $\hat{y}_{uv}$ denotes the probability that user u will engage with item v, and Θ denotes the model parameters of function $\mathcal{F}$.

3.2 KGCN Layer

KGCN is proposed to capture high-order structural proximity among entities in a knowledge graph. We start by describing a single KGCN layer in this subsection. Consider a candidate pair of user u and item (entity) v. We use $\mathcal{N}(v)$ to denote the set of entities directly connected to v,[2] and r_{e_i,e_j} to denote the relation between entity e_i and e_j. We also use a function $g : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ (e.g., inner product) to compute the score between a user and a relation:

$$\pi_r^u = g(\mathbf{u}, \mathbf{r}), \tag{1}$$

where $\mathbf{u} \in \mathbb{R}^d$ and $\mathbf{r} \in \mathbb{R}^d$ are the representations of user u and relation r, respectively, d is the dimension of representations. In general, π_r^u characterizes the importance of relation r to user u. For example, a user may have more potential interests in the movies that share the same "star" with his historically liked ones, while another user may be more concerned about the "genre" of movies.

To characterize the topological proximity structure of item v, we compute the linear combination of v's neighborhood:

$$\mathbf{v}_{\mathcal{N}(v)}^u = \sum_{e \in \mathcal{N}(v)} \tilde{\pi}_{r_{v,e}}^u \mathbf{e}, \tag{2}$$

where $\tilde{\pi}_{r_{v,e}}^u$ is the normalized user-relation score

$$\tilde{\pi}_{r_{v,e}}^u = \frac{\exp(\pi_{r_{v,e}}^u)}{\sum_{e \in \mathcal{N}(v)} \exp(\pi_{r_{v,e}}^u)}, \tag{3}$$

and $\mathbf{e}$ is the representation of entity e. User-relation scores act as *personalized filters* when computing an entity's neighborhood representation, since we aggregate the neighbors with bias with respect to these user-specific scores.

In a real-world knowledge graph, the size of $\mathcal{N}(e)$ may vary significantly over all entities. To keep the computational pattern of each batch fixed and more efficient, we uniformly sample a fixed-size set of neighbors for each entity instead of using its full neighbors. Specifically, we compute the neighborhood representation of entity v as $\mathbf{v}_{\mathcal{S}(v)}^u$, where $\mathcal{S}(v) \triangleq \{e \mid e \sim \mathcal{N}(v)\}$ and $|\mathcal{S}(v)| = K$ is a configurable constant.[3] In KGCN, $\mathcal{S}(v)$ is also called the (single-layer) *receptive field* of entity v, as the final representation of v is sensitive to these locations. Figure 1a gives an illustrative example of a two-layer receptive field for a given entity, where K is set as 2.

The final step in a KGCN layer is to aggregate the entity representation $\mathbf{v}$ and its neighborhood representation $\mathbf{v}_{\mathcal{S}(v)}^u$ into a single vector. We implement three types of aggregators $agg : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}^d$ in KGCN:

- *Sum aggregator* takes the summation of two representation vectors, followed by a nonlinear transformation:

$$agg_{sum} = \sigma\left(\mathbf{W} \cdot (\mathbf{v} + \mathbf{v}_{\mathcal{S}(v)}^u) + \mathbf{b}\right), \tag{4}$$

  where $\mathbf{W}$ and $\mathbf{b}$ are transformation weight and bias, respectively, and σ is the nonlinear function such *ReLU*.
- *Concat aggregator* [7] concatenates the two representation vectors first before applying nonlinear transformation:

$$agg_{concat} = \sigma\left(\mathbf{W} \cdot concat(\mathbf{v}, \mathbf{v}_{\mathcal{S}(v)}^u) + \mathbf{b}\right). \tag{5}$$

[2]The knowledge graph $\mathcal{G}$ is treated undirected.
[3]Technically, $\mathcal{S}(v)$ may contain duplicates if $\mathcal{N}(v) < K$.

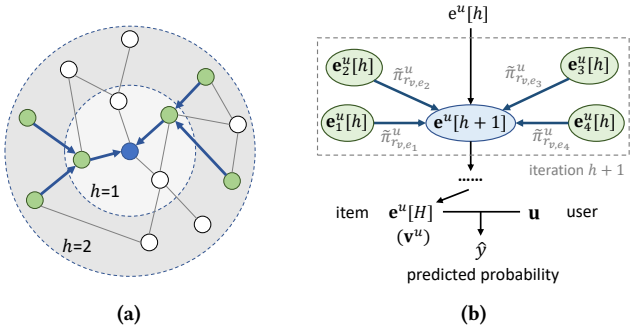

Figure 1: (a) A two-layer receptive field (green entities) of the blue entity in a KG. (b) The framework of KGCN.

- *Neighbor aggregator* [15] directly takes the neighborhood representation of entity v as the output representation:

$$agg_{neighbor} = \sigma\left(\mathbf{W} \cdot \mathbf{v}_{\mathcal{S}(v)}^u + \mathbf{b}\right). \tag{6}$$

Aggregation is a key step in KGCN, because the representation of an item is bound up with its neighbors by aggregation. We will evaluate the three aggregators in experiments.

3.3 Learning Algorithm

Through a single KGCN layer, the final representation of an entity is dependent on itself as well as its immediate neighbors, which we name 1-order entity representation. It is natural to extend KGCN from one layer to multiple layers to reasonably explore users' potential interests in a broader and deeper way. The technique is intuitive: Propagating the initial representation of each entity (0-order representation) to its neighbors leads to 1-order entity representation, then we can repeat this procedure, i.e., further propagating and aggregating 1-order representations to obtain 2-order ones. Generally speaking, the h-order representation of an entity is a mixture of initial representations of itself and its neighbors up to h hops away. This is an important property for KGCN, which we will discuss in the next subsection.

The formal description of the above steps is presented in Algorithm 1. H denotes the maximum depth of receptive field (or equivalently, the number of aggregation iterations), and a suffix $[h]$ attached by a representation vector denotes h-order. For a given user-item pair (u, v) (line 2), we first calculate the receptive field $\mathcal{M}$ of v in an iterative layer-by-layer manner (line 3, 13-19). Then the aggregation is repeated H times (line 5): In iteration h, we calculate the neighborhood representation of each entity $e \in \mathcal{M}[h]$ (line 7), then aggregate it with its own representation $\mathbf{e}^u[h-1]$ to obtain the one to be used at the next iteration (line 8). The final H-order entity representation is denoted as $\mathbf{v}^u$ (line 9), which is fed into a function $f : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ together with user representation $\mathbf{u}$ for predicting the probability:

$$\hat{y}_{uv} = f(\mathbf{u}, \mathbf{v}^u). \tag{7}$$

Figure 1b illustrates the KGCN algorithm in one iteration, in which the entity representation $\mathbf{v}^u[h]$ and neighborhood representations (green nodes) of a given node are mixed to form its representation for the next iteration (blue node).

Algorithm 1: KGCN algorithm

Input: Interaction matrix $\mathbf{Y}$; knowledge graph $\mathcal{G}(\mathcal{E}, \mathcal{R})$; neighborhood sampling mapping $\mathcal{S} : e \to 2^{\mathcal{E}}$; trainable parameters: $\{\mathbf{u}\}_{u\in\mathcal{U}}$, $\{\mathbf{e}\}_{e\in\mathcal{E}}$, $\{\mathbf{r}\}_{r\in\mathcal{R}}$, $\{\mathbf{W}_i, \mathbf{b}_i\}_{i=1}^{H}$; hyper-parameters: H, d, $g(\cdot)$, $f(\cdot)$, $\sigma(\cdot)$, $agg(\cdot)$

Output: Prediction function $\mathcal{F}(u, v|\Theta, \mathbf{Y}, \mathcal{G})$

1 **while** *KGCN not converge* **do**
2 **for** (u, v) *in* $\mathbf{Y}$ **do**
3 $\{\mathcal{M}[i]\}_{i=0}^{H} \leftarrow$ Get-Receptive-Field (v);
4 $\mathbf{e}^u[0] \leftarrow \mathbf{e}, \forall e \in \mathcal{M}[0]$;
5 **for** $h = 1, ..., H$ **do**
6 **for** $e \in \mathcal{M}[h]$ **do**
7 $\mathbf{e}^u_{\mathcal{S}(e)}[h-1] \leftarrow \sum_{e'\in\mathcal{S}(e)} \tilde{\pi}^u_{r_{e,e'}} \mathbf{e}'^u[h-1]$;
8 $\mathbf{e}^u[h] \leftarrow agg\left(\mathbf{e}^u_{\mathcal{S}(e)}[h-1], \mathbf{e}^u[h-1]\right)$;
9 $\mathbf{v}^u \leftarrow \mathbf{e}^u[H]$;
10 Calculate predicted probability $\hat{y}_{uv} = f(\mathbf{u}, \mathbf{v}^u)$;
11 Update parameters by gradient descent;
12 **return** $\mathcal{F}$;
13 **Function** Get-Receptive-Field (v)
14 $\mathcal{M}[H] \leftarrow v$;
15 **for** $h = H-1, ..., 0$ **do**
16 $\mathcal{M}[h] \leftarrow \mathcal{M}[h+1]$;
17 **for** $e \in \mathcal{M}[h+1]$ **do**
18 $\mathcal{M}[h] \leftarrow \mathcal{M}[h] \cup \mathcal{S}(e)$;
19 **return** $\{\mathcal{M}[i]\}_{i=0}^{H}$;

Note that Algorithm 1 traverses all possible user-item pairs (line 2). To make computation more efficient, we use a negative sampling strategy during training. The complete loss function is as follows:

$$\mathcal{L} = \sum_{u\in\mathcal{U}} \left(\sum_{v:y_{uv}=1} \mathcal{J}(y_{uv}, \hat{y}_{uv}) - \sum_{i=1}^{T^u} \mathbb{E}_{v_i\sim P(v_i)} \mathcal{J}(y_{uv_i}, \hat{y}_{uv_i}) \right) + \lambda \|\mathcal{F}\|_2^2, \tag{8}$$

where $\mathcal{J}$ is cross-entropy loss, P is a negative sampling distribution, and T^u is the number of negative samples for user u. In this paper, $T^u = |\{v : y_{uv} = 1\}|$ and P follows a uniform distribution. The last term is the L2-regularizer.

4 EXPERIMENTS

In this section, we evaluate KGCN on three real-world scenarios: movie, book, and music recommendations.

4.1 Datasets

We utilize the following three datasets in our experiments for movie, book, and music recommendation, respectively:

- **MovieLens-20M**[4] is a widely used benchmark dataset in movie recommendations, which consists of approximately 20 million explicit ratings (ranging from 1 to 5) on the MovieLens website.

[4]https://grouplens.org/datasets/movielens/

Table 1: Basic statistics and hyper-parameter settings for the three datasets (K: neighbor sampling size, d: dimension of embeddings, H: depth of receptive field, λ: L2 regularizer weight, η: learning rate).

	MovieLens-20M	Book-Crossing	Last.FM
# users	138,159	19,676	1,872
# items	16,954	20,003	3,846
# interactions	13,501,622	172,576	42,346
# entities	102,569	25,787	9,366
# relations	32	18	60
# KG triples	499,474	60,787	15,518
K	4	8	8
d	32	64	16
H	2	1	1
λ	10^{-7}	2×10^{-5}	10^{-4}
η	2×10^{-2}	2×10^{-4}	5×10^{-4}
batch size	65,536	256	128

- **Book-Crossing**[5] contains 1 million ratings (ranging from 0 to 10) of books in the Book-Crossing community.
- **Last.FM**[6] contains musician listening information from a set of 2 thousand users from Last.fm online music system.

Since the three datasets are explicit feedbacks, we transform them into implicit feedback where each entry is marked with 1 indicating that the user has rated the item positively, and sample an unwatched set marked as 0 for each user. The threshold of positive rating is 4 for MovieLens-20M, while no threshold is set for Book-Crossing and Last.FM due to their sparsity.

We use Microsoft Satori[7] to construct the knowledge graph for each dataset. We first select a subset of triples from the whole KG with a confidence level greater than 0.9. Given the sub-KG, we collect Satori IDs of all valid movies/books/musicians by matching their names with tail of triples *(head, film.film.name, tail)*, *(head, book.book.title, tail)*, or *(head, type.object.name, tail)*. Items with multiple matched or no matched entities are excluded for simplicity. We then match the item IDs with the head of all triples and select all well-matched triples from the sub-KG. The basic statistics of the three datasets are presented in Table 1.

4.2 Baselines

We compare the proposed KGCN with the following baselines, in which the first two baselines are KG-free while the rest are all KG-aware methods. Hyper-parameter settings for baselines are introduced in the next subsection.

- **SVD** [11] is a classic CF-based model using inner product to model user-item interactions.[8]
- **LibFM** [14] is a feature-based factorization model in CTR scenarios. We concatenate user ID and item ID as input for LibFM.

[5]http://www2.informatik.uni-freiburg.de/~cziegler/BX/
[6]https://grouplens.org/datasets/hetrec-2011/
[7]https://searchengineland.com/library/bing/bing-satori
[8]We have tried NCF [8], i.e., replacing inner product with neural networks, but the result is inferior to SVD. Since SVD and NCF are similar, we only present the better one here.

Table 2: The results of *AUC* and *F1* in CTR prediction.

Model	MovieLens-20M		Book-Crossing		Last.FM	
	AUC	*F1*	*AUC*	*F1*	*AUC*	*F1*
SVD	0.963 (-1.5%)	0.919 (-1.4%)	0.672 (-8.9%)	0.635 (-7.7%)	0.769 (-3.4%)	0.696 (-3.5%)
LibFM	0.959 (-1.9%)	0.906 (-2.8%)	0.691 (-6.4%)	0.618 (-10.2%)	0.778 (-2.3%)	0.710 (-1.5%)
LibFM + TransE	0.966 (-1.2%)	0.917 (-1.6%)	0.698 (-5.4%)	0.622 (-9.6%)	0.777 (-2.4%)	0.709 (-1.7%)
PER	0.832 (-14.9%)	0.788 (-15.5%)	0.617 (-16.4%)	0.562 (-18.3%)	0.633 (-20.5%)	0.596 (-17.3%)
CKE	0.924 (-5.5%)	0.871 (-6.5%)	0.677 (-8.3%)	0.611 (-11.2%)	0.744 (-6.5%)	0.673 (-6.7%)
RippleNet	0.968 (-1.0%)	0.912 (-2.1%)	0.715 (-3.1%)	0.650 (-5.5%)	0.780 (-2.0%)	0.702 (-2.6%)

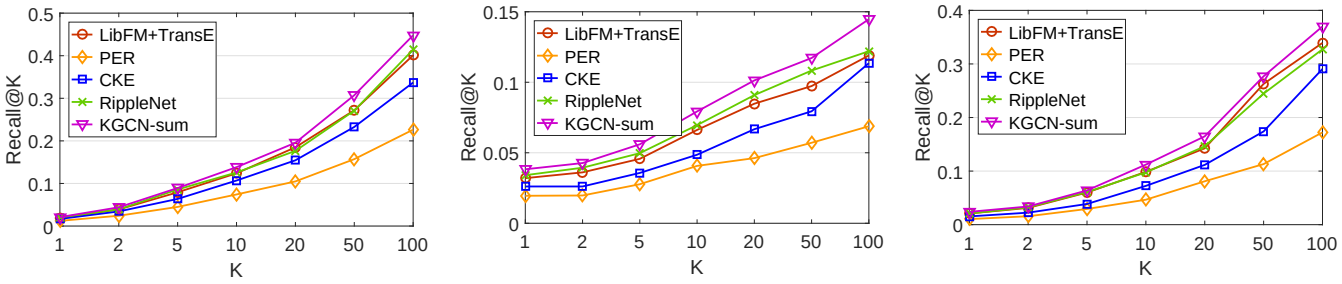
KGCN-avg	0.975 (-0.3%)	0.929 (-0.3%)	0.722 (-2.2%)	0.682 (-0.9%)	0.774 (-2.8%)	0.692 (-4.0%)

* Statistically significant improvement by unpaired two-sample t-test with $p = 0.1$.

- **LibFM + TransE** extends LibFM by attaching an entity representation learned by TransE [1] to each user-item pair.
- **PER** [22] treats the KG as heterogeneous information networks and extracts meta-path based features to represent the connectivity between users and items.
- **CKE** [23] combines CF with structural, textual, and visual knowledge in a unified framework for recommendation. We implement CKE as CF plus a structural knowledge module in this paper.
- **RippleNet** [18] is a memory-network-like approach that propagates users' preferences on the KG for recommendation.

4.3 Experiments Setup

In KGCN, we set functions g and f as inner product, σ as *ReLU* for non-last-layer aggregator and *tanh* for last-layer aggregator. Other hyper-parameter settings are provided in Table 1. The hyper-parameters are determined by optimizing *AUC* on a validation set. For each dataset, the ratio of training, evaluation, and test set is $6:2:2$. Each experiment is repeated 3 times, and the average performance is reported. We evaluate our method in two experiment scenarios: (1) In click-through rate (CTR) prediction, we apply the trained model to predict each interaction in the test set. We use *AUC* and *F1* to evaluate CTR prediction. (2) In top-K recommendation, we use the trained model to select K items with highest predicted click probability for each user in the test set, and choose *Recall@K* to evaluate the recommended sets. All trainable parameters are optimized by Adam algorithm. The code of KGCN-LS is implemented under Python 3.6, TensorFlow 1.12.0, and NumPy 1.14.3.



The hyper-parameter settings for baselines are as follows. For SVD, we use the unbiased version (i.e., the predicted rating is modeled as $r_{pq} = \mathbf{p}^\top \mathbf{q}$). The dimension and learning rate for the four datasets are set as: $d = 8$, $\eta = 0.5$ for MovieLens-20M, Book-Crossing; $d = 8$, $\eta = 0.1$ for Last.FM. For LibFM, the dimension is $\{1, 1, 8\}$ and the number of training epochs is 50. The dimension of TransE is 32. For PER, we use manually designed user-item-attribute-item paths as features (i.e., "user-movie-director-movie", "user-movie-genre-movie", and "user-movie-star-movie" for MovieLens-20M; "user-book-author-book" and "user-book-genre-book" for Book-Crossing, "user-musician-date_of_birth-musician" (date of birth is discretized), "user-musician-country-musician", and "user-musician-genre-musician" for Last.FM). For CKE, the dimension of the three datasets are 64, 128, 64. The training weight for KG part is 0.1 for all datasets. The learning rate are the same as in SVD. For RippleNet, $d = 8$, $H = 2$, $\lambda_1 = 10^{-6}$, $\lambda_2 = 0.01$, $\eta = 0.01$ for MovieLens-20M; $d = 16$, $H = 3$, $\lambda_1 = 10^{-5}$, $\lambda_2 = 0.02$, $\eta = 0.005$ for Last.FM. Other hyper-parameters are the same as reported in their original papers or as default in their codes.

4.4 Results

The results of CTR prediction and top-K recommendation are presented in Table 2 and Figure 2, respectively (SVD, LibFM and other variants of KGCN are not plotted in Figure 2 for clarity). We have the following observations:

- In general, we find that the improvements of KGCN on book and music are higher than movie. This demonstrates that KGCN can well address sparse scenarios, since Book-Crossing and Last.FM are much sparser than MovieLens-20M.
- The performance of KG-free baselines, SVD and LibFM, are actually better than the two KG-aware baselines PER and CKE, which indicates that PER and CKE cannot make full use of the KG with manually designed meta-paths and TransR-like regularization.
- LibFM + TransE is better than LibFM in most cases, which demonstrates that the introduction of KG is helpful for recommendation in general.
- PER performs worst among all baselines, since it is hard to define optimal meta-paths in reality.
- RippleNet shows strong performance compared with other baselines. Note that RippleNet also uses multi-hop neighborhood structure, which interestingly shows that capturing proximity information in the KG is essential for recommendation.

The last four rows in Table 2 summarize the performance of KGCN variants. The first three (sum, concat, neighbor) correspond to different aggregators introduced in the preceding section, while the last variant KGCN-avg is a reduced case of KGCN-sum where

(a) MovieLens-20M **(b) Book-Crossing** **(c) Last.FM**

Figure 2: The results of *Recall@K* in top-K recommendation.

Table 3: *AUC* result of KGCN with different neighbor sampling size K.

K	2	4	8	16	32	64
MovieLens-20M	0.978	**0.979**	0.978	0.978	0.977	0.978
Book-Crossing	0.680	0.727	**0.736**	0.725	0.711	0.723
Last.FM	0.791	0.794	**0.795**	0.793	0.794	0.792

Table 4: *AUC* result of KGCN with different depth of receptive field H.

H	1	2	3	4
MovieLens-20M	0.972	**0.976**	0.974	0.514
Book-Crossing	**0.738**	0.731	0.684	0.547
Last.FM	**0.794**	0.723	0.545	0.534

neighborhood representations are directly averaged without user-relation scores (i.e., $\mathbf{v}^u_{\mathcal{N}(v)} = \sum_{e \in \mathcal{N}(v)} \mathbf{e}$ instead of Eq. (2)). Therefore, KGCN-avg is used to examine the efficacy of the "attention mechanism". From the results we find that:

- KGCN outperforms all baselines by a significant margin, while their performances are slightly distinct: KGCN-sum performs best in general, while the performance of KGCN-neighbor shows a clear gap on Book-Crossing and Last.FM. This may be because the neighbor aggregator uses the neighborhood representation only, thus losing useful information from the entity itself.
- KGCN-avg performs worse than KGCN-sum, especially in Book-Crossing and Last.FM where interactions are sparse. This demonstrates that capturing users' personalized preferences and semantic information of the KG do benefit the recommendation.

4.4.1 Impact of neighbor sampling size. We vary the size of sampled neighbor K to investigate the efficacy of usage of the KG. From Table 3 we observe that KGCN achieves the best performance when $K = 4$ or 8. This is because a too small K does not have enough capacity to incorporate neighborhood information, while a too large K is prone to be misled by noises.

4.4.2 Impact of depth of receptive field. We investigate the influence of depth of receptive field in KGCN by varying H from 1 to 4. The results are shown in Table 4, which demonstrate that KGCN is more sensitive to H compared to K. We observe the occurrence of serious model collapse when $H = 3$ or 4, as a larger H brings massive noises to the model. This is also in accordance with our intuition, since a too long relation-chain makes little sense when inferring inter-item similarities. An H of 1 or 2 is enough for real cases according to the experiment results.

Table 5: *AUC* result of KGCN with different dimension of embedding.

d	4	8	16	32	64	128
MovieLens-20M	0.968	0.970	0.975	**0.977**	0.973	0.972
Book-Crossing	0.709	0.732	0.733	0.735	**0.739**	0.736
Last.FM	0.789	0.793	**0.797**	0.793	0.790	0.789

4.4.3 Impact of dimension of embedding. Lastly, we examine the influence of dimension of embedding d on performance of KGCN. The result in Table 5 is rather intuitive: Increasing d initially can boost the performance since a larger d can encode more information of users and entities, while a too large d adversely suffers from overfitting.

5 CONCLUSIONS AND FUTURE WORK

This paper proposes knowledge graph convolutional networks for recommender systems. KGCN extends non-spectral GCN approaches to the knowledge graph by aggregating neighborhood information selectively and biasedly, which is able to learn both structure information and semantic information of the KG as well as users' personalized and potential interests. We also implement the proposed method in a minibatch fashion, which is able to operate on large datasets and knowledge graphs. Through extensive experiments on real-world datasets, KGCN is shown to consistently outperform state-of-the-art baselines in movie, book, and music recommendation.

We point out three avenues for future work. (1) In this work we uniformly sample from the neighbors of an entity to construct its receptive field. Exploring a non-uniform sampler (e.g., importance sampling) is an important direction of future work. (2) This paper (and all literature) focuses on modeling item-end KGs. An interesting direction of future work is to investigate whether leveraging user-end KGs is useful in improving the performance of recommendation. (3) Designing an algorithm to well combine KGs at the two ends is also a promising direction.

ABSTRACT

Network embedding is a method to learn low-dimensional representation vectors for nodes in complex networks. In real networks, nodes may have multiple tags but existing methods ignore the abundant semantic and hierarchical information of tags. This information is useful to many network applications and usually very stable. In this paper, we propose a tag representation learning model, Tag2Vec, which mixes nodes and tags into a hybrid network. Firstly, for tag networks, we define semantic distance as the proximity between tags and design a novel strategy, parameterized random walk, to generate context with semantic and hierarchical information of tags adaptively. Then, we propose hyperbolic Skip-gram model to express the complex hierarchical structure better with lower output dimensions. We evaluate our model on the NBER U.S. patent dataset and WordNet dataset. The results show that our model can learn tag representations with rich semantic information and it outperforms other baselines.

1 INTRODUCTION

Network embedding is a method to learn low-dimensional representation vectors for nodes in complex network and has drawn much attention recently [16, 27, 30]. The representation vectors helps to complete many machine learning tasks, such as node classification [3], node clustering [23] and link prediction [21].

But in real networks, nodes are often attached with multiple tags, and each tag represents a characteristic of the node. For example, there are interested domain tags of researchers in academic networks and discussion topic tags of users in forum networks [20]. Tags have abundant semantic information, which can be used to measure the semantic distances between tags. For example, in academic networks, considering the semantic distance between two interested domain tags, Artificial Intelligence is closer to Machine Learning than Operating System. In addition, tags have abundant hierarchical information. For example, Optics and Transportation are the sub-categories of Mechanical, which should be considered when leaning their representations. But considering tags as discrete features with one-hot encoding in previous work is based on a simple assumption that different features are irrelevant. It will also cause the sparsity of vectors and inefficiency of algorithms.

Therefore, similar to learning the node representation vectors, we want to learn the tag representation vectors in networks, so that the semantic distances between tags can be reflected. On the one hand, because of the semantic and hierarchical information of tag representations, they can help to improve the performance of network applications and study the characteristics and behaviors of tags. On the other hand, as tags are usually stable, we can obtain good representations even though part of networks is lacking.

Existing network embedding methods, such as DeepWalk [27] and LINE [30], only learn the node representations. But tag networks are a special kind of heterogeneous networks which contains the interaction relationship between nodes as well as the affiliation relationship of tags and nodes. There are two main challenges of learning tag representations in the heterogeneous networks:

- *How to learn the semantic information of tags?* If two nodes have tags with similar semantic information, they will have small semantic distance. If two tags have many members with close relationship, they will be close as for semantic

distance. So in tag representation learning, we have to consider the semantic information of nodes and tags. Besides, we need to distinguish the interaction relationship between nodes and the affiliation relationship between tags.

- *How to represent the tags?* In tag representation, we describe the complex traverse and vertical structure of tags with the help of interaction relationships between nodes and affiliation relationships between nodes and tags. Traditional embedding methods learn interaction relationships in Euclidean spaces, but ignore affiliation relationships. If we use tree-like structure to describe the data in Euclidean spaces, it will causes the problem of high computational cost and data sparsity when the hierarchical structure becomes complex.

In this paper, we propose a tag representation learning model, Tag2Vec. We learn the representation vectors of tags to reflect their semantic information and hierarchical structure. Firstly, we mix tags and nodes into a hybrid network to consider the influence of semantic information between tags and nodes. We adopt the parameterized random walk strategy to generate the context that reflects the semantic distance between tags. Then, because of the disability of learning vertical affiliation relationship in Euclidean spaces, we propose the hyperbolic Skip-gram model to learn representation vectors in hyperbolic spaces. Hyperbolic spaces are a kind of metric spaces, and they expand exponentially with regard to the radius r. They confirm to the growth of hierarchical relationship of tags so that learning representations in hyperbolic spaces can better describe the affiliation relationship of tag networks.

The main contribution of this paper is:

- We propose a tag representation learning model Tag2Vec, which learns tag representation vectors in networks to reflect the semantic information of tags.
- We design a parameterized random walk strategy to generate the context with semantic information. It sets parameters to control the proportion of different semantic information.
- We propose hyperbolic Skip-gram model to learn representations in hyperbolic spaces. We improve the representative ability of tag vectors with the help of two advantages of hyperbolic spaces: capable to learn affiliation relationship and reduce the dimensions.

We conduct experiments on two datasets. The results demonstrate that our model can learn representations with rich semantic information of tags and is superior than baselines.

2 RELATED WORK

As tags are usually text or labels, they can be regarded as special nodes in heterogeneous networks or attributes of nodes. Meanwhile, the hierarchical structure of tags can be expressed in hyperbolic spaces. So we discuss related work of three kinds of network embedding methods [9] separately: structure-preserving, attribute-preserving and hyperbolic network embedding.

Many successful network embedding methods have been proposed recently for preserving topological structure [7, 12, 16, 27, 30, 31]. They are working on a homogeneous network but insufficient in networks with tags for the ignorance of tag information. A feasible method is to build heterogeneous networks, where tags are regarded as another type of nodes. Existing heterogeneous network embedding methods can be achieved by partitioning heterogeneous networks into a set of networks [29, 33], establishing a deep learning structure [8, 32], or using meta path based models [10, 13, 19]. However, these methods ignore the higher status of tags in hybrid networks and also leave the hierarchy between tags hidden. Therefore, Tag2Vec is proposed in order to represent tags with both semantic and hierarchical information clearly.

Attribute-preserving network embedding methods embed nodes according to both the graph topology and the node attributes. An attribute of a node can be a text [34], a label [18, 26], or the node content [26, 28]. If two nodes have similar attributes, they will have close embedding vectors. However, attribute-preserving network embedding does not give every attribute an embedding vector and does not learn semantic information between attributes explicitly. Tag2Vec learns the representations of tags and nodes simultaneously, modelling the relationship between nodes and between tags.

Many real world networks actually have hierarchical or tree-like structure [1]. Learning representations in Euclidean spaces requires large dimensions to hold a network with complex hierarchical relationships[6, 24]. Hyperbolic space [4, 15] can reflect the latent hierarchy of embedded nodes with low dimensions. Poincare network embedding [25] embeds words into hyperbolic space in a way such that their distance in the embedding space reflects their semantic similarity. [14] embeds acyclic graphs into hyperbolic space to learn their hierarchical features. But these methods only focus on learning representations in homogeneous networks without tags. In this work, we learn the representations of both nodes and tags under the hyperbolic space.

3 PROBLEM DEFINITION

In this section, we define some problems in tag embedding formally.

Definition 3.1. A **Tagged Network** is defined as $G =< V, E, T >$, where $V = \{v_i\}, i = 1, 2, ..., n$ represents the set of nodes, $E = \{e_{ij}\}, i, j = 1, 2, ..., n, i \neq j$ represents the set of edges, and $T = \{T_i\}, i = 1, 2, ..., n$ represents the set of tags that each node belongs to. Each tag corresponds to a literal symbol and labels a characteristic of a a node. Each node v_i have k tags $T_i = \{t_{i_1}, t_{i_2}, ..., t_{i_k}\}, t_{i_j} \in T$. If node v_i is labeled by tag t, node v_i has a tag t.

In a tagged Network, an edge between two nodes reflects their interaction relationship, while an edge between a node and a tag reflects their affiliation relationship. For example, in social networks, a node is a user, and two users have friend relationship if there exists an edge between them. A tag of the node may be a characteristic label, an interested topic or a community of the user. A node corresponds to multiple tags and a tag corresponds a set of nodes.

The text of a tag can only reflect part of the semantic information. Its semantic information is decided by the characteristic of its nodes in spirit. Therefore, we introduce ground-truth community to define the semantic distance between tags.

Definition 3.2. A **Ground-truth Community** C_t is the set of nodes labeled by tag t.

A tag corresponds to a ground-truth community. The distance between tags is defined by the relationship between their ground-truth communities. In the following, we introduce two types of relationships between Ground-truth Communities.

Definition 3.3. **Member Similarity** is the ratio of the common members to all members in two ground-truth communities, which is extended from the definition of common neighbor similarity [11]:

$$D_{MS}(C_{t_1}, C_{t_2}) = \frac{|C_{t_1} \cap C_{t_2}|^2}{|C_{t_1}| \cdot |C_{t_2}|}.$$

For two tags in a tagged network, they are closer semantically if their ground-truth communities have more common members.

Definition 3.4. **Social Closeness** is the ratio of the connected edges between members of two ground-truth communities to all their inter-connected edges:

$$D_{SC}(C_{t_1}, C_{t_2}) = \frac{|Edge(C_{t_1}, C_{t_2})|^2}{|Edge(C_{t_1}, V - C_{t_1})| \cdot |Edge(C_{t_2}, V - C_{t_2})|},$$

where $Edge(C_{t_1}, C_{t_2})$ is the set of the connected edges between members of C_{t_1} and C_{t_2}, and $Edge(C_{t_1}, V - C_{t_1})$ is the set of all inter-connected edges of C_{t_1}.

For two tags in a tagged network, they may be close semantically if the members of their ground-truth communities have close relationship.

Definition 3.5. Given a tagged network $G =< V, E, T >$, the problem of **Tag Embedding** aims to represent each tag $t \in T$ in a low-dimensional space $\mathbb{R}^d$. In other words, it aims to learn a mapping function $f : T \to \mathbb{R}^d$, where $d << |V|$, and the representation vectors in $\mathbb{R}^d$ preserve both member similarity and social closeness between ground-truth communities.

The computational complexity of member similarity and social closeness is $\Theta(|T|^2)$, where $|T|$ is the number of tags. As the complexity of social closeness is related to node numbers of communities, average degrees of communities, and neighborhood orders, it will be much higher in realit. Therefore, to avoid the expensive computation, we mix the nodes and tags into the same network to learn their semantic information, including the member similarity and social closeness between the tags. And we call the mixed network as node-tag hybrid network:

Definition 3.6. A **Node-Tag Hybrid Network** $H =< V', E' >$ is derived from a tagged network $G =< V, E, T >$, where $V' = V + T, E' = E + E_T$. For $v' \in V'$, v' is a plain node if $v' \in V$. Otherwise, it is a tag node if $v' \in T$. For $e' \in E'$, e' is an interaction edge if $e' =< v_1, v_2 > \in E$. Otherwise, it is an affiliation edge if $e' =< v, t >$ and node v is labeled by tag t.

4 TAG REPRESENTATION LEARNING MODEL

If we regard a node-tag hybrid network as a normal network and use traditional network embedding methods, we can get the representations for both plain nodes and tag node. However, the difference between plain nodes and tag nodes in the Node-Tag Hybrid Network are ignored. And we can't learn the semantic information of tags explicitly, neither.

In this section, we propose Tag2Vec, a tag representation learning model. In a node-tag hybrid network, we design a new strategy, parameterized Random walk, to generate the context with both member similarity and social closeness information between tags. Meanwhile, We train a hyperbolic Skip-gram model with the generated context to learn the hyperbolic representation vectors of plain nodes and tag nodes. It can reduce the output dimensions and describe the transverse and vertical relationship between tags more accurately.

4.1 Parameterized Random Walk

We design a Tag2Vec parameterized random walk strategy in a node-tag hybrid network. Firstly, it can reflect both member similarity and social closeness between tags, and the ratio between their weights can be controlled by the parameter. Secondly, it should contain hierarchical information of both transverse and vertical relationship between tags for hyperbolic Skip-gram model, and the ratio between their weights can be controlled by the parameter, too. Specifically, we adopt two strategies to control parameters for different semantic information and different dimensional information.

4.1.1 Walk Patterns for Semantic Information. If two tags have similar semantic information, their representation vectors should be closer in the vector space. So, tag nodes with smaller semantic distance should appear more simultaneously in the context. As the semantic distance is decided by member similarity and social closeness, we consider two basic walk patterns for them respectively.

- **MS-driven walk.** As shown in Figure 1(a), in MS-driven walk, tag nodes with common members may appear simultaneously in the random walk sequences. There must be one and only one plain node between a pair of tag nodes, and the plain node is the common member of two tags.
- **SC-driven walk.** As shown in Figure 1(b), in SC-driven walk, tag nodes with connected members may appear simultaneously in the random walk sequences. There must be more than two plain nodes between a pair of tag nodes, and the adjacent plain nodes are connected.

(a) MS-driven walk. (b) SC-driven walk.

Figure 1: Walk Patterns.

We notice that in a node-tag hybrid network, there are no edges between tag nodes. Combining the two basic walk patterns, we find that when the current node is a tag node, the next node must be a plain node. When the current node is a plain node, the next node may be a tag node or a plain node.

When the current node is a tag node, we should select a member node from the ground-truth community of the tag. We consider that members with high social influence are more important to the community. So we calculate the weights of tag-to-plain edges according to the centrality, such as degree centrality, of plain nodes in the original network.

When the current node is a plain node, we should select the type of nodes as the next step, a tag node or a plain node. A tag node corresponds to MS-driven walk, and a tag node corresponds to SC-driven walk. So we set a parameter p as the probability to select a tag node and adopt the strategy of MS-driven walk.

4.1.2 Transverse and Vertical Relationship. As we discussed above, we introduce the hyperbolic representation vectors to distinguish the transverse interaction and vertical affiliation relationships, and discover the hierarchical semantic information of tags. This requires that the context generated by random walk must contain enough transverse and vertical relationships between tags. However, in a node-tag hybrid network, there are no edges between tags, and the correlation information between tags is obtained implicitly by the random walk sequence. We can know which type of relationship two tags have only when we finish the learning procedure. So we want to control the relationship between tags in the same sequence and the ratio between two types of relationships.

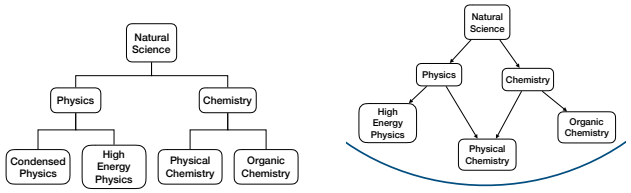
We find that the sizes of ground-truth communities are effective to infer the relationship between tags. If two tags have transverse interaction relationship, the difference between their community size may be small. While two tags with vertical affiliation relationship, the difference between their community size may be large. Thus, we can control the selection of the next tag in the random walk sequence according to their community sizes.

Specifically, in the random walk, if the current node is a plain node, we have to select a tag node from the tag neighbors as the next tag t. We consider the last tag t_{last} in the current random walk sequence and compare the community size of t_{last} with t. We consider two strategies.

- **Transverse Interaction Relationship.** If the next step is to sample for transverse social relationship, we tend to select the tags having similar community size with the last tag.

$$W_{simi}(v,t) = B \cdot \exp(-(|t| - |t_{last}|)^2)$$

- **Vertical Affiliation Relationship.** If the next step is to sample for vertical affiliation relationship, we tend to select the tags having different community size with the last tag.



$$W_{diff}(v,t) = B \cdot \exp((|t| - |t_{last}|)^2)$$

Notice that B is the normalization constant. We set a parameter q as the probability to adopt the transverse interaction relationship.

4.2 Hyperbolic Skip-Gram

In tag representation learning, the relationships between tags contain both transverse interaction relationships and vertical affiliation relationships. But in fact, most tag relationship is between transverse and vertical. For example, in Figure 2(a), it is a tree describing the relationships between research fields. A node and one its children have affiliation relationship, while the children of a node may have interaction relationship. But as for two subjects, Physics and Physical Chemistry, we can't describe their relationship in this tree.

Hyperbolic geometry is a non-Euclidean geometry that studies the spaces of constant negative curvature. It is capable to model the hierarchical structure with low dimensions. Meanwhile, in continuous hyperbolic spaces, there are no distinct hierarchies, which means there are no distinct affiliation relationships. In general, nodes with higher levels are placed closer to the origin of the sphere and the children of a node are placed in the area with similar angle and longer distance to the origin. We show relationships discussed above in a two-dimensional hyperbolic space in Figure 2(b). It describes the relationships between Physical Chemistry, Physics and Chemistry suitably. Besides, Euclidean spaces expand polynomially

(a) Tree Structure (b) Hyperbolic Structure

Figure 2: The Structure of A Tag Network

while hyperbolic spaces expand exponentially with regard to the radius r. So we can learn the representations in hyperbolic spaces with less parameters and lower dimensions. Therefore, embedding in hyperbolic spaces can not only describe the complex relationship between tags, but also reduce the output dimensions.

Existing network embedding method[25] uses a pure strategy that models the edge probability and it is not a Skip-gram procedure. That is to say that we can't learn the hyperbolic representation vectors from the context generated by Tag2Vec paratemeterized random walk. Thus, we propose a method to learn the representations on the Poincare ball with Skip-gram, as Poincare disk is a common and simple way to model htperbolic geometry.

Euclidean and hyperbolic spaces are both Riemannian spaces. Their difference is that Euclidean spaces have isotropic Riemannian metric tensor $g^{(E)}$. While in hyperbolic spaces, the metric tensor is:

$$g_x^{(H)} = (\frac{2}{1 - \|\vec{x}\|^2})^2 g^{(E)}. \tag{1}$$

Therefore, in hyperbolic spaces, $g_x^{(H)}$ is related to the vector $\vec{x}$ and it is not shift-invariant. So there isn't a simple formation of global inner-product. But there is still the definition of the distance between two points in hyperbolic spaces:

$$d_H(\vec{u},\vec{v}) = \cosh^{-1}(1 + \frac{\|\vec{u} - \vec{v}\|^2}{(1 - \|\vec{u}\|^2)(1 - \|\vec{v}\|^2)}). \tag{2}$$

In traditional Skip-gram model, we use the scoring function $s(w,h)$ between the word w and the context h to evaluate their closeness. Then we have the probability distribution of the context h given the word w in the neural probabilistic language model [2] $P(h|w) = \frac{\exp(s(w,h))}{\sum_{h'} \exp(s(w,h'))}$.

Traditionally, $s(w,h)$ is a linear function, where we calculate the inner-product of $\vec{w}$ and $\vec{h}$. It is an operation in Euclidean spaces and we want to transfer it into hyperbolic spaces. But as mentioned above, there is no definition of inner-product in hyperbolic spaces. So we transform $s(w,h)$ into a function with regard to the distance:

$$s(w,h) = -A\|\vec{w} - \vec{h}\|^2 + B = -A(d^2(\vec{w},\vec{h})) + B, \tag{3}$$

where A and B are parameters. But as the probability is normalized by a constant $\sum_{h'} \exp(s(w,h'))$, they have no influence on the model. So the probability distribution $P(h|w)$ can be calculated according to the Euclidean distance:

$$P(h|w) = \frac{\exp(\Phi(d(w,h)))}{\sum_{h'} \exp(\Phi(d(w,h')))}, \tag{4}$$

where Φ can be a non-linear operator.

Therefore, we replace Euclidean distance d_E with hyperbolic distance d_H. For simplicity, we let Φ as an identify function and define the loss function using maximum likelihood estimation. We use negative sampling to accelerate and the final loss function is

$$L(\vec{w}) = -\sum_{(i,j)\in D} \log \sigma(-d_H(\vec{w}_i, \vec{h}_j)) + k \cdot \mathbb{E}_{h_n \sim P_n(h)} \left[\log \sigma(d_H(\vec{w}_i, \vec{h}_n))\right], \tag{5}$$

where $\sigma(x) = \frac{1}{1+\exp(-x)}$ and $P_n(h)$ is the noise distribution for negative sampling.

4.2.1 Optimization. As we use distance function $d_H(w, h)$ in hyperbolic spaces, the loss function can be optimized with Riemannian stochastic gradient descent (RSGD) optimization method [5].

5 EXPERIMENT

In order to demonstrate the superiority of our tag embeddings, we conduct the experiment on two datasets.

5.1 Dataset

We have to choose datasets with tags of nodes, such as communities, categories, and other discrete features. Meanwhile, these tags may have implicit hierarchical correlation.

- **NBER Patent Citation Data** [17] describes patents in U.S. over the last 30 years. Each patent is a node and each citation is an edge in our network. Each node has one class, one category and sub-category as its tags. There are 6 categories, 35 sub-categories, and 426 classes classified by USPTO. We extract a sub-network from the dataset with 401 nodes, 462 tags and more than 3000 edges. To be notified, the affiliation relationship between categories and sub-categories is not part of the input and we will learn it from our model.
- **WordNet Data** [22] is a lexical database. It groups English words into sets of synonyms called synsets and records relations among these synonym sets or their members. We extract a subset from the dataset and construct a network. Each node in the network is a leaf in the tree and its tags are k-order ancestors and each edge in the network represents the genetic relationship between two words.

5.2 Baselines

We use the following baselines comparing with our model. Except the first baseline, we learn the representation vectors of nodes and tags simultaneously in a node-tag hybrid network.

- Origin: We construct a plain network without tags and learn the representation vectors of nodes by DeepWalk. Then we encode the tags into one-hot vectors, and concatenate the node vectors and node vectors together.
- DeepWalk [27]: It generates context of nodes by random walks and adopts Skip-gram model.
- LINE [30]: It preserves both first-order and second-order proximities between nodes.
- Node2Vec [16]: It is an improvement of DeepWalk, and it adds more flexibility in exploring neighbors.

5.3 Tag Representation Visualization

Figure 3 shows the visualization of tags learned from our model on NBER Patent Citation dataset. It is obvious that the tag representations learned from our model have good hierarchical property. 6 categories are distant from each other and dispersed in the space. Sub-categories of the same category are close to each other and cluster around the category. For example, Optics and Transportation are sub-categories of Mechanical, and they are close around Mechanical.

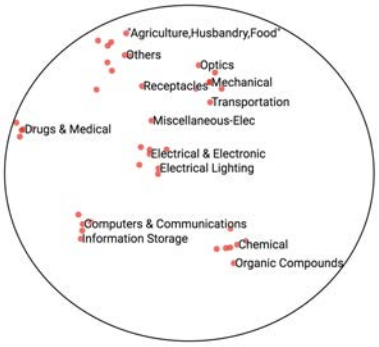


Figure 3: Tag Visualization

5.4 Results

5.4.1 Node Classification. On NBER patent citation dataset, we concatenate the node and tag vectors together as the expended representations to classify the nodes. The classes and sub-categories are tags of nodes. We use F1 score as the evaluation metric.

Figure 4 shows the results of node classification. It can be seen that origin has the worst result. This is because it encodes tags into one-hot vectors so that all tags have the same status and their distances are ignored. While the rest methods mix the nodes and tags into a hybrid network to learn the relationships between tags. An exceptional case is that LINE not performs well because it ignores the global information. Furthermore, our model outperforms DeepWalk and Node2Vec, as parametrized random walk can better learn the semantic information, and hyperbolic Skip-gram helps to learn the hierarchical information. It demonstrates that the representations learned from our model have stronger ability for classification.

5.4.2 Similar Community Detection. We detect the similar communities on the NBER patent citation dataset. A community corresponds to a tag, including classes, categories and sub-categories. We calculate distances between tag vectors. As for a community, the community with closest distance is its similar community. The similar community refers to the one with most common members or most connections. We use AUC as the evaluation metric.

Figure 5 shows the results of similar community detection. For all baselines, we mix the nodes and tags into a hybrid network. The representation vectors learned from our model can predict the similarity relationships between communities and analyze the community features of complex networks.

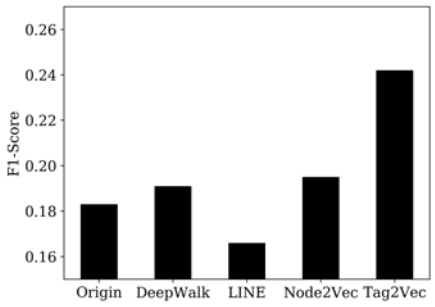

Figure 4: Node Classification

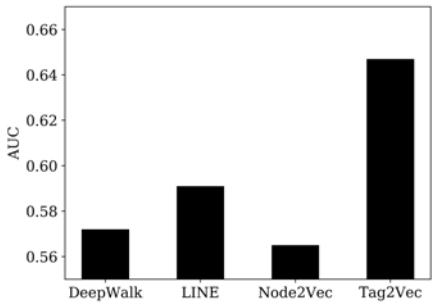

Figure 5: Similar Community Detection

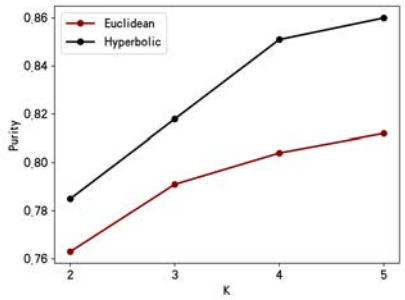

Figure 6: Reconstruction of K

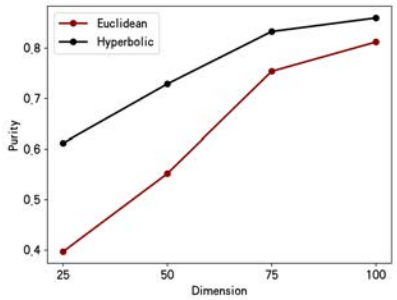

Figure 7: Reconstruction of Dimension

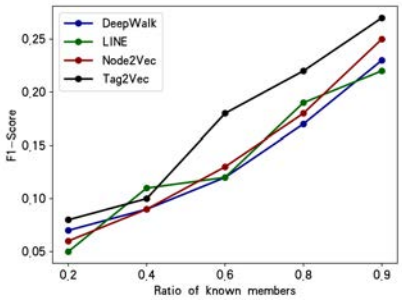

Figure 8: Stability

5.4.3 Hierarchical Structure Reconstruction. Comparing with Euclidean spaces, Skip-gram model in hyperbolic spaces has two advantages: reducing the dimensions of vectors and reflecting affiliation relationships better. To evaluate this, we conduct the experiment of hierarchical structure reconstruction on WordNet dataset to compare the performance of representation vectors from Euclidean and hyperbolic spaces. We reconstruct the word tree by clustering the tag representation vectors and evaluate the results with purity $\sum_i^K \max_j\{p_{ij}\}$, where K is cluster number, and p_{ij} is the probability that members in cluster i belong to class j. Purity measures the correctness of hierarchical structure reconstruction. If we can cluster correctly, it means that we can discover the complex hierarchical structure of ground-truth communities of tags with the help of the behaviors of their members in the network.

Figure 6 shows the purity of clustering with different order of ancestors k in two spaces. k measures the richness of tags and the complexity of hierarchical information. The larger the k is, the more tags a node has. The result shows that embedding in hyperbolic spaces is superior with the best reconstruction performance. Meanwhile, when there are more tags and more complex structure, the advantage of hyperbolic spaces is greater.

Figure 7 shows the purity of clustering with different dimensions. When the dimensions are lower, embedding in hyperbolic spaces performs significantly better than embedding in Euclidean spaces. It indicates that in hyperbolic spaces, we can learn good representations with low dimensions.

5.4.4 Tag Stability. In real networks, tags of nodes often make changes. Besides, part of interaction records may be missing. However, we consider that changes or lacking of few members may not influence the semantic information of tags greatly. To demonstrate the stability of tags learned from our model, we extract part of plain nodes as known members and all tag nodes to construct a network and learn the tag representations. Then we extract another part of plain nodes to construct another network without tags, learn the representation vectors of plain nodes and combine them with tag vectors learned before to predict the node labels.

The results are shown in Figure 8. When the known members reach a certain proportion(60%), F1-score of TagVec is higher than other baselines obviously. This is because in the parameterized random walk, we emphasize the importance of tags when generating context. When some members are missing, we can still learn good tag representation vectors thanks to their stronger stability.

6 CONCLUSION

In this paper, we analyze semantic and hierarchical information between tags and propose a novel tag representation learning model, Tag2Vec. The experimental results show that the tag representations learned from our model have strong representative ability.

ABSTRACT

With the blossoming of social networking platforms like Twitter and Facebook, how to infer the opinions of online social network users on specific topics they had not directly given yet, has received much attention. Existing solutions mainly rely on one's previous posted messages. However, recent studies show that over 40% of users opt to be silent all or most of the time and post very few messages. Consequently, the performance of existing solutions will drop dramatically when they are applied to infer silent users' opinions, and how to infer the opinions of these silent users becomes a meaningful while challenging task. Inspired by the collaborative filtering techniques in cold-start recommendations, we infer the opinions of silent users by leveraging the text content posted by active users and their relationships between silent users. Specifically, we first consider both observed and pseudo relationships among users, and cluster users into communities in order to extract various kinds of features for opinion inference. We then design a coupled sparse matrix factorization (CSMF) model to capture the complex relations among these features. Extensive experiments on real-world data from Twitter show that our CSMF model achieves over 80% accuracy for the inference of silent users' opinions.

1 INTRODUCTION

Recent years have witnessed a booming development of online social networking platforms like Twitter and Facebook. In online social networks, even active users will not publish messages to directly show their opinions towards all topics. As a result, inferring users' opinions on specific topics they had not directly given yet, has attracted increasing attention [11, 13, 26]. When inferring a user's opinion on a specific topic, existing solutions generally are based on his/her previous posted messages on other topics, in order to profile himself/herself [7] or find his/her neighbors with similar user personal interests [9, 17, 30]. For example, [7] extracted two types of features from a user's posted content about other topics to tell if the user has certain opinion bias on all topics (i.e., some users are more likely to be positive or negative). Then the user's opinion on a specific topic can be correlated with or similar as his/her opinions on some other topics.

However, recent work on social science [6, 10, 22] has shown that a significant proportion (over 40%) of users choose to be *silent* all or most of the time, and seldom publish messages to express their opinions towards various topics. Having a better understanding of these silent users' opinions is important, as it greatly helps us to avoid misjudgement of overall population-level opinions, and advances a variety of real-world applications, such as targeted advertising [5, 14] and political election predictions [8]. Inferring the opinions of silent users is a quite challenging task. As silent users do not generate sufficient content, existing solutions which rely on one's historical posted messages often only focus on users who have historical messages, but ignore these silent users who do not post anything in a long period time. The performance of existing solutions will drop dramatically when they are used to predict the opinions of silent users [7, 17]. Different from existing work on opinion inference, we take a step towards the inference of silent users' opinions in this paper.

We find that inferring silent users' opinions is intrinsically similar to cold-start recommendation problem, whose objective is to predict rating scores for specific items rated by new users without any historical preference information. In recommendation systems, users tend to have similar tastes with their friends. As a result, rating scores of new users can be predicted by considering the preference information of their friends in social networks [16, 19]. Similarly, existing studies on social science theories have verified that users that are connected (become friends) are prone to exhibit similar opinions on a certain topic [2, 3, 18]. Therefore, we argue that we can infer silent users' opinions by leveraging the text content generated by active users and their relationships between silent users.

However, applying the methods designed for cold-start recommendations to infer silent users' opinions still entails many challenges due to the following reasons. 1) *Diversity of user-user relations*: Existing studies [4, 24] on social science have found that

observed relationships (i.e., the follower/followee network structure) are only one type of user-user relations, while other types of user-user relations are also very important for shared opinions among users. 2) *Heterogeneous fusion*: Many features need to be considered when characterizing silent users and inferring their opinions, including structural features of the user-relationship network, opinion information of text content, users' interests, etc. Simultaneously considering all these features extracted from heterogeneous sources is quite difficult.

To address the aforementioned issues, the inference of silent users' opinions is modeled as a matrix factorization problem in this work, and a coupled sparse matrix factorization (CSMF) model is proposed to fuse text content data and user-relationship data for accurate inference. The main contributions of this paper are summarized as follows:

- To extract features of silent users, we first infer user-user relations and cluster users into communities. Then three sets of features are extracted for each user.
- A coupled sparse matrix factorization (CSMF) model is proposed to capture the complex relations among various features and infer silent users' opinions.
- We validate the effectiveness of our CSMF model based on real-world dataset from Twitter. Experimental results demonstrate that our model can be effectively used to infer silent users' opinions.

2 DATA DESCRIPTION

In this paper, Twitter is employed as the basis for our opinion inference experiments. The Twitter data we used consists of over 70,000 messages on 20 hot political topics and the follower/followee network structure among over 6,000 users. For each Twitter message, it is assigned an opinion label: -1 (negative), 0 (neutral) or $+1$ (positive). We employ 20 people to manually assign an opinion label for each message. In this paper, we restrict our attention mainly to negative, neutral and positive user-topic opinions. Then the final opinion of each user on a specific topic is computed by averaging the opinion labels of all his/her posted messages on this topic.

One factor we need to consider is whether we should require both users in a potential pair to connect with each other. On Twitter, mutual connections presumably indicate closer relationships, while one-way connections may correspond to a desire to pay attention (e.g., to a famous singer), rather than necessarily personal relationships. Existing studies [23] have shown that attention effects may be more important than homophily effects with respect to shared opinions in social networks. Therefore, we consider two possibilities when we define that a connection (edge) between a pair of users exists.

- Directed follow network: user u_i follows user u_j (u_j may or may not follow u_i in return).
- Mutual follow network: user u_i follows user u_j, and u_j follows u_i at the same time.

3 FEATURE EXTRACTION FOR USERS

In this section, we extract features for both silent and active users based on text content data and follower/followee network structure.

3.1 Inferring User-User Relations

Existing work [4] has found that there are two types of user-user relations in online social networks: observed relationships (or explicit relationships) and pseudo-relationships. Observed relationships can be reflected by the follower/followee network structure, and provide information on personal relationships among users. Pseudo-relationships are extracted from sentimental text content, where a connection between a pair of users is created if they hold consistent opinions on different topics. Since the inference of silent users' opinions is largely dependent on user-user relations, it is not a trivial matter to infer pseudo-relationships among users and consider both observed and pseudo relationships when inferring silent users' opinions.

Intuitively, a pseudo-friend relationship between a pair of users is likely to exist when they share the same opinions on many topics. In contrast, a pseudo-foe relationship between two users may exist if they have conflicting opinions. To infer the pseudo-relationship between two users, we first introduce the *meta path*, which is used to capture a sequence of relations defined between users [21]. For example, two users u_i and u_j are connected via the path "user-message-topic-message-user" (i.e., U-M-T-M-U) if both u_i and u_j have posted at least one message about a same topic T. Given a meta path (e.g., $\mathcal{P}$=U-M-T-M-U), the similarity between u_i and u_j is computed as follows:

$$sim(u_i, u_j) = \frac{2 \sum_{m_k \in M_{u_i}, m_l \in M_{u_j}} (1_{(p_{u_i \rightsquigarrow u_j} \in \mathcal{P})} \cdot Sc(m_k, m_l))}{|\{p_{u_i \rightsquigarrow u_i} \in \mathcal{P}\}| + |\{p_{u_j \rightsquigarrow u_j} \in \mathcal{P}\}|} \tag{1}$$

where M_{u_i} denotes the set of messages published by user u_i, and $p_{u_i \rightsquigarrow u_j}$ represents a path instance between u_i and u_j that follows the defined meta path $\mathcal{P}$. $Sc(m_k, m_l)$ is calculated as:

$$Sc(m_k, m_l) = \begin{cases} +1 & \text{if } sl(m_k) = sl(m_l) \\ -1 & \text{otherwise} \end{cases} \tag{2}$$

where $sl(m_k)$ is the opinion label of message m_k.

From the definition of $sim(u_i, u_j)$, we can find that it is a real value ranging between -1 and 1. A score $sim(u_i, u_j)$ close to 1 indicates that users u_i and u_j hold similar opinions with respect to different topics, and we denote them as *pseudo-friends*. On the contrary, two users with a score $sim(u_i, u_j)$ close to -1 indicates that they are *pseudo-foes* who hold conflicting opinions on many topics. Moreover, a score close to 0 indicates that these two users share both consistent and conflicting opinions. In this paper, we define a pseudo-connection between users u_i and u_j exists if their $sim(u_i, u_j)$ is larger than a threshold γ.

3.2 Clustering Users into Communities

We need to cluster users into communities, and extract a user's features based on the text content posted by the users in the same community and community structure information. Therefore, in this subsection, we shift our focus to how to cluster users into communities.

A lot of community detection algorithms have been proposed in order to group the users of a network into groups of users with denser connections internally and sparser connections between groups [15, 28, 29]. With user-user relations (including observed

relationships and pseudo-relationships) in place, we employ the method proposed in [25], which can achieve the best performance of community detection on large social networks currently as far as we know, to cluster both silent and active users. This method unifies several commonly used clustering quality functions including modularity, cluster deletion, and sparsest cut, and places all these clustering quality functions within a unified optimization framework.

3.3 Features for Opinion Inference

In this subsection, we extract three sets of features for both silent and active users.

Content Features: Content features are used to describe the interested topics of users and the distribution of their opinions. As silent users publish very few messages, we cannot directly extract content features for them from their posted text content. To solve this problem, for each user, we consider the messages posted by both himself/herself and other users in the same community when extracting content features for him/her. For user u, his/her content feature vector is represented as:

$$f_u^C = (< tp_1, s_1 >, < tp_2, s_2 >, ..., < tp_N, s_N >) \tag{3}$$

where N is the total number of topics we consider, $tp_i (1 \leq i \leq N)$ equals to 1 if user u has posted messages about the i-th topic, and 0 otherwise. As mentioned before, we define the opinion of a user on a particular topic as the average opinion labels of all his/her published messages on this topic if he/she has posted messages on this topic. Here, we set s_i as user u's opinion on the i-th topic if u has posted messages on this topic, the average opinion of other users in the same community on the i-th topic if u has not but other users in the same community have posted messages on this topic, and the average opinion of all users in our dataset on this topic otherwise.

Intra-Community Structural Features: To extract intra-community structural features for each user, we consider the user-user relations among the whole users in the same community. For user u who resides in community C, we compute his/her degree, the average distance between u and all other users in C, the number of shortest paths between any two users in C that pass through u, and the Katz centrality [1], which is calculated as:

$$C_{Katz}(u) = \sum_{k=1}^{\infty} \sum_{v=1}^{|C|} \alpha^k (\mathbf{A}^k)_{u,v} \tag{4}$$

where α is an attenuation factor between 0 and 1, and matrix $\mathbf{A}$ is the adjacency matrix, i.e., $a_{u,v} = 1$ if user u is connected with user v, and $a_{u,v} = 0$ otherwise.

Inter-Community Structural Features: For each user, we employ inter-community structural features to indicate which community he/she is located in and the connections between the user and users in other communities. Given a set of users, if these users are clustered into K communities by the aforementioned community detection algorithm, the inter-community structural feature vector for user u can be represented as:

$$f_u^{Inter} = (s_1, s_2, ..., s_K) \tag{5}$$

where $s_i (1 \leq i \leq K) \in \{-1, 0, 1\}$. s_i equals to 0 if user u is located in the i-th community, 1 if u is connected with any user in the i-th community, and -1 otherwise.

4 INFERRING SILENT USERS' OPINIONS

In this section, we introduce how to utilize various kinds of features, and design a matrix factorization based framework to infer the opinions of silent users.

4.1 Data Modelling

We can extract various kinds of information from text content and user-user relation data. Here we build several matrices to capture features extracted from different sources and the relations among them.

Features of a user: For each user, we extract content features f^C, intra-community structural features f^{Intra} and inter-community structural features f^{Inter}. Then we place f^C, f^{Intra} and f^{Inter} of each user into a user feature matrix $\mathbf{Z}$, where each row denotes a user and each column stands for a kind of feature.

Opinion distribution patterns: To reflect opinion distribution patterns for individual users and communities, we extract user-topic opinion matrix $\mathbf{O}$ and community-topic opinion matrix $\mathbf{C}$. Specifically, each row of matrix $\mathbf{O}$ denotes a topic, and each column represents a user. Each element $o_{i,j}$ in $\mathbf{O}$ stands for the opinion of the j-th user on the i-th topic. $o_{i,j}$ equals to *null* if the j-th user had not posted messages on the i-th topic. Matrix $\mathbf{O}$ is very sparse because silent users seldom post messages and active users do not publish messages for all topics. To capture the community-topic opinion information, matrix $\mathbf{C}$ is built. Matrix $\mathbf{C}$ represents opinion distribution patterns for communities, where each row denotes a topic and each column stands for a community. Each community contains several users, and each element of $\mathbf{C}$ is the average opinion labels of users in a particular community on a particular topic. Compared with $\mathbf{O}$, $\mathbf{C}$ is a higher level but denser representation for opinion distribution patterns.

4.2 Coupled Sparse Matrix Factorization (CSMF) Model

In this subsection, we infer the opinions on different topics for each silent user, based on various matrices mentioned before. In the previous subsection, we build three matrices $\mathbf{O}$, $\mathbf{C}$ and $\mathbf{Z}$. Given the above settings, the goal of inferring the opinion of a specific user u_j on a particular topic t_i can be converted into filling the missing value in i-th row and j-th column of $\mathbf{O}$ with the help of $\mathbf{C}$ and $\mathbf{Z}$.

Basically, this goal can be achieved by solely factorizing matrix $\mathbf{O}$. Specifically, a more accurate but compact representation for users and topics in a low-rank space can be found through matrix factorization, and matrix $\mathbf{O}$ can be approximated by a multiplication of two low-rank matrices:

$$\mathbf{O} \approx \mathbf{T} \times \mathbf{U}^T \tag{6}$$

where $\mathbf{T} \in \mathbb{R}^{N \times D}$ and $\mathbf{U} \in \mathbb{R}^{M \times D}$ are low-rank matrices with $D \ll min(M, N)$, and M and N denote the total number of users and topics, respectively. The row vector $T(i,:)$ in $\mathbf{T}$ $(1 \leq i \leq N)$ and $U(j,:)$ in $\mathbf{U}$ $(1 \leq j \leq M)$ are the latent representations for the

i-th topic and j-th user, respectively. In traditional matrix factorization methods, matrix $\mathbf{O}$ can be approximated by minimizing the following objective function:

$$\min_{\mathbf{T},\mathbf{U}} \mathcal{L} = \frac{1}{2}||\mathbf{I} \circ (\mathbf{O} - \mathbf{T}\mathbf{U}^T)||_F^2 \tag{7}$$

where $||\cdot||_F$ represents the Frobenius norm of a matrix. $\mathbf{I}$ is an indicator matrix with its element $I_{i,j}$ equals to 0 if $o_{i,j}$ is *null*, 1 otherwise. The operator "$\circ$" denotes the entry-wise product (i.e., Hadamard product).

Note that in our case, the user-topic opinion matrix $\mathbf{O}$ is quite sparse since the observed user-topic opinions are only a small percent. As a result, the approximation of $\mathbf{O}$ will be not accurate enough if we solely factorize itself. To solve this problem, we can incorporate another two matrices $\mathbf{C}$ and $\mathbf{Z}$ to decompose these matrices collaboratively. To be more specific, we first factorize community-topic opinion matrix $\mathbf{C} \in \mathbb{R}^{N \times K}$ into two low-rank latent matrices $\mathbf{T} \in \mathbb{R}^{N \times D}$ and $\mathbf{G} \in \mathbb{R}^{K \times D}$, where K is the total number of communities. Since matrices $\mathbf{O}$ and $\mathbf{C}$ share the latent topic matrix $\mathbf{T}$, we can make $\mathbf{T}$ more accurate by jointly decomposing $\mathbf{O}$ and $\mathbf{C}$. Likewise, user feature matrix $\mathbf{Z}$ is also employed to help determine the latent user matrix $\mathbf{U}$ more accurately by factorizing $\mathbf{Z} \in \mathbb{R}^{M \times L}$ into $\mathbf{U} \in \mathbb{R}^{M \times D}$ and $\mathbf{F} \in \mathbb{R}^{L \times D}$, where L is the dimension of the user feature vector, and $\mathbf{O}$ and $\mathbf{Z}$ share the latent user matrix $\mathbf{U}$. Since matrices $\mathbf{C}$ and $\mathbf{Z}$ are much denser than $\mathbf{O}$, community-topic opinion matrix $\mathbf{C}$ and user feature matrix $\mathbf{Z}$ can make contributions to facilitating a more accurate factorization of $\mathbf{O}$ through shared matrices $\mathbf{T}$ and $\mathbf{U}$. That is to say, we can collaboratively decompose $\mathbf{O}$, $\mathbf{C}$ and $\mathbf{Z}$ as follows:

$$\mathbf{O} \approx \mathbf{T} \times \mathbf{U}^T; \mathbf{C} \approx \mathbf{T} \times \mathbf{G}^T; \mathbf{Z} \approx \mathbf{U} \times \mathbf{F}^T \tag{8}$$

where $\mathbf{O}$ and $\mathbf{C}$ share latent topic factor $\mathbf{T}$, and $\mathbf{O}$ and $\mathbf{Z}$ share latent user factor $\mathbf{U}$. Then we can achieve this goal by forming and minimizing the following objective function:

$$\begin{aligned}\min_{\mathbf{T},\mathbf{U},\mathbf{F},\mathbf{G}} \mathcal{L} = &\frac{1}{2}||\mathbf{I} \circ (\mathbf{O} - \mathbf{T}\mathbf{U}^T)||_F^2 + \frac{\lambda_1}{2}||\mathbf{C} - \mathbf{T}\mathbf{G}^T||_F^2 \\ &+ \frac{\lambda_2}{2}||\mathbf{Z} - \mathbf{U}\mathbf{F}^T||_F^2\end{aligned} \tag{9}$$

where $\lambda_1 > 0$ and $\lambda_2 > 0$ are used to control the loss in the matrix factorization. After the factorization, we can recover matrix $\mathbf{O}$ through the production of $\mathbf{T}$ and $\mathbf{U}^T$.

To further alleviate the data sparsity problem, we also take the correlations between users into account. Let matrix $\mathbf{S}$ be the correlation matrix of users, with each element $s_{i,j}$ denoting the correlation (similarity) between users u_i and u_j. $\mathbf{D}$ is a diagonal matrix with the i-th diagonal element as $d_{i,i} = \sum_{j=1}^{M} s_{i,j}$, and $\mathbf{L_S} = (\mathbf{D} - \mathbf{S}) \in \mathbb{R}^{M \times M}$ is the Laplacian matrix of the user correlation graph. Here, we use Pearson correlation analysis method [20] to obtain user correlation matrix $\mathbf{S}$ and the corresponding Laplacian matrix $\mathbf{L_S}$. Then the correlation information between users is considered as the trace of matrix $\mathbf{U}^T\mathbf{L_S}\mathbf{U}$, and can be obtained through the following deduction, which can guarantee that for two users u_i and u_j with higher correlation (i.e., the value of $s_{i,j}$ is large), they will be also closer in distance between the row vectors $U(i,:)$ and $U(j,:)$ in the matrix $\mathbf{U}$.

$$\begin{aligned}&\frac{1}{2}\sum_{i,j} s_{i,j}||U(i,:) - U(j,:)||_F^2 = \frac{1}{2}\sum_{i,j}\sum_{k=1}^{D} s_{i,j}(U(i,k) - U(j,k))^2 \\ &= \sum_{i,j}\sum_{k=1}^{D} s_{i,j}U^2(i,k) - \sum_{i,j}\sum_{k=1}^{D} s_{i,j}U(i,k)U(j,k) \\ &= \sum_{k=1}^{D} U^T(:,k)(\mathbf{D} - \mathbf{S})U(:,k) = tr(\mathbf{U}^T(\mathbf{D} - \mathbf{S})\mathbf{U}) \\ &= tr(\mathbf{U}^T\mathbf{L_S}\mathbf{U})\end{aligned} \tag{10}$$

where $tr(\cdot)$ represents the matrix trace. In this way, user correlation matrix $\mathbf{S}$ contributes to a more accurate $\mathbf{U}$.

After all components mentioned are combined, the final objective function of the coupled sparse matrix factorization model is formally defined as:

$$\begin{aligned}\min_{\mathbf{T},\mathbf{U},\mathbf{F},\mathbf{G}} \mathcal{L} = &\frac{1}{2}\underbrace{||\mathbf{I} \circ (\mathbf{O} - \mathbf{T}\mathbf{U}^T)||_F^2}_{\text{user-topic factorization}} + \frac{\lambda_1}{2}\underbrace{||\mathbf{C} - \mathbf{T}\mathbf{G}^T||_F^2}_{\text{community-topic factorization}} \\ &+ \frac{\lambda_2}{2}\underbrace{||\mathbf{Z} - \mathbf{U}\mathbf{F}^T||_F^2}_{\text{user feature factorization}} + \frac{\lambda_3}{2}\underbrace{tr(\mathbf{U}^T\mathbf{L_S}\mathbf{U})}_{\text{user correlation}} \\ &+ \frac{\lambda_4}{2}\underbrace{(||\mathbf{T}||_{2,1} + ||\mathbf{U}||_{2,1} + ||\mathbf{G}||_{2,1} + ||\mathbf{F}||_{2,1})}_{\text{row-wise sparsity regularization}}\end{aligned} \tag{11}$$

Finally, we can utilize the factorized matrices $\mathbf{T}$ and $\mathbf{U}$ to reconstruct $\mathbf{O}$ to $\widetilde{\mathbf{O}}$, namely $\widetilde{\mathbf{O}} = \mathbf{T} \times \mathbf{U}^T$. For a silent user u_j, his/her opinion on topic t_i is the value in i-th row and j-th column of $\widetilde{\mathbf{O}}$. In the objective function, the last term is a regularization of penalty to prevent overfitting, where the $\ell_{2,1}$-norm regularization is added on each latent matrix. The features we extract contain different types of knowledge, and we assume that only parts of them are useful for opinion inference. The $\ell_{2,1}$-norm can promote row-wise sparsity of the target matrix, making it suitable for feature selection. Hence, the last term can also help control group feature selection.

5 OPTIMIZATION ALGORITHM

The objective function we defined in the previous section is not jointly convex to all the variables. As a result, it is not easy for us to obtain a closed-form solution for minimizing this objective function. To solve this problem, we utilize an iterative algorithm, where we alternatively update one variable while fix other variables until convergence. Note that $\ell_{2,1}$-norm is not continuous on the origin. Hence, we cannot minimize the compound $\ell_{2,1}$ objective function directly. Motivated by recent studies on half-quadratic minimization approaches [27], we can first introduce an auxiliary variable, and then apply this auxiliary variable to transform the $\ell_{2,1}$-norm term of the objective function into an approximate form. For instance, $\mathbf{G}$ can be transformed as:

$$||\mathbf{G}||_{2,1} \approx tr(\mathbf{G}^T\mathbf{Q_G}\mathbf{G}) \tag{12}$$

where $\mathbf{Q_G}$ is a diagonal matrix with the i-th diagonal element as $q^g_{i,i} = \frac{1}{2||\mathbf{g_i}||_2}$. $\mathbf{T}$, $\mathbf{U}$ and $\mathbf{F}$ can be dealt with in the same way.

After having the above transformations, we then compute the derivative of the objective function with respect to $\mathbf{T}$, $\mathbf{U}$, $\mathbf{G}$ and $\mathbf{F}$ respectively:

$$\begin{aligned}
\frac{\partial \mathcal{L}}{\partial \mathbf{T}} &= [\mathbf{I} \circ (\mathbf{T}\mathbf{U}^T - \mathbf{O})]\mathbf{U} + \lambda_1(\mathbf{T}\mathbf{G}^T - \mathbf{C})\mathbf{G} + \lambda_4 \mathbf{Q}_\mathbf{T}\mathbf{T} \\
\frac{\partial \mathcal{L}}{\partial \mathbf{U}} &= [\mathbf{I} \circ (\mathbf{T}\mathbf{U}^T - \mathbf{O})]^T\mathbf{T} + \lambda_2(\mathbf{U}\mathbf{F}^T - \mathbf{Z})\mathbf{F} \\
&\quad + \lambda_3 \mathbf{L}_\mathbf{S}\mathbf{U} + \lambda_4 \mathbf{Q}_\mathbf{U}\mathbf{U} \\
\frac{\partial \mathcal{L}}{\partial \mathbf{G}} &= \lambda_1[\mathbf{T}\mathbf{G}^T - \mathbf{C}]^T\mathbf{T} + \lambda_4 \mathbf{Q}_\mathbf{G}\mathbf{G} \\
\frac{\partial \mathcal{L}}{\partial \mathbf{F}} &= \lambda_2[\mathbf{U}\mathbf{F}^T - \mathbf{Z}]^T\mathbf{U} + \lambda_4 \mathbf{Q}_\mathbf{F}\mathbf{F}
\end{aligned} \tag{13}$$

With the derivatives in place, a conjugate gradient method can be employed to iteratively minimize the objective function. We show the detailed process of the optimization algorithm in Algorithm 1.

Algorithm 1 Algorithm to minimize the objective function

Input: User-topic opinion matrix $\mathbf{O}$, community-topic opinion matrix $\mathbf{C}$, user feature matrix $\mathbf{Z}$, Laplacian matrix $\mathbf{L}_\mathbf{S}$ and regularization parameters.

Output: $\mathbf{T}$ and $\mathbf{U}$.

1: Initialize $\mathbf{T}$, $\mathbf{U}$, $\mathbf{G}$ and $\mathbf{F}$ randomly.
2: Compute the diagonal matrices $\mathbf{Q}_\mathbf{T}$, $\mathbf{Q}_\mathbf{U}$, $\mathbf{Q}_\mathbf{G}$ and $\mathbf{Q}_\mathbf{F}$.
3: **repeat**
4: Update $\mathbf{T}$, $\mathbf{U}$, $\mathbf{G}$ and $\mathbf{F}$ according to Eq. (13) by using the conjugate gradient method.
5: Update $\mathbf{Q}_\mathbf{T}$, $\mathbf{Q}_\mathbf{U}$, $\mathbf{Q}_\mathbf{G}$ and $\mathbf{Q}_\mathbf{F}$ with $q^t_{i,i} = \frac{1}{2||\mathbf{t_i}||_2}$, $q^u_{i,i} = \frac{1}{2||\mathbf{u_i}||_2}$, $q^g_{i,i} = \frac{1}{2||\mathbf{g_i}||_2}$, $q^f_{i,i} = \frac{1}{2||\mathbf{f_i}||_2}$.
6: **until** convergence

6 EXPERIMENTS

6.1 Evaluation Metrics

We employ two popular metrics, i.e., root mean square error (RMSE) and Accuracy, to measure the performance of opinion inference task. The metric RMSE is defined as:

$$RMSE = \sqrt{\frac{1}{N_T}\sum_{i,j}(o_{i,j} - \widetilde{o}_{i,j})^2} \tag{14}$$

where N_T stands for the number of opinions for testing. Since the value of $\widetilde{o}_{i,j}$ may be not an integer which exactly equals to -1, 0 or 1, we map the value of $\widetilde{o}_{i,j}$ with the *sign function* before computing the Accuracy. $\widetilde{o}_{i,j}$ is mapped to -1 if $\widetilde{o}_{i,j} \in (-\infty, -0.5]$, 0 if $\widetilde{o}_{i,j} \in (-0.5, 0.5)$, and 1 if $\widetilde{o}_{i,j} \in [0.5, +\infty)$. In experiments, a smaller RMSE value or a higher Accuracy value indicates a better inference performance.

6.2 Comparison with Baselines

In this subsection, we compare our CSMF model with several baseline methods. To analyze how the performance of these methods changes with the change of active user size, we select 30, 40, 60, 70 and 80 percent of the most active users as active users, and infer the opinions of the remaining portions of users (silent users). For users in the test set (silent users), all their posted messages are removed when extracting features for them, and their observed user-topic opinions are regarded as ground truth data. Then we predict their opinions using different methods. The baseline methods are listed as follows:

- RK: Regression-Kriging is a liner combination estimator that combines a regression of the dependent variable on auxiliary variables with the regression residuals.
- MF: This method is the basic low-rank matrix factorization model, as shown in Eq. (7).
- STMF: It is proposed in [17], where a matrix factorization framework is built to predict user-topic opinions by considering users' previous posted text content and the similarities between different users.
- DCMF: This method [12] first learns hash codes for users and topics from content information, and then introduces an interaction regularization to tackle the data sparsity problem.
- OP-SVM: It is an opinion prediction model based on two types of features (sentiment features and opinion features) extracted from one's historical posted messages on other topics [7].
- LoCo: It is a matrix factorization framework designed for cold-start recommendation systems [19]. The inference of silent users' opinions is intrinsically similar to cold-start recommendation problem. Therefore, we adopt this method as a baseline method.

Table 1: RMSE comparisons using different methods and sizes of active users.

Active users	*RK*	*MF*	*STMF*	*DCMF*	*OP-SVM*	*LoCo*	*CSMF*
30%	0.92	0.80	0.75	0.71	0.68	0.70	**0.59**
40%	0.88	0.76	0.71	0.67	0.66	0.65	**0.56**
60%	0.87	0.72	0.69	0.64	0.65	0.64	**0.52**
70%	0.83	0.71	0.68	0.63	0.62	0.60	**0.50**
80%	0.81	0.71	0.65	0.62	0.61	0.58	**0.49**

In this experiment, for the methods using regularization constraints, we adjust the regularization parameters of them in order to obtain their best performance. In our CSMF model, the best result is achieved when λ_1, λ_2, λ_3 and λ_4 are set as 1, 10^{-1}, 10^{-1} and 1 respectively. In addition, we only consider directed follow network when extracting features for users, and set γ, α and K as 0.7, 0.6 and 65 respectively based on the results of pre-performed testing for parameter tuning. We display the experimental results measured by RMSE and Accuracy in Table 1 and Figure 1.

From Table 1 and Figure 1, we can see that all these methods can achieve much better performance than randomly guessing (which is $\frac{1}{3}$ in our task). When we increase the size of active users, the performance of these methods gets improved gradually. RK method achieves the worst performance among all baseline methods, both by RMSE and Accuracy. The underlying reason may be that the relationships among different features are so complex that they cannot be captured by a liner model. Compared with basic MF model,

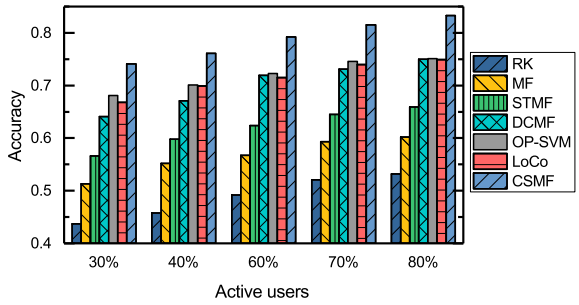

Figure 1: Accuracy comparisons using different methods and sizes of active users.

STMF, DCMF, LoCo and CSMF can obtain significantly improved results, indicating that the regularization constraints improve the inference of silent users' opinions. STMF performs much worse than DCMF, OP-SVM, LoCo and CSMF, which may be caused by that STMF relies on a large number of previous published messages per user to compute the similarities between users while few messages are available for each user in our dataset. For OP-SVM model, one type of features used in the model (i.e., opinion features) cannot be extracted when the user's all ground truth opinions on other topics are not available. As a result, OP-SVM model also obtains worse result than our CSMF model. Our proposed CSMF model always generates the best performance, and this observation demonstrates that incorporating text content and network structural features actually benefits the inference of silent users' opinions.

6.3 Effect of User-User Relations

When considering the explicit relationships (i.e., the follower/followee network structure) among users in the previous section, we define two types of connections between users, i.e., directed follow network and mutual follow network. In addition, we infer pseudo-relationships among users before extracting structural features for users. Here we analyze how the performance of inferring silent users' opinions is affected by the type of connection and pseudo-relationships. In this experiment, we select 60% of the whole users as active users. The experimental results are shown in Figure 2.

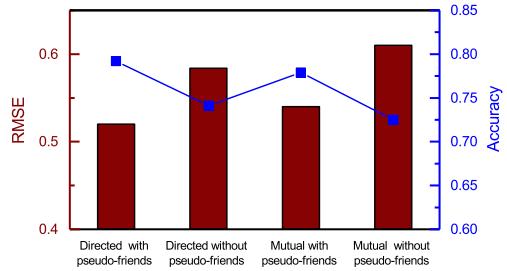

Figure 2: Effect of user-user relations on RMSE and Accuracy.

As we can see from Figure 2, the best performance is achieved when both directed follow network and pseudo-friend information are taken into consideration. For both two types of connections between users, much better results are generated after pseudo-relationships are combined with the explicit relationships. This result demonstrates that the pseudo-relationships are indeed highly correlated with shared opinions among users. Comparing the directed network with the mutual network, the directed network performs slightly better than the mutual network, indicating that attention effects are more important than homophily effects for shared opinions in social networks.

7 CONCLUSION

Existing studies on inferring users' opinions basically rely on one's previous posted messages. As silent users do not generate sufficient content, the performance of existing solutions will drop dramatically if they are applied to infer the opinions of silent users. To solve this problem, we model the opinion inference problem as a matrix factorization problem, and propose a coupled sparse matrix factorization (CSMF) model to infer the opinions of silent users. We propose several sets of features for opinion inference from different perspectives, and capture the complex relations among these features through the CSMF model. Experimental results based on real-world data from Twitter demonstrate that our model achieves much better result than the state-of-the-art methods.

ABSTRACT

The task of temporal slot filling (TSF) is to extract the values (or called facts) of specific attributes for a given entity from text data and find the time points when the values were valid. It is challenging to find precise time points with incomplete and noisy temporal contexts in the text. In this work, we propose an unsupervised approach of two modules that mutually enhance each other: one is a reliability estimator on fact extractors conditionally to the temporal contexts; the other is a fact trustworthiness estimator based on the extractor's reliability. The iterative learning process reduces the noise of the extractions. Experiments demonstrate that our approach, with the novel design, can accurately and efficiently extract precise temporal facts from newspaper corpora.

1 INTRODUCTION

Can AI read ten million news articles in two minutes and then fill in the three slots below:

("vicente_fox", per:is_president_of, "□", [□ , □]) ?
(entity, attribute, value, [beginTime, endTime])

The first slot □ is the value of a specific attribute (e.g., country's president) for an entity (e.g., the person "vicente_fox"). Here the value should be a country's name. The second and third slots are the *beginning* and *ending* time points of the attribute value being valid. We name this task "precise temporal slot filling" (PTSF).

PTSF techniques will facilitate the automation of knowledge base construction and question answering.

Existing TSF task presents the time as a single slot and expects to extract time expressions directly from sentences to fill the slot. For example, given a sentence in the newspaper:

"*...Vicente Fox served as the President of Mexico from 2000 to 2006,...*"

TSF looks for "mexico" to fill the value slot and the time expression "from 2000 to 2006" to fill the time slot. Decomposing this time expression into two time values is not hard in this case, in order to solve PTSF with the TSF result. However, we observe from a data set of ten million news articles that among all the sentences that contain time expressions, fewer than 0.1% contain at least two time points like "from 2000 to 2006:" most of the expressions are shorter like "in 2002," which indicates a time point of the fact but cannot precisely complete the *beginTime* and *endTime* slots.

We examined two information extraction methodologies: open-domain IE (OpenIE) and pattern-based IE (PatternIE). We find that the OpenIE approaches [1, 2, 7, 10, 25] generate *low precision on the value slots* and *lower-than-0.1 recall on the time slots*. First, OpenIE relies on predicates to extract relations between a subject and an object, however, the attribute may not be a predicate. Given the above sentence example, OpenIE generates ("vicente_fox", "serve_as", "president_of_mexico") instead of finding "mexico" as the value of attribute "is_president_of". Second, OpenIE could not find the precise time points if there was very few such long time expressions as "from 2000 to 2006" in the sentences that contain the fact. On the other hand, PatternIE methods [16, 17, 22] use textual patterns to find the attribute values, but very few methods associate the values with time information. A pattern-based temporal anchoring method [23] assumes that both types of temporal contexts, time expression and document post time, are accurate to be the time of the attribute value being valid. However, this assumption is too strong to find precise temporal slots from the noisy contexts. For example, given the sentences:

"*In 1979, the [former U.S. President Jimmy Carter] deregulated the American beer industry...*" (posted on August 5, 2010), "*[Donald Trump, now President of United States,] published his first book in 1987...*" (posted on June 3, 2017),

the post time in the first sentence "2010" is not in the presidential term of President Carter (1977–1981), and the time expression in

Table 1: Pattern's reliability scores for country's presidency.

Textual Pattern p	$r^{(post)}(p)$	$r^{(tag)}(p)$
$Country president $Person	0.91	0.53
$Country 's president $Person	0.86	0.84
president $Person of $Country	0.84	0.70
former $Country president $Person	-1	0.85
$Country 's former president $Person	-0.81	0.83
$Person , now president of $Country ,	0.95	-0.89
current $Country president $Person	0.93	-0.59
$Country 's current president , $Person ,	0.81	0
new $Country president , $Person ,	0.57	-0.25
$Country 's newly elected president , $Person ,	0.20	-0.64
current $Country prime minister $Person	-1	-1
$Country premier $Person	-0.82	-0.86
$Country foreign minister $Person	-1	-1
$Country golfer $Person	-1	-1

the second sentence "1987" is not in the term of President Trump, either. We observe that different textual patterns may have different *reliability* on extracting the time points, conditionally to the temporal contexts (including time expression and post time):

• Pattern [former $Country president $Person] is reliable for the time expression "1979", not the post time "2010."

• Pattern [$Person, now president of $Country,] is reliable for the post time "2018", not the time expression "1987."

In this work, we propose a novel unsupervised approach based on PatternIE to infer the precise temporal slots from *incomplete* and *noisy* temporal contexts. For an attribute, PatternIE discovers a large set of textual patterns and uses them to extract EVT-tuples from text data: $p \rightarrow \{(e, v, t)\}$, where p is a textual pattern, e denotes the entity, v denotes the attribute value, and t is a time point from either time expression or post time. The goal is to infer temporal fact tuples $\{(e, v, [t_b, t_e])\}$, where t_b/t_e is beginTime/endTime, from millions of EVT-tuples (e.g., 5.3M for country's president). Our idea is to jointly estimate the pattern's reliability and the tuple's trustworthiness: if a set of tuples (including the time point) are more trustworthy, the pattern that extracted these tuples is more likely to be reliable; and, if a pattern is more reliable, its extractions are more likely to be true. Effectiveness of this iterative truth-discovery methodology has been demonstrated for finding the book's true author names from information on book-selling websites [18, 34].

Unfortunately, the truth-discovery algorithms cannot be directly applied to the proposed problem because they often hold the single-truth assumption (e.g., a book has only one true author list) to find conflicting values and thus capture unreliable sources [9, 19, 31, 34]. However, in the task of fact extraction, an entity may have multiple values at multiple time points. Then how can we know that the tuple ("u.s.", "jimmy_carter", 2010) is wrong (w.r.t. country's president) when United States had multiple presidents? Our common sense can help: if we had a trustworthy tuple ("u.s.", "barack_obama", 2010) and we knew that one country is likely to have *only one* president in one year, we would have a chance to find the conflicts.

Based on the above observation, we propose to use *the World's invariants* (i.e., quantitative common senses) including time-irrelevant and time-relevant constraints to find the conflicts and the truth. In the following section, we show that with just one seed pattern, we can generate and validate (1) time-irrelevant hypotheses:

• H1: one country is likely to have *multiple* presidents in the history;
• H2: one president is likely to serve *only one* country;
and (2) time-relevant hypothesis:
• H3: in one year, one country is likely to have *only one* president.
H2 and H3 can be used as constraints to find conflicts between tuples while H1 cannot. For example, suppose the fact ("barack_obama", "u.s.", [2009, 2017]) is true. So ("barack_obama", "china", 2014), which was extracted from the following sentence:

"*[President Barack Obama visited China] and attended the APEC summit...*" (posted on November 11, 2014),

is false because of H2 and ("jimmy_carter", "u.s.", 2010) is false because of H3. Then we know that (1) the pattern [president $Person visited $Country] is unreliable to extract a fact of country's president and (2) [former $Country president $Person] is unreliable to claim the fact's time point as the post time.

Based on the above ideas, estimating pattern reliability and finding conflicts with the World's invariants, we propose a Truth Finding-driven framework using the World's INvariants, called TFWIN, to extract precise temporal facts from text corpus. First, it uses PatternIE to structure the corpus into textual patterns and (e, v, t)-tuples. Second, it uses hypothesis testing to derive time-irrelevant and time-relevant constraints. Third, it iteratively evaluates pattern's reliability (upon two different temporal context types), estimates time point's trustworthiness, updates beginTime/endTime slots, and detects false tuples using the constraints. Two important properties of this algorithms are: (1) the time complexity is *quasi-linear* to the corpus size; and (2) it requires *NO* expensive annotations or heavy parameter tuning.

Table 1 presents the reliability scores given to a few pattern examples by our algorithm, where $r^{(post)}(p)$ and $r^{(tag)}(p)$ denote the reliability of pattern p on claiming the post time and temporal tag (i.e., time expression) as a valid time point, respectively. The score ranges from -1 to 1: -1 means that the extractions by the pattern are very likely to be false w.r.t. the specific attribute; 1 means the extractions are likely to be true; 0 means the extractions have very little correlation with the attribute. We observed that a textual pattern could be positive or negative on both, or positive on one and negative on the other, or vice versa. The pattern reliability match our intuition and effectively estimates the truth of value, beginTime, and endTime slots.

We summarize our main contributions as follows.

- We study the problem of precise temporal slot filling and point out the limitations of existing OpenIE and PatternIE.
- We propose the ideas of estimating pattern reliability and detecting conflicts with the World's invariants to handle incompleteness and noise of temporal contexts in text data.
- We propose a novel unsupervised framework (TFWIN) to find precise temporal facts from massive general corpora with no requirement of human annotations.
- Experiments demonstrated the effectiveness. AUC and F1 were improved by 25+% over the state-of-the-art.

The rest of this paper is organized as follows. Section 2 provides data preprocessing and problem definition. Section 3 presents the overview and details of the proposed framework. Experimental

results can be found in Section 4. Section 5 surveys the literature of related works. Section 6 concludes the paper.

2 PRELIMINARIES

We first introduce the techniques to turn the text data into "pattern-to-(entity, value, time)-tuples." Then we define the problem.

2.1 Structuring Text into "Pattern-Tuple"

Pattern-based methods are the most popular for information extraction in an unsupervised way from massive text corpora. The idea is that the textual patterns become frequent when entity names in the patterns are replaced by symbols $E (entity) or $V (value) [12, 13, 33] or their types like $Person or $Country [16, 22]. The type-level textual patterns can generate a large set of concrete (entity, value)-tuples from sentences. Then we will introduce how to have the "pattern-(entity, value, *time*) tuple" structures in detail.

2.1.1 Entity recognition and typing. We use the entity recognition and typing techniques to jointly recognize entity names and their *fine-grained* types simultaneously. For example, country names such as "United States", "Mexico", and "Burkina Faso" are recognized and typed as "$Location.Country" (simplified as "$Country").

2.1.2 Textual pattern mining. We use the textual pattern mining method MetaPAD [16] to discover "meta patterns" as information extractors. The meta pattern is defined in [16] as below.

Definition 2.1 (Meta Pattern). A meta pattern refers to a frequent textual pattern of entity types (e.g., $Country, $Person), words, and possibly punctuation marks, which serves as an integral semantic unit in certain context.

2.1.3 EVT-tuples and precise temporal fact tuples. For a specific attribute (e.g., country's president), the meta patterns of the corresponding entity type (e.g., $Country) and value type (e.g., $Person) can generate a set of (entity, value)-pairs. To discover temporal facts, we attach two types of time signals to the tuples: One is the "post time" which is the time of the document being posted, and the other is "time expression" or called "temporal tag" which is the nearest temporal tags (within a 20-word window) to the entity mention. We use a popular tagging tool [29] to extract the temporal tags. Now we can define the EVT-tuples as below.

Definition 2.2 (EVT-tuple). For a specific attribute a that refines the entity type as $c_e(a)$ and the value type as $c_v(a)$, an EVT-tuple refers to an (e, v, t)-tuple, where the type of e is $c_e(a)$, the type of v is $c_v(a)$, (e, v)-pair is extracted by a pattern p, and t is the timestamp attached to the pair.

Given the text data, we use the above techniques to preprocess the data and find millions of textual patterns, EVT-tuples, and their associations. We look for precise temporal fact tuples:

Definition 2.3 (Precise temporal fact tuple). For a specific attribute a, a temporal fact tuple refers to an $(e, v, [t_b, t_e])$-tuple, where for any time $t \in [t_b, t_e]$, v is a valid attribute value of e's attribute a. The beginTime t_b and endTime t_e must be precisely specified as time values (e.g., a concrete year, month, or date) instead of text-based time expressions (e.g., "from ... to ...", "since ...").

Table 2: Symbols and their descriptions.

Symbol	Description
$\mathcal{D}^{(*)}$ $* \in \{\text{"}post\text{"}, \text{"}tag\text{"}\}$	"Pattern-tuple" extraction list in which time signal comes from $*$
$\mathcal{P}$	The set of textual patterns
(e, v, t)	EVT-tuple (entity, value, time)
$c^{(*)}(p, (e, v, t))$	The count of times p extracts (e, v, t)
$(e, v, [t_b, t_e])$	Precise temporal fact tuple
$\mathcal{F}$	The list of true temporal facts
$r^{(*)}(p)$	The reliability score of pattern p
$w((e, v, t))$	The trustworthiness score of EVT-tuple
$\mathcal{H}$	A set of hypotheses to define conflicts
$f((e, v, t), \mathcal{F}, \mathcal{H}) \in$ $\{\text{"}T\text{"}, \text{"}F\text{"}, \text{"}U\text{"}\}$	Flag of checking (e, v, t) with $\mathcal{F}$ on $\mathcal{H}$: True, False, Undetermined
$\mathcal{P}^{(*)}_{(e,v,t)}$	Pattern set that extracts (e, v, t) from $\mathcal{D}^{(*)}$
$\mathcal{D}^{(*)}_{p}$	EVT-tuple set extracted by p from $\mathcal{D}^{(*)}$

2.2 Problem Definition

Table 2 describes the symbols we use in this paper. With the above concepts defined in Section 2.1, we define the problem of precise temporal fact extraction on the "pattern-tuple" structured data.

Problem (Precise Temporal Fact Extraction)**. Given** two "pattern-tuple" structured extraction lists $\mathcal{D}^{(post)}$ and $\mathcal{D}^{(tag)}$, that can be represented as $\mathcal{D}^{(*)} = \left\{\left(p, (e, v, t), c\right)\right\}$ in which the time t comes from two kinds of signals, i.e., "post" for the time of document being posted and "tag" for the nearest temporal tag, and where c can be concretely written, for example, $c^{(tag)}(p, (e, v, t))$ is the count of times that textual pattern p extracts the (e, v, t)-tuple along the temporal tag t, **(1) estimate** the reliability of each textual pattern that is described as a function $r^{(*)}(p) : p \in \mathcal{P} \rightarrow [-1, 1]$, where $\mathcal{P}$ is the set of textual patterns, **(2) infer** the trustworthiness of each EVT-tuple that is described as a function: $w(e, v, t) : (e, v, t) \rightarrow [-1, 1]$, and **(3) find** the list of true temporal fact tuple $\mathcal{F} = \left\{\left(e, v, [t_b, t_e]\right)\right\}$.

3 THE PROPOSED APPROACH

3.1 Overview

Figure 1 presents the illustration of the proposed TFWIN framework using the attribute *country's president* as an example.

The unsupervised approach is initialized by one seed pattern (assuming that it has high reliability) and iteratively does two-step learning: step (a) is to estimate the tuple trustworthiness based on pattern reliability and to update the two precise time slots of temporal facts with trustworthy time points; step (b) is to find true EVT-tuples (if satisfies the precise temporal facts) and false EVT-tuples (if conflicts with the World's invariants), and then to estimate the pattern reliability based on tuple trustworthiness. It will converge when all the EVT-tuples were separated into two parts: one can be located into the precise temporal facts, and the other violate at least one precise temporal fact holding the constraints.

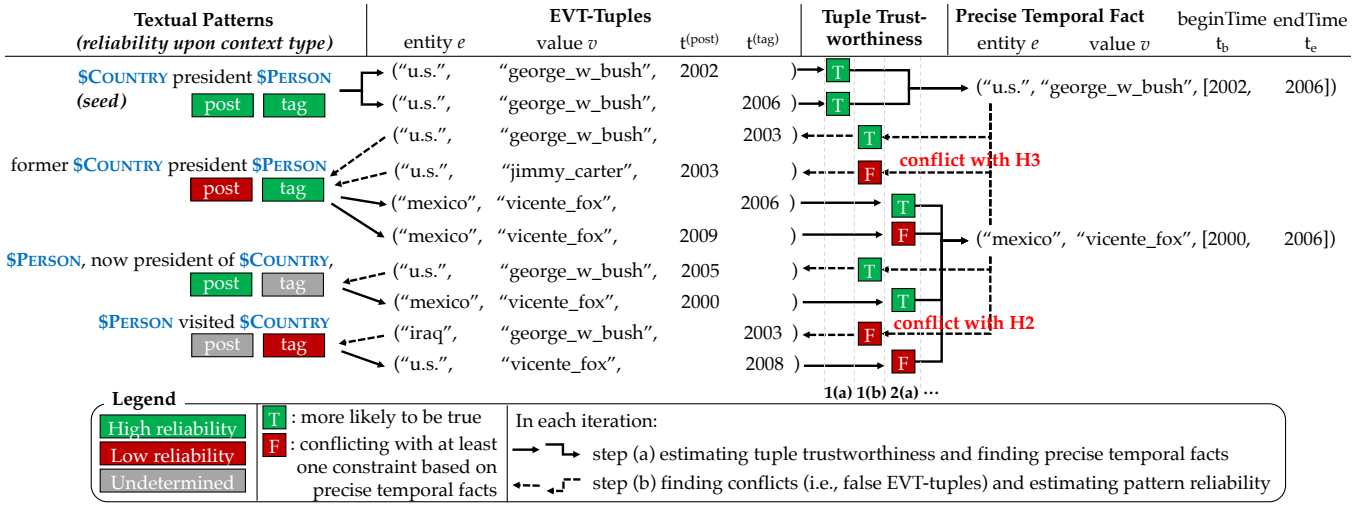

Figure 1: Our proposed TFWIN framework iteratively estimates reliability of textual patterns as information sources, infers trustworthiness of temporal facts, and resolves conflicts defined by the World's invariants (e.g., H2 and H3).

3.2 The Iterative Learning Algorithm

Generally, the algorithm is an iterative method. It starts with very light supervisory information, that is, *one* highly reliable pattern. Usually we use the pattern [$TypeOf*e* *a* $TypeOf*v*] as the seed pattern for attribute *a*. This pattern is not necessarily the most frequent one though most of the time it is. Since only one pattern is needed as the seed pattern, it will not take a lot of effort to find one. For example, [$Country president $Person] is a reliable seed pattern for the attribute *country's president*.

We use the frequent EVT-tuples extracted by the seed pattern to generate seed temporal fact tuples till *a conflict occurs*. Then we generate negative labels (i.e., false EVT-tuples) based on the constraints. With the positive and negative tuples, we iteratively estimate the reliability of textual patterns and infer the trustworthiness of undetermined tuples. We use tuples of good trustworthy scores, from the highest to low non-negatives, to update the positive labels (i.e., temporal fact tuples) till *a conflict occurs* or *the tuple's support is below a threshold* α and re-generate the negative labels. When it comes to convergence, the algorithm returns the final set of temporal facts.

3.2.1 Conflicts and negative label generation. Here we define a function of checking if an (e, v, t)-tuple is conflicted with existing true temporal facts $\mathcal{F}$ based on the set of hypotheses $\mathcal{H}$:

$$f((e,v,t),\mathcal{F},\mathcal{H}) = \begin{cases} \text{“}T\text{”}, & \text{if a fact tuple in } \mathcal{F} \text{ includes } (e,v,t); \\ \text{“}F\text{”}, & \text{if } (e,v,t) \text{ conflicts with } \mathcal{F} \text{ on any hypothesis } H \in \mathcal{H}; \\ \text{“}U\text{”}, & \text{else;} \end{cases}$$

where “T” denotes for True, “F” denotes for False, and “U” denotes for Undetermined. More formally, $f((e,v,t),\mathcal{F},\mathcal{H}) = \text{“}T\text{”}$ for $\forall\mathcal{H}$, if the statement

$$\exists(e,v,[t_b,t_e]) \in \mathcal{F}, t_b \le t \le t_e \tag{1}$$

is true. $f((e,v,t),\mathcal{F},\{H_{1e-to-1v}\}) = \text{“}F\text{”}$, if the statement

$$\exists(e,v',[t_b,t_e]) \in \mathcal{F}, v' \neq v \tag{2}$$

is true. $f((e,v,t),\mathcal{F},\{H_{1v-to-1e}\}) = \text{“}F\text{”}$, if the statement

$$\exists(e',v,[t_b,t_e]) \in \mathcal{F}, e' \neq e \tag{3}$$

is true. $f((e,v,t),\mathcal{F},\{H_{(1t)1e-to-1v}\}) = \text{“}F\text{”}$, if the statement

$$\exists(e,v',[t_b,t_e]) \in \mathcal{F}, t_b \le t \le t_e \text{ and } v' \neq v \tag{4}$$

is true. $f((e,v,t),\mathcal{F},\{H_{(1t)1v-to-1e}\}) = \text{“}F\text{”}$, if the statement

$$\exists(e',v,[t_b,t_e]) \in \mathcal{F}, t_b \le t \le t_e \text{ and } e' \neq e \tag{5}$$

is true. At the i-th iteration, given $\mathcal{F}^{(i)}$ and $\mathcal{H}$, we assign *polarized* trustworthiness score to tuples as below:

$$w((e,v,t)) = \begin{cases} 1, & \text{if } f((e,v,t),\mathcal{F},\mathcal{H}) = \text{“}T\text{”}; \\ 0, & \text{if } f((e,v,t),\mathcal{F},\mathcal{H}) = \text{“}U\text{”}; \\ -1, & \text{if } f((e,v,t),\mathcal{F},\mathcal{H}) = \text{“}F\text{”}. \end{cases} \tag{6}$$

Then we have positive/negative labels to estimate pattern reliability.

3.2.2 Pattern reliability estimation. The reliability score of pattern p can be estimated from the trustworthiness of its EVT-tuples:

$$r^{(*)}(p) = \frac{\sum_{(e,v,t)\in\mathcal{D}_p^{(*)}} c^{(*)}(p,(e,v,t))w((e,v,t))}{\sum_{(e,v,t)\in\mathcal{D}_p^{(*)}} c^{(*)}(p,(e,v,t))|w((e,v,t))|} \in [-1,1], \tag{7}$$

where $*$ is for temporal context type (or called time signal source, either “post” for post time or “tag” for temporal tag) and $c^{(*)}(p,(e,v,t))$ is the count of times that the (e,v,t)-tuples are extracted by p. The idea is that a pattern is more (un-)reliable, if its EVT-tuples are more (un-)trustworthy. Note that the pattern reliabilities are separately modeled based on different time signal sources. In the experiments, we will compare the performances of our algorithm's settings: (1) between source-aware and source-unaware modeling and (2) between considering and not considering counts.

3.2.3 Tuple trustworthiness inference. When the pattern reliabilities are estimated, we evaluate the trustworthiness of the *undetermined* tuples as below:

$$w((e,v,t)) = \frac{\sum_* \sum_{p \in \mathcal{P}^{(*)}_{(e,v,t)}} c^{(*)}(p,(e,v,t)) r^{(*)}(p)}{\sum_* \sum_{p \in \mathcal{P}^{(*)}_{(e,v,t)}} c^{(*)}(p,(e,v,t))} \in [-1,1], \quad (8)$$

where we integrate pattern reliability's contributions from both time signal sources. If an EVT-tuple is often extracted by (un-)reliable patterns, it is more (un-)trustworthy. In the experiments, we will investigate the effectiveness of considering counts c.

4 EXPERIMENTS

Here we conduct experiments to answer the following quesitons:

Q1. (Effectiveness) Is TFWIN effective in mining temporal facts from text data? Do both time sources (post time and temporal tag) help? Does the truth finding module improve the mining process? Does the World's Invariants derived from significance tests help?

Q2. (Interpretability) Do textual patterns have different reliabilities? For one pattern, are its reliabilities the same or different upon different time sources?

4.1 Experimental Settings

Text data description. The dataset has 9,876,086 news articles (4 billion words) published from 1994–2010.

Structured data size and ground truth. We focus on finding precise temporal facts on *country's president*. For *country's president*, we have 53,298 textual patterns of $Country and $Person, 116,631 unique EVT-tuples, and as many as **5,335,344** tuple extractions, where the timestamps are refined to the *year* level. We collected the ground truth from Google and Wikipedia, which contains 365 $(e,v,[t_s,t_e])$-tuples of 130 countries and can then be split into 3,175 (e,v,t)-tuples.

Evaluation methods. We evaluate the performance of our method and all baselines on mining the 3,175 true (e,v,t)-tuples using standard Information Retrieval metrics: *precision*, *recall*, *F1 score*, and *AUC* (Area Under the Curve). Precision is the the fraction of true (e,v,t)-tuples among the (e,v,t)-tuples split from $(e,v,[t_s,t_e])$-tuples. Recall is the fraction of true (e,v,t)-tuples among the (e,v,t)-tuples split from the ground truth. F1 score is the harmonic mean of precision and recall. For all of the metrics, the higher scores indicate that the method has better performance.

Baseline methods and parameter settings. There was no existing work that introduces the idea of truth discovery methodology to the problem of temporal fact extraction from unstructured data. Our work proposes to structure the data with textual patterns and use the World's invariants for truth finding. We compare our method with existing iterative-based (or called propagation-based) truth finding algorithms as well as its multiple variants when given the structures. As shown in Table 3, the methods are as follows.

(1) MajVote-t [11]: it uses the weighted majority voting strategy and returns the most frequent (e,v,t)-tuples;
(2) MajVote-$[t_s,t_e]$: it composites frequent (e,v,t)-tuples into $(e,v,[t_s,t_e])$-tuples, where $t_s = \min t$ and $t_e = \max t$;
(3) TruthFinder-$H_{1e-to-1v}$ [34]: we modify TruthFinder by taking its hypothesis as $H_{1e-to-1v}$, because it assumes "one book only has one author list". Then the patterns and facts of attribute are regarded as the *websites* and *books' author list*, respectively.
(4) TruePIE [17]: it assumes hypothesis $H_{1v-to-1e}$ without considering time-relevant invariants which are very important for temporal fact extraction;
(5) TFWIN and its variants: all TFWIN methods use the valid time-irrelevant hypothesis $H_{1v-to-1e}$ and the valid time-relevant hypothesis $H_{(1t)1e-to-1v}$ that were derived from hypothesis tests. The four variants discuss whether the count of pattern-tuple extraction $c(p,(e,v,t))$ matters in evaluating the pattern reliability $r(p)$ (Eq.(7)) and tuple trustworthiness $w((e,v,t))$ (Eq.(8)).

4.2 Experimental Results

In this section, we present results on both effectiveness and interpretability of the proposed approach.

4.2.1 Effectiveness. Table 3 presents the AUC and F1 of all the methods on finding *country's president* in the "pattern-tuple" structures from text data.

Overall performance. The best baseline method MajVote-$[t_s,t_e]$ gives an AUC of 0.4958 when integrating post time and temporal tag for tuple majority voting, and gives an F1 of 0.6049 on post-time-only tuples. Our TFWIN, which conducts truth finding with two valid hypotheses and source-aware pattern reliability modeling, generates an AUC of 0.6146 (**+24.0%** over the baseline) and an F1 of 0.7572 (**+25.2%**), when $\alpha = 10$. The best of TFWIN ($\alpha = 7$) shows an AUC of 0.6216 (**+25.4%**) and an F1 of 0.7654 (**+26.5%**). Details of different experimental settings will be discussed as follows:

TFWIN vs majority voting. Table 3 shows that MajVote-$[t_s,t_e]$ performs significantly better than MajVote-t (+48.6% AUC; +37.3% F1) because the attribute *president* has $[t_s,t_e]$-period property.

TFWIN vs TruthFinder and TFWIN: comparing with existing iterative-based truth finding methods. TruthFinder [34] assumes one object has only one true fact; however, it doesn't make sense to assume $H_{1e-to-1v}$ (one country has only one president). It is no longer the book's authorlist case. So the AUC and F1 are very poor (< 0.01). We derive two World's invariants, a time-irrelevant constraint $H_{1v-to-1e}$ and a time-relevant constraint $H_{(1t)1e-to-1v}$. TruePIE [17] can be applied to time-irrelevant cases that follow $H_{1v-to-1e}$. The AUC is 0.06 and the F1 is 0.14. The performance is better than TruthFinder, because TruthFinder does not use this correct hypothesis. Our TFWIN uses both valid invariants as well as the time-relevant invariants, and therefore, it outperforms TruthFinder and TruePIE: the AUC becomes 0.62 (10.6× higher) and the F1 is 0.76 (5.4× higher). These demonstrate the power of using the valid World's invariants in true fact discovery.

4.2.2 Interpretability. Table 1 presents the reliability scores of some textual patterns upon the *post time* and *temporal tag* sources. Table 4 shows a subset of temporal facts TFWIN generates.

Pattern reliability modeling. From Table 1, we observe that (1) the top three frequent patterns on *country's president* have good reliability scores upon both time sources; (2) if a pattern has the words indicating past tense like "former", it has good reliability

Table 3: TFWIN wins against truth-discovery baselines on finding true *country's president* from unstructured data.

	Weight in pattern reliability estimation in Eq.(7)	Weight in tuple trustworthiness inference in Eq.(8)	Post time only		Temporal tag only		Post time + Temporal tag			
							Source unaware		Source aware	
			AUC	F1	AUC	F1	AUC	F1	AUC	F1

Table 4: Temporal fact $(e, v, [t_s, t_e])$-tuples and the truth.

Attribute value v	Start year t_s (truth $\hat{t}_s$)	End year t_e (truth $\hat{t}_e$)
entity e = "United States", attribute a = "president"		
F. D. Roosevelt	1933	1944
H. S. Truman	1945	**1953** (1952)
D. D. Einsenhower	**1954** (1953)	1960
J. F. Kennedy	1961	**1963** (1962)
L. B. Johnson	**1964** (1963)	1968
R. M. Nixon	1969	**1974** (1973)
G. R. Ford	**1975** (1974)	1976
J. E. Carter	1977	1980
R. W. Reagon	1981	1988
G. H.W. Bush	1989	**1993** (1992)
W. J. Clinton	**1994** (1993)	2000
G. W. Bush	2001	2008
B. H. Obama	2009	2016
entity e = "Burundi", attribute a = "president"		
C. Ntaryamira	1994	1994
S. Ntibantunganya	**1995** (1994)	1996

upon temporal tag but poor reliability upon post time, because the person is absolutely no longer the president at the post time but the temporal tag around the pattern may present the time when the person was on the stage; (3) if a pattern has the words like "now", "newly" or "current", it has good reliability upon post time but poor reliability upon temporal tag; (4) if a pattern has the words of other occupations such as "premier" and "golfer", the reliabilities are negative upon both sources. For (3), note that if a person is newly elected as a president in a year, he/she may still not be in office, so the reliability upon post time is only 0.20.

Results on temporal fact mining. Table 4 shows the names and presidential terms of United States presidents since the year 1933. We observe that the president names v are all correct, and the t_s and t_e of TFWIN's prediction sometimes has only one year difference from the ground truth. The prediction well preserves the valid invariants $H_{1v-to-1e}$ and $H_{(1t)1e-to-1v}$.

5 RELATED WORK

In this section, we review two relevant fields to our work, temporal fact extraction and truth discovery.

5.1 Temporal Fact Extraction

The task is defined as extracting (entity, attribute name, attribute value)-tuples along with their time conditions from text corpora [4, 15, 26, 27, 35]. The concept of fact is broader than the relation between two entities. There are two series of existing natural language processing models: one is based on dependency parsing [5, 8, 21, 24], and the other is based on learning neural networks with human annotations [6, 20, 28]. These models usually work on individual sentences/paragraphs [10, 30], and suffer from high complexity and unavailability of training data [14]. It is important to leverage the data amount and evaluate the trustworthiness of extracted information using the truth finding technology. Fortunately, textual patterns, such as E-A patterns [12], parsing patterns (by PATTY [22]), and meta patterns (by MetaPAD [16]), have been proposed to turn text data into structures in an unsupervised way. However, it was not designed for the problem of temporal fact extraction: it did not consider the two types of temporal contexts. We infer precise temporal slots from post time and time expressions.

5.2 Truth Discovery

The era of big data draws the serious issue of "Veracity" on resolving conflicts among multi-source information [3]. Truth discovery, which integrates multi-source noisy information by estimating the reliability of each source, has emerged as a hot topic [19]. Several truth discovery methods have been proposed for various scenarios, and they have been successfully applied in diverse application domains. TruthFinder proposed the source consistency assumption, iteratively estimated source reliabilities and identified truths [34]. CRH estimated the source reliability on heterogeneous data [18] The evolution of source reliability has been explored in [32]. We propose to apply truth discovery of estimating information extractor reliability to temporal fact extraction.

6 CONCLUSIONS

In this paper, we studied a challenging problem of precise temporal slot filling and point out the limitations of existing OpenIE and PatternIE. We proposed a novel unsupervised, pattern-based, truth finding-driven framework to find precise temporal facts from text data without human annotations. Experiments demonstrated the effectiveness and efficiency.

ABSTRACT

Users are usually involved in multiple social networks, without explicit *anchor links* that reveal the correspondence among different accounts of the same user across networks. Anchor link prediction aims to identify the hidden anchor links, which is a fundamental problem for user profiling, information cascading, and cross-domain recommendation. Although existing methods perform well in the accuracy of anchor link prediction, the pairwise search manners on inferring anchor links suffer from big challenge when being deployed in practical systems. To combat the challenges, in this paper we propose a novel embedding and matching architecture to directly learn binary hash code for each node. Hash codes offer us an efficient index to filter out the candidate node pairs for anchor link prediction. Extensive experiments on synthetic and real world large-scale datasets demonstrate that our proposed method has high time efficiency without loss of competitive prediction accuracy in anchor link prediction.

1 INTRODUCTION

With the benefit of socialized online services, users are often active across multiple online social networks simultaneously. The integration of user's data from multiple social networks can help to describe comprehensive user profile and interests so as to provide various of applications, including precision marketing and cyber security [3, 25, 29]. Meanwhile, the transferred user data from well established social media sites can mitigate the data sparsity and solve cold start problem for new founded sites [11, 15]. The key of bridging user identities across multiple social networks can be formalized as *anchor link prediction* (ALP) [1, 21, 22, 36], i.e., identifying hidden inter-network links connecting the accounts from the same users across different networks.

(a) Traffics between the most popular social networks (from May 2018 to July 2018).

(b) Time consumption when executing 100 million ALP tasks on different scale of social networks by the different search strategies.

Figure 1: The necessity of anchor link prediction and high efficient solutions.

Most of existing studies in literatures attempt to improve inference accuracy leveraging types of information. The first category of methods relies on the profile information of users by pairwise similarity measures [12, 14, 33, 35]. However, the performance of these methods heavily depends on the availability and quality of user profile [4, 25, 30]. Consequently, these methods are difficult to be generalized to various scenarios [31, 32]. The second category of methods, in contrast, resorts to structural information, anticipating good generalization capability. Typical examples include exploiting local and global consistence pairwisely in topology and structures [7, 8, 19, 23, 24] across networks. Although existing methods perform rather well in the accuracy of anchor link prediction [9, 13, 16, 18, 20, 34], the pairwise search manners on inferring anchor links suffer from big challenge when being deployed in practical systems.

The most prominent challenge for anchor link prediction lies in *scalability*. According to the statistical report on the most popular social media[1], millions of co-visits exist between social media (see Figure 1(a)). However, the time consumption for searching anchor links would be extremely increased by the network size in traditional pairwise manners. As shown in the Figure 3(d), the

https://doi.org/10.1145/3308558.3313430

time cost will be over 2 million years when executing 100 million ALP tasks on Facebook, Instagram or Youtube. Meanwhile, the time consumption is still up to 14.7 days even if applying tree-based search methods.

In this paper, we propose a novel architecture for learning binary hash codes across networks with characteristics in low storage cost and fast retrieval speed by the means of indexing candidate users in anchor link prediction. The goal of our proposed method is to map the structural features from different networks into a Hamming space of binary codes, preserving the similarity between user identities. The compact binary codes are capable of highly efficient retrieval on large-scale datasets [2, 5, 6, 27, 28]. Two anchor-link-aware stages, including embedding and matching, are introduced for efficient usage of labeled data in our proposed learning architecture. Firstly, we conduct network embedding on each network to capture structural features. Embedding method is compatible with learning effective representation of users in low-dimensional space. Besides, the learned embeddings are subject to the explicit constraints on labeled anchor links, eliminating the inference bias by inhomogeneous learning process across networks. In matching stage, the network embeddings from different networks are mapped into a common Hamming space which enables the retrieval process in an indexing way. More specifically, the main contributions of this work are three-folds:

- To solve the challenge in scalability, we propose a novel anchor link modeling method with learning binary hash codes according to network structures. The proposed modeling method is characteristic in low storage cost and fast retrieval speed.
- To solve the inhomogeneity in learned embeddings acr-oss networks, we introduce an anchor-link-aware constraint on network embedding, which can improve the prediction performance in the next matching stage.
- Experiments on time consumption show the potentials of our proposed method in real applications with large-scale networks. Meanwhile, the prediction performance resulted by our proposed method is also competitive to state-of-the-art methods.

2 PROBLEM DEFINITION

In this section, we introduce some basic notations and definitions in anchor link prediction task. A social network can be denoted as $G = \{\mathcal{U}, \mathcal{E}\}$, where $\mathcal{U}$ contains all user identities and $\mathcal{E} \subseteq \mathcal{U} \times \mathcal{U}$ is the set of social relationships in the network. Without loss of generality, we focus on the anchor link prediction on two social networks, denoted as network G^s and network G^t respectively. Note that the settings of anchor link prediction on two networks can be easily extended to multiple social networks. For each user identity in one network, the objective of anchor link prediction is to identify, if any, its counterpart in another network. This task can be formally formulated as follows.

Definition 2.1. **Anchor link prediction:** Given two social networks $G^s = \{\mathcal{U}^s, \mathcal{E}^s\}$ and $G^t = \{\mathcal{U}^t, \mathcal{E}^t\}$, the objective of anchor link prediction is to learn the discriminative function $\mathcal{F}$: $\mathcal{U}^s \times \mathcal{U}^t \to \{0, 1\}$, which estimates whether a pair of user identities from two networks belong to the same nature person, i.e.,

$$\mathcal{F}(u, v) = \begin{cases} 1, \text{if } u \in \mathcal{U}^s \text{ and } v \in \mathcal{U}^t \text{ belong to same person,} \\ 0, otherwise. \end{cases}$$

A labeled set of anchor links, denoted as $\mathcal{A} = \{(u, v) | u \in \mathcal{U}^s, v \in \mathcal{U}^t, \mathcal{F}(u, v) = 1\}$, is also provided as the supervised information for learning function $\mathcal{F}$.

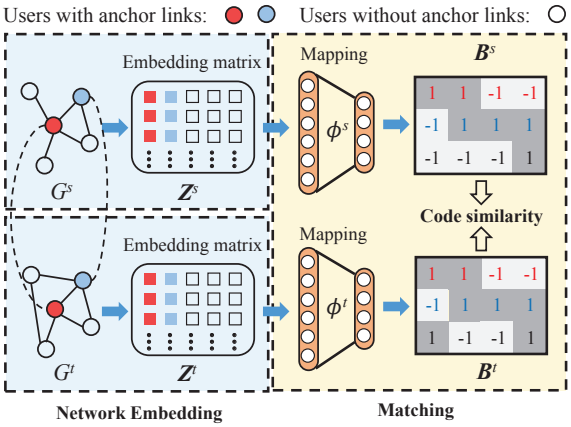

Figure 2: The framework of our proposed HALF model.

We propose a supervised **H**ash-b**A**sed **L**earning **F**ramework for ALP with two anchor-link-aware stages, called HALF. The architecture of proposed model is shown in Figure 2. In this model, the first stage conducts network embedding on each network respectively. The objective of network embedding is to compress the high dimensional sparse network structure (i.e., adjacent matrix) into a low dimensional dense representation, preserving social structures of users. The second stage maps network embedding from each network into a common Hamming space and identifies the anchor links in the mapping space. Formally, the objective function of our proposed model can be presented as

$$\min_{\mathbf{Z}^s, \mathbf{Z}^t, \mathbf{B}^s, \mathbf{B}^t} \mathcal{L} = O\left(G^s, G^t, \mathcal{A} | \mathbf{Z}^s, \mathbf{Z}^t\right) + \mathcal{F}\left(\mathcal{A} | \mathbf{B}^s, \mathbf{B}^t\right), \quad (1)$$

where $\mathbf{Z}^s$ and $\mathbf{Z}^t$ are the embedding matrices of network G^s and G^t respectively. The anchor-link-aware embedding loss $O\left(G^s, G^t, \mathcal{A} | \mathbf{Z}^s, \mathbf{Z}^t\right)$ reflects the capability of generating networks by $\mathbf{Z}^s$, $\mathbf{Z}^t$ under the constraints of $\mathcal{A}$. In the second part of the objective function, the symbol $\mathbf{B}$ refers to $\text{sign}(\Phi(\mathbf{Z}))$ with each element being defined as follows:

$$\mathbf{B} = \text{sign}(\Phi(\mathbf{Z})) = \begin{cases} 1, \Phi(\mathbf{Z}) \geq 0, \\ -1, \Phi(\mathbf{Z}) < 0, \end{cases}$$

where the mapping functions $\Phi : \mathbf{Z} \to \mathbf{R}^K$ try to map each user representation into a data point which can be easily transferred into a binary Hamming space. Note that the inputs and the parameters are independent in $\mathbf{B}^s$ and $\mathbf{B}^t$ respectively, we use the same notation for briefly illustrating the objective function. Therefore, the matching loss $\mathcal{F}\left(\mathcal{A} | \mathbf{B}^s, \mathbf{B}^t\right)$ depicts how well the learned binary hash codes capture the observed anchor links.

Direct optimization on Eq. (1) is quite difficult because of the interdependence between $\mathbf{Z}^s$, $\mathbf{Z}^t$, $\mathbf{B}^s$ and $\mathbf{B}^t$. Therefore, we turn to optimize the objective function by two stages separately, including network embedding and matching. Next we will introduce our proposed model in detail.

3 MODEL

In this section, we will introduce the detail of our proposed model by two anchor-link-aware stages: network embedding and matching.

3.1 Network embedding

Network embedding aims to embed a network into a low dimensional latent space, where each user is represented as a d-dimensional vector. The learned user representations are capable of depicting neighborhood similarity and community membership, which are important features for exploring anchor links. However, under the issues of anchor link prediction, independently learning embeddings for each network may lead to great matching errors when trying to map user representations from independent embedded spaces. Therefore, we introduce an anchor-link-aware network embedding method, exhibiting better performance in anchor link prediction.

Firstly, we introduce two vectors z_i and z'_i for user i, where z_i is user i's representation and z'_i is her *context* representation. For each directed edge $\langle u_i, u_j \rangle$, we define the probability of *context* u_j generated by user u_i as follows,

$$p\left(u_j|u_i\right) = \frac{\exp\left({z'_j}^T \cdot z_i\right)}{\sum_{k=1}^{|\mathcal{U}|} \exp\left({z'_k}^T \cdot z_i\right)}, \tag{2}$$

where $|\mathcal{U}|$ is the number of users in the network. The Eq. (2) captures the similarity between two users who share common neighborhoods. According to Eq. (2), the embedding loss of network G^s and G^t can be respectively formalized as

$$O\left(G^s\right) = -\sum_{\langle u_i^s, u_j^s \rangle \in \mathcal{E}^s} \log p\left(u_j^s|u_i^s\right), \tag{3}$$

and

$$O\left(G^t\right) = -\sum_{\langle u_i^t, u_j^t \rangle \in \mathcal{E}^t} \log p\left(u_j^t|u_i^t\right). \tag{4}$$

For circumventing the performance reduction introduced by independently embedding networks, we introduce constraints to all the nodes in the labeled anchor link set. For each anchor link $(u_i^t, u_j^s) \in \mathcal{A}$, we define the probability of its generation as

$$p\left(u_i^t, u_j^s\right) \sim \frac{z_i^t \cdot z_j^s}{\|z_i^t\| \|z_j^s\|}, \ \textit{iff}\ (u_i^t, u_j^s) \in \mathcal{A}, \tag{5}$$

and the negative logarithmic likelihood of anchor link set $\mathcal{A}$ can be formulated as

$$O\left(\mathcal{A}|G^s, G^t\right) = -\sum_{(u_i^t, u_k^s) \in \mathcal{A}} \log p\left(u_i^t|u_k^s\right) \tag{6}$$

According to Eq. (3), Eq. (4) and Eq. (6), we have the anchor-link-aware embedding loss in the embedding stage, described as

$$\min_{\mathbf{Z}^s, \mathbf{Z}^t} O\left(G^s\right) + O\left(G^t\right) + \gamma_e O\left(\mathcal{A}|G^s, G^t\right), \tag{7}$$

where γ_e is a hyper-parameter.

3.2 Matching

In previous works, finding one user's counterparts in other networks needs to loop over all possible candidates, resulting in huge, matching cost. In this paper, we adopt a learning method to map user representations from the original space into a Hamming space of binary codes. The binary codes can preserve the similarity in the original space and improve retrieval speed in anchor link prediction task. Thus, we introduce an end-to-end deep architecture for efficiently learning binary codes in the matching stage.

Firstly, we learn two mapping functions on each network, transferring the network embeddings into a continuous common space so as to determine whether the user identities are matched. We define $\phi_i^s = \Phi^s(z_i^s)$ and $\phi_j^t = \Phi^t(z_j^t)$, referring to the outputs of mapping function Φ^s and Φ^t with $z_i^s \in \mathbf{Z}^s$ and $z_j^t \in \mathbf{Z}^t$ serving as inputs respectively. The matching problem is formalized as a multi-class classification issue where the inputs are the outputs of mapping functions from two networks. We define the probability of the anchor link with u_i^s and its counterpart u_j^t in two networks as

$$p\left(u_j^t|u_i^s\right) = \frac{\exp\left({\phi_j^t}^T \cdot \phi_i^s\right)}{\sum_{u_k^t \in \mathcal{U}^t} \exp\left({\phi_k^t}^T \cdot \phi_i^s\right)}. \tag{8}$$

According to the probability defined in Eq. (8), the matching loss can be formulated as follows,

$$\mathcal{L}_{match} = -\sum_{(u_i^s, u_j^t) \in \mathcal{A}} \log p\left(u_j^t|u_i^s\right). \tag{9}$$

Then we learn the binary codes based on the continuous common space. We define the loss between binary codes and mapped user representations as

$$\mathcal{L}_{hash} = \|\mathbf{B}^s - \vec{\phi}^s\|_F^2 + \|\mathbf{B}^t - \vec{\phi}^t\|_F^2, \tag{10}$$

where $\vec{\phi}$ is the matrix of mapped user representations where the i-th column corresponds to user u_i. The loss limits the distance between the outputs of mapping functions and corresponding binary codes. The way of relaxation on binary codes avoids discrete learning problem, which may deteriorate the accuracy of the learned binary codes.

Overall, we define the loss of entire matching stage as follows,

$$\begin{aligned}\mathcal{F}\left(\mathcal{A}|\mathbf{B}^s, \mathbf{B}^t\right) =& \mathcal{L}_{match} + \gamma_m \mathcal{L}_{hash} \\ &+ \eta_m \left(\|\vec{\phi}^s\|_F^2 + \|\vec{\phi}^t\|_F^2\right),\end{aligned} \tag{11}$$

where γ_m and η_m are hyper-parameters. The third term $\left(\|\vec{\phi}^s\|_F^2 + \|\vec{\phi}^t\|_F^2\right)$ regularizes the learned mapping results.

After obtaining the binary code of each user in two networks, we can use hashing-based search algorithms, e.g., locality sensitivity hashing, to calculate the similarity between binary codes and choose the most similar ones as the inferring results.

4 OPTIMIZATION

In this section, we develop algorithm to estimate the parameters of the proposed model.

4.1 Optimization on embedding stage

The direct optimization on Eq. (2) is computational expensive, requiring the summation over the entire set of users. To address this problem, we adopt the approach of negative sampling proposed in [17]. We define the negative sampling by the formalization as follows

$$\log \sigma\left(z_j'^{T} \cdot z_i\right) + \sum_{k=1}^{K} E_{u_k \sim P_n(u)}\left[\log \sigma\left(-z_k'^{T} \cdot z_i\right)\right], \qquad (12)$$

which is used to replace every $\log p\left(u_j|u_i\right)$ term in the objective function of the embedding stage. The function $\sigma(x) = 1/\left(1+\exp(-x)\right)$ is the sigmoid function. The negative sampling distinguishs the edge $\langle u_i, u_j\rangle$ from K noise edges $\langle u_i, u_j\rangle$ sampled from noise distribution $P_n(u)$. We set the noise distribution $P_n(u) \propto {d_u}^{3/4}$, where d_u is the out-degree of user u. Besides, we introduce pre-trained process in order to stabilize the training process [10].

4.2 Optimization on matching stage

The optimization on logarithmic Eq. (8) also suffers high computational cost when summarizing compositions on all possible anchor links $\mathcal{A}$. To efficiently estimate the parameters on mapping, we maximize the $\log p\left(u_i^s, u_j^t\right)$ with negative sampling as

$$\log \sigma\left(\phi_j^{t\,T} \cdot \phi_i^s\right) + \sum_{k=1}^{K} E_{u_k \sim P_n'(u)}\left[\log \sigma\left(-\phi_k^{t\,T} \cdot \phi_i^s\right)\right], \qquad (13)$$

where the negative samples are drawn from $P_n'(u) = 1/|\mathcal{U}|$. Meanwhile, we construct a generalized linear function as the mapping functions with shared parameters across networks to handle the overfitting problem caused by scarce labeled anchor links in real applications, that is, $\phi_i = \tanh(w \cdot z_i + bias)$ where w is a parameter matrix.

According to the formalization on matching stage, the best matching performance is achieved when the binary codes from labeled anchor links are set to be the same. Hence we regularize $b_{(i,j)} = b_i^s = b_j^t$, *iff* $(u_i, u_j) \in \mathcal{A}$ in the training process. If we only consider the observed anchor links, the function $\|\mathbf{B}^s - \vec{\phi}^s\|_F^2 + \|\mathbf{B}^t - \vec{\phi}^t\|_F^2$ can be unfolded as

$$\sum_{(u_i,u_j)\in\mathcal{A}} \left(\|b_{(i,j)}\|^2 + \|\vec{\phi}_i^s\|^2 + \|\vec{\phi}_j^t\|^2 - 2b_{(i,j)}^T \cdot \left(\vec{\phi}_i^s + \vec{\phi}_j^t\right)\right).$$

It can be easily derived that the minimization of function $\|\mathbf{B}^s - \vec{\phi}^s\|_F^2 + \|\mathbf{B}^t - \vec{\phi}^t\|_F^2$ is equivalent to maximizing $b_{(i,j)}^T \cdot (\vec{\phi}_i^s + \vec{\phi}_j^t)$, when $\vec{\phi}^s$ and $\vec{\phi}^t$ are fixed. Therefore, we have $b_{(i,j)} = \text{sign}(\vec{\phi}_i^s + \vec{\phi}_j^t)$.

At the end, we can reformulate the matching loss in Eq. (11) as follows,

$$\begin{aligned}\mathcal{F}'\left(\mathcal{A}|\mathbf{B}^s, \mathbf{B}^t\right) = &-\log \sigma\left(\phi_j^{t\,T} \cdot \phi_i^s\right) - \sum_{k=1}^{K}\left[\log \sigma\left(-\phi_k^{t\,T} \cdot \phi_i^s\right)\right] \\ &+ \gamma_m \sum_{(u_i,u_j)\in\mathcal{A}} \left(\|b_{(i,j)} - \vec{\phi}_i^s\|^2 + \|b_{(i,j)} - \vec{\phi}_j^t\|^2\right) \\ &+ \eta_m \left(\|\vec{\phi}^s\|_F^2 + \|\vec{\phi}^t\|_F^2\right).\end{aligned}$$

The HALF algorithm for parameter estimation is described in Algorithm 1. Also we introduce optimization technics for achieving high computational efficiency and prediction accuracy, such as negative sampling and pre-training in embedding stage, parameter sharing in matching stage.

Algorithm 1 HALF

Input: Social network G^s and G^t, labeled anchor links $\mathcal{A}$.
Output: Network embedding $\mathbf{Z}^s$ and $\mathbf{Z}^t$, binary hash code matrices $\mathbf{B}^s$ and $\mathbf{B}^t$.

Initialization: Initialize parameters with random values, including $\mathbf{Z}^s$, $\mathbf{Z}^t$, ϕ^s and ϕ^t.

5 EXPERIMENT

In experiments, we compare our proposed method to the state-of-the-art methods for anchor link prediction on both synthetic data and real data. The results show that the proposed method achieves better performance in predicting anchor links with higher prediction accuracy and time efficiency.

5.1 Comparative methods

Previous anchor link prediction methods seldom can be well applied to large-scale data, suffering high computational cost in network embedding and matching. To better illustrate the performance of our proposed model, we choose scalable methods as baselines. The compared methods are summarized as follows:

- **FRUI-P** [37]: This work proposes an unsupervised method. We use the method to illustrate the performance when confronting with scarce label data.
- **MNA** [9]: This method models anchor link prediction as a classification problem based on human-craft features.
- **PALE-MLP** [16]: This method is a two-stage model, including separated network embedding and matching.
- **IONE** [13]: This method proposes a joint learning framework on embedding and matching.

As only orientation of vector is kept in Hamming space, hash codes would suffer from loss of information. For better illustrating the prediction accuracy, we introduce the codes from our proposed method without binarization to compare with the baselines.

5.2 Evaluation

We regard the prediction task of finding the matching node in another network as a ranking problem with the similarity score of two nodes' representations being served as ranking scores. Due to

the high matching cost in baselines, 10 random nodes are sampled for each node. These sampled nodes, together with the ground truth matching node, are provided as candidate set. Each model is expected to correctly recognize the ground truth matching node from the candidate set. The prediction performance is evaluate by *Mean Reciprocal Rank* (MRR). Larger MRR values indicate better performance.

5.3 Experiments on synthetic data

The goal of experiments on synthetic data is to validate the effectiveness of our proposed models in prediction accuracy and time complexity.

5.3.1 Dataset. The synthetic data is built from a dataset crawled from Blogcatalog[2], processed by Tang and Liu [26]. The dataset contains 10,312 bloggers and 333,983 social links of bloggers. We follow the sampling strategy mentioned in [16] where $\alpha_s = 0.5$ and $\alpha_c = 0.8$ to sample two sub-networks from Blogcatalog network to serve as source network G^s and target network G^t in anchor link prediction. Every node in one sub-network has a matched node in the other sub-network, marked as anchor link. All labeled anchor links are randomly separated into two datasets by a fixed proportion, denoted as training and test datasets. Next, we conduct experiments with different settings on training data size in order to validate the effectiveness of our proposed model on label sparsity.

5.3.2 The effects of label sparsity. We examine the effects of training data size by varying the size from 5% to 60% of the entire labeled data. The experimental results are shown in Figure 3(a). In the figure, we can see that our proposed method achieves the best performance on MRR than all baselines under different settings of training data size. It is interested that FRUI-P is the second-best solution when merely given 5% of labels for training. It indicates that supervised methods would be invalid under the problem of label sparsity. However, our proposed method is still competitive to unsupervised method with scarce labeled data, showing the better performance with 5% of labeled data for training.

5.4 Experiments on real data

The goal of the experiments on real data is to demonstrate the effectiveness of our proposed models in real applications. The performance is evaluated by prediction accuracy and efficiency in retrieval time.

5.4.1 Dataset. Networks from two popular social networking services in China are adopted as datasets:

- **Douban**[3]: Douban offers services for their users to freely share favorite content through social network, including movies, books, music and other off-line events.
- **Sina Weibo**[4]: Weibo is a very popular microblogging platform in China. The number of registered users has exceeded 300 millions by the end of 2017.

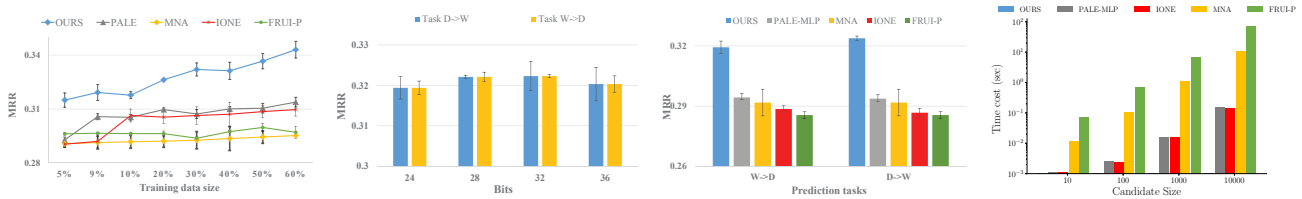
The anchor link set is crawled though Douban data service API. In Douban, users would prefer to post the links to their own Weibo accounts in descriptions. According to this reliable information, we link 15,009 pairs of accounts across the two social networks. Then we extract the social networks relative to the labeled users in each network. The basic statistics of extracted real data is illustrated in Table 1. As described in the table, we can see that only 1.9% of total Weibo users and 0.7% of total Douban users have their anchor links being labeled in our dataset. The scarcely labeled anchor links with huge network size pose a big challenge in both optimization and matching in anchor link prediction. In the following experiments, we conduct two series of experiments, denoting "D → W" where we try to find the connected Weibo account for a Douban account and vise versa for "W → D".

Table 1: Real data description

	#Users	#Links	#Anchor links
Douban	2,046,509	6,493,150	15,009
Weibo	788,524	4,413,187	

5.4.2 The length of binary codes. The length of binary hash codes has great influence on captured structural properties, storage cost and retrieval speed. However, long binary codes may suffer overfitting problem in modeling. Therefore, we conduct experiments with code length varying in 24, 28, 32 and 36 bits respectively, to validate its influence on prediction performance. The 70% of entire labeled anchor links serves as training data. The experimental results are recorded in Figure 3(b). As we can see, the best prediction performance is achieved when the length of binary codes is 32 bits. Short bits of binary codes may cause more conflicts in matching, resulting in the reduction of prediction performance. However, long bits of binary codes may suffer overfitting problem when the labeled anchor links is not enough to learn the matching model. Thus, we set the length of binary codes to be 32 bits in our following experiments.

5.4.3 Evaluation on prediction accuracy. We conduct experiments on 70% of labeled data and examine prediction accuracy of all compared methods on the rest of labeled anchor links. As shown in the Figure 3(c), our proposed method significantly outperform all baselines on both prediction tasks "D → W" and "W → D". The MRR values from our proposed method are 0.32(±0.003) and 0.32(±0.001) on "D → W" and "W → D" respectively, achieving 8% and 10% improvement than the second-best solution.



5.5 Time cost on inferring anchor links

With the binary hash codes, we can fast retrieve the potential anchor links by indexing way in our proposed method. The experiments are implemented with Python 2.7 on Intel(R) Xeon(R) CPU ES-2640 @ 2.40GHz with 10 cores and 128GB memory. We examine the time cost when inferring anchor links given 10, 100, 1,000 and 10,000 candidates. The experimental results are shown in Figure 3(d). We can see that our proposed method optimizes the inference time in order of magnitude comparing to other pair-wise solutions.

5.6 Other discussions

In this section, we discuss two remaining issues, i.e, effect of anchor-link-aware constraint formulated in Eq. (6) and the loss of binary codes with consideration of prediction accuracy. The experimental

Table 2: The effect of anchor-link-aware constraint in embedding stage and the loss of binary codes in prediction accuracy.

	Synthetic data	Real data	
		W→D	D→W
Has Eq. (6)	**0.34(±0.005)**	**0.32(±0.003)**	**0.32(±0.001)**
No Eq. (6)	0.29(±0.003)	0.29(±0.005)	0.29(±0.004)
Cont. codes	**0.34(±0.005)**	**0.32(±0.003)**	**0.32(±0.001)**
Binary codes	0.29(±0.004)	0.29(±0.003)	0.29(±0.002)

p.s. Cont. codes refer to the codes without binarization.

results related to the two issues are show in Table 2. We can observe that the prediction performance is boosted with the supplementary of the anchor-link-awared constraint in embedding stage on both synthetic and real data. It means that the representation learning could be inductive to capture common structural features across networks, resulting high prediction accuracy. Besides, although the binary codes would cause loss of prediction accuracy in ALP, the results are still considerable when comparing to the MRR values resulted by PALE, MNA, IONE and FRUI-P methods under the same experimental settings which achieve to 0.31 ± 0.003, 0.29 ± 0.002, 0.31 ± 0.004, 0.30 ± 0.003 and 0.29 ± 0.002 on synthetic data, 0.29 ± 0.007, 0.28 ± 0.002 and 0.28 ± 0.002 on task "W→D", and 0.29 ± 0.007, 0.29 ± 0.002, 0.28 ± 0.002 and 0.28 ± 0.002 on task "D→W" respectively.

6 CONCLUSION

In this paper, we point out one of big challenges for ALP, i.e., scalability when deployed in practical systems. To combat this problem, we propose a novel learning architecture with two stages for learning binary codes across networks. In embedding stage, we embed each user from high-dimensional and sparse raw representaion into a low-dimensional and dense representaion in each network. In matching stage, we propose an efficient matching model for learning binary codes based on learned user representations. The experimental results show the great potential of our proposed model in real applications.

ABSTRACT

Chinese named entity recognition (CNER) is an important task in Chinese natural language processing field. However, CNER is very challenging since Chinese entity names are highly context-dependent. In addition, Chinese texts lack delimiters to separate words, making it difficult to identify the boundary of entities. Besides, the training data for CNER in many domains is usually insufficient, and annotating enough training data for CNER is very expensive and time-consuming. In this paper, we propose a neural approach for CNER. First, we introduce a CNN-LSTM-CRF neural architecture to capture both local and long-distance contexts for CNER. Second, we propose a unified framework to jointly train CNER and word segmentation models in order to enhance the ability of CNER model in identifying entity boundaries. Third, we introduce an automatic method to generate pseudo labeled samples from existing labeled data which can enrich the training data. Experiments on two benchmark datasets show that our approach can effectively improve the performance of Chinese named entity recognition, especially when training data is insufficient.

1 INTRODUCTION

The goal of named entity recognition (NER) is to identify entity names from texts and classify their types into different categories such as person, location and so on [9, 26]. For example, given a sentence "Bill Gates is the founder of Microsoft", a NER tool can recognize that "Bill Gates" is a named entity of person and "Microsoft" is a named entity of organization. NER is an important task in natural language processing field [25, 28], and an essential step for many downstream applications such as entity linking [11], relation extraction [20] and question answering [8].

NER has been studied for many years and various methods have been proposed [16, 25]. Most of these methods are designed for NER of English texts. For example, Settles [29] proposed to use conditional random fields (CRF) for English medical text NER and incorporated both orthographic features and semantic features. Huang et al. [14] proposed a LSTM-CRF neural model for English NER. They combined spelling features (e.g., whether a word starts with a capital letter), context features (unigrams and bigrams), and word embeddings to build features for words. Chiu and Nichols [3] proposed to learn word- and character-level features using LSTM and CNN networks for English NER. In their method, the word features include word embeddings, character embeddings learned from characters using CNN network, and capitalization features.

Compared with NER of English texts, Chinese NER is more difficult [6, 19]. First, Chinese texts lack strong indications of entity names existing in English texts such as capitalization [27]. Second, Chinese entity names are highly context-dependent. Almost every Chinese character and word can be used in Chinese entity names. The same word can be used as entity names or non-entity words in different contexts. For example, in the sentence "文献是朝阳区区长", "文献" is a named entity of person. However, in most cases the word "文献" is used as a non-entity word in Chinese texts with the meaning of "literature". In addition, the same word can be used as names of different kind entities. For instance, the word "阿里" can be the name of person entity (e.g., "拳王阿里是个传奇"), location entity ("西藏阿里美不胜收"), and organization entity ("杭州阿里吸引了很多人才"). Third, different from English texts, there is no delimiter such as whitespace to separate words in Chinese texts, making it more difficult to identify entity boundaries [24]. For example, a Chinese NLP tool may segment the sentence "习近平常与特朗普通电话" into "习近/平常/与/特朗/普通/电话" and

predicts that "特朗" is a person name, while in fact "习近平" and "特朗普" are correct named entities of person. Besides, annotating sufficient data for training CNER models is very expensive and time-consuming, and the training data in many domains is limited. Thus, CNER is quite challenging.

In order to handle these challenges, in this paper we propose a neural approach for Chinese named entity recognition. First, in our approach we propose a CNN-LSTM-CRF architecture to fully capture both local and long-distance contexts for CNER. Our model contains three layers, i.e., a convolutional neural network (CNN) [18] layer to learn contextual character representations from local contexts, a bidirectional long-short term memory (Bi-LSTM) [13] layer to learn contextual character representations from long-distance contexts, and a CRF layer to jointly decode character labels. In addition, we propose a unified framework to jointly train CNER and Chinese word segmentation (CWS) models in order to improve the ability of CNER model in predicting entity boundaries. In our framework, the CWS model shares the same character embeddings and CNN network with the CNER model, and has an independent CRF layer for label decoding. Besides, we propose an automatic method to generate pseudo labeled samples based on existing labeled data by randomly replacing entity names in labeled sentences with other entity names of the same concept. These pseudo labeled samples are usually correct in grammar and smooth in semantics, and can enrich the training data and improve the generalization ability of CNER model. Extensive experiments are conducted on two benchmark datasets. The experimental results show that our approach can significantly improve the performance of Chinese named entity recognition and outperform many baseline methods.
